This case presents a few retrofitting project by the commercial architects Atkins Walters Webster, AWW. The main case, Broad Quay comprises the partial demolition and regeneration of a 1970s office tower in Bristol city centre and the construction of new buildings on the site. The tower which is transformed into a hotel is re-clad and the original slab slightly extended outwards to suite the new use as a hotel. The 18 story hotel will be equipped with AC. The rest of the site will be developed for residential units, leisure and retail. Issues that the project has brought up are: the importance of an intelligent assessment of the existing structure and basement in order to support recycling instead of demolishing; and the commercial value of a good basement and piling that can be reused (for example car parking). This case shows that the reuse of the original foundation, not making changes to the infrastructure can be very commercially beneficial.

The architects own offices in a 1970s office building has undergone an interim recycling, a kind of refreshment to modern standards resulting in good presentable offices but with lower rent levels than a state-of-the-art new built office. The lower floor levels have low density occupancy and are naturally ventilated. The top floor, a lightweight construction has high density occupancy and AC. The concrete slab has been left bare for thermal adjustment and purging of heat at night.

The former Dingles department store a listed 19th century building originally built as residential has undergone a major redevelopment to host shops on the ground floor and residential apartments in the upper floors. The project can be described as recycling a site as only the exterior facades are kept and all slabs are changed to fit new uses. The recycling of the listed façade has been an expensive venture resulting in some qualities but also compromises in use.

4.4 The Greenbank Chocolate Factory – Sustainable retrofitting and the Community

After 100 years of chocolate production, Elizabeth Shaw closed the Bristol Greenbank factory in 2006, with the loss of 145 jobs. A volume house developer made a proposal to demolish the existing building and build a new residential block. The local community opposed to the development with the aim to save the historically important site. Bristol planners rejected the scheme and it was upheld that it was important to retain the site for local work space. The site was sold to Bristol based developer Squarepeg who develops a new scheme with the approval of the community to provide a mix of affordable work space, retail, leisure, and community space. The aim is to use state-of-the-art sustainable building practices to create a pioneering development. The architect George Fergusson from Acanthus Fergusson Mann has experience from similar projects. In 1995, he saved the Tobacco Factory in Bristol from demolition and redeveloped it into a successful cultural venue that is likely to have supported the regeneration of the local area.

5. Results and Discussion

The interviews with Bristol based commercial property sector actors as well as the presented case studies point to some broad issues that will be further discussed. First, the raised importance of the sustainability agenda will be discussed, and the commercial move from retrofitting towards regeneration. Second, mechanisms related to motivation, enablers but also problems in retrofitting and recycling activities will be further explored.

5.1 The Sustainability Agenda and Regeneration

The interviews reveal a shift as the sustainability agenda has gained in importance over the last 1,5 to 4 years. Including the commercial agents acclaim that sustainability is now part of their business agendas. However, barriers remain. A few respondents find that there are not yet enough reliable renewable energy technologies on the shelf. They think that this problem will be solved in the coming five years and prefer to wait before investing in these technologies.

The case studies show a bias for retrofitting in a regeneration perspective, with more or less involvement of the local community, while high ambitions for energy efficiency are less apparent. Compared to recent Swedish development with a strong single focus on energy efficient building and passive house concepts (Femenias *et al*, 2008), the UK cases seem to address a more socioeconomic then environmental agenda. From the perspective of developers and investors, regeneration is interesting as developments that address local concern easier receives planning consent and can be given subsidies (Pivo and McNamara, 2005). The 2007 IPD Regeneration Index states market advantage in investing in regeneration over the long-term. Their study shows that total returns for all property in regeneration areas has outperformed all UK property over the last five years. Regeneration is claimed to be no longer a niche market but mainstream.

5.2 Retrofitting Decision Making Mechanisms

How does the commercial property sector deal with decision making facing retrofitting and recycling of existing buildings and structures? There are a number of factors that will enable the recycling and retrofitting of existing buildings. From a commercial point of view the market is the starting point. Some of the case studies show expensive engineering and design solutions that can only be carried through when there is a strong demand. Urban Splash in their approach to commercial development shows a way to create market demand. If instead the market demand is low, it can be a business case to do only an interim refurbishment for lower costs. The application on the Part L in the building regulations on energy efficiency should be applied on all planning permissions why necessary refurbishment activities in low budget projects can be called off.

It is seldom that physical deterioration defines the timing and nature of retrofitting activities (e.g. Ball, 2003; Bradley and Kohler, 2007). Often triggered by ownership changes or in between lease contract it is generally functional or locational obsolescence that will determine if the building will be recycled or demolished. Functional obsolescence can originate from several aspects: changes in the market with new user demands, development of internal equipment technology or simply due to poor initial design. The study points to some key design criteria important in this decision process. The floor to ceiling height will determine the possibility to install raised floors and AC. Low floor to ceiling heights can be a determining factor for demolition or change of use to residential (not in need of raised floors/AC). The size and flexibility of floor space are other important factors. Modern offices often demand large open floor space for good communication and more productive working conditions. Functional obsolescent buildings in city centres are probably more often subject to demolition to reach higher density and better functionality in a new building, which is an economically more attractive solution (e.g. Bradley and Kohler, 2007).

In order to reduce energy and especially electricity use, natural ventilation and natural lighting are issues in current UK property development. The depth of the building plan will be determining for the use of natural ventilation with a maximum width about 15 metres. A shallow plan but a low floor to ceiling height can be compatible with natural ventilation depending on the location: noise and pollution levels, heat islands in city centres, occupancy rates and the height of the building (when over 14 stories windows can not normally be opened). Thermal mass is advantageous for naturally ventilated as well as air-conditioned (and night cooled/ventilated) offices.

Several respondents brings up the issues of spending 10% more initially to get better design quality, for example higher floor to ceiling heights, that will be of advantage in future retrofitting. This is often the case with head quarter buildings and buildings for other well-established institutions. It can also be argued that older buildings develop status and prestige that could justify higher rent levels and motivate recycling instead of demolishing (Ball, 2003). The intelligent assessment of the value of the existing structure is important. As expressed by one director of architect AWW: “A building that has a good frame and a good basement is a good asset”.

5.3 The Archaeology of Retrofitting and Rewiring the City

The empirical studies point to the importance of thorough initial analysis of the existing structures. One problem is that the records of the existing structure and the infrastructure are often missing. The cases show that even for rather recent buildings, from the 1970s, drawings can not always be found and not structural data. It can be very costly to analyse a structure and it can lead to just-in-case reinforcements or even demolition. The infrastructure issue is of great importance for future retrofitting of urban areas. The large costs that are related to under ground work, locating and relocating pipes and wires will be of additional commercial benefit for the recycling of structures and in particular valuable basements and piling.

6. Subjects for the Continued Research

Several broad areas for further studies can be drawn from the project at this stage. First, are the tendencies reflected in the empirical study signs of a long-term shift towards more sustainable property management? Are on-going activities the result of enlightened clients, one-off market events, or business cases: what are the real mechanisms that enable these projects? The study does indicate that once sustainability issues begin to bite there will be a switch to a market situation where failure to take this in account will lead to increased exposure to financial risk. Second, the study points to the need for further studies of the links between on the one hand retrofitting of existing buildings, or parts of the structure, and environmental impact and commercial value, and on the other hand the link between commercial regeneration and local sustainable development. Will regeneration projects as those studied actually contribute and sustain the local economy and the quality of life for the actual local population? What are the long-term effects of the projects? Third, retrofitting of cities involves a broad field of areas from infrastructure and recycling of existing material capital to the relive of degenerated areas. There is a need for further reflection on the organisation and documentation of work in the retrofitting of cities.

Acknowledgement

We wish to thank all the actors in Bristol that has contributed with their experiences in this study.

Keywords: autonomous house, Buddhist economics, Right Livelihood, holistic and organic world view.

Summary

Despite increasing awareness of the need for a sustainable society to tackle the global crises mankind is confronting, the industrial-affluent-consumer society still remains mainstream. To implement ecological philosophies so as to promote the transition to a sustainable world order, demonstrations of alternative lifestyles and settlements are key, as when industrial society runs into really severe problems people will be able to see that there is another more practical, wise and ecologically sustainable way. Among eco-philosophies Buddhist economics is used as a yardstick here to measure buildings, such as the autonomous house, which affect the lifestyles of their occupants. Buddhist economics provides the ideas of a sustainable way of living, while the autonomous house develops and demonstrates the possibility of these ideas in practice. The Vales, the architects, builders and occupants of the autonomous house have executed key principles of Buddhist economics in a real situation. More significantly, the new autonomous house frees the Vales from the modern materialist way of life. It signifies the fundamental idea of Buddhist economics: Right Livelihood. This paper identifies the main principles of Buddhist economics, which are used to analyse the autonomous house from qualitative, moral and philosophical perspectives, to offer new explanations of the latter.

Introduction

It has been increasingly comprehended that the industrial-affluent-consumer society has entered a terminal phase. “The Age of Plenty” has ended (Schumacher, 1993). The problems of existing society with its growth economy are so overwhelming that a “paradigm shift” to a quite different society - a sustainable society - is not only essential but also inevitable (Bookchin, 1980; Milbrath, 1989; Trainer, 1995). One of the crucial factors that will promote transition to a sustainable state for society is a fundamental change in the economy. It is generally accepted that the economy is the means to tackle social problems (Smith, 1993). However, the modern growth economy has become a root cause of the predicaments that man now confronts (Trainer, 1996). It is, therefore, certain that a new kind of economics is needed in order to bring forth a sustainable society. Buddhist economics, popularized in the west by E.F. Schumacher, published originally in 1966 and republished in 1973 in a collection of his well-known writings *Small is Beautiful: a Study of Economics as if People Mattered*, is economics of this kind. While the modern economy acts free of morality, ethics and spirituality (Daly, 1996) Buddhist economics with its holistic and organic approach combines economics with moral considerations and spirituality, and provides an insight into “Right Livelihood”. It consists of the ideas of harmonious attitude towards nature, quality of life, alternative technology and decentralisation.

Brenda and Robert Vale have put these ideas into practice by means of designing, building and living in the autonomous house. The autonomous house, published in the 1975 book of the same name and actually completed in Southwell, Nottinghamshire, in 1993, goes beyond measurements in quantity; it offers a much more sustainable way for improving life in quality. Apart from its technological and technical solutions, focusing on the performance of the building, it has more far-reaching social, economic and philosophical implications and applications. It demonstrates that sustainable living is both cheap in the long-run and possible. The Vales (2003:52) maintain that “demonstration is a very powerful motivator.” After completion of the first autonomous house in Southwell, some five further autonomous houses were built in the next village of Hockerton to designs by the Vales. The local authority is also committed to an expanding programme of zero space heating and autonomous dwellings centered on the Sherwood Energy Village (Vale, 2003). Ted Trainer (1998:26) thinks that demonstration may serve as the best contributor in the transformation to a sustainable society by claiming “sustainable practitioners should put most of their energy into developing and demonstrating alternative lifestyles, settlements and systems, so that when the consumer society runs into really serious problems people will be able to see that there is another way, one that is more sane, workable, attractive, just and ecological sustainable.” The Vales have achieved this through the autonomous house. It is a demonstration of Buddhist economics. It is interesting to note that both Buddhist economics and the autonomous house were accomplished in theory in the late sixties and early seventies. It was the period of the environmental movement: the period when sustainable pioneers began to recognise environmental crises and the “limits to growth” (Meadows et al, 1972). Over three decades later, radical change from a society of growth and greed has not yet been triggered. People in general still give little attention to the limits to growth analysis. Indeed there seems to be less willingness to think about these issues now than there was thirty years ago (Trainer, 1998). This paper, by tracing back to the attitudes of the environmental movement, provides a new interpretation of the autonomous house by means of exploring it in terms of the ideas of Buddhist economics, showing how the autonomous house creates a feasible condition for a sustainable way of life, and in turn could bring forth a sustainable society through change in lifestyles (Milbrath, 1989; Trainer, 1995).

The Holistic and Organic World View

Schumacher (1973:44) began his view of Buddhist Economics by identifying two problems of modern economics: specialisation and freedom from moral values, stating "Economists themselves, like most specialists, normally suffer from a kind of metaphysical blindness, assuming that theirs is a science of absolute and invariable truths, without any presuppositions. Some go as far as to claim that economic laws are as free from metaphysics or values as the law of gravitation." These problems may have stemmed from the mechanistic world view, started in the Age of Scientific Revolution and mainly formed in the Age of Enlightenment. The world view proposed by mechanistic science takes the world to pieces, focusing on objects rather than interrelations between them (Capra, 1983). The mechanistic world view, along with division of labour (Smith, 1937), has created industrialised specialisation. The drawback of specialisation lies in the fact that it blinds people so they take one aspect or one dimension of reality and think of it as total reality (Kumar, 1982). In addition, the mechanistic world view has caused one-sided development of the two modes of consciousness, and in turn a profound imbalance between development of intellectual power, scientific knowledge and technological skills on the one hand, and of wisdom, spirituality and ethics on the other (Capra, 1982). The two modes of consciousness are usually called the rational and the intuitive modes, or the scientific and religious modes. The Chinese have named them the yang and yin. Modern economics, however, has consistently favoured the yang over the yin: rational knowledge over emotional needs, objectivity over subjectivity and economic growth over spirituality. The job of modern economists seems to be to devise well-reasoned models to help society rise above fear, greed and hatred. Rarely, however, do they examine the basic question of fear and the emotional need for security that drives human beings (Payutto, 1994). As a consequence, their theoretical models remain rational solutions to largely irrational problems. Fear and desire drive modern men to their worst economic excesses. The forces of greed, exploitation and over-consumption seem to have overwhelmed modern economics in recent decades (Payutto, 1994). The materialistic society offers people little choice but to exploit and compete for survival in today's dog-eat-dog world. But at the same time, it is obvious that these forces are the primary causes of social and environmental problems. Moreover, like other sciences, modern economics strives for objectivity. In the process, however, subjective values such as ethics are excluded due to the one-sidedness of the approach. Schumacher (1997) believed that economics without spirituality could provide temporary and physical gratification, but that economics could not offer internal fulfilment. By contrast, spiritual economics bring service, compassion and relationships into equal play with profit and efficiency. Both economics and spirituality are needed together.

Unlike modern economics which is guided by the mechanistic world view, Buddhist economics is based on a holistic and organic world view as was shared by mainstream societies in the West before the sixteenth century and in the East before westernisation took effect. According to this world view, the universe is made up of a multitude of objects, but has to be pictured as one indivisible, dynamic whole whose parts are essentially interrelated and can be understood only as patterns of a cosmic process. The focus of this ecological world view is laid on relationships rather than on objects (Bateson, 1979). Under its guidance people lived in small, cohesive communities and experienced nature in terms of an organic relationship, characterised by the interdependence of spiritual and material phenomena and the subordination of individual needs to those of the community (Capra, 1983). For Buddhist economics to be based on the holistic and organic world view depends on four aspects: it rejects industrialised specialisation; it links moral values and spirituality with economics; it holds a harmonious attitude towards nature; and it adopts a balanced view of technology. This is "Middle Way technology" or "intermediate technology." Schumacher (1973: 51) called it "A technology more productive and powerful than the decayed technology of the ancient East, but at the same time non-violent and immensely cheaper and simpler than the labour-saving technology of the modern West."

Based on the holistic and organic world view, the autonomous house also presents the features of Buddhist economics mentioned above. Realising the problems of specialisation in the field of architecture, the autonomous house involves ideas of participation of the users in the process of building. The wide perception of the mechanistic world view in the Age of Scientific Revolution and Enlightenment provided a philosophical support to specialisation in architecture which started in the medieval period, became evident in the seventeenth century, and reached a peak in the Industrial Revolution. Since then it has been further enhanced by the separation of professional institutions, recently between the technologist and the architect, and by professional protectionism. Specialisation has isolated architects from the process of making and the users of the building (Lawson, 1997). The Vales (1991) believe that this separation of designing from making, and designers from consumers, does not necessarily promote better design. The autonomous house, however, is quite different from the modern house as the Vales have woven together the role of the users and the process of building. They themselves were the architects, part builders and the users of the autonomous house (Vale, 2003). They understand the process of building but also emphasised the need to understand it by utilising alternative technology, simple technology that could be constructed and managed by the occupants without recourse to specialised training (Vale, 1975). "The users have been able to deal with a number of operational problems without the need for calling for expert assistance. The simple technologies used, for sewage treatment, water supply and waste water disposal for example, have been easy to manage, and easy to adjust and modify as necessary" (Vale, 2000:233) (Figure 1). This idea of adjustment once something is constructed is also important as it suggests that design is and never should be perfect. Yet the modern method of design leaves all such adjustment to the users. Unless designers also learn from such adjustments design can never move forward in any coherent way, as it used to do with development in the context of the vernacular.

Figure 1: composting WC operated by hand.

Figure2: rain water collection from roof

Figure 3: recycled orange juice containers for rain water storage

Furthermore, the combination of moral values with the way of living in the autonomous house again proves that it is based on the holistic and organic world view. The autonomous house makes its occupants aware of their moral responsibility for the natural environment and others. For example, the water supply entirely depends on the collection of rain water (Vale, 2000) (Figures 2 3). It suggests that when taking a shower, the user cannot let the water run freely, needing to consider the limit imposed by the weather and the availability of water for other users. It was the Vales' intention to change individual values through the autonomous house (Vale, 2000). This is one of the reasons why they selected a house to be autonomous rather than a commercial building due to the universality of a house. As the Vales (2000) have claimed "everyone has to live somewhere, and the home has an immediate impact on personal circumstances and values in a way that the office or workplace probably do not. If sustainability is to become acceptable or desirable, it could be argued that it is only through the home that values can be changed" (Vale, 2000:46). This is what they later coined as "sustainable development begins at home" (Vale, 2002). James Garbarino (1992) holds the same point of view and states that the family is a basic unit that can bring forth a sustainable society. According to a Confucian doctrine, social change starts with change in the family. As the family is the place where values are first established, change in value systems may lead to behavioural change. Research conducted by Robert Vale (2005) demonstrates that reduction in ecological footprints through behaviour changes is more significant and much cheaper than through built environment changes. Like the "Middle Way in technology" of Buddhist economics, the holistic and organic world view is also reflected in the autonomous house through the balanced and holistic approach to technology. The alternative technology used in the house is technology between modern advanced technology such as mass-produced, prefabricated construction with automated controls, and the decayed technology of the past. Only sufficient technology to do the task in hand is used. This kind of holistic and balanced thinking, exemplified by the Vales' choice of power linkage between solar energy and the National Grid, pervaded every other issue they confronted as they built from windows to thermal mass (Perlin, 2000). However, this paper has focussed only on features indetified with Buddhist economics, guided by the holistic and organic world view.

Harmonious Attitude towards Nature

The holistic and organic world view guiding both Buddhist economics and the autonomous house is apparent in the harmonious attitude towards nature. Under this world view in the past, the goals of science were wisdom, understanding the natural order and living in harmony with it (Capra, 1983). Science was pursued 'for the glory of God.' By contrast, under the mechanistic world view, the goal of science has been knowledge that can be used to dominate and control nature, and today science and technology are used predominantly for purposes that are profoundly anti-ecological (Capra, 1982). The universe has been treated as a machine, and the world-machine has become the dominant metaphor of the modern age. The Scientific Revolution transformed nature from sustaining matter into a machine and a source of raw material (Capra, 1983). With this transformation all ethical and cognitive constraints against nature's violation and exploitation were removed. The Industrial Revolution converted economics from the prudent management of resources for subsistence and satisfaction of basic needs into a process of commodity production for profit maximization. Industrialism created a limitless desire for resource exploitation, and the mechanistic world view provided the ethical and cognitive licence to make such exploitation possible, acceptable and even desirable (Shiva, 1989).

Base on the holistic and organic world view, Buddhist economics and the autonomous house both show a positive attitude to nature. The attitude of Buddhist economics is centred on two respects, the frugal use of natural resources and recognition of the difference between renewable and non-renewable resources. From the Buddhist point of view, nature is regarded as income, not capital. The essential difference between non-renewable fuels like coal and oil on the one hand and renewable fuels such as solar power and water power on the other cannot be simply overlooked. Non-renewable goods must be used only if they are indispensable, and then only with the greatest care and the most meticulous concern for conservation. To use them heedlessly or extravagantly is an act of violence, and while complete non-violence may not be attained on this earth there is nonetheless an ineluctable duty on man to aim at the idea of non-violence in all he does (Schumacher, 1973). These ides have been embodied in the autonomous house. One of the primary goals of the autonomous house is to tackle the problem of resource depletion (Vale, 2000). It was designed to avoid the use of materialis with a high energy content, to eliminate toxic materials, and to use waste and recycled materials wherever possible. It is self-sufficient in energy, water supply, sewage treatment and waste water disposal, and is connected to no main services except the telephone and electricity, so that it can export surplus solar power to the National Grid (Vale, 1997). Recognising the problem of non-sustainability and the considerable environmental impact of non-renewable fuels, the autonomous house completely relies on renewable resources. Rainwater is collected from the house roof and that of the conservatory to form the only water supply. Electricity comes from the sun through photovoltaic panels (Vale, 2000) (Figures 4 5).

Figure 4: photo-voltaics and the veggie patch

Figure 5: grid connected PV system

In terms of Buddhist economics, the exploitation of natural resources at an ever increasing rate is an act of violence that must almost inevitably lead to violence between men (Schumacher, 1973). Since the Enlightenment, the new relationship of man's domination and mastery over nature has been associated with new patterns of domination and mastery over women (Shiva, 1989; Plant, 1991), and others (Bookchin, 1980) and the underdevelopment of the Third World (Trainer, 1985). The exploitation of nature and people may result from the unlimited desires of modern man. Since modern man has lost control of his direction owing to the absence of a goal for life, he attempts to regain what he has lost by an inordinate and frantic search for those commodities that will stimulate his sense and thus temporarily quiet his sense of lost direction, or by seeking power that allows him to control the lives of others. This control over nature, other things and other people becomes a surrogate for having control over his own life. Lacking the power, ability and will to submit the direction of his own life to an appropriate final goal, modern man seeks the false remedy of gaining power over nature, things and persons (Smith, 1993). In this sense, awareness of the meaning of life and returning a sense of control to every person are crucial with regard to a sustainable and just society. This can be fulfilled by decentralisation which forms the next discussion point of this paper.

Decentralisation

In Buddhist economics, decentralisation is closely related to the ideas of self-sufficiency, local resources for local needs and "small is beautiful" (Schumacher, 1973). Edward Goldsmith (1972) has claimed that decentralisation is fundamental to the green vision of a sustainable society. Andrew Dobson (1991) has summed up most of the arguments in favour of decentralisation which are outlined below. He states that face-to-face communities encourage a sense of social responsibility which is lacking in the anonymity of large-scale industrial and city life; that local production for local use with less trade and travel reduces a community's impact on its environment; that 'human-scale' forms of living are more congenial than their modern counterparts; and that decentralised forms of production and exchange satisfy a human demand for improvements in the quality of life rather than catering for the modern, misplaced emphasis on quantity. The autonomous house involves these decentralist ideas. Resources utilised in the autonomous house are virtually on-site and local. Its self-sufficiency is a non-violent attack on centralised and industrialised systems. From the point of view of Buddhist economics, people who live in a highly self-sufficient way are less likely to get involved in large-scale violence than those whose existence depends on worldwide systems of trade. Nevertheless, the modern economic system relies on international trade. Adam Smith (1937), who is claimed to be the father of modern economics, maintained that the big market is essential for economic growth. For him, the division of labour is a crucial tool for the accumulation of wealth, but it is limited by the extent of exchange, that is, the extent of the market. Therefore, a big market means a powerful exchange and division of labour, and in turn economic growth. This kind of obsession with bigness has become a stereotype of modern society. Vance Packard (1959:16) realised this desire for bigness, stating "stratification (formalised inequality of rank) is becoming built-in as our increasingly centralised society moves at almost every hand towards bigness. Bigness is a really major factor altering our class system." However, both a giant economy and giant organisations are anti-human (Schumacher, 1997). In a big school, pupils are reduced to numbers; in big hospitals, patients are reduced to numbers; in big factories, workers are reduced to numbers. The pursuit of bigness has led the modern economy to emphasise growth in quantity only. The result is a purely exponential increase in numbers and sizes without considering qualitative factors. Bigness has come to be seen as a symbol of success, but human relationships have become secondary (Schumacher, 1997). Interpersonal relationships have depended on the exchange of labour in a commercialised way. The preference for smallness is obvious in the autonomous house and may be another reason for the Vales' choice of a house rather than a school or a library to be self-sufficient. The localness and self-sufficiency of the autonomous house create a condition for people to start true relationships, rather than those formed on commercial critetria, and it becomes a manifesto, fighting against the centralised economic system.

Another decentralising feature of the autonomous house is its autonomy as its name suggests, or self-governance. The house is not linked to the main services of gas, water or drainage, and it exports surplus solar electricity to the national electricity grid, thus interacting with it (Vale, 1997). In the centralised world, the control of electricity supply is in the hands of a few distant and powerful officials located somewhere in a mammoth central bureaucracy. Virtually all functions performed by government and commerce are organised in this manner. As well as being less democratic than they could and should be, centralised systems involve what can be a heavy overhead cost (Trainer, 1985). If many houses sent surplus electricity to the grid this relationship would no longer be centralised and one way but far more interactive and shared. The autonomous house gives its control to the users who are in control of their own heating, lighting and food production (Vale, 1975). John F.C. Turner (1972:6) who is in favour of the shift of control to dwellers, has claimed, "When dwellers control the major decisions and are free to make their own contribution to the design, construction or management of their housing, both the process and the environment produced stimulate individual and social well-being. When people have no control over, nor responsibility for, key decisions in the housing process, on the other hand, dwelling environments may instead become a barrier to personal fulfilment and a burden on the economy." The autonomous house returns a sense of control to ordinary people, thus relieving the exploitation of nature and others. It has achieved this by means of alternative technology, decentralising technology in Turner's terms (Turner, 1976), or people's technology as Schumacher (1973) called it. Simply technologies used in the autonomous house not only avoid the problem of industrialised specialisation as discussed above, but also serve as a means of decentralisation. The reason that modern technology has become increasingly inhuman is that it is a tool for a few people in control of it to generate wealth. In the industrial-affluent-consumer society, technological inventions are essential to generate new wants to sell goods to people. This can be seen in recent refinements of the technology of the car, making it increasingly complicated and something only specialists can mend, thereby selling the service of the mending as well as the car to the consumer. Alternative technology frees the users from the exploitation of the modern economic system. Turner (1976) believes that if the possibilities of self-governing network structures and decentralising technologies are realised, it is through those which do not demand highly centralised production, distribution or servicing systems that an alternative and viable world order will occur. The Vales (1975:17) are convinced that decentralisation would bring forth an autonomous society "where there would be no growth in the economy, where population size was strictly controlled, where resources were shared equally between every man, where freedom to act was curtailed by the need to survive."

Quality of Life

Buddhist Economics is the necessity of Right Livelihood through which quality of life or well-being can be achieved (Schumacher, 1973). The lifestyle offered in the autonomous house paves the way to the attainment of well-being. No one would deny that happiness is a crucial indicator of the quality of life. However, there exists an erroneous belief that happiness is to be obtained through limitless material acquisition, and that the more production and consumption, the happier. This false belief is preached incessantly by every American television set (Milbrath, 1989). Quality of life seems often to be equated with standard of living due to the lack of moral values and spirituality in modern economics. The standard of living is measured by the amount of annual consumption. Therefore, the logic suggested by modern economics is that people who consume more are happier than those who consume less. Nevertheless, in the Buddhist view, consumption is merely a means to human well-being, and the maximum of well-being should be attained with the minimum of consumption (Schumacher, 1973). Over-consumption and material affluence do not lead people to quality of life, well-being or happiness. In fact, the opposite is true. Trainer (1985) has argued that the more people pursue affluence and growth the worse their quality of life becomes. Human thirst for happiness is unquenchable. It means that human beings have a spiritual nature. They have needs that cannot possibly be satisfied by material objects. The human desire for happiness is infinite, but material things are finite; hence they can never quench the desire. Humans all seek unlimited joy, but material objects, being limited, can never offer that. The limited cannot yield the unlimited. In terms of the teaching of Buddhism, happiness, well-being or quality of life can be attained through the Middle Way, the right amount and knowing moderation, and all of these terms may be considered as synonyms for the idea of balance or equilibrium (Payutto, 1994). Knowing moderation means knowing the optimum amount, how much is 'just right.' It is an awareness of that optimum point where the enhancement of true well-being coincides with the experience of satisfaction. This optimum point, or point of balance, can be obtained when people experience satisfaction at having answered the need for quality of life or well-being. Consumption, for example, which is attuned to the Middle Way, must be balanced to an amount appropriate to the attainment of well-being rather than the satisfaction of desires. Thus, in contrast to the modern economic equation of maximum consumption leading to maximum satisfaction, a sustainable way of living should have moderate or wise consumption, leading to well-being. A further meaning of the term 'just the right amount' is of not harming oneself (by causing a decline in the quality of life) and others (by causing problems in society or imbalance in the environment) (Payutto, 1994).

Figure 6: roof insulation

Figure 7: triple glazed window

Figure 8: wall insulation

The Middle Way has been practiced in the autonomous house by means of comfort, satisfaction of 'enough is best', constraints and responsibility. The autonomous house points the way forward to sustainability by offering its occupants not "luxury", but comfort and services in terms of not "more" but "enough" (Vale, 1975, 1997, 2000) For instance, it has a limited range of electrical appliances---no dishwasher, no freezer---and those it does have are used in unconventional ways; the washing machine is used only with cold water and no heating. Average winter indoor temperatures in the living areas are in the region of 18°C, but the low temperature is mitigated by the high radiant temperature resulting from the thermally massive externally insulated construction (Figures 6 7 8). It may be cold for some, but still comfortable. In the mid-winter the Vales' tea consumption increased--- a very efficient form of interior heating---and they went to bed earlier than usual, getting up with light. This again made it very clear that the house was entirely dependent on the sun. The water consumption is constrained by the amount of rainwater, so the water is carefully used for personal hygiene as mentioned before. The comfort provided by the autonomous house implies the idea of knowing moderation, the optimum amount. This optimum point is reached when the comfort is achieved which ensures true well-being and the satisfaction of 'enough is best'. Consumption in the house services is a merely a means to achieve quality of life, not for satisfaction of desires. The living offered by the autonomous house actually puts brakes on the desire for an affluent and materialistic way of life. It invites the occupants to realise that the meaning of life is not wealth, but "something better than money" (Ruskin, 1909). It saves their time and energy for mental and spiritual development. In doing so, it enhances the quality of life and helps obtain happiness. Happiness can also be attained in the house by doing no harm to oneself (through increasing the quality of life) and others (through taking responsibility for society and the natural environment). The autonomous house sets up the constraints for living, such as the indoor temperature and water consumption. These constraints may not appear desirable for those who have been accustomed to modern, affluent lifestyles. They may even argue that these constraints are the violation of individual freedom. Indeed, these constraints seem to contradict individual freedom on the basis of self-interest, as imposed by the industrial-affluent-consumer society. However, the autonomous way of living meets the basic and intermediate need of all people on the earth. Len Doyal and Ian Gough (1991) maintain that a truly democratic and just society will occur if everyone's basic needs including survival and autonomy, and intermediate needs like health, food, and housing are satisfied. Garrett Hardin (1977) has argued that true freedom is the recognition of necessity, and that the most important aspect of necessity that modern men must now recognise is the necessity of abandoning the commons in breeding and accepting the need for constraint. Freedom based on self-interest is freedom for a few, while constraint means ecological freedom for all people. It is a return to moral codes. At a deeply serious level, constraint means waiting

(Tuan, 1989). Modern consumers are often shocked by having to wait for what they want. Yet without waiting, there is no value. The Vales have (1997) stated "having to wait for the sun in the autonomous house is valuable experience in a world where we are used to getting everything that we want immediately." The autonomous house helps its occupants to realise the value of waiting, thus slowing down the speed of life. It does no harm to others by establishing the constraints.

Another important indicator of the quality of life would be fulfilling work and leisure time. However, modern society, with its growth economy and advanced technology, destroys the nature of work and turns work against leisure. The modern economist would regard work as little more than a necessary evil (Schumacher, 1973). Buddhist economics, however, view work differently. The nature of work has three vital aspects: to give a man a chance to utilise and develop his faculties; to enable him to overcome his egocentredness by joining with other people in a common task; and to bring forth the goods and services needed for a proper existence (Schumacher, 1973). In addition, from the Buddhist perspective, work and leisure do not contradict one another, but are complementary parts of the same living process and cannot be separated without destroying the joy of work and the bliss of leisure. To strive for leisure as an alternative to work would be a complete misunderstanding of the true relationship between work and leisure (Schumacher, 1973). Nevertheless, work offered by modern society is often repetitive, mindless and soul-destroying (Schumacher, 1997). Thomas Aquinas saw each person as a being with a brain and hands, who enjoys nothing more than being creatively, usefully and productively engaged with both hands and brain. But the so-called 'labour-saving' technology is most successful in reducing or even eliminating the skilful and productive work of human hands, which have previously been in touch with real materials of one kind or another. The veggie patch of the autonomous house provides an opportunity for the occupants to use both their hands and their brain, and leisure time productively (Figure 4). For modern people who have become familiar with sitting in front of a television set to be entertained in their leisure time and manipulated by endless advertising, producing their own food at home would be a another kind of 'tough work.' Since modern society has destroyed the nature of work by making work unfulfilling, it is not surprising that the most common leisure activity modern men engage in is watching TV. Producing one's own food as much as possible at home, as happens in the autonomous house is done not just because food is the largest energy flow through any household due to the energy bound up in growing, transporting, processing and retailing it (Vale, 2003) (Figure 9). More importantly, it offers a chance for the occupants to use both their hands and brains, and leisure time productively, and thus feeling fulfilled. There is no doubt that quality of life will be improved once people feel fulfilled.

Figure 9: conservatory for growing food

Conclusion:

The autonomous house has put the ideas of Buddhist economics into practice, and demonstrated the possibility and feasibility of living in a sustainable way. Guided by the holistic and organic world view, it frees people from the exploitation of nature and others through a harmonious attitude towards nature and alternative technology. It non-violently attacks the root causes of the industrial-affluent-consumer society through decentralisation, and improves the quality of life through the Middle Way and using leisure productively. It sets up the constraints against freedom based on self-interest, but offers ecological freedom for everyone. It invites people to change their values by taking moral responsibility for the natural world and others. It is a workable example that means all people could participate in sustainable development and is a fundamentally architectural response to the call of sustainability. It could form a basic unit of a sustainable society, and is the starting point for making the world a better place.

BIOLOGICAL SPECIES INVENTORY SYSTEM AND ASSOCIATIONS OF SYMBIOTIC SYSTEM: AN EXAMPLE ON THE ARCHILIFE SYMBIOSPHERE I CENTER

Yeong-Tyi DAY, Dr. Sci.[1]

[1] Department of Landscape Architecture, Chung Yuan Christian University, Chung-Li, 32023, Taiwan, timday@cycu.edu.tw

Keywords: species inventory, community ecology, small world network, symbiotic system, urban ecology, green village, biodiversity, symbiolization

Summary

The Archilife Symbiosphere I Center (ASIC) is a human-centered ecosystem with complicate ecological linkages between human, crops, and other biological species. Organisms, providing food production and interacting among species, are all antagonism in the ASIC. It is essential to describe the species composition and their biological association in the “Symbiotic Ecological Environment” (SEE) and to understand the impacts of human decision, operation, and natural factors on the SEE. The objectives of this study were to reveal biological compartments and their roles in the SEE with empirical data from the ASIC. A hierarchy model of system theory, named “symbiome”, was built with examining the characteristics of the ASIC, and was constructed with keynote species, major symbionts, and cosymbionts. The keynote species of symbiome was human. Major symbionts were crop species proven to be adaptable to human digestive system. Cosymbionts were biological species occurred with major symbiont in one of the biological interactions such as mutualism, commensalism, exploitation, and competition. In order to establish a suitable information management system, inventory systems of natural resource management and biological survey were reviewed. Then, a species inventory system for the symbiome was designed for data input and analysis.

1. Introduction

The Archilife Living Research Center was established at Fulong Taipei in October 2002, which consisted of two portions, management building and experiment building. The latter was also named “Archilife Symbiosphere I Center” (ASIC). The research teams of the Archilife Research Foundation (ARF) had worked on various disciplines, such as physical environment, biological environment, agriculture, aquaculture, history, and cultural study since the last 2-3 decades (Huang 2002). Thoughts, discourses, and inventions of these researches became the design groundwork of the ASIC. The ASIC is experimental place for residency, and it is considered as a human-centered ecosystem in terms of ecology. The food chain (or food web) was formed with links (Paine 1980) in the above ecological system; i.e. the predation for human on other biological species.

Based on the awareness of life-threatening by the 100,000-yeared periodical disasters, all Archilife research teams had been focused on the ASIC since 2004, in order to optimize continuously and to improve the ASIC through concentrated efforts. Thereby the maturity of the ASIC would formulate a strategy for Taiwan to cope with such a drastic environment change. The strategy would solve potential problems due to the global climate change, as a regional strategy, in Taiwan. Furthermore, the experience would be expanded gradually and would assist other international communities to overwhelm the crisis.

The most important objective of the ASIC operation was to increase the efficiency of material transfer rates between its bio-processing units. Four main units organized a close recycling living-supporting system (Su et al. 2002). (1) Food supply system, including mainly vertical planting system (Tang, 2005) and vine shelves, produced food by green plants. (2) “Solar dietary” was a way of eating, and used solar energy for food processing. (3) Excretory materials were collected using “dry toilet” system. (4) Secondary “composting system” ensured fully the extermination of disease-caused bacteria and parasites. Above units introduced the solar energy into the symbiotic system, and energy depositing in the plant tissue was digested by human body. Excretion became fertilizer back to the soil. Such symbiotic system, or “Symbiotic Ecological Environment” (SEE), provided food production for human, and its interactions were kept stable among biological species by antagonistic mechanism between subsystems which were organized with each cropped species and its symbionts.

Most biological species were introduced by residents in the ASIC on purpose; however, some of them occurred in a natural process. The pattern may be an analogy to the species colonization process as a volcanic island being formed. Island ecology gathers many theories and examples on phenomenons that biological species colonized in diverse situation. Species richness is one of indicator presenting the degree of species diversity in certain ecological community, which is the union of all biological species in an area (Bagon, et al. 1990). In addition, each species has its unique “niche” in the community where all species are inter-related with prey-predator linkages (Bagon, et al. 1990). Biological association is a subgroup of plant species in a community, which tends to occur in the same space (co-existence). It also means a ranked category in the classification of vegetation (Krebs 1978). A climax plant community is characterized by two or more dominant species which have the life-form typical of formation to which the association belongs (Krebs 1978).

The impact of human activities and decision to the SEE should be fully understood, and even natural factors would be essential. Therefore it is important to know the composition, structure, and interactions of this symbiotic system. The objectives of this study were to establish the framework of collection, database structure, and its management pertaining to the information of biological species in the symbiotic system. Furthermore, a model theory for symbiotic system was developed with the empirical data of the species inventory system for the ASIC.

2. Methods

A broad survey on literatures about inventory database of natural resource management was conducted to look for an existing usable standard, or an existing system needed only slightly modification. If there was not any usable one, a brand new system would be constructed. At the same time, the process of system design went to validation and modification stages with empirical data collected between 2003 and 2007 from the ASIC *in situ*.

A theory of human-centered system, more comprehensive than the classical energy-based ecosystem model, was developed by bibliographic review. A conceptual model was built to clarify the characteristics of the symbiotic system according to above realistic data.

2.1 Coefficient of Association

A plant basket of the vertical planting system (VPS; Tang, 2005) or vine shelves was regarded as a sampling unit (SU). The number of SU that both species present (a), both absent (d), and absent at one and present at the other (b, c) were calculated. Coefficient of association (V; equation 1) represents the strength of connection between two species in a community, and its value is between -1 to +1 (Krebs 1978). If V = 0, then there is no connection. If V > 0 and $\chi^2 > 3.84$ (equation 2), it indicates a positive association. If V < 0 and $\chi^2 > 3.84$, it represents a negative one (Krebs 1978).

$$V = \frac{ad - bc}{\sqrt{(a+b)(c+d)(a+c)(b+d)}} \quad (1)$$

$$\chi^2 = \frac{n(ad - bc)^2}{(a+b)(c+d)(a+c)(b+d)} \quad (2)$$

3. Inventory System

A common structure of database management system for the natural resource management consisted of user and other 5 subsystems (Fig. 1), i.e., administrative subsystem, maintenance subsystem, data collection subsystem, data processing and storage subsystem, and retrieval, reprocessing, and display subsystem (Myers and Shelton 1980). The “species inventory system” in the ASIC adopted data collection subsystem to analyze the developing process, structure, and functions of SEE (Fig. 1). Data sources include reports of the “Archilife SEE Researches”, “Green Paradise Web Site”, the Archilife Intranet, and automatic monitoring system.

3.1 The Format, Attributes, and States of Species Inventory System

The coding process was simple and undemanding. Microsoft Excel™, was used as data processing software for its popularity. The format and states of each attribute had been modified on yearly bases since the operation of the ASIC began in 2004. Two stages of procedure were determined in the very beginning of this project. The primary data set was mainly produced by direct collection from the literature and reports on the

ASIC, while the secondary data set was produced after manually analysis by the database manager (Fig. 1; Table 1).

3.2 Primary Data Set

Primary data set was the group of worksheets containing the original data, which were mainly articles and images. The titles of worksheets were named Reports, BibList, ArtList, and FigList. The coder must be familiar with the building structure and operation of the ASIC (Table 1).

Table 1 Data file and spreadsheet of the specie inventory system for the Archilife Symbiosphere I Center

Filename	Worksheets	Description
PrimaryDataSet.xls		To store the photographs and literatures out of reports, Green Paradise Web Site, and the Intranet of the Archilife Living Research Center in spreadsheets.
	Reports	✓ Containing bibliography of the Archilife Research Foundation reports. All reports until 2004
	BibList	✓ Recording the biological species mentioned in above reports
	ArtList	✓ List of articles containing the occurrence of biological species
	FigList	✓ List of photographs containing the occurrence of biological species
	AMList	✓ List of image taken from the automatic monitoring system
SecondaryDataSet.xls		✓
	SpList	✓ List of species occurred. Summarized from the primary data set
	LocList	✓ List of localities where the biological species occurred
	SrcList	✓ List of data source
	IntAna	✓ Summary of interaction occurred between biological species
	SptAna	✓ Spatial analysis on the occurrence of biological species
	TmpAna	✓ Temporal analysis on the occurrence of biological species
Readme.doc		✓ Illustration document ✓ To interpret the format and construction process of this database

3.3 Secondary Data Set

The secondary data set were the group of worksheets containing records transformed from the primary data set via certain analytical procedures. There were two types of worksheet (6 in total) in the secondary data set. IDList, SrcList, and LocLIst belonged to “structure” sheets, which were only modified as the change and increment of data. IntAna, TSAna, and SpAna were named “analytic” sheets, which were produced after certain data analysis from the primary data set (Table 1).

There were 335 records in SpList which indicated the total number of biological species occurred in the ASIC (Table 2). There were 355 and 155 records in TSAna and IntAna respectively, which summarized the temporal and spatial interaction between biological species in the ASIC. In addition, there were 12, 4, and 12 records in LocList, SrcList, IDList respectively to conclude the localities, data sources, and data types (Table 2).

Table 2 Number of records in the Species Inventory System from 2003-2007

PrimaryDataSet.xls		SecondaryDataSet.xls	
Worksheet	No. record	Worksheet	No. record
Reports	114	SpList	335
BibList	153	TSAna	355
FigList	195	IntAna	155
ArtList	302	LocList	12
AMList	0	SrcList	4
		IDList	12

3.3 Spatial and Temporal Analyses

Between the beginning operation of the ASIC and February 2007, data were collected and analyzed by space and time. The number of species was the most in the VPS (89), which included many plants introduced by residents. Animal species were attracted by those plants as their symbionts (Table 3). There were 48 species occurred in the 3rd floor with horticultural boxes and vine shelves (Table 3). Additionally, there were 1, 11, and 7 species occurred in the second floor, first floor, and basement respectively.

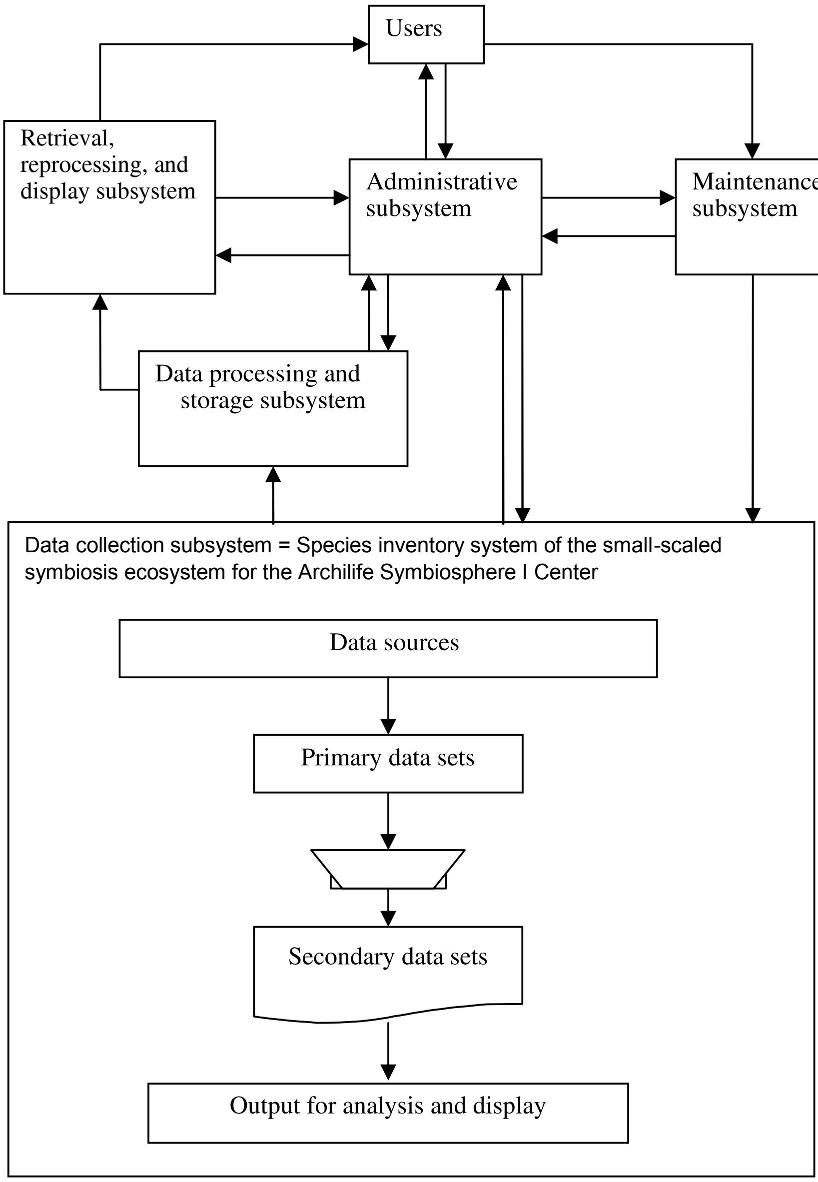

Figure 1 The process of species inventory system of the symbiome for the Archilife Symbiosphere I Center

Table 3 Spatial distribution of number of species recruitment in the Archilife Symbiosphere I Center

Space	No. records	No. Species recruitment
Vertical Planting System	151	89
Attic	3	3
3rd Floor	85	48
2nd Floor	1	1
1st Floor	16	11
Basement	7	7
Fish Pond	14	2
Other	3	2

Spatial effect on the distribution of species occurrence was also able to analyze (Table 4). The number of species introduced into the ASIC was different upon seasons and years. The recruitment of new species was declining year by year. In spring they were the greatest in spring 2003 and 2004; however, were the greatest in autumn 2005 and 2006 (Table 4).

Table 4 The seasonal and yearly variation of species recruitment in the Archilife Symbiosphere I Center

Year	Spring	Summer	Autumn	Winter
2003	53	32	17	11
2004	48	18	5	1
2005	1	8	13	7
2006	8	8	19	2
Total	110	66	74	21

4. Modeling of a Symbiotic System

The concept of symbiome originated from a human-centered prototype which was described by President J. H. Lin of the ARF (Fig. 2A). Symbiosis has been gradually understood as the driving force and mechanism of biological evolution recently (Margulis and Fester 1991).

4.1 Deficiency of Classical Energy-based Ecosystem Model

The biotic community in an ecosystem usually gathers more than 2 biological species. However, 6 basic types of interactions between 2 species have been recognized (Table 5: May 1973; Putman 1994); i.e., mutualism (+ +), commensalisms (+ 0), exploitation (+ -), neutralism (0 0), Antagonism (- 0), and competition (- -).

Most models of ecological systems based solely on prey-predator relationship, a subtype of exploitation. Mutualism and commensalisms have seldom been considered in any ecological system theory. Only prey-predator relationship was recognized as links between compartments in the previous energy-based ecosystem model. Twenty-four attributes were considered to illustrate the development of ecosystem, which were all based on the concept of Bioenergetics (Odum 1969). However, according to the symbiotic continuum theory (Starr, 1975), links between species should be all kinds of biological relationship, which included both positive and negative ones. Only few ecologists noticed above theoretical deficiency (Kareiva and Bertness 1997; Sapp 2004). Stability of a system depends on its week link rather than the strong ones according to theory of small world network (Watt 1999).

Table 5 Types of biological interactions (May 1973; Putman 1994)

		Effect of specie j on i (i.e. sign of a_{ij})		
		+	0	-
Effect of specie i on j (i.e. sign of a_{ji})	+	+ +	+ 0	+ -
	0	0 +	0 0	0 -
	-	- +	- 0	- -

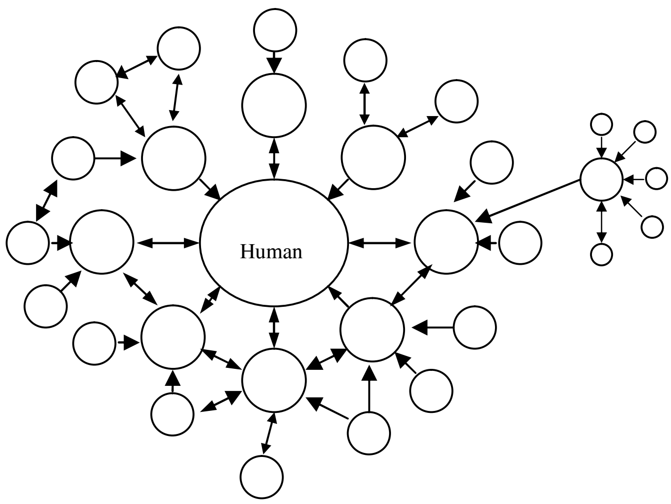
4.2 A Systematic Model Building by the Viewpoint of Symbiosis - Symbiome

A human-centered model (Fig. 2A) rephrased the concept to a human-residential environment, which was very different from the traditional ecosystem model (Table 6). According to the “symbiotic continuum”, the greatest fitness of life history strategy through evolutionary process decided the type of interaction between two biological species (Starr, 1975).

“Symbiome” indicates originally a biological system that organisms (animals, plants, and protists) live closely with micro-organisms (Sapp 2004). On the other hand, endo-symbiosis hypothesis reveals that the complex organisms are a symbiotic system of simple organisms (Margulis and Fester 1991). Therefore, a symbiotic system is a super-organism consisting of many symbionts which has greatest fitness for all kinds, within the abiotic environment. Once the interaction between two species begins, it indicates a simplest symbiome has been formed. The process of expansion of symbiotic system is named “symbiome development”, while the recruitment and extinction of symbionts is called “symbiome assembly”.

Figure 2B illustrates the hierarchy structure of symbiome. Human is in the core. Crop species of plants are “major symbionts” in the primary layer. Human gets benefit by having foods, while crops obtain a secure survival environment. The symbionts of a major symbiont are “co-symbiont” in the secondary layer, which may be the primary consumer, decomposer, bacteria, parasites, and/or habitat-provider of a major symbiont. Any organisms that are the symbionts of a co-symbiont are named “sub-cosymbiont” in the tertiary layer. If human turns out to be a symbiont of certain organism, a small world network may be established.

(A)



(B)

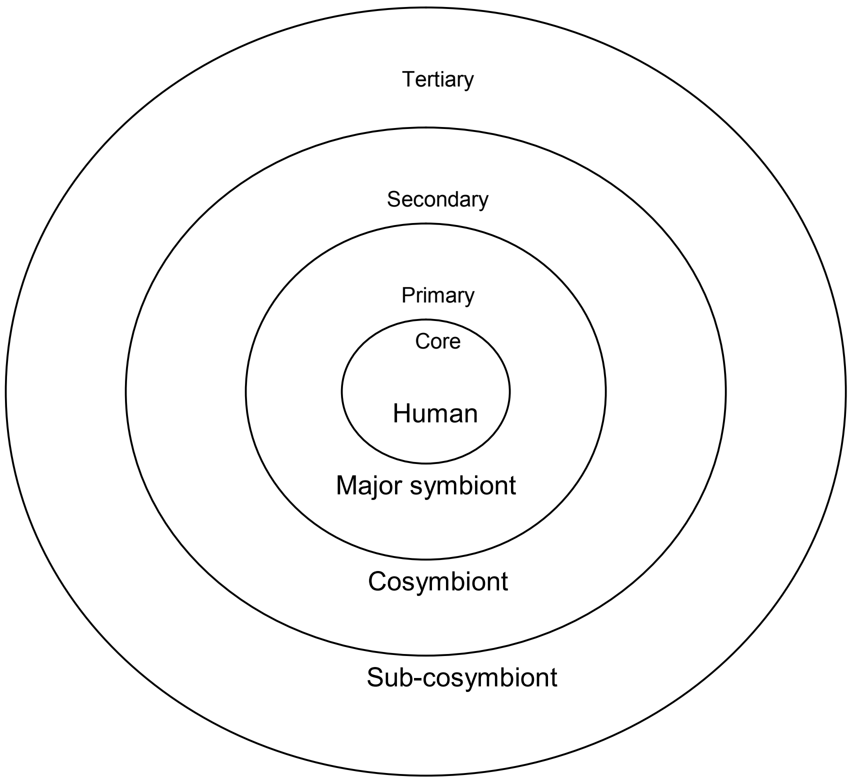


Figure 2 (A) Prototype of the human-centered ecosystem model. Circle indicates symbiotic species. Arrow means formation of symbiosis. Two headed arrow represents obligatory symbiosis, while one headed arrow indicates non-obligatory. (B) Concentric model illustrates the hierarchy of symbiome.

4.2 Interactions among Organisms – Symbiolink

Many biological relationships have been neglected by the energy-based ecosystem model, which only link species with negative interactions (predation). Symbiolink includes positive and negative interactions to form a symbiotic system or symbiosystem (Table 6). Ecosystem consists of biotic and abiotic portions, while symbiome connects biological species with symbiolinks and encloses biotic portion with abiotic environment. Biome is a large ecosystem in a geographic scale, which contains typical animal and plant communities. A large symbiotic system is defined as “symbiome”. Biosphere refers to the range of all organisms on the earth, which symbiosphere indicates the union of all symbiomes.

Table 6 Comparison between energy-based ecosystem (Odum 1997) and symbiotic system

Odum's energy-based ecosystem	Symbiotic system
Biosphere	Symbiosphere
Biome	Symbiome
Ecosystem	Symbiome/Symbiosystem
Interspecific interaction	Symbiolink

4.3 Symbiome and Small World Network

Small-world network is a type of mathematical graph in which most nodes are not neighbors of one another, but most nodes can be reached from every other by a small number of hops or steps. Simplest graph of graph theory indicates the relation of two vertices and one edge. Simplest graphs of graph theory were adopted to build the model of a symbiome. Circle indicated actor and square indicated reactor. The direction of arrow indicated the benefit side (+), and dash line indicated a "00" relationship. Directed graph represents the mutualism, commensalisms, and predation in symbiome, while undirected graph indicates neutralism. If there are N species of symbionts (vertices) in a symbiome (a ring lattice), every species has k symbiolinks (edges) to others. Stability and strength of symbiolinks of a symbiome may be measured with parameters of its particular graph.

5. Realistic Symbiome of the Archilife Symbiosphere I Center

Gynura bicolor was the most abundantly eaten species among 56 species of major symbionts in the ASIC during 2003 to 2006. To illustrate primary and secondary layers of this symbiotic system, the simplest graph of madeira vine (*Anredera cordifolia*) was shown (Fig. 3). Relationships of major symbiont and cosymbionts were illustrated with the analysis of biological association among crops at vine shelves in the ASIC (Fig. 4). Nine out of 28 species co-existed as a big community (Fig. 4). Two sub-communities were recognized, i.e. "lavender sorrel-Asiatic centella" community and "oil grass-vegetable fern" community. The species on the VPS were also analyzed, which were not shown in this paper.

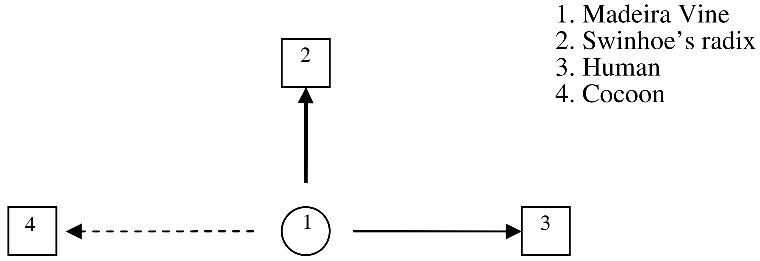

Figure 3 An example expressed relationships among major symbiont (Madeira vine) and its symbionts in the symbiome of the Archilife Symbiosphere I Center. This realistic model adopted simplest graph diagrams. Circle indicated actor and square indicated reactor. The direction of arrow indicated the benefit side (+), and dash line indicated Neutralism (00). There were 7 records from the secondary data set of the species inventory system to generate this diagram.

All crop species are symbiosis with human being and every species has its own symbionts (such as insects and microorganisms). Analysis of biological association clarified the relationships among crops in the first step.

6. Conclusions

The appearance of biological species in the developing process of a symbiotic system might reveal the mechanism of symbiosis. Observations were made and data were collected by the residents. The requirement of a coder for the species inventory system was being familiar with the building structure and its operation, and being capable to use Microsoft Excel, which a common college student can operate. Therefore, a college resident, who living in his/her specific symbiotic community (or a green village), will be able to do the coding and/or the database manager.

After an inventory net work being established, primary data sets will come from different symbiotic communities. Even data from different countries can also be gathered via internet. Only a few analyzers and database managers are needed. This DBMS may become one of the most efficient GBTools to evaluate the status and the degree of symbiolization for a specific green village.

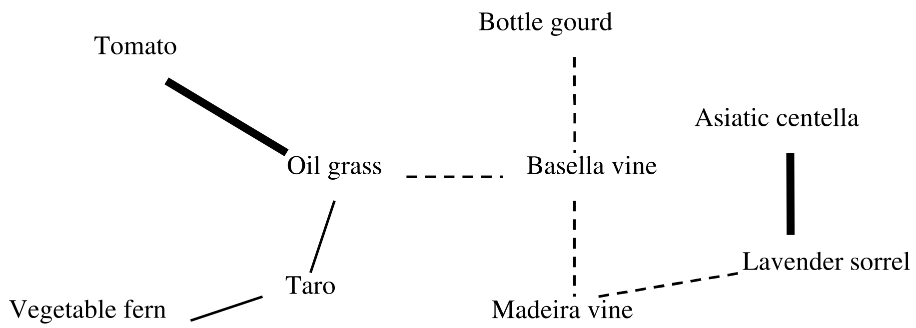

Figure 4 Biological association of crops in the vine shelves of the Archilife Symbiosphere I Center. Solid line indicates the positive association (v>0, p<0.05), while broad solid line indicates strong positive association (v>0, p<0.01). Dash line indicates negative association (v<0, p<0.05).

The key difference between the model of symbiotic system and classical ecosystem is that the relationships of individual species are not only predation but also all positives ones. The parameters to examine the status of a symbiome would be degree of link, stability of community, network efficiency, etc. Therefore, comparison between the symbiome of different symbiosis villages turns out to be achievable. In addition, this brand new concept about human ecosystem would be principles for ecological rehabilitation of an eco-city.

New economic incentives for sustainable building: Density bonuses and domestic carbon project

Dominique Sellier[1], ARENE[2]

[1] Head of Prospective Studies, Economics and Sustainable Urban Planning, d.sellier@areneidf.org
[2] Paris Region Agency for the Environment and New Energies

Keywords: density bonuses, carbon trading, economic incentives, eco-conditionality

Abstract

Land use density bonuses and the implementation of domestic carbon projects in the building industry attest to the rise in prominence of an entire panoply of economic incentive tools, such as preferred mortgage loans, the "eco-conditionality" approach to subsidies and energy performance contracts. These instruments serve to complement the range of purely regulatory or fiscal tools for overseeing sustainable construction practices.

1. Land use density bonuses

1.1 Description of the tool

The planning instrument of granting land use density bonuses on building permits is being increasingly applied in various international contexts. A number of Swiss cantons have adopted this instrument in order to promote the construction of buildings that comply with the *Minergie* energy quality label. Other cities across the world, like Arlington County, Virginia and New York City in the United States, have introduced comparable measures revolving around broader environmental criteria.

The 2005 Energy Law in France provides municipalities with the possibility of increasing land use density ratios (building coverage ratios, i.e. the net floor area derived from use of the maximum building footprint allowable on a given parcel divided by the total parcel land area) by up to 20% for energy-efficient construction that relies on renewable energy sources. This net floor area is calculated without including attic or basement space that could not be made suitable for human habitation, nor does it include roof terraces, balconies and loggias.

The application conditions for this density bonus measure were stipulated in a May 2007 decree, which states: "New clustered construction must satisfy a very high-performance energy efficiency standard specifically dedicated to renewable energies (or "THPE Enr") or low-energy consumption buildings ("BBC", on the order of 65 kWh of primary energy / m^2 / year of net surface area in northern France for heating, cooling, air conditioning, domestic hot water and lighting consumption). New single-family homes must consume 20% less energy than the specified thermal regulation amounts and introduce alternative options from among wood sources, photovoltaic cells, solar hot water and a heat pump with an annual performance coefficient exceeding 3.5. For existing buildings, the planned extension must be aimed at achieving energy neutrality, with an overall insulation of upper floors under the attic space and the installation of facilities adapted to wood, photovoltaic, solar hot water or a heat pump set-up. A solar hot water system must cover at least 50% of total needs, i.e. 3 m^2 per housing unit. The photovoltaic modules must account for at least 25 kWh/m^2 of the net floor area, or a surface area equal to 10% of the net floor area.

Beyond just the energy performance conditions, other parameters in the land use plan may be enhanced by means of conditional waivers or in percentage terms (e.g. increase in building height), according to environmental criteria:

- accepting a waiver on the number of mandatory parking spaces in the event of installing a structure to accommodate bicycle parking, which could reduce the need for underground parking by 20% to 50%, depending on the specific context. This could potentially represent one less underground parking level;
- raising the ground coverage ratio (i.e. the percentage of building footprint with respect to the land area of the parcel designated for construction) for dwellings that incorporate a rainwater recovery device; and

- including a range of greened surfaces (e.g. roofs, decks, walls) to help meet the green space requirement on the designated parcel.

1.2 Application examples

This land use density bonus instrument was initially presented to planning directors of 7 municipalities within the Paris Region participated in a series of workshops organized in 2006 by the ARENE regional agency (for the environment and new energies), in partnership with ADEME (Agency for the Environment and Energy Recovery). Since May 2007, several municipalities from the region have also decided to introduce the measure, led by Paris, Bry-sur-Marne and Issy-les-Moulineaux.

Bry-sur-Marne is a very residential suburb located 12 km from Paris with a population of 15,000. The municipal council has authorized a 20% increase in land use density for all single-family type residential zones as well as mixed-use areas with a housing concentration. Four building permits have already been approved with the land use bonus: they concern subsidized multi-family units that have been targeted for additional insulation beneath the roof and double-glazed windows, as well as solar panels for domestic hot water. In practical terms, this possibility of awarding bonuses actually represents one additional building story (i.e. from a 5-story to 6-story building).

1.3 Outlook for sustainable construction

The benefits of building density bonuses are numerous:
- more stringent sustainable construction requirements: the tool serves to introduce demanding energy and environmental performance requirements in construction projects, especially from the standpoint of the "Factor 4" energy policy (i.e. a fourfold reduction in greenhouse gas emissions by 2050);
- a "win-win" strategy: the inherent incentive principle allows rewarding good environmental practices. The classic objection of "investment overruns" is no longer valid thanks to the economic benefit tied to the number of additional m^2 available to project owners for construction. The total cost drops, while the building use value increases and future occupants take advantage by saving on charges.
- a modular tool, in favor of urban renewal: this instrument applies to all existing urban layouts and not just development projects underway in newer districts. It meets the diversity of land use situations and enables proceeding with "customized approaches" depending on planning priorities adopted by municipalities and the level of environmental awareness shown by the local population;
- an easy-to-implement operational tool: it serves the purpose of translating into practical terms the city's environmental objectives at the construction project scale, with a simple activation process (municipal council deliberation);
- an innovation-enhancement tool: municipalities are able to develop new building projects and renovations with truly exemplary qualities. Such a tool incites cross-disciplinary approaches rallying municipality departments around a common project. This aspect provides an initiation for both decision-makers and professionals to energy and environmental performance issues;
- a contribution to both local and global environmental objectives: the resulting projects contribute to combating the greenhouse effect, conserving water and non renewable energy resources, and improving the environment from a local perspective;
- a valuable action lever during this transitional period: the tool offers the possibility of making progress with motivated actors, without having to wait for a consensus opinion and for the group of economic actors to accept mention of imposing strict energy and environmental requirements in urban planning documents.

Moreover, this measure favoring higher building coverage ratios lies within a general framework for raising density and fighting against urban sprawl, by targeting a greater urban dynamic in optimizing urban networks and services through the guarantee of ecological buildings intended not to compromise lifestyle quality.

As part of recent work conducted at the time of France's multi-party environmental debates, it was decided to generalize, based on experience gained from the land use bonus, these incentive measures on the planning code in order to support sustainable construction, and to raise the possible land use density until 30%.

A reasonable hypothesis calling for adoption by 50% of France's municipalities over the time frame through 2012, then reliance upon the bonus in 50% of building permit applications, would lead to a direct savings of 500,000 tons of CO_2 out to 2012 in all of France (based yearly on one ton of CO_2 saved per new or refurbished dwelling or office).

2. Domestic carbon project

2.1 Description of the tool

In France, just a quarter of the greenhouse gas emissions, accounting for 132.8 million tons of CO^2, are actually covered by the European quota exchange system, within the scope of the national quota allocation plan. Sectors of diffuse emissions, such as the construction, are exempt. A domestic "building" project, pertaining to new construction or energy-oriented building renovations, provides the potential for reducing greenhouse gases throughout the entire nation and, as such, is eligible to generate revenue stemming from the sale of carbon credits. These projects are categorized as joint implementation (JI) from the standpoint of the Kyoto Protocol, i.e. they make it possible for economic actors from one country to contact partners in other industrialized countries in order to yield emission reduction units (ERU) that may be sold on the international market.

Several conditions need to be fulfilled for any given domestic project:

- Reductions in greenhouse gas emissions must be realized during the period 2008-2012;
- The project cannot focus on installations with a power rating of more than 20 MW in order to avoid "double counting" with the national allocation plan;
- Cumulative project components, which means that the project could not be conducted under satisfactory economic conditions without the contribution of carbon credits;
- The project sponsor must make use of an efficient tool for regularly tracking emissions, in the aim of accurately evaluating the quantity of $C0_2$ actually avoided;
- Validation of emission calculation methods by the joint ministerial mission to combat the greenhouse effect.

In France, the *Caisse des Dépôts et Consignations* (a public-sector financial institution) launched a call for projects at the end of 2007 as a means of inciting use of this new economic instrument for an investment envelope of 5 million tons of CO_2 equivalent over the period 2008-2012, with an average redemption price on the order of € 10 per ton of carbon. Around 20 projects in all sectors have been already selected, representing more than 2 million tons of $CO_{2.}$

For the building industry, the potential target in terms of actual projects would be in the range of 20 million tons of CO_2 for the 2008-2012 period, on the basis of a theoretical total deposit of 90 million tons of CO_2, i.e. 4 to 5 million tons for the Paris Region alone, which represents some 15% of all emissions from the residential and tertiary sectors. Among these high-potential target projects would be the reduction in HFC emissions by means of fluid substitution or refrigeration installation change, improvement in tertiary building management or the introduction of biomass boilers.

2.2 Application examples

Two major categories of projects can be distinguished in the Paris Region: those centered on making energy supply modifications to buildings, and "CO_2 dedicated" programs:

- shifting in favor of renewable energies for building heating. Given a boiler with a 1 MW power rating, the transition from gas supply to biomass will allow saving approximately 1,500 tons of CO_2 equivalent in emissions each year. To supply a residential building containing 20 units, the transition to a wood-fired boiler compared with a fuel oil- or gas-fired boiler will generate 25 tons in savings per unit, or for the whole building 500 tons of CO_2 equivalent. The resultant carbon credit would be situated around € 5,000 (i.e. € 10 x 500), or 20% for an investment of € 25,000;
- extending the decarbonized heat networks by means of a geothermal connection for buildings conventionally heated with fuel oil or gas;

- developing, for tertiary office buildings, interest in geothermal heat pumps mounted on piles since residential buildings in the Paris Region sit on a sedimentary basin that often necessitates the installation of piles;
- anticipating, for the set of dedicated CO_2 programs likely to be supported by the Paris Regional Council, a subsidy for either the construction of 500 BBC-certified housing units or the renovation of single-family dwellings resulting in a 50% drop in CO_2 level.

2.3 Outlook for sustainable construction

The advantage of domestic carbon projects is to gain access to both the most sensitive sectors, due to the rise in their emission levels, and the most diffuse in terms of emissions by sending a price signal relative to carbon. The French system, backed by the *Caisse des Dépôts et Consignations*, offers an innovative economic mechanism: it actually represents Europe's first domestic carbon system. Moreover, it incites the "decarbonation" step within economic sectors like construction and urban development, while lowering the total cost associated with emissions reduction. Participation in such projects serves to familiarize economic actors with mechanisms relevant to the carbon markets, which will be expanding over the coming years.

3. Conclusion

Land use density bonuses and domestic carbon projects for the building industry provide two complementary, yet distinct, tools. They open the door to incentive measures that make it possible to reward good practices aimed at generating greater energy efficiency and an improved ecological assessment of the buildings in our environment. Beyond their power of legal, fiscal and public subsidy incentives, these innovative tools serve to revamp the range of economic and financial instruments capable of introducing greater durability into the construction sector from the perspective of "carbon neutrality".

PROMOTION OF GREEN AND SUSTAINABLE BUILDINGS IN A HIGH DENSITY BUILT ENVIRONMENT

Hau-wai CHEUNG[1]

[1] Director of Buildings, Hong Kong Special Administrative Region Government, Hong Kong, China, hwcheung@bd.gov.hk

Keywords: incentives, balance, permeability, set-back, mandatory, heritage, labeling, sustainability

Summary

Hong Kong is a very compact city. The current building law controlling intensity of building development was enacted at a time when the city was undergoing fast economic and population growth. In step with the rising aspirations of our society for improved quality of living space and sustainable built environment, the Government launched an incentive scheme to encourage the incorporation of green and amenity features in buildings. Since then, a number of surveys and studies have been carried out to assess the effectiveness of the scheme and to gauge public views on the effectiveness of these green and amenity features and their impact on the urban environment. To further improve the living environment, various options are being considered, including lowering development density in congested localities, introducing measures to strike a balance between the provision of green features and their effects on building height and bulk, promoting building set back, and increasing permeability of buildings and greenery. Other initiatives, including providing facilities for separating refuse at source, introducing a mandatory building energy code, promoting and mandating regular maintenance of buildings, supporting a comprehensive green building labeling scheme and promoting adaptive reuse of heritage buildings, which are conducive to the quality of the built environment, are also being pursued.

1. Historical Development

Hong Kong is a very compact city. It tops the world cities on the number of tall buildings. With a population of nearly 7 million, only 21% of Hong Kong's total land area, equivalent to approximately 226 sq. km., is developed or urbanized, with another 2% occupied by rural settlements. The rest are mainly woodland, farmland and other rural uses including over 400 sq. km. of protected country parks.

The current building law governing the intensity of building development was enacted in year 1962. It was a time when the city was undergoing fast economic and population growth. Since then, buildings have continued to grow in size and height, taking advantage of new building technologies and the prosperous economy. Many commercial buildings in the urban areas have been built to the maximum development potential with a total gross floor area (GFA) equivalent to 15 times the size of the building lot. Given limited land resources, the development potential of building projects in most of the urban area is maximized and the city has developed into a compact and vibrant place. The construction of the mass transit railway has further improved the accessibility of the city and makes life more convenient for all.

2. Incentives for Quality Living

2.1 Amenities in Buildings

With a view to promoting the provision of a range of building features and facilities to improve the livelihood of people in a densely populated environment, the Buildings Department has been providing incentives by exempting amenity features from the calculation of GFA in building developments, including for example air-conditioning platforms, counters for management staff, service rooms, mail rooms, horizontal screens, recreational facilities and club houses (Figure 1). Such amenity features, though not required by statute, are desirable to improve the quality of a building and living standard of the residents. Provision of such features enhances the sense of care and pride for buildings, thereby inducing proper maintenance and repair.

Figure 1 Club house (left) and management room (right) are examples of amenity features

2.2 Green Features in Buildings

In step with the rising aspirations of our society for improved quality of living space and sustainable built environment, the Government introduced measures (two Joint Practice Notes for building professionals in year 2001 and 2002) to encourage the incorporation of green features in buildings for the use and well-being of building occupants.

Under the Joint Practice Notes, eleven types of green features were promulgated, namely balconies, wider common corridors and lift lobbies, communal sky gardens, communal podium gardens, acoustic fins, sunshades and reflectors, wing walls, wind catchers and funnels, non-structural prefabricated external walls, utility platforms, mail delivery rooms with mailboxes and noise barriers. Subject to fulfillment of certain specified conditions and design requirements, these green features may be exempted from GFA and site coverage calculations.

2.3 Adoption of Green Features

Up to end of April 2008, a total of over 190 completed residential projects have been constructed with green features in response to and in accordance with the Joint Practice Notes. During the same period, a total of about 560 new building projects were completed. It may be noted that some features are more popular than others: balconies are by far the most popular green features, 95% of these completed projects have balconies, 44% have wider common corridors and lift lobbies and 64% have utility platforms.

It is very encouraging to see that the industry has taken up the green concept beyond the scope of the Joint Practice Notes. The wider use of precast concrete is a vivid example (Figure 2). Despite the adoption of precast concrete in public housing projects since the 1980's, the uptake of this environmentally friendly construction method had been slow in the private sector. However, since the issue of the Joint Practice Notes, the Buildings Department has given approval to nearly 100 projects using precast concrete elements. The industry has used precast concrete not only to facades, but also to other elements that would not require exemption from the GFA calculations. In fact, about 60% of these projects adopt elements such as precast stairs, semi-precast slabs and precast structural elements.

Figure 2 Precast stair (left) and precast façade (right)

2.4 Surveys and Opinions from Stakeholders

Since the promulgation of incentives to encourage the incorporation of amenity features in buildings and the issue of the Joint Practice Notes, a series of surveys and studies have been carried out to gauge the public response and review the effectiveness of the incentive scheme. This encompasses:

- conducting questionnaire surveys with stakeholders;
- carrying out on-site evaluation on the usage of green and amenity features in sample buildings;
- conducting focus group meetings with green groups and the professional institutes;
- conducting public opinion surveys.

The majority of the respondents have highly rated the effectiveness of the green and amenity features in improving the living environment and quality of living (Figure 3). Mandatory requirement for the provision of these features is however not supported as it reduces design flexibility.

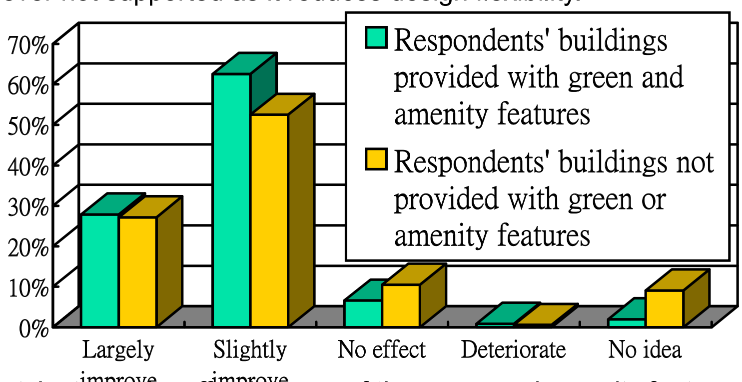

Figure 3 Respondents' rate on the effectiveness of the green and amenity features in improving the living environment and quality of living

There are different views on the impact of the height and bulk of a building on the cityscape of the neighbourhood (Figure 4). Over 60% of the respondents considered that a building which was very tall but occupied a relatively small site area, would be less preferable in terms of its impact on the cityscape and living environment of respondents' neighbourhood, while only around 10% considered a building which was not that tall but occupied a very large site area as less preferable. Protection of important ridgelines and harbour view is also amongst their concerns.

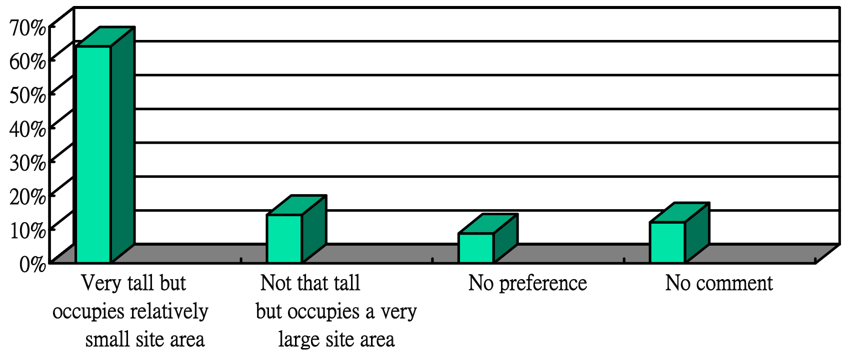

Figure 4 Views on impact of building height and bulk on the cityscape of the respondents' neighbourhood

Many respondents considered it appropriate to exercise suitable control on the amount of GFA exemption. Some have expressed that the magnitude of concessions should be decided after balancing the effectiveness of the incentive and its impact on building bulk.

3. A Balanced Approach

The results of the reviews and surveys have indicated that the incentives are generally effective in promoting the construction of green and innovative buildings. Furthermore, the offer of incentives in the form of GFA exemption is considered to be appropriate and generally welcomed. However, the exemption has an impact on the height and bulk of the concerned building developments. As the city becomes more built up, the effect of high-rise and bulky development is more apparent. It is necessary to take a more balanced approach when granting GFA concessions.

To consider the impact of building height and bulk, it is best assessed by considering the individual building design in relation to its surrounding developments, location and the particular setting of the site or area, the natural topography and the configuration of surrounding streets and pedestrian circulation patterns. Different designs and dispositions of a building, even with the same GFA, may offer different visual and environmental impacts to its surrounding. However, such an assessment entails a complex and lengthy process. It is also site specific and may not fully address district wide concerns.

Another approach is to take a broader view by first reviewing the planning restrictions on development densities and height profiles of the sites and areas and, secondly, reviewing the amount of GFA concessions that may be suitable for different types and densities of development and finally, identifying desirable building forms and configurations that may improve pedestrian comfort and enhance the environment of the surrounding areas.

3.1 Development Densities and Height Profiles

There are many advantages living in a compact urban development. With the associated mixed uses and use of mass public transport, especially rail-based systems, a compact urban development would minimize road traffic and help preserve the rural hinterland from urban sprawl. It can achieve greater energy savings with more efficient utilities services and infrastructural support. However, a high-density built environment may also lead to urban problems, such as stagnant air and heat island effect.

3.1.1 Outline Zoning Plans

To strike a balance between development needs and creation of more open space and less densely built environment, the Government has been reviewing and is undertaking a comprehensive review of the extant statutory Outline Zoning Plans to stipulate additional development restrictions, where justified, for all to follow. Such restrictions may be in the form of lower development density and stepped building heights that may help preserve views, provide visual and spatial relief and achieve wind penetration and circulation. Review priority will be given to those areas subject to high development or redevelopment pressures, waterfront areas along the Victoria Harbour and congested built-up areas. Up to June 2008, 13 revised plans have been published to incorporate building height and/or development density restrictions and concerned parties can voice their views on the proposed amendments.

3.1.2 Lease Conditions

Furthermore, the Government will examine each major sites to be sold carefully and may specify in the Conditions of Sale development parameters like building height limits, maximum GFA and site coverage, setback, non-building areas or open space provisions, where applicable. The Government has also conducted various air ventilation assessments so that any appropriate development restrictions arising from such assessments could be incorporated in the sale conditions.

3.2 GFA Concessions

When reviewing GFA concessions, the Buildings Department is exploring various options to address the concerns of different sectors on the impact on building height and bulk. Such options should strike a balance between the impact of GFA concessions on building height and bulk on the one hand and, on the other hand, the need for the provision of green and amenity features and basic and essential facilities in modern buildings as well as compensation for dedication or surrender of private land for public use.

Measures to reduce the impact of the GFA concessions on building height and bulk that are being explored include:

- reviewing the size of individual green and amenity features such as the sky gardens, podium gardens and recreational facilities;
- reviewing the overall amount of GFA concessions in relation to the size of the development;
- assessing the benefits of combining sky gardens with refuge floors where practicable to help reduce the overall building height;
- assessing a maximum headroom restriction for sky or podium gardens (Figure 5), as preliminary findings of an air ventilation assessment study indicate that the additional positive effect on air ventilation performance tends to diminish when the clear headroom of a covered garden reaches a certain height .

When reviewing these options, tools such as air ventilation assessment survey (Figure 5) and photomontages are adopted to help compare the general effect of building height and bulk on air ventilation and visual impact to the surrounding area.

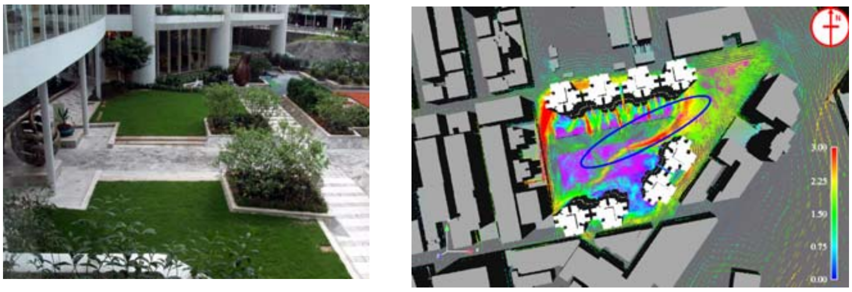

Figure 5 Podium garden (left) and air ventilation assessment survey (right)

3.3 Building Design

In addition to the above measures, the Buildings Department has commissioned a consultancy study entitled "Building Design that Supports Sustainable Urban Living Space in Hong Kong". Results of the consultancy show that better building designs can help reduce the visual and spatial impacts posed by tall and bulky buildings. Better building designs can also help improve the air ventilation between buildings and hence the urban living environment. Recommendations put forward by the consultant that are being considered for application in new development sites include:

3.3.1 Building permeability

Increased building permeability can provide “air paths” through the development site to the neighboring areas (Figure 6). Building permeability may be provided in the form of building separation and by stipulating a maximum permissible length of building facade. Easy-to-use guidelines may be established by making reference to the length of adjoining building facades and the width of the adjoining streets. Design flexibility is given by permitting the use of air ventilation assessment to determine an equivalent performance.

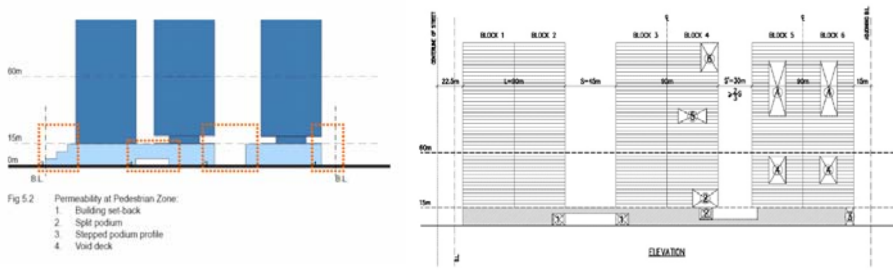

Figure 6 Permeability study diagrams

3.3.2 Building setback

Building setback can help mitigate the deep street canyon effect and hence improve the pedestrian environment (Figure 7). A critical part of air volume affecting the pedestrians at street level has been identified and focus is placed on the improvement to the air volume at this pedestrian zone. Such building setback requirement may be particularly applicable to development sites abutting narrow streets.

3.3.3 Greening

Greenery can mitigate the heat island effect and enhance public health and amenities (Figure 7). Different requirements on the amount of planting area may be applied to different sizes of development sites.

4. Legislative Measures

Green buildings do not stop short at the design and construction stage. They should facilitate occupants' pursuit of green life styles and, through regular maintenance, be sustainable to withstand the test of time.

Experience has shown that the offer of incentives in the form of GFA concessions is effective in promoting certain green and amenity features as described above, but not all, in particular those requiring continuing maintenance and management throughout the operational phase of a building. Furthermore, despite the offer of various financial incentives and technical and social support, some owners of existing buildings are reluctant to take up regular inspection and maintenance of the buildings which could lengthen the life cycle and sustainability of a building.

The Government is proposing various legislative measures to help promote a sustainable built environment as detailed below.

4.1 Refuse Storage and Material Recovery Room

There is an imminent waste problem as the landfills in Hong Kong will be running out of space in the early to mid 2010's. To reverse the rising trend of waste requiring disposal, the Government has been taking various measures to promote waste reduction and enhance source recovery of waste for recycling. Through source separation and other complementary measures, the domestic waste recovery rate has increased from 14% in 2004 to 23% in 2007.

A major problem encountered in implementing the source separation of domestic waste programme is that the majority of domestic buildings in Hong Kong do not have a refuse storage and material recovery room on every floor and there is often a lack of space for placing waste separation facilities. Although the building laws have been amended in 2000 to allow such facilities be disregarded in the GFA calculation, it is noted that few new building developments have provided such facilities.

The Government has therefore proposed to amend the building laws to make the provision of refuse storage and material recovery room on every floor a mandatory requirement for new domestic buildings and the domestic part of new composite buildings. Such legislative amendment was passed on 12.7.2008 and the amendment regulation will come into operation on 1.12.2008. Apart from facilitating the recovery of recyclable materials, the provision of a refuse storage and material recovery room on every floor of buildings can also help to alleviate potential fire hazards and hygiene problems.

4.2 Building Energy Codes

There is a strong link between energy consumption and emissions of greenhouse gas. About 50% of the energy consumed was electricity consumption, of which 89% was for buildings. As electricity generation is the single largest source of air pollution in Hong Kong, it follows that improving energy efficiency would also help improve local air quality. It also makes economic sense for the community as a whole to make higher upfront investment in energy-efficient installations which will be more than compensated by the subsequent saving in electricity bills.

However, since 1998 when the Government implemented a voluntary Hong Kong Energy Efficiency Registration Scheme for Buildings, only very few non-government premises have come forward for registration. As voluntary compliance with a higher energy efficiency standard appears not to be forthcoming and amidst growing environmental concerns, there is a need to pursue mandatory implementation of the building energy codes. A public consultation has been conducted early this year and results of which are being compiled. In the meanwhile, the Government will continue with its various energy efficiency initiatives, such as stepping up publicity and educational efforts to change consumers' perception and to encourage the public to take actions to save energy.

4.3 Mandatory Building and Window Inspection Schemes

Since 2001, the Buildings Department has intensified the enforcement actions and embarked on a number of large-scale operations to clear unauthorized building works and repair defective drains and buildings. Results have been encouraging, but government actions have its limitation and active participation of the public will improve efficiency. Afterall, proper maintenance of buildings and premises is the ultimate responsibility of building owners.

To attain a long-term solution to the problem of building neglect, the Government has conducted a series of public consultation and is currently developing a legislative amendment proposal to introduce a mandatory building inspection scheme and a mandatory window inspection scheme.

When developing these schemes, the Buildings Department has reviewed its policy from the owner's perspective and has aimed to strengthen all the support services and assistance available to owners. A Code of Practice will set out the control mechanism, the site supervision requirements and the inspection and repair standards clearly and systematically so that the quality of work can be guaranteed.

To complement the scheme, the support of a non-government organization with special expertise in building management and maintenance, the Hong Kong Housing Society, has been solicited to provide assistance to owners in need. The Housing Society has committed a total of $4 billion to put in place a range of financial incentives, technical support and assistance throughout the rehabilitation process from pre-inspection stage to final completion of rectification works.

In addition, the Buildings Department currently operates a $700 million Comprehensive Building Safety Improvement Loan Scheme that offers low interest or interest-free loans to those owners in need. On top of this, the Government has recently allocated a capital grant of $1 billion for the next five years to establish a Building Maintenance Grant Scheme for Elderly Owners. The objective is to provide financial assistance to eligible elderly owner-occupiers for timely building maintenance and repair and again, the Hong Kong Housing Society will help implement the Scheme.

In the meanwhile, the Buildings Department will strive to continue its enforcement work, in particular against uncooperative owners in the removals of unauthorized building works in order to assist other owners or the owners' corporations to organize building repairs.

5. Green Labelling

Promotion of green and sustainable buildings will be incomplete if there are no benchmarks to help building professionals, the industry and the public to measure the performance achieved and to give recognition to exemplary buildings. Two schemes are being developed and the Government is lending its support to both schemes.

5.1 Voluntary Building Classification Scheme

The Hong Kong Housing Society and related bodies are working on a Voluntary Building Classification Scheme (VBCS) that is specially designed to give positive recognition to properly maintained and well-managed buildings. It focuses on the satisfactory maintenance and management of existing buildings to ensure health and safety to occupants and the public. Buildings accredited with good ratings under the VBCS are proposed to be exempted from the proposed mandatory building inspection scheme.

5.2 Integrated Building Environmental Assessment Method

Features of an existing assessment scheme, the Hong Kong Building Environmental Assessment Method (HK-BEAM), are being refined by incorporating the desirable features of the Comprehensive Environmental Performance Assessment Scheme which was previously developed under a consultancy commissioned by the Buildings Department. Upon completion of various enhancements, this will be an integrated building environmental assessment model for the local construction industry to give recognition to efforts made for greening throughout the life cycle of a building.

6. Adaptive Reuse of Heritage Buildings

Cultural life is a key component of a quality city life. It is also indispensable in any sustainable society. As Hong Kong develops progressively with some of its old and historic buildings replaced by modern ones, people are aspiring for better quality living and, in recent years, have expressed passionately to the conservation of historic sites and buildings.

To demonstrate the Government's commitment to heritage conservation, a comprehensive package of measures has been launched. In February this year, the Government introduced a Partnership Scheme to revitalize historic buildings in public ownership (Figure 8). Under the Scheme, stakeholders and the public are engaged to submit proposals for using these buildings to provide services or business in the form of social enterprises. For the first phase, a total of seven historic buildings have been identified. The response from the public is overwhelming and 113 proposals have been received from various non-profit-making organizations. The Government will provide professional support for successful applicants to take forward their proposals in the areas of heritage conservation, land use and planning, building architecture and compliance with building laws. Where justified, financial support will also be provided.

Figure 8 Lui Seng Chun (left) and Lai Chi Kok Hospital (right) are examples of historical buildings under Partnership Scheme

In addition, the Government has set up an Office of the Commissioner for Heritage to provide a focal point to take forward heritage conservation work. The Buildings Department has also recently set up a dedicated team, the Heritage Unit, to help process submissions related to heritage buildings, to provide technical advice to practitioners and other Government departments and to expedite pre-submission enquiries so that any issues relating to heritage conservation and compliance with building regulations could be resolved at the earliest opportunity. The Unit has also been tasked to prepare guidelines for adaptive reuse of heritage buildings to meet the required health and safety standards.

7. Concluding Remarks

The Government has been engaged in a continuing multi-pronged programme of promoting green and sustainable buildings in Hong Kong. The offer of incentives has encouraged building professionals and developers to enhance facilities and offer a plethora of green features to new building developments. When implementing the incentive scheme, due regard has to be given to the impact on the building height and bulk. Through good planning, environmentally friendly building designs, green life styles, proper building maintenance and adaptive reuse of historic buildings, people of Hong Kong can truly enjoy all the benefits of living in this high density built environment.

POLICIES FOR IMPROVING ENERGY EFFICIENCY IN THE BUILT ENVIRONMENT

Peter SZENTAL BA BSc MBA[1]

[1] Szencorp Sustainable Development – 40 Albert Road, South Melbourne 3205, Australia, peter.szental@szencorp.net

Keywords: efficiency, policy, emissions, measures, barriers, principles

Summary

This presentation covers the broad policy landscape for energy efficiency in Australia, including the role of buildings in energy consumption and in Australia's greenhouse gas emission profile; existing policies which aim to improve building energy efficiency, and the rationale for incentives to bring forward energy efficiency investment; the complementarity of energy efficiency with other measures to reduce greenhouse gas emissions; and the suite of policies recommended by industry to unlock the maximum energy efficiency potential of the building sector, across regulation, voluntary standards, market mechanisms, targeted financial incentives and awareness raising.

1. The opportunity for smarter energy use to reduce emissions

Becoming smarter about energy use is a proven method for households, government and businesses to benefit financially while reducing environmental impact. The Federal Government recognises that smarter energy use is Australia's most cost-effective means of reducing greenhouse gas emissions (Securing Our Energy Future, 2004). Not only does smarter energy use lower the cost of reducing greenhouse emissions, it reduces the costly network infrastructure investments otherwise required to meet growing demand. ABARE estimates that energy consumption (gas and electricity) will increase by 60% over the next 25 years under a "business-as-usual" scenario. The required increase in electricity generation to meet our growing power needs is expected to be 62% from 252 TWh in 2004/5 to 408 TWh in 2029/30.

Around the developed world expert analysis (including the International Energy Agency and UK Stern Review) indicates that improved energy efficiency offers large potential for greenhouse abatement at a positive financial return. This potential is especially large in Australia as its performance in energy efficiency has lagged the rest of the world. As recognised by the State Governments National Emissions Trading Discussion Paper (2007) and the report of the Federal Taskforce on Emissions Trading (2007), programs targeted at energy efficiency will also lower the economic cost of a given greenhouse emissions cap.

The economic potential of smarter energy use has been extensively modelled as part of developing the National Framework for Energy Efficiency, which has shown that 50% penetration over a 12 year period of a low energy-efficiency improvement scenario (excluding the electricity supply sector) delivers the following economic benefits:

- Real GDP would be $1.8 billion higher (+0.2%)
- Employment would increase by around 9000 (+0.1%)
- A 9% reduction in stationary final energy consumption (-213 PJ)
- A 9% reduction in greenhouse emissions from the stationary energy sector (-32 MT).

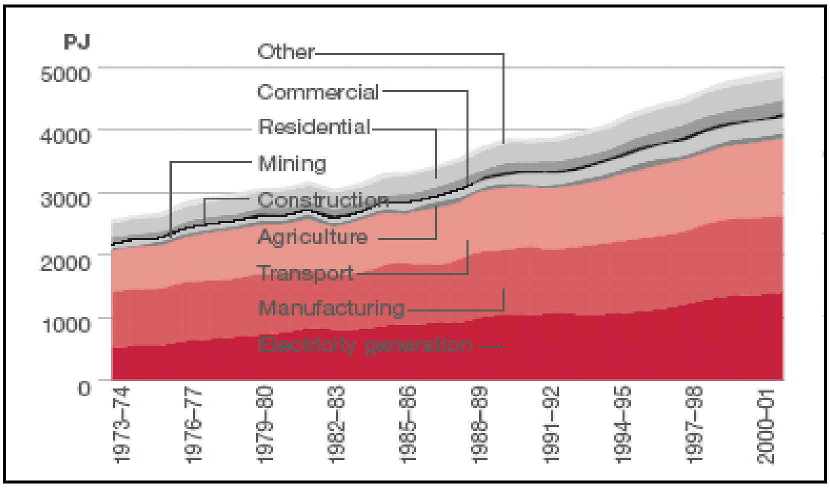

Figure 1 Australian Primary Energy Consumption by sector, 1973-74 to 2000-01

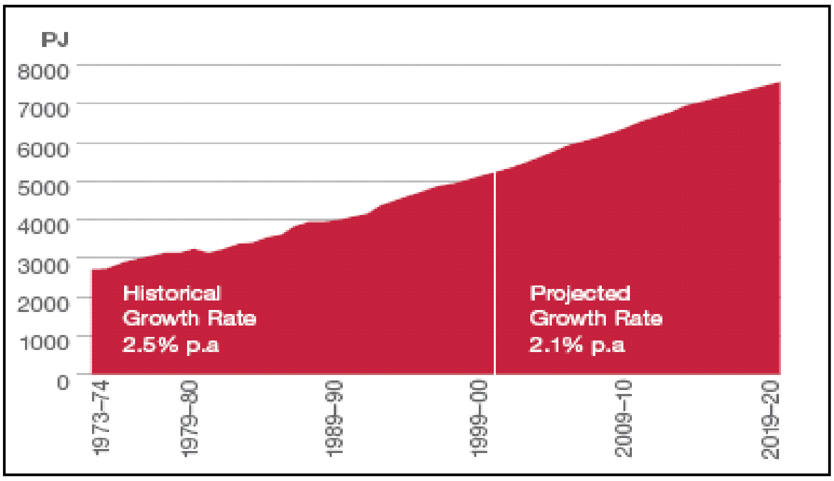

Figure 2 Australian Primary Energy Consumption – historical and projected

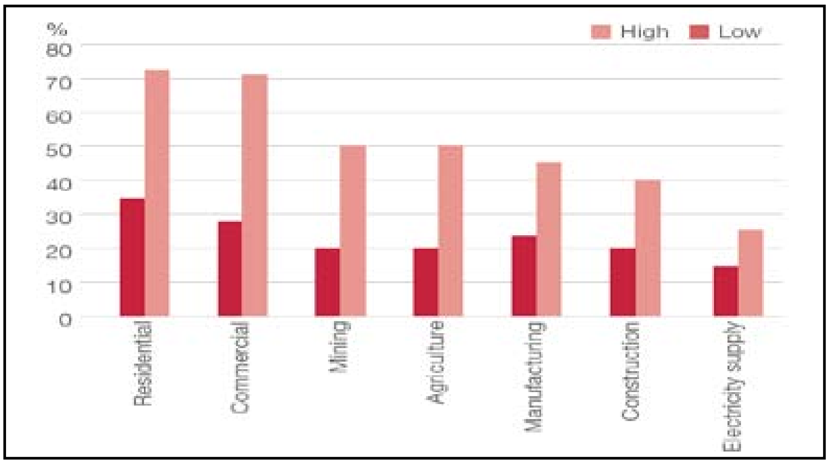

Figure 3 Cost–effective energy consumption reduction potential across sectors - NFEE analysis on percentage cost-effective energy consumption reduction. Low = currently commercially available technologies with an average 4 year payback and High = existing or potential technologies with an average 8 year payback.

These figures show that, outside of industrial efficiencies, cost effective opportunities for pursuing energy efficiency are significant. It is estimated that the buildings sector accounts for 23% of national emissions, given that most of our generated electricity is consumed within buildings.

On the other hand, the task of improving energy efficiency is complex. A key challenge in developing a comprehensive coordinated energy efficiency strategy is the diversity of the ways in which energy is used and the ways in which greater energy efficiency can be encouraged.

Szencorp firmly believes that existing building retrofitting must be the clear focus of any mitigation efforts. New buildings make up a tiny percentage of overall building emissions and policies that target them such as incremental improvements to building codes and standards will not provide the scale of momentum required for implementation of energy efficiency.

2. Barriers to greater energy efficiency

2.1 A behavioural economics approach

There is a general view held by some economic theorists that the potential for cost effective energy efficiency in existing buildings is being taken up; in economic terms, this view holds that agents are behaving rationally in delivering an optimal level of energy efficiency. However the market operates less than perfectly in delivering energy efficiency. Despite the apparent economic incentives, smarter energy use is often not taken up. A great deal of relevant work has been done that examines the true dynamics of decision making for energy efficiency, and its non-rational behavioural aspects (see in particular IEA (2005) and works authored/co-authored by Richard Thaler in "Useful References and Further Reading" listed below).

Clearly, private actors face barriers other than financial barriers, real or perceived, which inhibit better energy practice. As a result incremental increases in financial incentives by, for instance, attributing a price to carbon dioxide emissions through emissions trading will not in themselves unlock the energy savings potential through ever louder appeals to economic rationality; complementary measures are required to be directed specifically at initiating smarter energy use. In relation to energy efficiency a case can be made for what Sunstein and Thaler (2003) called "libertarian paternalism", that is, attempt to steer people's individual choices in welfare-promoting directions without eliminating freedom of choice, to the achievement of broader societal goals.

Barriers to the uptake of smarter energy use practice have been well recognised in many studies (including under the National Framework for Energy Efficiency, and in Issues Paper 5), the most important of which broadly include:

- *Behavioural issues (e.g. lack of priority, short-termism, cultural inertia, non-core business activity)* - electricity typically makes up a small percentage of business costs (estimated by the National Institute of Economic and Industry Research) at under 3% of total expenditure for most economic sectors. Further, there is a lack of understanding of potential cost-effective savings options and available expertise or mechanisms for financing and delivering them.
- *Split incentives* – in many cases the party incurring the capital cost of energy efficiency measures does not receive the saving benefits of the upgrade, e.g. between landlords and tenants of a building.
- *Transaction costs (especially measurement and/or verification)* - the recognition of savings often requires the aggregation of a large number of small energy saving actions, making transaction costs of realising the incentives prohibitive in some cases.
- *Coupling of energy consumption and electricity retailer and distributor profits* (noting that energy savings techniques and products can offer greater margins for retailers than the sale of electricity)
- *Network pricing (avoided infrastructure investment)* - due recognition is not currently given to the important role some technologies can play in reducing network costs and/or peak loads.
- *Bidding schemes* – Efforts put into submitting bids for funding waste scarce industry resources (engineering) and can create long delays or uncertainty for suppliers and customers
- *High hurdle rates and incrementalism* - the selective implementation of opportunities that could be considered "low hanging fruit" impedes implementation and cost-effectiveness of deeper saving programs. Technology for energy savings cannot be applied on a purely incremental basis – often to achieve greater savings projects must be tackled in an integrated way to achieve synergies.
- *Access to capital* – while energy efficiency can provide an attractive return there are many competing and better understood demands for investment capital.

- *Research, development and deployment issues.*

It can be argued that many of these transaction costs and information asymmetries do not automatically and of themselves justify government intervention. However the public good nature of the greenhouse abatement benefits and the reduced overall cost of abatement that can potentially be generated create a clear role for government to provide incentives to accelerate uptake of energy efficiency.

2.2 The need to recognise avoided network and transmission infrastructure

As noted in the fifth dot point above, not only does smarter energy use lower the cost of reducing greenhouse emissions, it reduces the costly network infrastructure investments otherwise required to meet growing demand. From an infrastructure point of view, it is conclusively cheaper to meet growing electricity demand at the margin not by creating new network capacity, but by improving the capability of the existing network by reducing waste. Estimates by NEMMCO put the cost of upgrading/augmenting Australia's electricity delivery infrastructure at approximately $37 billion dollars to 2020; approximately $4 billion a year has been committed for the next five years (sourced from reports at http://nemmco.com.au/nemgeneral/040-0048.htm).

Alongside the network infrastructure savings are savings in electricity transmission losses, which are significant depending on the age and condition of existing infrastructure. It is much more cost effective to generate electricity locally for local use than to create an electricity transport requirement through insistence on centralised power supply. This also carries benefits for the security of supply to particular regions. Current network pricing and regulatory regimes pay little acknowledgement to this aspect of electricity supply, such that distributed/embedded generation appears unfairly expensive in comparison to centralised options (e.g. fossil fuel, nuclear, large-scale wind or geothermal power supply options).

3. Policy design principles for smarter energy end use in buildings

- In order to be effective it is proposed that the following policy principles need to apply to any effective policies that might be put forward:
- *Long term certainty* – policy measures must not be subject to frequent change if they are to be effective in improving market conditions.
- *Technology neutrality* – any policy measures must not "pick winners" among particular technological solutions, thereby allowing for the possibility that better solutions may emerge.
- *Address long term non-price barriers* – while price incentives are important, key barriers to better take-up of energy efficiency are non price barriers.
- *Provide broad based incentives* – ideally measures will be able to apply across sectors, user groups and different actors.
- *Apply nationally* – application of numerous similar schemes at state or local level has led to higher admistrative burdens and administrative complexity, especially for organisations that operate across jurisdictions.
- *Create measurable results* – while gradual transformation of the market is important, measurable results are key to making inroads into greenhouse emission reductions and reducing future economic liabilities.
- *Minimise transaction costs* – efficacy of the measure is important both in terms of its administrative simplicity and its ability to capture small and disparate savings sources.
- *Price energy to more accurately reflect its true cost* – this particularly captures the need to recognise the delivery cost of energy in any analysis
- *Ensure equity for consumers* – any measure must not lead to unfair advantages or disadvantages for particular members of the community.

4. Key Policy Options

Each of the policy instruments is suggested below for consideration alongside the policy design principles in an effort to ensure that, if progressed, efficiency and efficacy of each measure would be maximised.

4.1. Energy Use Target

It is essential to policy development in this area to set out the scale of the expected policy impact, in this case, the quantum of energy to be saved. This target can then form the foundation stone of a comprehensive suite of energy savings actions, delivered by a broad spectrum of policy settings across different tools and audiences.

Given expected electricity demand growth of 2.1% p.a. to 2030 (ABARE 2005), a goal of restricting electricity demand growth to under 1% per year could also be an appropriate first step. This compares to recent EU estimates which set its cost-effective, technically feasible energy savings potential at more than 20%, which equates roughly to a 1% annual reduction in energy use (Commission of the European Communities, 2006).

The suggested target for Australia is relatively unambitious given the cost-effective opportunities that exist. For Australia, a target of restricting electricity demand growth to 1% p.a. means, in absolute terms:

- an electricity saving of 1.1% of total demand each year, or approximately 4000 GWh, which can be allocated to sectors of the economy according to identified potential.
- Greenhouse savings of the order of 4-5 million tonnes annually, cumulatively delivering a national greenhouse gas reduction of over 60 million tonnes by 2020, or more than 10% of current national emissions.

For Australia, a target of no electricity demand growth means, in absolute terms:

- an electricity saving of ~2.1% of total demand each year, or approximately 7000 GWh, *roughly the equivalent of avoiding the requirement to build a 500-1000MW power station each and every year*.
- Resultant greenhouse savings of ~8-10 million tonnes annually, cumulatively delivering a national greenhouse gas reduction of over 100 million tonnes by 2020, or more than 16% of current national emissions.

4.2. Smarter Energy Use Fund

This fund would build on the “Energy Savings Fund”/”Climate Change Fund” model used by NSW, and also cover recognition of distributed generation alongside energy savings, as part of recognising avoided infrastructure costs. The money for the fund could be raised via a levy on electricity network businesses, with the rationale that the extra cost associated will be more than offset by reduced energy consumption that will avoid the need for them to undertake costly network augmentations; essentially the fund should therefore provide a net positive financial outcome or at the very least be cost neutral.

The Government has already earmarked funds raised from the auctioning of permits under an emissions trading scheme to be diverted to energy savings activities, and this is also a likely source of permanent revenue for the Fund.

Impediments to the achievement of our energy savings potential occur across different sectors of the economy, and vary in their nature across the supply chain. Incentive programs must therefore target specific sectoral groups. A fund must therefore be flexible enough to target both “direct measures”, i.e. activities that bring about cost effective greenhouse abatement, and “market transformation”, i.e. those non price barriers that prevent even more widespread take-up of smarter energy use. Beyond this, funds would need to be allocated to research and development in energy efficiency, which does not stand still in a technology sense – new products and techniques are constantly emerging that can improve efficiency outcomes. While a great deal of focus is on costly development of new energy supply technologies, there is little or no focus on development of energy savings technologies.

From an equity perspective, some of the fund could also be targeted at lower income households through a “voucher”-style scheme which allows recipients to spend the money only on specific energy saving appliances. This also allows the fund to remain as broad based and market driven as possible.

A Smarter Energy Use Fund would provide long term certainty if a permanent funding source could be established, such as from the auctioning of permits under an emissions trading scheme. A percentage of the fund could be specified for energy efficiency projects or for use by particular instruments such as energy performance contracting.

Similar funds have demonstrated high transaction costs in conducting “bidding rounds”, however this can be overcome by creating a threshold cost level at which activities could pre-qualify for funding on a rolling basis.

4.2.1 Energy Performance Contracting

Another possible application for such a fund is in seeding or catalysing building energy retrofits using performance contracting. Performance contracting is a well developed technique that allows a specified improvement in building performance to be guaranteed by a specialist energy company, unlocking the potential for private finance to fund the initial upgrade.

4.3. "White Certificate" market-based energy savings scheme

Energy efficiency schemes are in operation in a number of countries with promising early experience emerging (World Energy Council, 2008). An Australia-wide market based mechanism/retailer obligation to support energy efficiency (extending to and expanding on the NSW and Victorian schemes) could operate in a similar manner to MRET. This will be an effective way to target and provide incentives for energy savings improvements for existing buildings across residential, commercial and industrial applications. To overcome transaction costs, pre-qualification of certain technologies would be appropriate, for example greenhouse savings from upgrades of chillers and lighting controls can be assessed according to a pre-approved methodology, rather than having to be assessed on a case by case basis for applicability. Special provision, also, should be given to projects which reduce transmission losses and peak demand requirements (e.g. distributed and intermittent generation technologies).

Such a scheme would run in parallel to an emissions trading scheme and, similar to MRET, would provide an appropriate complementary measure to emissions trading in stimulating investment in particular types of emission reductions activity that have great potential.

It is difficult for such schemes to be technology neutral, because Government must decide what's in and what's out. However, robust methodologies are being developed to ascertain the value of inclusion of particular technologies and activities under schemes such as these.

4.4 Improve baseline performance through standards and regulations

Experience has shown the efficacy of regulation and mandating of minimum efficiency standards for avoiding poor performance. This includes Minimum Energy Performance Standards (MEPS) on appliances, Australian Building Code requirements for residential and commercial construction, and voluntary/de facto standards for commercial buildings, all of which have been deployed to some effect and in which Australia has displayed international leadership. The previous Commonwealth Government's phasing out of incandescent lightbulbs through the setting of minimum energy standards is a good example of this. The regulatory approach may also be applied cost effectively to other product areas.

It is noted that minimum standards tend to capture worst performers only and do not unlock the true energy savings potential, for which further incentives are required.

4.5. Facilitate the creation of an informed market

Smarter energy use is ultimately about informed choice by individuals, not just government intervention. However, government has a role to play in ensuring individuals have the information to make informed choices in household and workplace contexts. A strategic, integrated education program could help to create better informed energy consumers in both households and businesses. This would include, for example:

- A nation-wide roll-out of the greenhouse and energy awareness raising Victorian Black Balloon promotion campaign to other states.
- An improved and enlarged energy performance labelling and disclosure framework for both buildings and appliances. In particular introduction of mandatory disclosure of energy performance of existing residential and commercial buildings when they are leased or sold. This has been a Government commitment under stage one of NFEE but several years on is still yet to be implemented. Requirements for information disclosure have been trialled in the ACT and NSW under the Energy Smart scheme, which highlighted the importance of enforcement of requirements for savings to be achieved.
- Continuation and expansion of energy performance assessment requirements for businesses (Currently Victoria, NSW and the Federal Governments all have their own mandatory energy assessment/audit programs but quality assurance of assessments is missing).
- National roll-out of electricity smart meters in conjunction with in-house displays to provide real-time information about energy use.

- Mandatory, public reporting of greenhouse emissions via a website, just as occurs with the National Pollutant Inventory for other pollutants.
- Supply intermediaries – builders, equipment suppliers, installers, planners, construction consultants and others also have important roles to play in delivering energy smart advice and products. Targeted information and facilitation of behaviour of these sectors towards energy savings is required.

It is noted that the creation of a comprehensive greenhouse and information reporting network under an emissions trading scheme will supersede the need for some aspects of information provision.

4.6. Develop the depth of Australia's skills base to deliver on the potential

The energy services industry in Australia remains small and will need to grow if the energy savings potential is to be realised. Developing Australia's skills capacity and educational infrastructure to deliver on smarter energy use will therefore be required. Training and accreditation programs for industry professionals need to be developed alongside other efforts to grow demand for energy efficiency.

4.7 A note on "green" depreciation

Green depreciation is a form of accelerated depreciation for buildings that meet a specified environmental standard. Some commentators have proposed that applying accelerated depreciation to existing non-residential buildings would provide a strong incentive for building owners to refurbish their existing building stock, bringing about a rapid reduction in the substantial environmental footprint of the buildings sector. This would create a cost to Government in terms of the tax revenue foregone, though this is recouped eventually, restricting the cost to Government to the time value of money. However, there is little if any incentive created by this measure for short to medium term investors looking to buy, upgrade a building and then on-sell, nor in the eyes of developers, designers or tenants. The result would simply be to increase capital gains tax liability (by decreasing the buildings value for calculating capital gains). Only long term institutional investors with a 15 year plus time frame could conceivably benefit, but it is unlikely that this would create more than a marginal improvement in incentive. It is likely that funding directed to specific successful implementation policies through a more direct funding program would achieve more cost effective results than any changes to the tax system, which may also be expensive and difficult to administer.

GREEN PRODUCTS FOR GREEN BUILDINGS THE ECOLABEL SOLUTION

Petar Johnson[1]
Sven Paufler [1]

[1] Good Environmental Choice Australia, Australia, pjohnson@geca.org.au

Keywords: ecolabelling, ISO 14024, sustainable, building, global, network, impact, environmental, GEN,

Summary

After the design and planning stage of a development the difficult question of choosing environmentally preferable materials can become a real challenge to most developments. Third party ecolabelling offers a solution with credible environmental information that has been independently assessed offering an overall environmental performance picture. ISO 14 024 based ecolabelling programs are spread across the different jurisdictions where new Green Building Councils are emerging having been established many years ago to aid green procurement. These established product based ecolabelling programs offer an important solution to Green Star projects that do now wish to be hampered by the time delays and limitations of green material and product selection in projects. There are however qualifications and analysis required to ensure that you are choosing the right ecolabelling program in considering transparency, life cycle multiple criteria completeness, verification accuracy among other considerations.

1. Introduction

To deliver environmentally preferable building architects and designers need to consider a wide range of design, material, maintenance attributes of a construction. However once the design, location and orientation, size and function attributes have been completed an architect is left with the problem of selecting between materials and products which may appear to have the same look and feel, but have very different environmental impacts. How designers choose different product materials on the basis of environmental performance is fundamental to the outcomes desired by any particular development on environmental grounds. The independent and comprehensive assurance of the environmental loads of a particular material such as carpets, paints, plasterboard, lighting, furniture and fittings, flooring is the preferred international best practice methodology. It is at this crucial stage of the development process that ecolabelling can be a fundamental asset to the environmental performance design tools available to developers.

Ecolabelling is a voluntary method of independent product environmental certification. An ecolabel identifies overall environmental preference of goods and services within a specific product category, based on product life cycle considerations. Ecolabelling programs are third party verification initiatives, which separate them from “green” symbols or claims made by manufacturers and service providers (first and second party initiatives[1]). Certified ecolabelling is not limited to a singular issue of the product. The unique improvement of ISO 14 024 ecolabelling is the use of multi criteria standards developed by considering the product’s whole life cycle. This distinguishes these ecolabels from single issue labels, which focus only on one environmental factor such as energy or water consumption. Unfortunately, by focusing on a single issue these claims / labels neglect all other environmental interactions of the product. This presentation focuses on voluntary third party, multi criteria ecolabelling programs and the contribution these deliver to a “greener”, more sustainable building industry. Furthermore, through a global network of harmonised ecolabelling organisations the tools are already in place to assure a “green” supply chain, which is appropriate in a globalised economy.

1.1 The Global Ecolabelling Network and international harmonising of ecolabelling

During the past three decades there has been growing need to have independent assurance of the environmental performance of products. This has led to the popularity and the emergence of numerous national ecolabelling programs operating around the world using the life cycle based approach to giving comprehensive and comparable information to consumers. The first program (Blue Angel) commenced in Germany in 1977 with most western Countries now having established national programs.

In 1994 some of these national ecolabelling programs founded the Global Ecolabelling Network (GEN) as an umbrella organisation for third party ecolabelling. GEN supports ongoing international and national ecolabelling discussions through a variety of activities. These aim to improve, promote and develop

[1] 1st party initiatives are self claims by the manufacturer and thus by those who directly benefit from the claim. 2nd party initiatives can also have vested interests.

ecolabelling of products, to foster co-operation, information exchange and harmonization among its members to encourage the demand for more environmentally responsible goods and services. By the end of 2006 the Global Ecolabelling Network had 27 member organisations, which operate ecolabelling programs in nations around the world.

In 1996 the International Organisation for Standardisation (ISO) published the ISO 14000 standard series to incorporate the many facets of Environmental Management Systems (EMS). As part of this series the ISO14020 standards were developed in the late 1990s, as a framework for environmental labels and declarations. Within this 14020 series, three types of initiatives are recognised:

Type 1: Environmental labelling programs (ISO 14024), which are voluntary, multi-criteria based, third party programs[2].

Type 2: Self-declared environmental claims (ISO 14021) and

Type 3: Environmental declaration programs (ISO 14025), which are based on life cycle assessments of products, without certification[3].

Several of the GEN member organisations made substantial contributions to the development of the ISO 14024 standard. Since then the GEN member organisations have implemented ISO 14024 as a code of best practice into their programs. This ensures the credibility, transparency and comparability of GEN's programs. In addition by operating under the framework of the same ISO standard, it opened the way to mutual recognition of the different national ecolabelling programs. Recently the ongoing harmonisation has resulted in a GEN Internationally Coordinated Ecolabelling System (GENICES) that enhances co-operation and information exchange between GEN members and increases credibility of the network and international acceptance of its members. (Further details for GEN are available at http://www.gen.gr.jp).

1.2 Striving for a sustainable property industry

Worldwide, the building and property industry impacts significantly on raw materials, energy and water consumption. Furthermore it contributes substantially to indoor air pollution and waste output. However the property industry has recognised that it can strive for sustainability and achieve the delicate balance between environmental, social and economic issues.

The main goal of the Green Building Councils (GBCs) in many countries around the world is to develop such a sustainable property industry. Each drives the adoption of green building practices through market based incentives, to minimise adverse impacts of buildings during their design, construction and operation phases on both the built and natural environment. Through their programs the GBCs aim is to improve the energy and resource efficiency in the property industry, to reduce greenhouse gas emissions, to enhance and protect ecosystems and improve biodiversity. Furthermore the GBCs focus on making buildings more usable, reducing operating costs and improving the social amenity in its industry sector. This needs credible tools to identify criteria to differentiate products along the whole supply chain. This is where the use of ecolabelled products strongly contributes to achieving the goal of the GBCs.

In Australia, New Zealand and other jurisdictions there are bridges growing between the national ecolabelling organization and the Green Building Councils of these countries. The reason primarily is the synergy and efficiency that can be gained by using ecolabelled products as the preferred materials in any new development. The benefits include the benefits of independence, consistent treatment of verifications, assessment against similar criteria, a whole of life assessment, clear pass or fail results, and typically a wide treatment of building products. The additional benefit making this bridge easy is that most ecolabelling organization have been established in their market longer than the respective Green Building Councils thereby having a wide range of products already licenced (see Table 1). Both organizations also share the same philosophical objectives with the aim of recognizing the leading products and building in a particular market at generally the 20-30% mark and the awarding of environmental certification based on an overall life cycle multi-criteria approach with independent verification against pre-determined criteria.

The approach has been successful in Australia fueling both the emergence and development of new national ecolabelling standards for building and construction materials and the widespread availability of certified and independently assessed products readily available to the industry.

[2] ISO 14024 Type 1 environmental labelling program: Voluntary, multi-criteria-based third party program that awards a licence, which authorises the use of environmental labels on products indicating overall environmental preferability of a product within a particular product category based on life cycle considerations [ISO 14024].

[3] ISO 14025 Type 3 environmental declaration program presents quantified, environmental information on the life cycle of a product to enable comparison between products that fulfill the same function. Such declarations are based on independently verified life cycle assessment data, life cycle inventory analysis data or information modules in accordance with the ISO 14040 series [ISO 14025].

Table 1: Corresponding Green Building Council Members and Global Ecolabelling Network Members by Jurisdiction.

Green Building Council Member	Ecolabelling Organisation	Green Building Council Member	Ecolabelling Organisation
Australia (GBCA)	Good Environmental Choice	New Zealand (NZGBC)	Environmental Choice
Brazil (GBCBrasil)	Rotulo Ecologico	Taiwan (TaiwanGBC)	EnviroMark
Canada (CaGBC)	EcoLogo	United Kingdom (UKGBC)	EU Flower
Germany (GeSBC)	Blue Angel	United States of America (USGBC)	Green Seal
India (IGBC)	CPCB	Japan (JSBC)	EcoMark

2. Methodology of ISO 14024 ecolabelling

The goal of ecolabelling is to encourage the demand for and supply of those products that cause less stress on the environment, thereby creating the potential for market-driven continuous improvement, and encouraging innovation in product development and design. ISO 14024 based ecolabelling programs establish product standards by identifying pertinent criteria derived from the methodology of life cycle assessment. With market uptake the standards are revised regularly to raise the benchmark in a process of continuous improvement maintaining the principle of rewarding the top ~20% in a particular market.

Ecolabelling programs undertake verification to measure product environmental performance against criteria in the relevant standard. After a successful verification the ecolabel is awarded as a symbol to customers that the product conforms with the stipulated environmental high criteria so the consumer can make an informed environmentally preferable choice.

2.1 Life Cycle Assessment in standard development

Life Cycle Assessment (LCA) methodology has emerged as an important scientific tool in identifying criteria determining benchmarks for environmental performance. The ISO 14040 standard methodology requires a quantification or qualification of the primary environmental impact categories of a product across the full life cycle including raw material extraction, production, consumption and environmental impacts at the end of life. By undertaking such a comprehensive analysis across different products seeking to fulfill the same function it is possible to identify environmentally preferable material choices, production innovation, considerations for longevity, low toxicity, biodiversity and general priority emissions such as greenhouse gases and water pollution. In particular the ISO 14040 standard provides agreed methodology that has overcome the problem of needing exact quantification of all environmental impact categories. This has been done by prioritization, normalisation and characterisation within the analysis of inventory data and the derivation of suitable, logical criteria for the product standard. Furthermore, Life Cycle Inventory (LCI) data of product systems can be used to check the completeness of the selected, draft criteria. The use of life cycle methodology has ensured an overall scientific approach which results in direct measurable performance criteria.

Non life cycle based environmental performance labels or declarations have the potential to seriously mislead the market and designers by only presenting selected and even irrelevant material as the basis of environmental assurance. As the growth of green markets continues there appears to be a corresponding growth in misleading and selective environmental statement arising in the market.

2.2 Standards development process in ecolabelling programs

The standard development process is very similar for all ISO 14024 based ecolabelling programs as used by member organisations of the Global Ecolabelling Network. To give an overview of the standard development process, below is a description of the process used by Good Environmental Choice Australia.

The aim of the standards development process is to define a set of minimum environmental performance criteria for a particular good or service category. These criteria are put into a standard which is set to a level that only the top twenty percent of the suppliers, manufacturers and providers in the Australian marketplace would be able to meet and thus be certified under the relevant GECA standard.

2.2.1 Initiation of a new standard

Development of a new standard for a product category is usually initiated when GECA receives an application for certification or numerous enquiries from an industry sector regarding the high demand for certification for its products. Where the product does not fit into the scope of an existing standard, a new product category is investigated. GECA always checks whether or not an environmental benefit can be expected by establishing a new standard by considering the size and quantities of environmental emissions and impacts from the product group. In some cases the increasing public interest and awareness of environmental impact from a specific product category gives clear indication that there would be a market benefit and it is suitable to establish a new standard for that product category.

If there is market and environmental benefit the Standards Committee then authorises the development of the new standard. Firstly there is a provisional definition of the product category. Then the initiation phase includes considerations about possible stakeholders and alliances with the industry sector.

2.2.2 Feasibility assessment

The purpose of the feasibility study is to assemble information about market size, competition and structure of the product's marketplace. The study provides indication whether market incentive in the context of competition could be influenced by ecolabelling. Also, at this stage, potentially interested parties and industry associations are identified, who could provide substantial information and technical know-how to assist the development of the standard.

2.2.3 Data collection and assessment

An important basis for the development of a new standard is the assembling of a Standard Expert Panel to form a working group of people from government, research organisations, industry and social groups. GECA Standards Division staff with experience in ecolabelling, ensures that the composition of the Expert Panel has the broad knowledge and experience essential to define environmentally meaningful criteria for the new standard.

The standard incorporates material gathered from a review of existing international ecolabelling standards for a similar product category and reviews available life cycle inventory (LCI) data or new environmental research on the product group. If insufficient data is available at the time, the Expert Panel may start new research on the Life Cycle Inventory of products in that particular category.

The resulting LCI data are used in a streamlined LCA to identify environmental impacts of the products, focusing on impact categories were an environmental impact differentiation between products within the category is apparent.

2.2.4 Setting environmental performance criteria

Based on the Life Cycle Inventory data and the identified key environmental factors, the Expert Panel establishes environmental performance criteria, which provide the basis for an environmentally meaningful differentiation between the products in the category. Recent, relevant, economic and technical developments are identified to ensure the criteria are technically and economically feasible for the leading manufacturers or service providers in the Australian context. Further criteria address more general, holistic concerns of the product category, if they are significant, and point to potential improvements in future technical development of the standard. All criteria are expressed in terms of performance and are directly measurable factors / loads / impacts, instead of descriptive or qualitative design characteristics. Through consideration of the goods and services from the perspective of their whole life cycle, the criteria also prevent the transference of environmental loads as well as eliminating some of the impacts.

Uniquely in Australia the standard also includes a set of criteria to address social issues. These include criteria for compliance with labour law, relevant social legislation, general environmental legislation and fitness for purpose of the product.

2.2.5 Presentation of the draft standard

The preliminary set of criteria is arranged into a draft standard. All aspects of the draft standard are checked for conformance in accordance with the principles of ISO 14 024 and is then presented to the Standards Committee. If the draft standard is accepted by the Committee, all stakeholders are informed and the standard is made publicly available on the GECA website and sent directly to interested stakeholders for comment and consultation for at least 60 days. The comments received are collected and documented. After consultation with the Expert Panel the Standards Division decides how to implement and incorporate the feedback comments into the draft standard. The new standard is finalised, endorse by the Standards Committee and published as final, normally for a period of three years depending on the life span of the product category in the Australian marketplace.

2.2.6 Review of the standard

Whenever technology changes significantly or the market share of leading manufacturers with certified products grows substantially, the standard is reviewed. The review process changes the level of the criteria to be more stringent to reflect the new situation. This is necessary to continue to reward and promote continual innovation in the specific industry sector and to raise the benchmark of environmental performance.

3. Case Study: GECA Furniture & Fitting Standard

As a result of the described methodology in the standards development process, the GECA Furniture & Fittings Standard 28 was published on 29 November 2006. The scope of this standard is written in a prescriptive yet open ended manner with a focus on materials allowing most types of non-electronic office or domestic furniture to be within the scope. GECA utilised input from Australian stakeholders and scientific papers on LCA and heavily on the substantial technical work by the European Union Flower Ecolabel to develop the environmental benchmark criteria for this standard.

Currently, there are over 36 companies licensed with diverse product lines under the Furniture & Fittings Standard and they range from workstations, paneling, chairs to mobile pedestals. Panel boards and chairs have been the most popular products certified because the incentive of the Australian Green Building Council is greater through the awarding of more Green Star Points for these furniture types generating a stronger market stimulus for environmentally preferable furniture.

The reduced environmental impacts from certified products are very broad as each criterion delivers at least one environmental benefit. In this presentation, there are three aspects selected as examples to focus on the issues of material sourcing, air emissions and end of life disposal.

3.1 Key impacts of furniture products

3.1.1 Material sourcing

GECA Standard 28 emphasises the increased use of recycled material as a key factor in reducing environmental impact. Another factor is the origin of the timber used in furniture making, which must come from a documented environmentally preferable source. Specifically, Forest Sustainability Council (FSC) or equivalent certification of the timber must be provided to pass the verification against the standard. In practice this means plantation-grown new timber, or recycled material may be used but timber from an unsustainably managed forest is not acceptable. Moreover, the range of chemicals that can treat the timber is stipulated.

Plastic in GECA-certified furniture can only be of types that could be recycled at local (i.e. non-specialist) facilities. A practical outcome from the standard is that it encourages the use of already-recycled plastic as a raw material.

The GECA Furniture & Fittings Standard does not fully address metal components of furniture currently because the Australian manufacturers are not positioned to be able to meet stringent criteria for proper recycling of the metal content of furniture at this time.

3.1.2 Air Emissions

Engineered timber products and other materials used in the manufacture of furniture often emit Formaldehyde which can be considered to be harmful to human health, both to workers and consumers. The GECA Furniture & Fittings standard defines an upper limit for Formaldehyde emissions from the product. The standard specifies a list of international recognised test methods which can be used to measure the Formaldehyde emission levels and also gives figures for each of these test methods which make it possible to compare these emission measurement results.

The standard also specifies criteria for adhesives used in furniture products by referring to GECA Standard 1 – Adhesives, which sets limits on VOC emissions. GECA also accepts adhesives certified against another relevant eco-standard by other recognised ecolabelling programs of the GEN network. In the same way, the standard specifies types of textiles which can be used in certified furniture by referring to the GECA Standard 19 - Textiles.

3.1.3 End-of-Product Life

The GECA Furniture & Fittings Standard requires that certified products must be easy to take apart to aid the recycling process. In additional as par of the verification requirements the manufacturer must have arrangements in place to acknowledge ownership of the product via a take-back scheme, where obsolete furniture can be re-used instead of disposed of in landfill. This is likely to translate into substantial material recovery from this sector without the necessary requirements of government regulation or joint industry product stewardship initiatives.

In addition, certified products must not contain chemicals that are known environmental pollutants. An example is Organic Tin Catalysts (OTCs) which, if used when making foam padding, must be disposed of by an approved hazardous waste dealer from the manufacturing site.

3.2. Benefits of the GECA Furniture & Fittings Standard

3.2.1 Technical and environmental benefits of the ecolabel awarded by GECA

By setting a standard that a product must pass, the ecolabel awarded by GECA assures the customer that the product has been independently assessed. It also means that the product is preferable, in the top 20 % of its category. If the proportion of certified manufacturers rises, then GECA raises the benchmark to make certification more challenging for the "followers". In this way the process meets the ISO principle to be continuously improving and to ensure that technological innovation is encouraged, and that innovators are given a distinction over competitors.

GECA-certified furniture has been assessed as having a lower environmental impact/ load /burden than a benchmark figure derived by studying the current industry best practice.

3.2.2 Market and Sustainability Benefits

Currently, there are 55 certified Green Star Projects (buildings) in Australia and the majority has incorporated GECA products. This is because GECA certified products satisfy some of the compliance requirements of various Indoor Environment Quality (IEQ) and Material credit criteria in the Green Star Rating Tools. A GECA Environmental Product Declaration (EPD) and Manufacturers GECA Licence satisfy Green Star compliance criteria. This has the added benefit for designers, architects and Green Star Accredited Professionals that complexity, paperwork and documentation time is reduced. The Green Building Council of Australia recognises the quality and assurance provided by the GECA ecolabel.

It is the aim of GECA that certification under the ecolabelling program is incorporated also into corporate and government procurement, such as Request for Tender documentation used by major purchasers. The demand for furniture with an overall lower environmental load and preferable manufacturing processes is given a boost through market demand. Importantly once manufacturing and material changes are achieved the environmental benefits are compounded continually ensuring environmental benefits that accumulate over time. Our experience to date is that these benefits are surprisingly large and permeate across the supply chain even through suppliers of materials that are not certified.

4. International Perspectives

Overseas other GEN members are servicing the building industry with a range of standards that are suitable for their regional jurisdiction. In Europe, the European (EU) Eco-label has twenty-seven product categories including a Hard Floor-Covering Standard, similar to the GECA Standard 40 – Hard Surfacing. The EU Eco-label focuses on a range of environmental and health issues from; minimising the effects of quarried materials on the environment, to reducing harmful air and water emissions as well as encouraging responsible waste management procedures (2002/272/EC). Currently there are seventeen producers and approximately two hundred products throughout Europe that are certified under the EU Hard Floor Covering Standard.

In Korea, the Korean Eco-Product Institute (Koeco) has a subcategory of standards catering for the construction and housing industry. The Construction and Housing Products subcategory contains sixty five standards ranging from Soundproofing Products for Building Floors to Water-saving Faucets and Decorative Textiles. A notable Koeco standard with substantial market uptake is Standard 241 – Paints. The paints standard contains explicit VOC emission limits and detailed testing methods. Despite the standard's stringent requirements, there are seventy-five manufacturers that have been awarded the Koeco ecolabel and four hundred and eighty- five products certified.

Within each country there are ecolabelling programs that enable the building and design industry to define environmentally preferable products. In the absence of relevant standards in a domestic market, GEN organisations have the capability to collaborate with each other and the relevant industry sector to establish standards based on market demand. In this way GEN promotes a synchronised approach to developing standards and thus allows for mutual recognition of certified products by its members.

5. Alternative Approaches to ISO 14024

Globally, there are a range of product environmental certification programs that provide alternative environmental certification approaches for building and interior fit out products. These vary from industry association standards, such as the Australian Business and Institutional Furniture Manufacturer's Association (BIFMA) standards, to industry independent programs such as the GREENGUARD Certification Program, the BRE Environmental Assessment Method (BREEM) and the McDonough Broungart Design Chemistry (MBDC) protocol. While some approaches are still LCA based and all aim to reduce harmful impacts on the environment and assure customer health and safety, none are as comprehensive as ISO 14024 based standards. The ISO 14024 approach to ecolabelling also includes production environmental requirements in addition to environmental criteria and quality assurance requirements.

Standards that are in accordance with ISO 14024 establish multi-criteria environmental assessments of products that cover the whole life cycle of the product. This holistic approach supports overall environmental preferability compared to single issue approaches, such as the GREENGUARD certification programs, which focuses on indoor air quality.

Table 2: Criteria to ensure credibility of an Ecolabelling Program.

Criterion	ISO 14 024 Ecolabels	BIFMA	BREEM	GREEN-GUARD	MBDC
LCA Considerations[4]	Yes	Yes	Yes	No	No
Consultation[5]	Yes	Yes	No	No	No
Transparency[6]	Yes	Yes	Yes	Yes	No
Scientific Basis[7]	Yes	No	Yes	Yes	Yes
Independence[8]	Yes	No	Yes	Yes	Yes
Comprehensive[9]	Yes	No	No	No	No
Selectivity[10]	Yes	Yes	Yes	Yes	Yes
Verification[11]	Yes	No	No	Yes	No
Product Function Criteria[12]	Yes	No	No	No	No
Production Considerations outside of final product[13]	Yes	No	No	No	No

7. Concluding Considerations for the Building Industry

With the variety of ecolabelling programs available to the design and construction industry sector, there are numerous considerations to take account when finding a credible ecolabelling program. Such considerations include programs that are LCA based and have an approach that foresee and consider multiple environmental loads during the entire lifespan of a product or building. This is particularly needed in the building industry where products may not have been manufactured using sustainable materials. Ecolabelling programs also support innovation and technological advancement within a given sector and recognise environmental leadership by producers.

Type III ecolabelling programs contain all these characteristics and are able to clearly communicate to businesses and customers that certified products with their ecolabel are environmentally preferable, compared with other products in the marketplace. ISO accredited ecolabelling programs also inherently assure transparency and credibility in the implementation of such labelling programs. While 'green' building rating tools such as GBCA's Green Star encourage a low environmental impact of a whole building during its design and construction phase, third party ecolabelling programs ensure that the entire supply chain of the manufacturing process supply building materials equally have clear and measurable environmental benefits. The ability of Green Building Projects around the world to have access and to transparent and credible environmental information and generate demand for greener building products is fundamental to changing the building product supply chain. This objective is made easier through using the substantial work in products standards and extensive certifications done by ISO 14 024 based ecolabelling programs.

[4] Criteria are based on indicators arising from life cycle considerations covering the whole products life span.
[5] Program is committed to a formal open participation among interested parties which shall be established at the outset for the purpose of selecting and reviewing product categories, product environmental criteria and product function characteristics.
[6] Program ensures transparency through all stages of its development and operation. This implies that information shall be available to interested parties for inspection and comment where appropriate. Adequate time shall be allowed for comments to be submitted.
[7] The development and selection of criteria is based on sound scientific, regulatory and engineering principles. The criteria should be derived from data that support the claim of environmental preferability.
[8] Program is operated by an organisation independent of vested commercial or other interests. Program independence also extends to how product categories and environmental award criteria are determined
[9] Program ensures that criteria that are stipulated are the most significant environmentally.
[10] Program ensures that voluntary environmental labelling standard criteria are established to differentiate environmentally preferable products from others in the product category, based on a measurable difference in environmental impact.
[11] Verification independence relates to conformity assessment to international environmental auditing requirements (ISO 19011).
[12] The fitness for purpose of the product and levels of performance are taken into account. In the context of environmental labelling, fitness for purpose implies that a product satisfies health, safety and consumer performance needs.
[13] Standards and product function requirements for each product category are set for a predefined period and then are reviewed within a predefined period, taking account of factors such as new technologies, new products, new environmental information and market changes.

Appendix 1: GECA ecolabel standards related to the Building Industry

Table 3: GECA ecolabel standards related to the Building Industry

Standard	Product Scope
GECA-01 Adhesives	Household and commercial adhesives
GECA-02 Recycled Plastic Products	Products made from recycled plastics
GECA-03 Recycled Rubber Products	Applies to a broad range of products made partially or fully from recycled rubber
GECA-04 Panel Boards	Applicable to a broad range of panel board products for use in interior architectural applications, interior paneling as well as for use in further processed products such as furniture
GECA-07 Wool Carpets	Wool Rich (70%), Wool Pile (100%), Wool Blend and Modular Wool Carpets
GECA-19 Textiles	Textile clothing, interior/indoor textiles excluding floor coverings, yarn and fabric intended for use in clothing or indoor textile products and textile bags such as shopping, laundry and school bags
GECA-23 Architectural and Protective Coatings	Water-based coatings, Solvent-based coatings and Surface-coating systems
GECA-25 Floor Coverings	Includes floor coverings such as parquet, wooden planks, laminate and linoleum. Does not include floor coverings that are applied in a liquid state, or carpet products.
GECA-28 Furniture and Fittings	Applicable to a broad range of categories of final ready-to-use home and office furniture products.
GECA-30 Broadloom Polymer & Polymer Rich Carpets	Includes polymer fibre carpets which include nylon and nylon blends, olefin (polypropylene), polyester (PET) and acrylic
GECA-31 Commercial Modular Carpets	Includes polymer and wool-fibre modular carpets which include nylon and nylon blends, olefin (polypropylene), polyester (PET), acrylic and wool
GECA-33 Building Insulation Materials	Applicable to bulk (resistive-type) thermal insulation materials for use in building applications. It does not include foils, lagging, sarking or specialty insulation materials
GECA-40 Hard Surfacing	Applies to a broad range of products such as Natural stones, Agglomerated stones, Concrete paving units, Terrazzo tiles, Ceramic tiles, Clay tiles and Glass tiles

Keywords: concrete, cement, hemp, lime

Summary

This research focuses on the use of different binding agents used in the building material Lime-Hemp Concrete (LHC). It is a light composite building material that consists of building limes and hemp (Cannabis *sativa*). Contemporary LHCs only use the woody core part of the hemp, the shive. Using both hemp shives and fibres may improve mechanical strength. This would also eliminate the need for a fibre separation process which currently is not commercially available in Sweden. This research aims to elucidate the feasibility of using the entire fragmented hemp stem in a LHC. Furthermore the aim was to determine some important material properties of different LHC mixes, using varying compositions of the lime-based binder. Five mixes of the binding agents hydrated lime, hydraulic lime and cement were tested. Specimens were in total cured for 18 weeks at room temperature of which 40 days in a carbonatation room (4.5 vol% CO_2). They were tested for mechanical properties, water sorption and frost resistance. A compressive strength of 0.15-0.83 MPa was found for the five different binding agent mixes tested. Using both shives and fibres in LHC may be advantageous until possibilities to separate hemp fibres from hemp shives are commercially available in Sweden. The research project is ongoing and further experiments will be carried out during 2008.

1. Introduction

In recent years sustainability in architecture has become a key issue for architects and builders. Sustainability in architecture and building can be obtained in different ways. Energy that is used by buildings should be reduced, both during the building process as well as during occupancy. Also, building materials should be renewable and recyclable in the greatest extend possible. Schultmann and Sunke (2007) mentioned that the highest amount of construction and demolition waste over the life cycle of a building occurs during deconstruction. Therefore the use of renewable and recyclable raw materials in the building industry is imperative to reduce this waste.

In present research the use of the renewable material hemp (Cannabis *sativa*) as building material is studied. Hemp is a fast growing annual crop that can reach a height of 1.5-4m in northern Europe (Osvald, 1959). Growing industrial hemp became illegal in Sweden in 1965 but has been legalised again in 2003. According to the Swedish Board of Agriculture, 24 hectares of hemp were grown in Sweden in 2003. In 2007 this was 792 hectares. In the five years that hemp has been grown in Sweden, a viable commercial market has yet to be established. The greater part of the hemp cultivated in Sweden is used as biomass fuel. Hemp is pressed into briquettes and burned for energy purposes. Another part of the cultivated hemp is grown and analyzed for trials and research projects (Rolandsson, 2008). At the Swedish Hemp Seminar in Alnarp, 13th March 2008, it was underlined that there is a very small commercial market for hemp in Sweden. Therefore the Swedish market of non-food crops must find new products and possibilities to use Swedish hemp.

An advantageous application of hemp can be found in a lime-based cementitious building material; Lime-Hemp Concrete (Arnaud and Cerezo, 2001; Arnaud et al., 2006; Cerezo, 2005; Evrard, 2003). Lime-Hemp Concrete (LHC) is a composite building material containing hemp in a lime-based binder. In contemporary LHC the hemp shives, the woody core parts of the hemp plant, are used. The process to separate fibres from shives is complex and expensive, and requires a viable market for hemp fibres. No such commercial fibre separation facility currently exists in Sweden.

The compressive strength of contemporary LHC is not sufficient for the material to be load-bearing. In contemporary LHC only hemp shives were used. The aim of this research was to determine the feasibility of LHC as a load-bearing material using both hemp shives and fibres. Furthermore the aim was to determine some important material properties of different LHC mixtures, using varying compositions of the lime-based binder. Different ratios of hydrated lime, hydraulic lime and cement were used.

Using not only hemp shives, but also its fibres might influence mechanical strength of LHC. Also, this would eliminate the fibre separation process and create a market in Sweden for the entire fragmented hemp stem.

2. Materials and Methods

2.1 Hemp, Limes and Cement

The hemp variety *Futura 75* was used. It was acquired from a local farm in the province of Scania, Sweden. The hemp was spring-harvested in 2006. The entire hemp plant was harvested, baled and stored. Hemp bales were processed in an industrial shredder, displayed in Figure 1. Fibres, shives and dust were not separated in the shredder and ended up in the hemp material used in this research. The shredder cut the hemp plant in particles with an average length of 12 mm. The hemp material consisted of ⅓ parts fibres and ⅔ part shives. A small part of the material was dust.

Figure 1 Shredder.

2.2. Specimen preparation

Test specimens measuring 150×150×150 mm were made. Five mixes of the binding agents were prepared (Fig. 2). The ratio of hemp to binder was 1:3 by volume. The binder mix, water and hemp were allowed to rotate for a few minutes in a concrete mixer (Fig. 3). Test specimens were cast and then cured for 18 weeks. During this time they were exposed to 4.5 vol% CO_2 for 40 days to accelerate the carbonatation process.

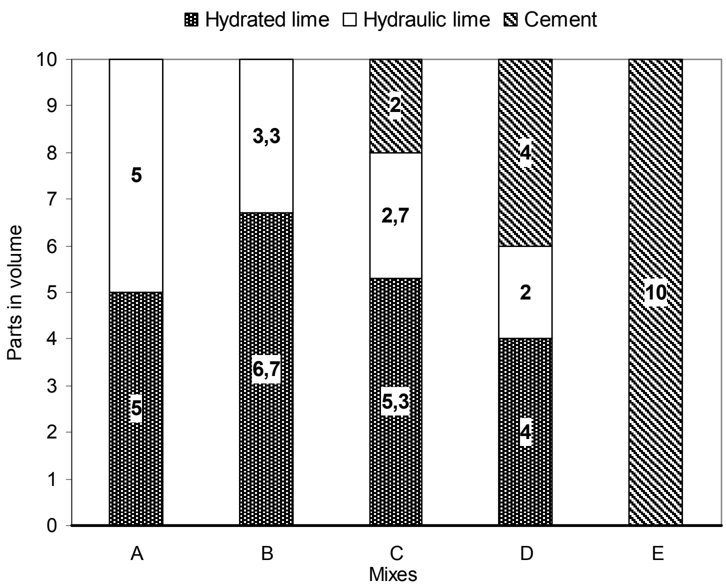

Figure 2 Binder mixes.

Figure 3 Concrete mixer.

2.3. Specimen measurement

A compressive strength test was performed on the test specimens. Six specimens were tested per mix.

Secondly, six specimens per mix were subjected to a total of 25 freeze-thaw cycles. The set temperature was +20 ºC for 12 hours followed by -20 ºC for 12 hours. After the freeze-thaw treatment the test specimens were tested for compression strength.

Thirdly, water sorption was tested by placing three test specimens per mix in a container with 5-10 millimetres of water (Fig. 4). The weight of the test specimens was measured at 12 occasions between 0 and 24 hours from the start.

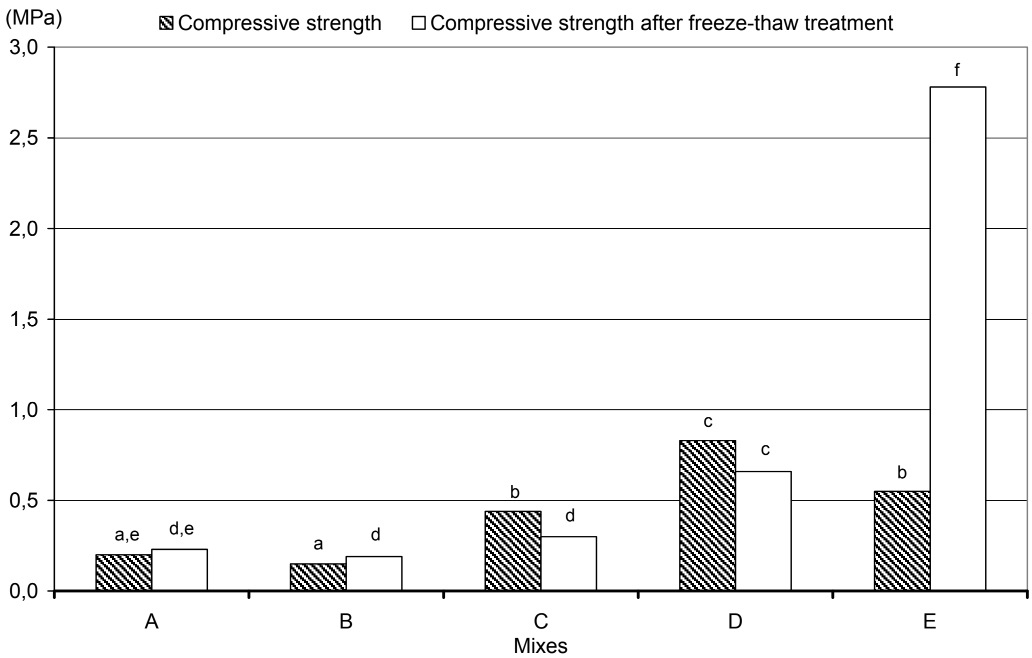
Figure 4 Water sorption test, specimens from mix B.

2.4. Statistical analysis

Statistical analyses were carried out with the software package Minitab 15 for Microsoft Windows (Minitab Inc., State College PA, USA). Appropriate *t*-tests, analysis of variance as well as Tukey's tests were carried out to determine if the tested mixes were significantly different ($P<0.05$)

3. Results

Compressive strengths for the mixes A-E ranged from 0.15 MPa to 0.83 MPa. Compressive strength after freeze-thaw treatment was similar to that of the test specimens that did not undergo freeze-thaw treatment, see Figure 5.



Different letters (a, b, c) indicate values that differ significantly ($P<0.05$).
Comparisons were not made between before and after freeze-thaw treatment for different mixes.

Figure 5 Compressive strength before and after freeze-thaw treatment.

The average water sorption coefficient for the five mixes was 0.15 kg/m²·√s. No significant differences between mixes A-E were observed.

4. Discussion

Compressive strengths of the specimens tested in this research were comparable to values found in other research. Compressive strengths of contemporary LHC were 0.4MP to 1.2 MPa (Arnaud, 2006) and 0.4 MPa (Evrard, 2003). Arnaud (2006) reports that compressive strength of LHC increases with time. This could explain the fact that compressive strength of contemporary LHC which had cured for a longer time, were slightly higher than the values observed in this research.

Not only hemp fibres were included in the hemp material, but also dust. The hemp dust may have had a negative influence on the mechanical properties of the LHC mixes. Also, hemp fibres differ greatly from hemp shives; this may have influenced mechanical strength of the material. However, tensile strength might be improved when using fibres as well as shives.

Comparing compressive strength before and after freeze-thaw treatment, values only significantly decreased for mix C. Values found for mix B and E even showed a significant improvement. Mixes A-E all underwent the same curing treatment. This meant that test specimens containing cement, mixes C-E, were not water cured. Watering fresh cement is very important for curing. Before the freeze-thaw cycles started, the test specimens were placed in water for 24 hours. This probably caused the noteworthy improvement in strength for mix E (binding agent cement).

No significant differences in water sorption coefficients were observed between the mixes. Important is not only water absorption, but also the rate at which the absorbed water can leave the material again, its desorption. In this aspect lime and cement behave differently.

5. Conclusion

Using the entire, shredded, hemp stem in a LHC created a material that seems to have the same characteristics as contemporary LHC. Compressive strength was rather low. Using a hemp material with both shives and fibres did not seem to create a mechanically stronger LHC.

Differences in mechanical strength between mixes were not big. However, mixes D and E showed the best results in compressive strength. Specimens with cement that were water cured after preparation would probably have improved the mechanical properties of the material. Mixes D and E contained most cement. Cement seemed to have a beneficial impact on the mechanical properties of the material. However, using cement in LHC might have a negative influence on the hemp material, which not studied in this research.

LHC is an interesting building material that uses the renewable raw material hemp. It can be used in combination with a load-bearing structure. The impact of freeze-thaw cycles on the material was low. Also water sorption was moderate. This shows potential for the material to be used in a Swedish climate with cold winters and rain all year round. The use of LHC as a building material in Sweden could increase the market for Swedish hemp, while introducing a durable and sustainable building material.

More research is needed in order to explore possibilities of the use of LHC.

Keywords: recycled aggregate, mortar, workability, water retention capability

Summary

The paper presents results of a study aimed to analyze the applicability of fine fraction of recycled aggregate (RA) in mortar. Mortars were tested for their workability assessed as flow and for their capability to retain mix water when placed on absorptive material. The latter was determined by the gravimetric method. Results are compared to the results obtained on mortar mixtures made of natural crushed aggregate (NA) with the same granulometric composition. Six mortar mixtures were prepared from each aggregate, namely mixtures containing 25, 30 and 35 % of overfill (f_{OF}) at water-binder (*wb*) ratios 0.7 and 0.8. Results show that flow of mortar is ~ 15 % lower when RA is used in comparison to NA mortars, however the difference decreases with the increase of *wb* and f_{OF}. Results of water retention capability are given as time (*t*) evolution of relative loss of water (u_w). Three distinctive regions of the process are perceived and are discussed in the paper. It was determined that in 5 min after placing mortar on a clay brick NA mixtures lose 32 % of water, whereas this value amounts to 26 % for RA mixtures. Maximum water loss was 59 and 45 % for NA and RA mortars respectively. In time interval from 5-60 min u_w shows linear dependency on sqrt(*t*). Values of correlation coefficient (*q*) were found to be ~ 0.038 and 0.030 min$^{-1/2}$ for NA and RA mortars respectively.

1. Introduction

Disposal of construction and demolition debris in landfills is considered as a big environmental problem of modern society and possibilities to implement sorting, recycling and reuse of these materials are studied worldwide. In this respect concrete debris was considered for production of recycled aggregate (RA), which could be used in new concrete mixes. However, studies carried out so far indicate, that fine fraction of RA, consisting of particles smaller than 4 mm, should not be used in concrete but should be replaced by natural sand (Ajdukiewicz and Kliszczewicz, 2002, Chen et al., 2003, Khatib, 2005, Tu et al., 2006). Thus, it is necessary to find alternative applications for the fine fraction of RA in order to implement the »Zero Waste« concept and attempts have been made to use it in mortar mixtures (Corinaldesi et al., 2002, Moriconi et al., 2003, Miranda and Selmo, 2006a-b). Although mortars can be considered as concrete of small sized aggregate with maximum grain size of about 4 mm, they are in fact used for different purposes than concrete and different technology is applied for their processing. Therefore, some specific properties of mortars are required. Most significant characteristics of hardened mortars are strength, elasticity, water permeability and resistance to weather conditions, whereas for fresh mixtures these characteristics are workability, setting time, adhesion and water retention capability. On the opposite of concrete where compressive strength is the major decisive factor of its applicability, the compressive strength of the mortar is found to have a low influence on the masonry behavior. In fact, masonry behavior significantly depends on deformability and bonding capacity of the mortar, which are both influenced by mortar workability (Moriconi et al., 2003). Workability is a significant factor for the successful use of application techniques for finishing layers as well. In the case of mortars workability is manly assessed by setting time, cohesiveness and water retention capacity (De Vekey, 2001). While setting time defines the period after mixing in which mortar can be placed, cohesiveness is essential for the placing itself since the mix should be plastic, adhesive and resistant to bleeding and segregation. Since mortars are often spread over absorptive materials (e.g. clay bricks) water retention capability of fresh mix is very important (Sebaibi et al., 2003). Namely, these materials readily absorb mix water from the mortar and this may lead to irregular hardening. In this case designed properties of the mortar are not achieved. Only by retaining enough water, mortar can preserve adequate plasticity and reach designed properties. Structure and texture of the aggregate significantly affect the quantity of water needed for required workability. It is well established that aggregates with higher porosity and larger surface area per unit volume absorb more water and hence mortar made of such aggregate is stiffer. In the case of

RA grains consist either of (i) natural stone originating from NA used in primary concrete, (ii) cement matrix of primary concrete or (iii) combination of both. Since cement matrix is in general more porous than natural sand, RA can absorb more water which might be released back to the matrix when desiccation occurs and thus effect positively on the hydration process of the mortar. The aim of the research presented in the paper was to asses the applicability of the fine fraction of RA in mortars in terms of mortar workability and ability to retain mix water when placed in contact with absorptive materials.

2. Experimental

RA used in the experimental study was obtained from laboratory samples of concrete with characteristic strength of 30 MPa. This primary concrete was in the form of cubes with sides of 15 cm as are used for compressive strength tests. Cubes were crushed in a mobile machine for recycling the construction and demolition waste. As reference aggregate natural crushed sand was used. This type of NA was chosen because the shape and the texture of the particles are more similar to RA than in the case of alluvial sand. Both aggregates were sieved on a composition of laboratory sieves. Fractions of each aggregate were mixed in mass proportions giving the granulometric composition shown in Fig. 1. The density of NA was determined in pyknometer whereas for RA it was estimated on the basis of primary concrete density. Compacted bulk density of each aggregate mixture was determined by placing three layers of aggregate into a standard 1 dm^3 container where each layer was manually compacted. The volume fraction of void space was calculated as

$$f_V = 1 - \frac{\psi}{\rho} \qquad (1)$$

where ψ is the compacted bulk density (kg m^{-3}) and ρ is the density (kg m^{-3}). Values of ψ, ρ and f_V for NA and RA are summarized in Table 1.

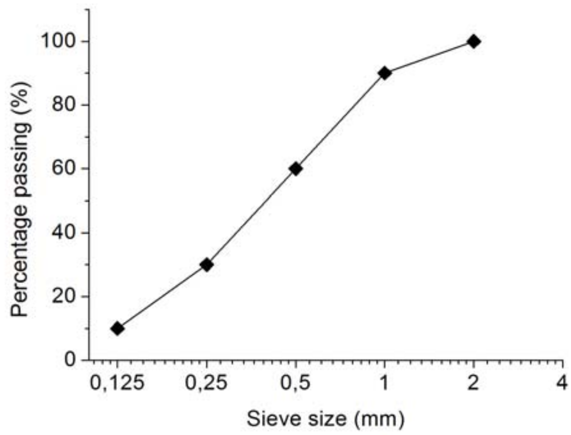

Figure 1 Granulometic curve according to which fractions of natural and recycled aggregate were combined.

Table 1 Density (ρ), compacted bulk density (ψ) and volume fraction of void space (f_V) for natural (NA) and recycled (RA) aggregate having granulometric composition given in Fig. 1.

Aggregate	ρ (kg dm^{-3})	ψ (kg dm^{-3})	f_V (%)
NA	2.787	1.819	34.7
RA	2.130	1.374	35.5

Design of mortar mixtures was based on two variables namely on water-binder (*wb*) ratio and on overfill of the binder paste. In general *wb* is ratio between mass of water and cumulative mass of binder materials, which in the case of mortars are usually cement, lime and gypsum. Overfill of the binder paste is regarded in the following manner: when aggregate particles of given granulometric composition are compacted there is a certain amount of void space between the particles which must be filled with the binder paste. This paste is regarded as a basic binder paste and its volumetric fraction (f_{BBP}) is equal to f_V. However, in order to achieve the adequate workability of the mortar a larger amount of the paste must be present in the mix. Hence, overfill is the excess binder paste present in the mortar mixture which is not needed to fill the voids between the aggregate particles and its volumetric fraction is denoted as f_{OF}. Total volume fraction of binder paste in the mortar is therefore

$$f_{BP} = f_{BBP} + f_{OF} = f_V + f_{OF} \quad (2).$$

For the experimental work six mortar mixtures were prepared from each aggregate. Binder consisted only of cement CEM I 42.5 R. Three mixtures of each aggregate were made with *wb* ratio 0.7 and three with the ratio 0.8. Three values of f_{OF} were used at each *wb* ratio namely 25, 30 and 35 %. Detailed mixture compositions specifying masses of aggregate (m_a), cement (m_c) and water (m_w) are given in Table 2. As may be perceived in Table 1 the difference between f_V of NA and RA is not significant, hence values of f_{BP} for mixtures made of NA and RA at given *wb* and f_{OF} are approximately the same. Consequently mass of cement needed for 1 dm^3 of mortar for equivalent NA and RA samples varies only for ~ 1 %.

Table 2 Mix proportions for 1 dm^3 of mortars made of natural (NA) and recycled (RA) aggregate at given water-binder (*wb*) ratio and volume fraction of overfill (f_{OF}). Masses of aggregate, cement and water are denoted as m_a, m_c and m_w respectively.

wb	f_{OF} (%)	NA mixtures			RA mixtures		
		m_a (g)	m_c (g)	m_w (g)	m_a (g)	m_c (g)	m_w (g)
0.7	25	1365	494	346	1030	500	350
	30	1274	526	368	962	531	372
	35	1183	558	390	893	563	394
0.8	25	1365	451	361	1030	456	365
	30	1274	480	386	962	484	288
	35	1183	508	407	893	513	410

Mortars were prepared with the use of standard laboratory mixer, which has a static pan and a mixing paddle that rotates in two directions. After mixing the consistency of each mortar was determined on a standard flow table. Spread was measured after 10, 15 and 20 jolts and mixture was visually inspected for segregation and bleeding. Measurements of water retention capability were carried out by the gravimetric method. For this purpose frames with dimensions of ~ 96 × 46 × 22.5 mm were placed on fired clay bricks having dimensions of ~ 120 × 65 × 45 mm. Bricks were dried in an oven before the experiment and cooled to a room temperature. Mortar vas placed into the frames as shown in Fig. 2. The following masses were determined: (i) mass of the brick (m_b), (ii) mass of the brick with the frame (m_{b+f}) and (iii) mass of the brick with the frame containing mortar (m_{b+f+m}). Six specimens were made of each mixture and were wrapped into a plastic foil in order to prevent evaporation. One frame together with mortar was removed from the brick in each predetermined period, namely after 5, 10, 20, 30, 60 and 120 min since the mortar was placed. Mass of brick containing absorbed water ($m_{b+\Delta w}$) was measured. Hence, mass of the water lost from the mortar ($m_{\Delta w}$) is determined as

$$m_{\Delta w} = m_{b+\Delta w} - m_b \quad (3).$$

Figure 2 Mortar placed in the frame on the top of the fired clay brick. Photo was taken 120 min after placing and the front of absorbed water is visible on the front side of the brick.

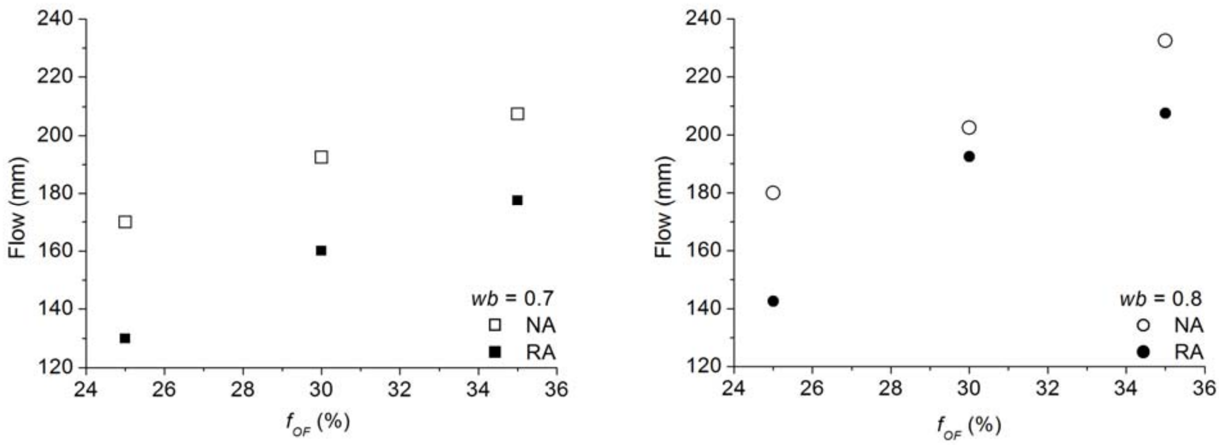
3. Results and discussion

Densities of fresh mortar mixtures are given in Table 3. It may be observed that the values of density of RA mixtures are ~ 8 % lower then values of equivalent NA mortars. Such difference is in compliance with the difference calculated from the rule of mixtures. Namely the volumetric fraction of aggregate in mortars was between 0.42 and 0.49 (calculated from data in Tables 1 and 2) whereas values of density and compacted bulk density of NA and RA differ for ~ 24 % (Table 1).

Results of consistency measurements are given in Fig. 3, where flow measured after 15 jolts is plotted against the volumetric fraction of overfill. Measurements obtained after 10 and 20 jolts gave equivalent results and are not shown separately. Results show that at the same *wb* and f_{OF} flow of mortar made of RA is lower in comparison to NA mixtures. The difference is larger at lower *wb* ratio. This can be explained by the porous nature of RA. Namely part of the mix water together with some cement particles is absorbed by the aggregate and thus, *wb* ratio of the remained binder paste and its quantity between the particles are reduced. As the consequence the lubricant effect is diminished. At higher *wb* ratios the effect of water absorption is less profound since enough water remains in the paste to assure lubrication. In order to achieve the same flow of RA mixture as in the case of NA either *wb* or f_{OF} have to be increased. Higher *wb* will result in lower cement content per unit volume of mortar, whereas increasing the f_{OF} will result in higher cement content and lower volumetric fraction of aggregate. Therefore both parameters have to be optimized. Upon the visual inspection of mortars no segregation was detected, whereas bleeding was observed only on mixture made with NA, having *wb* = 0.8 and f_{OF} = 35 %.

Table 3 Densities of fresh mortars made of natural (NA) and recycled (RA) aggregate at given water-binder (*wb*) ratio and volume fraction of overfill (f_{OF}).

Aggregate	Density (kg dm^{-3})					
	wb = 0.7			*wb* = 0.8		
	f_{OF} = 25 %	f_{OF} = 30 %	f_{OF} = 35 %	f_{OF} = 25 %	f_{OF} = 30 %	f_{OF} = 35 %
NA	2.350	2.305	2.310	2.349	2.351	2.297
RA	2.121	2.154	2.123	2.123	2.133	2.125



(a) (b)

Figure 3 Flow of mortars measured after 15 jolts on standard flow table in respect to volumetric fraction of overfill (f_{OF}) for mixtures made of natural (NA) and recycled (RA) aggregate with water-binder (wb) ratio of (a) 0.7 and (b) 0.8.

Results of water retention capability are evaluated as the relative mass of water lost from the mortar and is calculated as

$$u_w = \frac{m_{\Delta w}}{m_{wm}} \tag{4}$$

where m_{wm} is mass of water (kg) contained in the quantity of mortar placed on the individual brick. It was calculated upon the mass fraction (x_w) of the water in the mix which follows from Table 2 and the difference of measured values m_{b+f+m} and m_{b+f}. Hence

$$m_{wm} = x_w \left(m_{b+f+m} - m_{b+f} \right) = \frac{m_w}{m_a + m_c + m_w} \left(m_{b+f+m} - m_{b+f} \right) \quad (5).$$

Values of u_w plotted against square root of time (t) are given in Figs. 4-6. Results show that kinetics of water loss has three distinct regions. The first region is in the time interval from 0 to 5 min, during which NA mortars lose ~ 32 % of water whereas this value amounts to ~ 26 % for RA mixtures (Table 4). On the basis of collected data no correlation between u_w and wb or f_{OF} is observed. The second region covers the time interval from 5 to 60 min. In this period a linear correlation in the form of

$$u_w = q\sqrt{t} \tag{6}$$

is observed, where q is a correlation coefficient ($s^{-1/2}$). Eq. (6) has the same form as *Lucas-Washburn* equation which describes capillary absorption in porous materials. However in the case of capillary absorption the water source is considered to be infinitive and thus absorption kinetics is governed only by the properties of the absorptive material. In the case of water retention experiments absorption of water is governed by the absorptive properties of the brick, by the permeability of the mortar and by the content of free water in the mortar mixture. Therefore during the first time interval (0-5 min) absorption is fast because the water from the bottom layer of mortar is absorbed and the kinetics is governed mainly by the capillary properties of the brick. In the second interval (5-60 min) absorption is retarded because water must first percolate from the upper layers of mortar to the mortar-brick interface. In general initial set of cement takes place after 60 min which results in the stiffening of the mortar. In this period mix water is being consumed by hydration process so the amount of free water is reduced. Moreover its movement through the mortar is governed mainly by the diffusion mechanism. This results in additional retardation of water loss and presents the third region of the process.

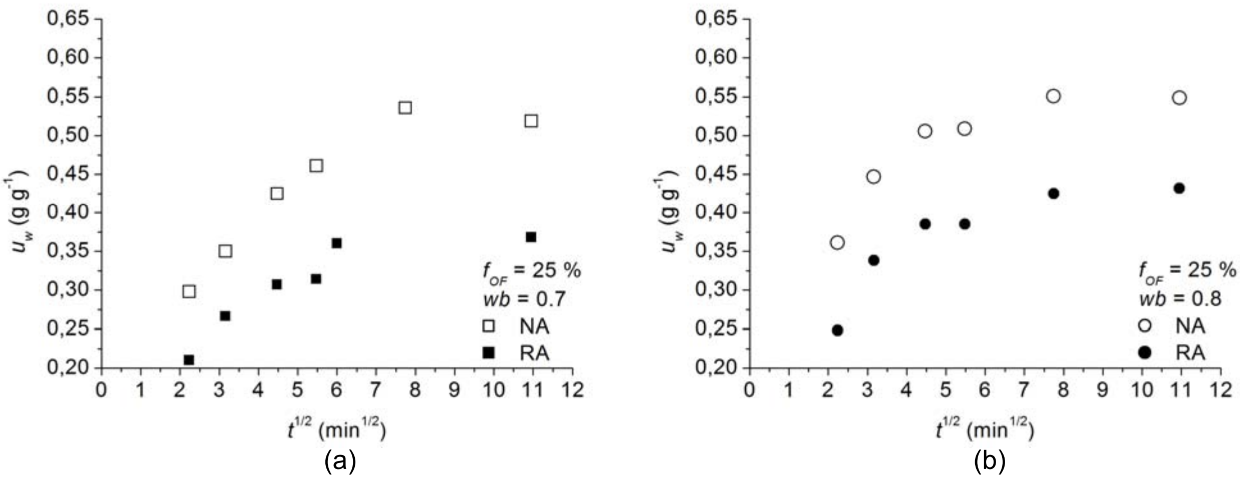


Figure 4 Relative mass of water (u_w) lost in the period of time (t) from the mortar made of natural (NA) and recycled (RA) aggregate containing 25 % of overfill (f_{OF}) and having water-binder (wb) ratio (a) 0.7 and (b) 0.8.

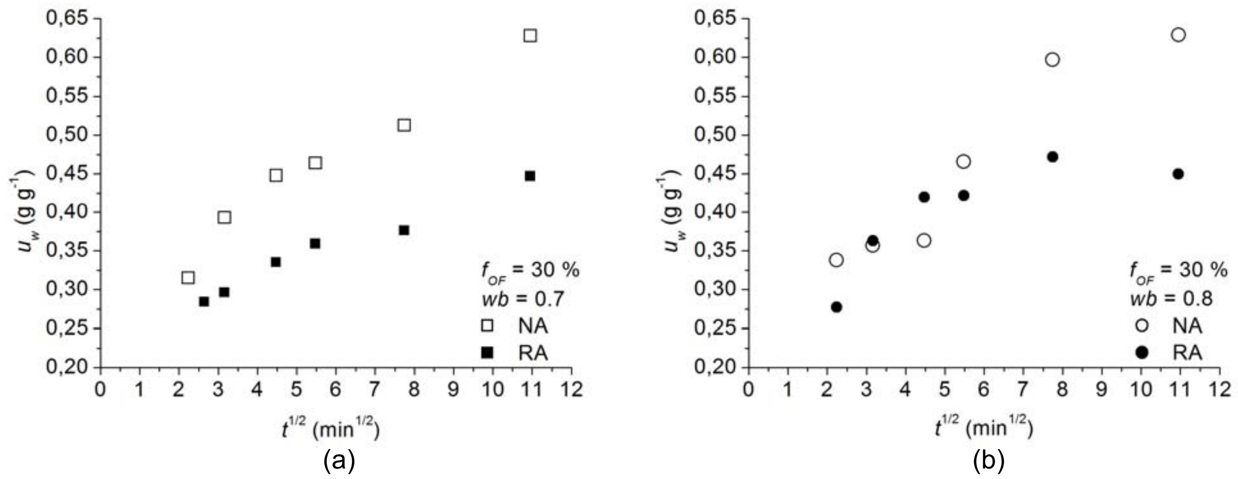

Figure 5 Relative mass of water (u_w) lost in the period of time (t) from the mortar made of natural (NA) and recycled (RA) aggregate containing 30 % of overfill (f_{OF}) and having water-binder (wb) ratio (a) 0.7 and (b) 0.8.

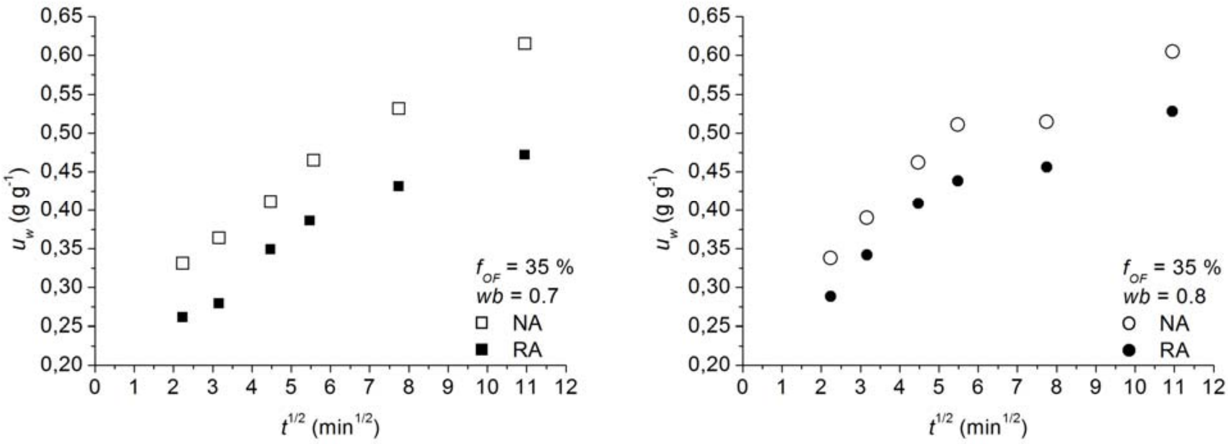

(a) (b)

Figure 6 Relative mass of water (u_w) lost in the period of time (t) from the mortar made of natural (NA) and recycled (RA) aggregate containing 35 % of overfill (f_{OF}) and having water-binder (wb) ratio (a) 0.7 and (b) 0.8.

Values of the correlation coefficient for the second region were obtained by fitting Eq. (6) to experimental data and values of q are given in Table 4 together with calculated and measured values of u_w at t = 5 min, which is the lower limit of the validity of Eq. (6). No correlation between u_w and wb or f_{OF} is observed. Average value of q for NA mixtures is found to be 0.038 min$^{-1/2}$ whereas this value amounts to 0.030 min$^{-1/2}$ for RA mortars, however standard deviation is 0.007 and 0.006 min$^{-1/2}$ respectively. Thus it may be concluded that percolation of free water through the studied fresh mortar mixtures is approximately the same. Still, maximum water loss is on average 59 and 45 % for NA and RA mixtures respectively. Therefore a positive effect of RA on water retention capability of the mortar is acknowledged.

Table 4 Values of correlation coefficient (q) defined by Eq. (6) together with calculated and measured values of relative water loss (u_w) 5 min after placing for mortars made of natural (NA) and recycled (RA) aggregate at given water-binder (wb) ratio and volume fraction of overfill (f_{OF}).

4. Conclusions

Due to environmental reasons possible applications of fine fraction of RA obtained from construction and demolition waste are considered. In the scope of presented research work selected properties of fresh RA mortar mixtures were studied and results were compared to mixtures made of crushed NA with the same granulometric composition. Each aggregate was used for preparation of three mortar mixtures with wb ratio 0.7 and three with wb 0.8, where values of f_{OF} were 25, 30 or 35 %. Density, flow and water retention capability of mortars were determined and the following conclusions are drawn:

1. Densities of RA mortars are ~ 8 % lower in comparison to equivalent NA mortars, which is the immediate consequence of lower density of RA.
2. Flow of mortar is ~ 15 % lower when RA is used in comparison to NA, however the difference decreases with the increase of wb and f_{OF}.
3. Water retention capability is given as the time evolution of relative loss of water from the mix and three distinctive regions of the process are detected.

4. The first region is in the time interval from 0 to 5 min after placing mortar on the fired clay brick and in this period NA mixes lose ~ 32 % of water, whereas this value amounts to only ~ 26 % for RA mixes.
5. The second region is in the time interval from 5 to 60 min in which relative water loss is linearly dependent on sqrt(*t*). Values of correlation coefficient were found to be ~ 0.038 and 0.030 $min^{-1/2}$ for NA and RA mortars respectively.
6. In the third region which starts 60 min after placing mortar on the fired clay brick water loss is significantly decreased and maximum water loss was measured to be ~ 59 % for NA mortars and only ~ 45 % for RA mortars.
7. On the basis of the experimental results positive effect of RA on water retention capability of cement mortars is acknowledged.

Study presented in the paper yielded favorable results for the use of RA in mortar mixtures and thus further research work is encouraged. In the scope of future work other properties of RA mortars like mortar-brick bond, strength and permeability should be studied. Different combinations of binders and admixtures should be considered as well.

Summary

The objective of this paper is to analyze and compare the amount and cost of major building materials throughout the construction stage for both Canadian and Japanese office buildings. Decision-making for different office construction development scenarios is investigated in assessing the material implementation techniques for both countries. This study provides initial information to characterize materials to explore effective construction techniques and to identify a great impact in many other industries for two regionally and culturally different situations.

Canada and Japan have agreed to the Kyoto protocol and had a common reason to be interested in meeting the CO_2 reduction targets. More fundamentally, the Canada-Japan bilateral trade and economic cooperation framework provides a number of similar construction market structures. It is meaningful to analyze and compare materials and services of both office building construction models to formulate the future industry-wide adopted construction strategies. This study helps to understand the environmental assessment mechanisms for the construction industry to achieve the Kyoto target reductions for CO_2 emissions through Canadian and Japanese office building construction activities.

Different from conventional environmental assessment methods which compare buildings against a common scale and require third-party verification, this paper suggests that the entire building construction process including other related industries' activities should evaluate in the context of building sustainability assessment method.

1. Introduction

Both Canada and Japan have agreed to the Kyoto protocol and have a common reason to be interested in trade arrangements that ease the burdens of meeting the reduction targets for Kyoto emissions. This study uses a Canada-Japan bilateral trade and economic cooperation framework to find a number of methodology-related points for a building construction method. This is because that building construction processes for both countries in procurement of materials, manufacturing, distribution, usage and disposal involve a number of various domestic and international industries' in multiple stages.

1.1 Target for Kyoto Protocol

According to the Kyoto protocol, Canada and Japan must bring down their CO_2 emissions levels over the period of 2008-2012 to a level which is 6% below their respective 1990 level. The total amount of CO_2 emissions has been increasing for both Canada and Japan. Over the period 1985-1995 CO_2 emissions climbed in volume from 435 million tons in 1985 to 478 million tons in 1990 and to 500 million tons in 1995 for Canada and from 895 million tons in 1985 to 1122 million tons in 1990 and to 1213 million tons in 1995 for Japan. The business sector (building construction sector) generates 40% of total CO_2 emission for both Canada and Japan.

1.2 Trading Partner–Canada and Japan

The United States is Canada's number one trading partner with 80% of Canada's exports destined to the US. Japan is Canada's second largest trading partner after the US but in comparison to the US this is extremely small. Approximately 75% of Canada's export to Japan is resource related goods from the agriculture, forestry, marine and minerals sectors and 90% of Canada's import from Japan occupies Machinery and Equipment and Automotive Products. (Figure1 and 2).

Country	Year	Agricultural and Fishing Products	Energy Products	Forestry Products	Industrial Goods	Machinery and Equipment	Automotive Products	Consumer Goods	Special Transactions	Total
US	07	1,473.8	7,537.5	2,000.4	5,333.2	4,910.9	5,999.9	1,061.5	591.8	28,908.9

Figure 2 - Domestic Exports to selected countries, customs basis, not seasonally adjusted

Looking from a broad macro perspective, the trend of the Canada-Japan trade relationship shows a decline in the trade balance for Canada over the past few years. This is partly due to the draw of a booming American economy during this time coupled with a stagnating Japanese economy. However, this doesn't mean there are no business opportunities for Canadian companies in the Japanese market. As a prime destination for Canadian building industries, the Japanese construction market is worth approximately $200 billion per year. Although entry into the Japanese market can often take time due to the complex nature of Japanese importing regulations and processes, there are many opportunities to explore possibilities to contextualize better the process of building construction for both Canadian and Japanese industries in this sector. From this point of view, it is necessary to understand the weakness and strength to enhance international trading to get construction materials to seek more environmentally friendly construction process.

1.3 Current Construction Market—Canada and Japan

The construction expenditures in Canada in 2006 were $195 billion. Construction activity on non-residential properties was high for a sixth consecutive year in 2006, due in large part to the booming economy of Western Canada. Among the nine provinces seeing growth in non-residential construction, Alberta showed the largest gain, at 40%, followed by British Columbia at 27%. Together, Alberta and British Columbia accounted for about 80% of the total increase in Canada's non-residential investment. Indeed, most of the spending includes government, public, and private non-residential buildings. Combined, these markets are receptive to green building concepts and products. This is evidenced by the growth of the Canada Green Building Council (CaGBC), which aims to advance the design and construction of green buildings in Canada. Since its launch in 2003, the membership of the CaGBC has risen to 1500 members. Members of the CaGBC have the opportunity to influence the direction and pace of the construction industry in Canada.

The Leadership in Energy and Environmental Design (LEED) has had great success to widespread the concept of green building techniques and to encourage the green building market in North America. In 2005-06 the green building market was an estimated US $15.7 billion. Canada has 26% of this market, which is equivalent to $4 billion. 13% is in the private non-residential sector market, 6% is in the residential sector and 7% is in the public sector. In Canada, the private non-residential and public construction market value was $90 billion in 2005. Spending in the residential sector totalled CAD $89 billon.

According to the Japanese Ministry of Land, Infrastructure and Transport (MLIT), total construction investment in the 2006 was estimated at $522 billion. Non-residential buildings represent 21 % of the total construction market. Compared with Canadian construction market, the Japanese market is not booming. However, the Japanese government predicts that construction investment remains stable, ranging from $500 to $550 billion over the next five years. Both the public and private sectors are planning a variety of projects including new buildings such as luxurious residential buildings and large-scale commercial facilities.

The Kyoto Protocol sets legally-binding targets to limit or reduce greenhouse gas emissions. The Japanese government has had a positive influence to increase the green building market growth on the Japanese building construction market. In 2001 the Japanese Comprehensive Assessment Scheme for Building Environmental Efficiency (CASBEE) was presented to accelerate the adoption of green building practices, technologies, policies and standards to the Japanese building market. Despite this strong interest, the market has just started growing and it is not yet widely recognized as one market segment. There is almost no research or statistical information available compared with Canadian green building market. However, this situation is changing quickly and the market is projected to take off in the near term.

Widespread recognized existing building assessment methods in Canadian and Japanese market are now evolving to embrace a broader range of stakeholders. However, while the framing of assessment methods is clearly broadening, both assessment tools still focus on an individual building. This study helps to establish future building assessment methods, likely to link across varying scales – buildings, neighborhoods, city, regions, countries etc – to permit the comprehensive framing of sustainability assessment. The primary future role of building assessment methods is to transform the culture of the construction industry to accommodate sustainability as a common, consistent and integral part of its decision-making (Cole, 2005).

1.4 Classification for Construction Material Flow

Assisting this concept, this paper analyzes the decision-making for the different office construction development scenarios for both two countries – Canada and Japan. To identify the significant economic and environmental impacts for office construction industries for both regions, *direct material* and *indirect material* are classified in this study (Fig.3).

- **Direct material** is calculated by the economic effect for the building construction process using major materials and services.
- **Indirect material** is calculated by the economic effect to produce major materials and services between industries in the economy beyond the direct effect.

This paper only focuses on the comparison for the amount and cost of “direct material" for both Canadian and Japanese office buildings to provide simple and clear construction analysis.

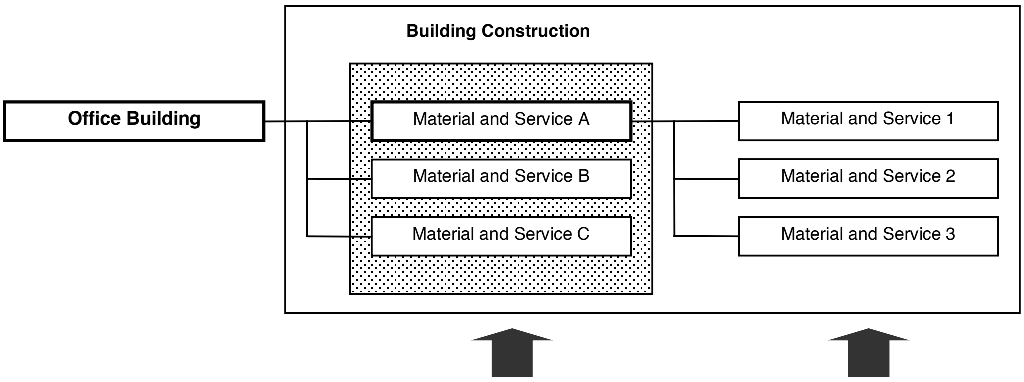

Figure 3 - Entire Economic Impacts for Office Building Construction

2. Analysis and Comparison for Construction Market

The total expenses for direct materials from various industrial sectors (such as steel and concrete) are given in this study. The information is currently produced for the effects of changed methods or conditions on the economics of the construction industry at both Statistics Canada (SC) and the Japanese Ministry of Land, Infrastructure and Transport (MLIT) on an annual basis. Also, SC and MLIT currently develop construction productivity indexes, including the I/O table, at an aggregate level using the different method. It is difficult to get data available which can be used to compare rates of productivity gains in various sectors of the both construction industries. While the data for “indirect materials” presents an overall perspective of construction industry’s activities, direct material analysis could provide a fairly refined level of industrial detail in this study.

2.1 Office Building Construction Price Indexes

The general construction prices for the office building are compared to analyze the difference the office construction market activities between Canadian and Japanese. All prices are collected directly by SC and

MLIT quantity surveyors and include costs for materials, labour, equipment, relevant federal taxes, and contractor's overhead and profit. Due to the lack of historical labeling of green buildings in Canada and Japan, it is difficult to definitively determine how much the green building practice affect in both Canada and Japanese construction market.

Discussed on the Section 1.3, Canadian construction industries are dramatically growing. As shown in Figure 4., it is apparent that interest in Canadian office construction market is also rising. Some involvement such as Vancouver 2010 Olympics is certainly the result of strategic business positioning, while other interest would be more altruistic. The figure shows the average annual increase is approximately 10% from 2004 to 2007 and SC analyzes the office construction market keeps growing. Many stakeholders tend to hold investing to the Canadian office construction market because the additional cost is usually required with the high market growth during construction period.

Figure 4 - office building construction price index 1997=100

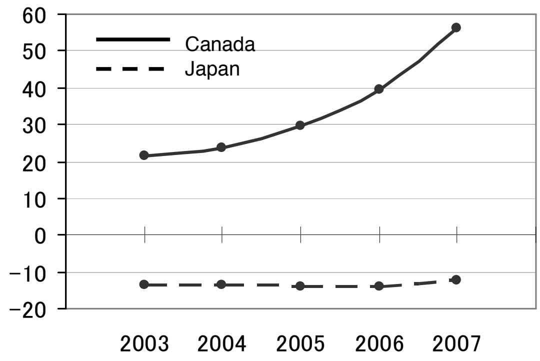

Figure 4 shows the 15% of office construction market approximately decreases compared with 1997 market condition. As Japanese office construction market was surprisingly very strong in 80' to 90', the current steady market situation is preferable for many stakeholders, developers, investors and owners. However, the supply volume of large-scale office buildings within Tokyo's 23 wards in 2006 reached 1.54 million sq.m., nearly double the 2005 level of 0.77 million sq.m. The supply volume in 2007 reached to 1.19 million sq.m, equivalent to 80% of the previous year. Since the majority of new projects consist of small- and medium-scale buildings with total gross floor area between 10,000 and 20,000 sq.m, the supply volume itself doesn't increase in line with the total number of new buildings. Continuing the trend from last year, many of these new plans include rebuilding or replacing existing buildings. Figure 4 doesn't include the construction cost for office renovations.

In this study, "direct materials" are first classified by 15 categories under both Canadian and Japanese construction industry (Figure 5). This data analysis presents how Canadian construction boom affects the cost of the construction materials compared with current Japanese construction market situations. As detailed case studies, the typical mid-size (10,000 m3) and small-size (5,000 m3) office buildings are investigated to estimate the total cost and amount of construction materials for both two countries. These case studies illustrate that the international trade between Canada and Japan provides the influence to the wood industries and the different background of architectural concepts affects the decision-making for a building envelop design. This study indicates the future potential for new office building construction technique and material choice to reduce environmental impacts such as CO_2 emission and energy consumption using the exchange of cross-cultural construction scenarios.

2.2 Direct Material Price Indexes

Using 2004 based Canadian and Japanese statistics information data, the percent increase and reduction for 15 direct materials are shown in Figure 5. Three important direct materials are particularly discussed in this section.

2.2.1 Plywood
Canada is the largest trading partner for Japanese forest industry and provides the 40% of wood products to the Japanese market. Although Japan's forests cover 66% of the land, the Japanese domestic wood products occupies 19.2% in 2003 for total wood products. This is because the Japanese forest industry has been defeated by cheap wood shipped from abroad. As Figure 5 shows, this current trading relationship with other countries influence the price increase for Japanese plywood market. According to the Nikkei Newspaper, the constrain for cutting rainforest in Indonesia and Malaysia to prevent global warming stimulates to increase the price of Japanese wood market. The price of plywood, especially using for concrete frames, is particularly high.

Although the demand for the plywood increases in Canadian construction market, the data shows the price for the domestic wood product market is steady. However, two countries have tentatively agreed on a common standard for construction grade plywood. The implementation of joint standards will enhance bilateral trade. The U.S.-Canadian Free-Trade Agreement has strengthened and enriched wood products trade between the two countries through improved market access.

2.2.2 Concrete
The price of concrete in Canadian construction market jumped 37 per cent between December 2005 and February 2006. Concrete prices are still rising after lumber prices have fallen well below their peak 2004 prices and steel prices have stabilized. SC predicts concrete prices continue increasing because Canadian cement capacity is not be enough to significantly relieve the current construction demand. However, Canadian cement market exports 50% of total production. The effective consideration for the import-export strategies for cement is required to provide enough amount of concrete and to prevent to increase the cost of

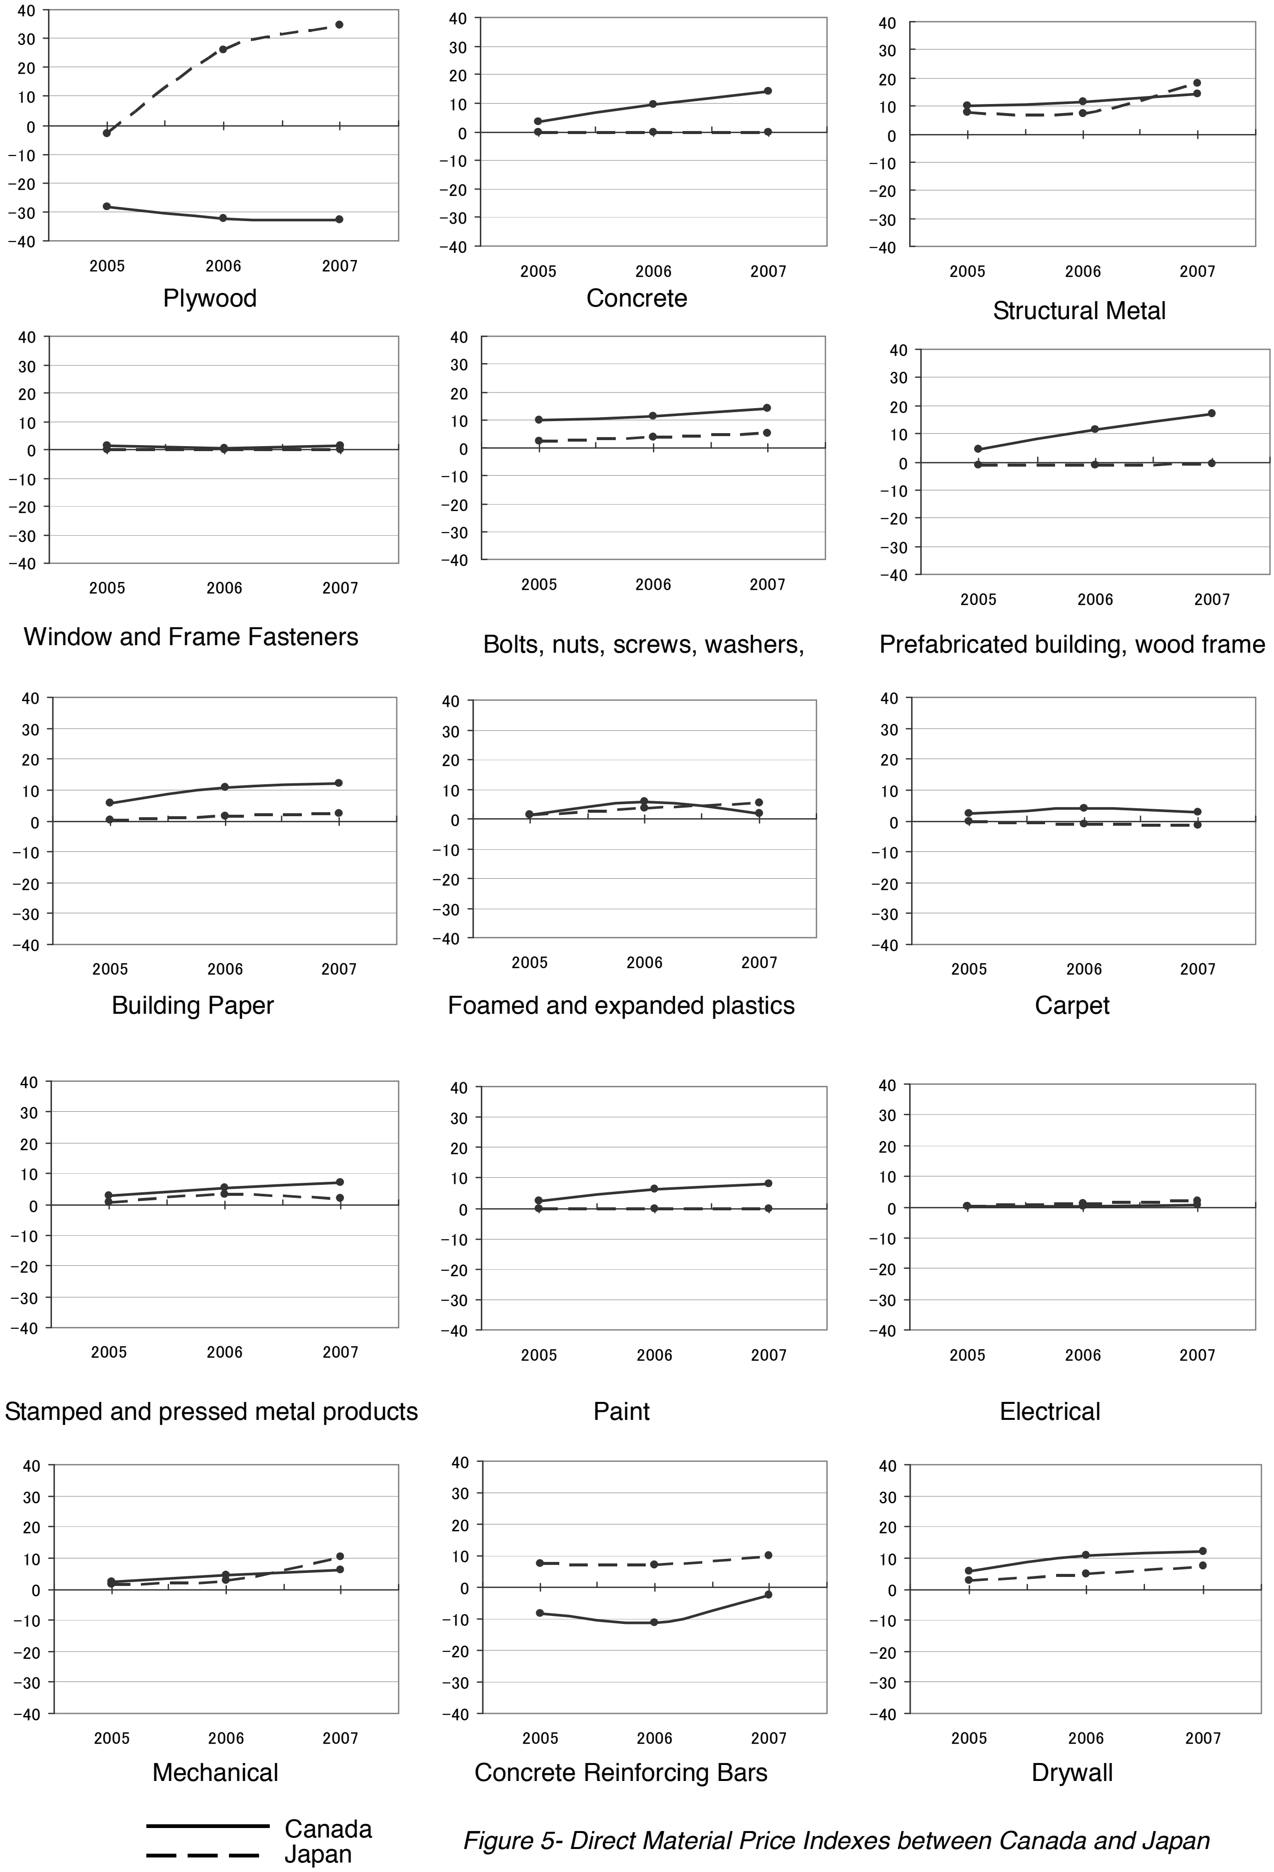

Figure 5- Direct Material Price Indexes between Canada and Japan

concrete for Canadian construction market. On the other hand, the total amount of exported cement is occupied on 9% for Japanese cement production. As Figure 5 shows, Japanese concrete price has been steady in the construction market for 30 years.

2.2.3 Steel and Concrete Reinforcing Bars
Both Canadian and Japanese construction industries indicate that the demand for steel increases and the supply for steel decrease simultaneously. All types of steel have increased in price compared with 2004. Figure 5 shows the structural metal products rise by approximately 20% in Japanese market.

China consumes about 25% of the world's steel supply. As China is a major country in the metal production market, it can redirect previously exported steel to overcome its own domestic demand for the material. This China's rapid growth stimulates to reduce the material's availability on the open market. This international metal market movement relatively affects Japanese market because the more than 90% of metal products are imported. SC predicts the cost of Canadian metal products also increases.

The important discussion in this section is that Japanese construction market strongly depends on the international trading to acquire the huge amount of construction materials such as plywood and steel compared with Canadian market. This market condition provides the high energy consumption and CO_2 emission for the transportation process. However, it is quite impossible to satisfy the entire Japanese market demand with just only domestic products. This market-based building construction analysis raises the issues of the direct martial acquisition for both countries.

3. Analysis for Specific Office Buildings

The scope of a case study is to investigate the amount and cost of office building construction materials to explore how the construction market affects other industries. The sample office buildings in this study chose from two regionally and culturally different countries, Canada and Japan. It is important to explore the different construction trends from two countries' construction market background rather than to focus on characteristics, strength or weakness comparing various office buildings from one specific region. The comparison for both construction techniques is easy to explore effective and ineffective construction method to apply a current each construction market. The key discussions associated with the evaluation for both office buildings are highlighted below:

- the different construction techniques based on building code or bylaw
- the trend of architectural design concept with different culture and social background
- the evolution and cross-cultural exchange for new construction techniques

3.1 Difference from Building Code and Bylaw

The evaluation for building structure is most significant study to find the different conflicting targets for both building construction methods. The reason is that the structure design clearly depends on the cultural and social building construction practice such as a bylaw or a building regulation rather than client and stakeholder interests. Figure 6 presents the amount of major office building structural materials (per sq.m), rebar, concrete, plywood and steel to illustrate the different structural mechanisms. This figure shows that the amount of the total structural components, concrete (0.69m2) and rebar (0.08t/m2), for Japanese office building is larger than Canadian office building. One of the reasons for this difference is the Japanese earthquake resistance regulation. The concrete quantity for building foundations is approximately double compared with Canadian construction techniques to apply this restrict regulation.

3.2 Trend of Architectural Design Concept

Limited property and extremely high land prices have generated Japanese characteristic compact urban centers and high-rise, high-density building. The result of tight spaces severely compromise spatial quality, privacy, natural lighting and ventilation, and view. The property value and building envelop design is most important factor to evaluate building value in the Japanese market. As Figure 6 shows the budget of exterior finish for Japanese office buildings spend more than 100$ per sq.m compared with Canadian office building and use window (curtain wall systems) 50% less than Canadian office. There are two reasons to discuss from two countries' architectural trend. Discussed above, as Japanese urban center is usually dense, curtain wall or expensive exterior materials are only installed on the main building façade to provide uniqueness in the competitive office building market. This design trend usually applies to small-and mid-size office buildings in Tokyo. On the other hand, the implementation of the market-placed curtain wall system is Canadian architectural trend for any size of office building with all faces for a building envelop. These two different architectural interests provide unique window and exterior finish data for both countries.

3.3 Innovative Construction Techniques

A number of innovative construction methods have been introduced and implemented to both construction markets. Increasing the importance and recognition of a green building concept in both Canadian and Japanese market, the designing of new construction techniques also considers to reduce environmental impacts during building construction process. A good example is that an innovative recyclable metal concrete frame system, E-PANET, is widely used for the substitution for plywood concrete frame system in Japanese market. As discussed in section 2.2, it is significantly effective to shorten the cost and amount of plywood to reduce environmental impacts for Japanese building construction process. According to the Nihon Kankyou Seizou, the 27% of commercial construction project uses E-PANET system in Japan.

Region		**Japan**		**Canada**
Size	2400 m²	15,000 m²	3250 m²	12450 m²
General Conditions	90.5 m²	82.6m m²	96.4 m²	77.2 m²

Window	0.14 m²	0.19 m²	0.31 m²	0.23 m²

Figure 7- the average amount of major direct materials for office building structure construction

4. Discussion

What is evident through the issues explored in this pare is a need for a greater understanding of the trend for building construction material industries and a strategic approach using innovative building construction techniques while understating cultural and social background for each countries. The following key points are discussed:

- Increasing building structural efficiency such as mximixing beam spans, downsizing column size, structure weight and foundation requirement
- Implementing suitable envelop design understanding a cultural and social trend
- Exploring new construction techniques
- Selecting appropriate construction materials, environmental friendly production and transportation process

There may be unavoidable situations for building construction scenarios that can be decided by government registrations such as Japanese earthquake regulation or Canadian building bylaw. However, determining a realistic and credible baseline for a building construction method listed above is necessary to answer a question “what is the effective office building construction scenario to minimize environmental impacts and how much impact does office building construction activities affect other industries?”. Exploring the effective implementation for building construction method and material encourage both countries’ construction industries to consider reducing environmental impacts at the building construction stage.

Keywords: urban microclimate, outdoor thermal comfort, urban heat island (UHI), residential development, mixed use street block

Summary

Majority of Hong Kong's population lives in high-rise high-density residential developments or mixed use street blocks. In such high-density living conditions, the provision of open space at neighborhood level is of vital importance to enable residents to enjoy better quality of life with the social, psychological and environmental benefits that open spaces can bring. However, when designing these public spaces, the effect of the overall build forms on the microclimate conditions need to be considered. Only when the conditions allow for human comfort would these spaces serve to promote sustainability. One significant factor having adverse effect on human comfort is heat stress. Heat stress in urban areas can be described by Urban Heat Island (UHI).

This study investigates the impact of design-related variables on outdoor micro level heat island effect in residential developments and mixed use street blocks in Hong Kong. It hypothesizes that a significant part of the differences in outdoor temperatures within and between the studied areas can be explained by the impact of design-related variables. The findings of the study will lead to specific environmental design guidelines to help practitioners to make design decisions at micro-urban and urban scales for more sustainable communities.

1. Introduction

Hong Kong has a population of 6.7 million, and a total land area of just 1,100 square kilometres, making it one of the most densely populated cities in the world. Due to the scarcity of available land (around 25% of the total area) for building in Hong Kong, most of the population lives in high-rise high-density residential blocks (privately developed or government subsidized) in urban areas, where the population density averages at around 26,000 persons per square kilometre and reaching 51,000 persons per square kilometer in the most densely populated area. The urban fabric is dominated by tall buildings with limited open space provision. (Figure 1a, b and c from left to right)

Figure 1a Large-scale residential developments with tower blocks of similar height and configurations

Figure 1b Sharp edged buildings of different height in urban street blocks

Figure 1c Newer taller developments form 'walls' surrounding older street block

It is well established that urban open spaces are vital to the well being of city dwellers. Urban spaces contribute to achieving sustainability and their importance for better quality of life is particularly crucial in high density cities such as Hong Kong. In light of the high density high rise environment of a compact city like Hong Kong, where the area of urban open space per inhabitant is only about 2.9 m^2 / inhabitant (Census and Statistics Department, 2001) as compared to the World Health Organization's recommendation of 10 m^2 / inhabitant, the importance of provision of high quality urban open spaces is further high-lighted.

Study by Lo et al (2003) on the analysis of attributes affecting urban open space design and their environmental implications concludes that microclimate is the most important criterion for urban open space users in Hong Kong. Research by S. B. A. Coorey (2008) on design of open spaces in public housing estates in Hong Kong also found that respondents' evaluation of physical environmental quality such as climatic comfort for open space scores comparatively high compared to other attributes such as crowding, privacy, safety and social interaction in achieving users' satisfaction of open space in high density contexts.

In light of these findings, microclimatic conditions are considered integral to the success of an urban open space, since they have significant influence on the level and satisfaction of use. The potential of urban open spaces in providing human comfort and promoting sustainability of urban living greatly depends on their thermal performance.

1.1 Background

Multiple and intensive land use is a sustainable approach in dealing with expanding metropolitan areas. Hong Kong has adopted the MILU model of development to cope with the increasing population and the economic need to expand the metropolitan area on very limited build-able land over the last five decades (Lau et al, 2005). The success of MILU model is evident in the development of Hong Kong into the metropolitan that it is at present, with many cities in China, such as Guangzhou and Shanghai following suite. However, the MILU model has also contributed to the adverse effect on microclimatic condition such as increased Urban Heat Island (UHI) in urban areas due to its typically high-rise high-density built form. The study of UHI in existing MILU developments would serve to inform other cities the possible adverse effects of adopting the MILU model and to make design decisions to avoid such effects.

The study of thermal environment of urban outdoor spaces requires understanding of urban morphology and climatology, both multi disciplinary study areas involving architectural design, planning considerations, building physics and atmospheric sciences. The local climate of an urban area can be greatly affected by the urban thermo-physical and geometrical characteristics and anthropogenic moisture and heat sources present in the area (H. Taha, 1997). In the high-density high-rise setting of Hong Kong, it can be anticipated that the adverse effect on the thermal conditions would be further aggravated since urban heat island intensity (UHI) rises with increased building density and canyon geometry (M. Santamouris, 2001). Hong Kong has one of the highest net urban densities in the world (Ganesan et al 2000). UHI is an outcome of modification brought into characteristic of land use in densely populated areas (Solecki et al 2005). In such scenario it is mandatory to integrate urban climotological elements (Abbate, 1997).

1.2 Hypothesis

This study investigates the impact of different form of open space configurations on outdoor micro level daytime and nocturnal heat island effect in residential and mixed use developments and street blocks in Hong Kong in order to understand the design implications involved in making comfortable outdoor open spaces for people's enjoyment. This paper hypothesizes that a significant part of the differences in outdoor temperatures within and between each studied site can be explained by the different typical open space configurations on the overall environment.

2. Methodology

The methodology used in this study is based on one that has been established by previous research on coastal UHI measurement in Hong Kong (Giridharan et al, 2004). The methodology has been improved by conducting simultaneous measurements at three different geographical zones for any given measurement period. 15 to 20 measurement points were chosen for each sample site, taking into account the maximum possible variations in design-related variables such as sky view factor, height to floor ratio and surface albedo.

Figure 2 Sky view images and photographs showing the variations in design-related variables

The data collection period was from 1300-2200, with hourly data collected at each measurement point. Data were collected simultaneously at 3 sites from different geographical zones for a period of 3 days.

In each of the studied site, 1 mini weather station measuring air temperature, relative humidity, wind speed and direction, and solar radiation was fixed at the most representative of the measurement points and 3 micro-loggers with sensors measuring air temperature, relative humidity and wind speed are fixed at other strategic measurement points, taking into account the variation in design descriptors of their location. Mobile measurement of air temperature, relative humidity and wind speed using an anemometer were carried out at all measurement points.

Figure 3 Photographs showing fieldwork equipment and measurement on site using fixed mini-weather station and mobile anemometer

2.1 Classification of Inner-city Areas

Inner city areas refer to the parts of Hong Kong Island, Kowloon Peninsula and the more urbanized parts of the New Territories which are not abutting the sea front, and are subject to minimal impact of the sea due to high density and height of buildings in the proximity. The characteristics of inner city residential developments and mixed use street blocks are identified as follows:

- Very dense construction and street blocks virtually walled by surrounding buildings;
- Construction materials used for vertical surfaces are of very high heat storage capacity;
- Very high degree of impervious horizontal surface (asphalt, concrete, cement stone paved);
- The block geometry generally traps radiation and creates air stagnation;
- Very tall and sharp edged buildings;
- Very low density of vegetation along the streets;
- Negligible extent of heat sinks due to small urban parks and lack of sizeable water bodies within the micro environment;
- High heat and waste release from residential and commercial space;
- High volume of traffic;
- High levels of commercial and street lightings;
- Canyon geometry ratio in the order of 3 to 6

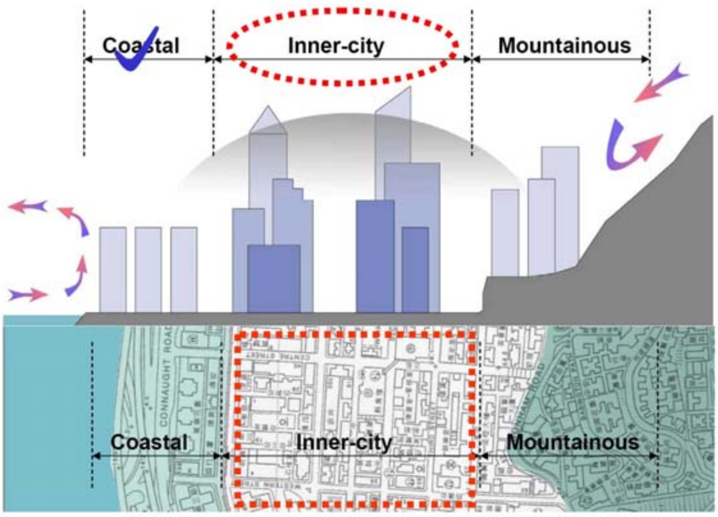

Figure 4 Conceptual section and plan of inner city classification

2.2 Surveyed Sites

A total of 18 sites, including public housing estates, private-sector residential developments and primarily residential mixed-use street blocks of similar scale were surveyed in this study. They are distributed in 6 different geographical zones. The samples are representative of the typical residential environment types in Hong Kong's most populated urban areas, chosen to incorporate the maximum possible variations in design-related descriptors. Attention is paid to select samples which have a larger variation in categories which have shown to make the most impact on UHI from previous study of coastal UHI in Hong Kong. Tower block residential developments as well as MILU street blocks were surveyed.

Figure 5 Location of surveyed sites in 6 different geographical zones in Northern part of Hong Kong Island and Central Kowloon Peninsula

In this paper, only one set of the 3 simultaneously surveyed sites will be discussed, the built form and urban fabric of the three sites are shown in the figures below:

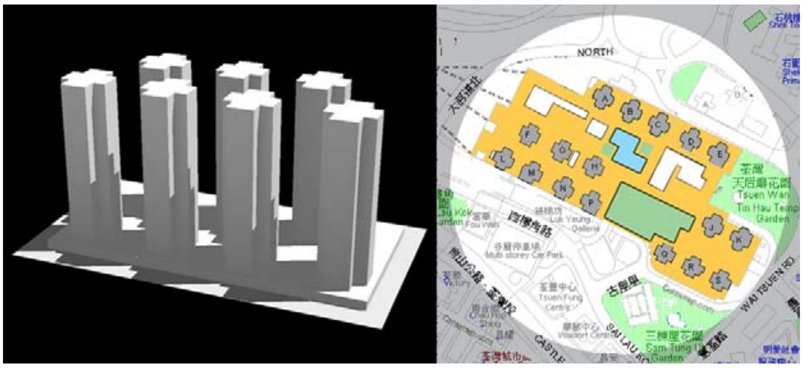

Figure 6 Site A -Towers on podium type configuration typical in residential developments

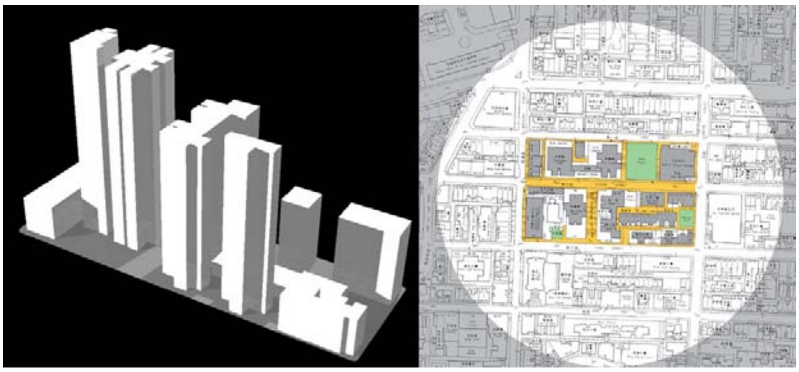

Figure 7 Site B - Mixed use / residential street block with small pocketed open spaces

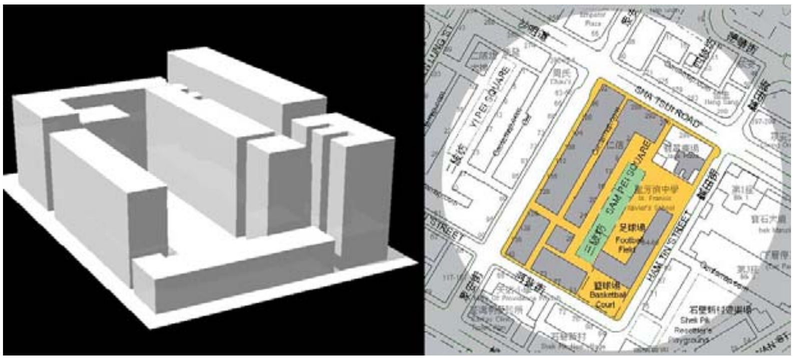

Figure 8 Site C - Mixed use / residential street block with courtyard type centralized open space

3. Findings and Observations

The initial findings show that the majority of urban open spaces in Site A, B and C do not have the ability to improve the urban microclimate and mitigate the heat island effect by reducing summer air temperatures in dense urban areas by 3-4 ºC as suggested by simulation studies (Dimoudi and Nikolopoulou, 2003). The maximum intra-site temperature differences for both daytime and nocturnal measurements were found in Site C at only 1.8 ºC and 1.1 ºC respectively, which are significantly lower than the reduction suggested by simulation studies.

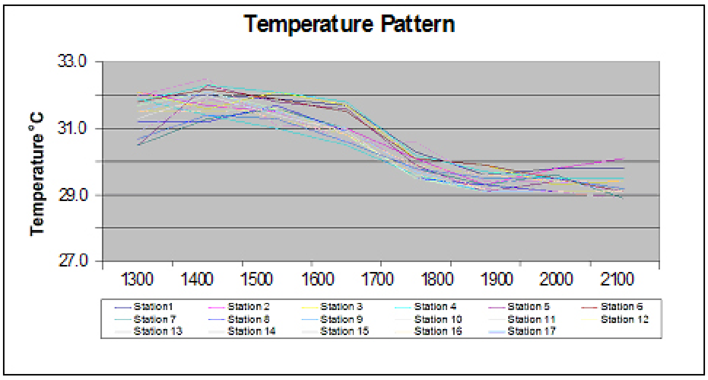

Figure 10 Temperature patterns of all measurement stations of Site C

The lowest temperatures were recorded at the 'central courtyard' type open space and the highest temperatures were recorded at the stations most exposed to heavy vehicular traffic. The lowered temperature measurements were only recorded at the measurement points within the boundaries of the open space, but have minimal effect on mitigating the UHI effect in the surrounding areas. This is probably due to the low level of vegetation present at these urban open spaces and also the low albedo material used in paving these spaces and in the vertical surfaces.

The reduction of the cooling effect can also be explained by the different urban morphology. The cooling effect is more evident in samples where the surrounding building configuration allows for sufficient air ventilation to pass through the open space. The size of the open spaces and their proximity to anthropogenic heat sources such as road traffic also has effect on their thermal performance. Figure 11 shows the comparison of temperature pattern for the main open space of Site A, B and C.

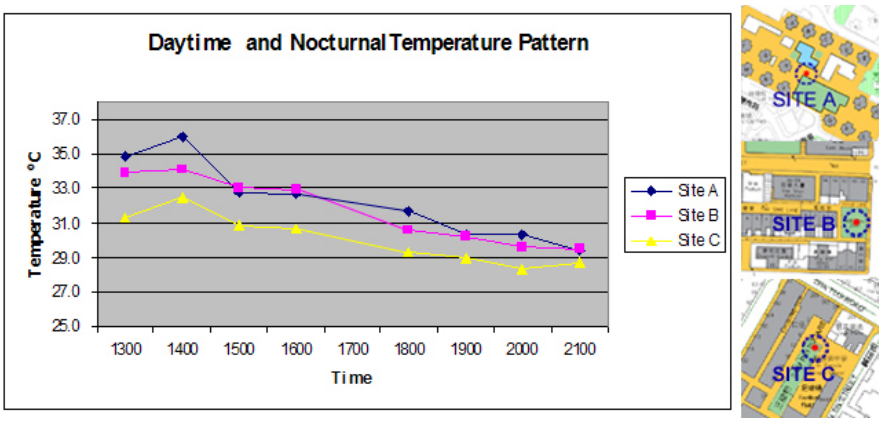

Figure 11 Temperature Pattern of Main Open Space of Site A, B & C

The comparison shows that Site A (podium type open space) and Site B (small pocket open space) has similar temperature pattern, with Site A having a slightly higher mean temperature. Site C ('central courtyard' type open space) has the lowest temperature. The mean daytime and nocturnal temperature difference between Site A and C is 2.7ºC and 1.6ºC respectively.

4. Conclusion

Urban Heat Island (UHI) varies with geographical, latitudinal and urban density and population changes (Oke, 1988). To understand this UHI profile and further derive planning and design strategies for mitigating summertime UHI will greatly benefit the urban thermal environment and improve comfort of users.

This study focuses on potential alleviating function of urban open spaces in high rise high density residential and mixed use developments and street blocks. The initial findings show that different urban morphologies alter the thermal performance of the urban open space. A previous study (Giridharan, Lau et al, 2007) suggested that with the same amount of tree cover in high rise high density coastal building area, the open space in the form of pocket parks comes with lower air temperature of about 0.5 -1.0 °C compared to a landscaped courtyard. While the present study indicates the opposite in inner city area, with temperature of the central courtyard significantly lower than those of the podium and pocket park (Figure 11). The shift of temperature pattern between inner city and coastal area could be due to the influence of sky view factor. Further, as ventilation potential is greatly undermined by surrounding buildings, the pocket park and podium may not enjoy better advection cooling although they are more open than the courtyard space.

Further analysis is needed to determine to how, and to what extent these urban morphologies (building, form, fabric and configuration), and site specifics (volumetric composition, and orientation) constitute to a more sustainable urban environment by providing thermally desirable open spaces for social use.

Acknowledgement

This research work is sponsored by the Hong Kong Government Research Grants Council, Project number HKU7293/04H: Urban design to lower space conditioning energy in inner city mixed use residential street blocks in Hong Kong. The authors are grateful to the management of the surveyed sites for granting permission to access their properties and providing assistance during conducting the fieldwork measurements.

Keywords: sustainable buildings, user perceptions, environmental quality, questionnaires, commercial buildings, institutional buildings

Summary

During the last four years the authors investigated the performance in practice of a range of commercial and institutional buildings worldwide. Around 30 buildings in 11 countries have been studied - in all cases either recipients of national awards for sustainable design or highly rated in terms of the relevant building sustainability rating tool. These investigations included a questionnaire survey seeking the users' perceptions of a range of factors: Operational (space needs, furniture, cleaning, meeting room availability, storage arrangements, facilities, and image); Environmental (temperature and air quality in different climatic seasons, lighting, noise, and comfort overall); Personal Control (of heating, cooling, ventilation, lighting, and noise); and Satisfaction (design, needs, productivity, and health).

This paper presents the users overall perception scores for the following aspects – lighting, noise, temperature and air quality in summer and winter, comfort overall, design, needs health and productivity, together with comfort, satisfaction and summary indices compiled from these factors. Most buildings had average scores above the mid-point of their respective scales, performing particularly well in terms of lighting overall, design and needs. The performance of the buildings on two rating scales is also presented. These indicate that the majority are performing at the 'Above Average' or 'Good Practice' level

1. Introduction

Over the last decade or more there has been a proliferation of Building Sustainability Rating Tools (BSRTs) around the world. Designed largely to quantify the environmental benefits of adopting particular building design strategies, and usually geared to the environmental issues peculiar to their country of origin, these tools are gaining increasing acceptance. Cole (2005, 2006) provides a useful overview and discussion of a number of the more established BSRTs.

Increasing numbers of owners are now arranging for their buildings to be assessed by the tool relevant to their country or needs; and some major (frequently governmental) tenants are requiring that the buildings they occupy meet a particular level on the relevant rating scale. This trend appears to be due to a number of reasons. Owner-occupiers, particularly where their business has a strong emphasis on sustainable products or services, are highly motivated to be seen to be 'practicing what they preach'; building developers and owners are keen to gain the competitive advantage they perceive from 'going green'; and many tenants, particularly (but not exclusively) government departments, wish to demonstrate their commitment to sustainability in their choice of building.

At present, most of these tools are focused on the design and as-built stages of the building process, taking some account of the quality of the environment that the building is intended to provide for the users. However, with moves afoot to develop BSRTs for buildings in operation, there is the opportunity to make a more direct assessment by, for example, asking the users directly. Given that salary costs are usually many times the building costs, organizations have every incentive to participate. In this paper the authors will present information on how the users perceived a range of aspects of the internal environment in a number of buildings around the world.

2. Research Methods

2.1 General Overview

For the last four years the performance in practice of around 30 commercial and institutional buildings in 11 countries worldwide has been investigated (Baird, 2009). These investigations involved the principal author undertaking one or more visits to each of the buildings, and the personal distribution and collection of a questionnaire survey seeking the users' perceptions of a range of factors: operational, environmental, personal control and satisfaction. During these visits, a formal, structured, transcribed interview was conducted with a key architect and environmental engineer from the design team, and a detailed tour undertaken of each building and its facilities, photographing key features, and collecting relevant documentation.

2.2 Characteristics of the Buildings

The buildings surveyed were as follows, by country:

- Australia: 40 Albert and 60L, Melbourne; Red Centre and Institute of Languages, UNSW, Sydney; Student Centre and General Purposes Building, Newcastle University; Scottsdale Forest Ecocentre, Tasmania.
- Canada: Computer Science and Engineering, York University; Liu Institute, University of British Columbia; Toronto Military Families Resource Centre; National Engineering Yards, Vancouver.
- Germany: Sciencepark, Gelsenkirchen.
- India: Torrent Research Centre, Ahmedabad (both conventionally and evaporatively airconditioned).
- Ireland: St Mary's Credit Union, Navan.
- Japan: Nikken Sekkei HQ, Tokyo; Earthport, Yokohama.
- Malaysia: Menara UMNO, Penang; MEWC HQ, Putrajaya .
- New Zealand: AUT Akoranga, Auckland; Landcare Research, Auckland; Mathematics Statistics and Computer Science, Christchurch.
- Singapore: Institute of Technical Education, Bishan
- UK: Arup Campus, Solihull; City Hall, London; Eden Foundation, St Austell; Gifford Studios, Southampton; Renewable Energy Systems HQ, Kings Langley; Zicer Building, University of East Anglia.
- USA: Natural Resources Defence Council, Santa Monica; NRG Systems, Vermont.

These were selected on the basis of their sustainability ‘credentials’. Virtually all of them were recipients of national awards for sustainable or low energy design, or were highly rated in terms of their respective countries building sustainability rating tool (LEED, BREEAM, CASBEE, Green Globes, etc) or in some way pioneered green architecture. Of course, willingness on the part of the building owner and tenants to be surveyed was also an essential prerequisite, and not all building owners felt in a position to accept our invitation.

Of the 30 buildings, 13 accommodated office activities predominantly, 10 were tertiary level academic teaching buildings, 4 housed laboratories or research organisations, and 2 contained a combination of industrial and administrative functions.

While most of the buildings were in temperate climates of one kind or another (ranging from warm-temperate to cold-temperate) a significant number were located in warm-humid climates. Their systems of ventilation ranged from full air conditioning, through mixed-mode (concurrent, changeover and zoned) to natural ventilation (both conventional and advanced) and in one case Passive Downdraft Evaporative Cooling (PDEC).

2.3 Nature of the Questionnaire

The questionnaire has evolved over several decades, from a 16-page format used for the investigation of sick building syndrome in the UK in the 1980s, to a more succinct 2-page version. Developed by Building Use Studies (BUS, 2004) for use in the Probe investigations (BRI, 2001/2), it is available under licence to other investigators.

The sixty or so questions cover a range of issues. Fifteen or so elicit factual background information on matters such as the age and sex of the respondent, how long they normally spend in the building, and whether or not they see personal control of their environmental conditions as important. However, the vast majority ask the respondent to rate some aspect of the building on a seven-point scale; typically from 'unsatisfactory' to 'satisfactory' or 'uncomfortable' to 'comfortable', where a '7' would be the best score.

The aspects covered in the questionnaire include matters to do with the building overall, such as its design, how well it meets the respondents' needs, the effectiveness of the use of space, how satisfactory are the cleaning arrangements, the availability of meeting rooms, and the suitability of storage arrangements; matters connected with the respondents specific work requirements, health, productivity and degree of personal control; and matters related to the thermal environmental conditions and air quality in summer and winter, as well as the lighting and noise conditions.

Analysis of the responses yielded a mean value (on a 7-point scale) for each variable. In addition to calculating the mean value for each variable, the analysis also computed a number of ratings and indices in an attempt to provide indicators of particular aspects of the performance of the building or of its 'overall' performance.

For this paper, the authors focus on the Rating Scales and Indices (Comfort, Satisfaction and Summary) and on the users overall perception Scores for the following aspects – *lighting, noise, temperature* and *air quality* in *summer and winter*, *comfort overall, design, needs, health and productivity*. In each case the distribution of the ratings or scores will be presented and described.

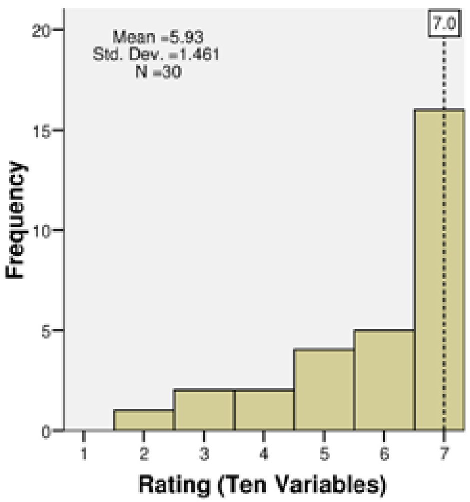
3. Results – BUS 7-Point Ratings

Two rating scales, one made up of '10 variables' and one using 'All variables' (around 45 in total), are used to provide an overall statistical snapshot of occupants responses. Each variable in the rating scale is scored on a scale from 1 to 5 depending on whether they are perceived as being significantly worse, slightly worse, the same as, slightly better, or significantly better than the BUS benchmarks (based on the previous 50 or so buildings surveyed) and the scale mid-point. These scores are then summed and the percentage is then transformed to the following 7-point scale:

1 'Very Poor'; 2 Poor; 3 Below Average;4 Average; 5 Above Average; 6 Good Practice; and 7 'Exceptional'.

The variables included in the 10-variable rating scale are – *comfort overall, design, health, image, lighting overall, needs, noise overall, productivity, temperature in summer overall* and *temperature in winter overall*.

While it could be argued that there is a certain amount of arbitrariness in the selection of the above variables and the terminology of the Rating Scale, and that the scoring process requires careful judgement, they do have the inestimable merit of clarity and simplicity, and can be readily modified



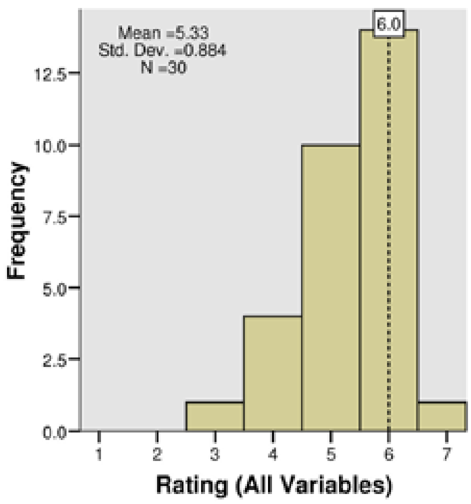


Figure 1 BUS 7-Point Rating Scale (Ten Variables) *Figure 2 BUS 7-Point Rating Scale (All Variables)*

Figure 1 *(ten variables)* demonstrates that, of the 30 buildings in this sample, more than half were in the top 'Exceptional' category with a score of '7'. Only 3 buildings were considered to be 'Below Average'.

This high percentage of excellent buildings continues even when 'All variables' were input into the rating scale as can be seen in Figure 2. Although only one building was still rated as "Exceptional' (7 on the scale), 24 out of the remaining 29 were considered to be 'Good Practice' or 'Above Average'.

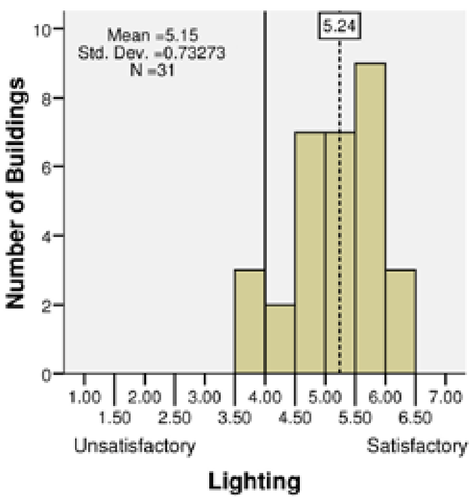
4. Results – Overall Perception Scores and Indices

This section details the average scores for a range of variables associated with the users' comfort and satisfaction with the buildings. The methods of estimating suggested overall indices of comfort, of satisfaction, and of a summary index are detailed, and their results presented.

4.1 Comfort Scores

While the questionnaire sought responses to a large number of factors associated with the different aspects of comfort, the following results focus on users overall perceptions of *lighting, noise, temperature and air quality in summer and winter,* and *comfort overall*. All of these were on 7-point scales where a higher value is better

Figures 3 and 4 illustrate the distribution of two of these factors to illustrate the findings from this set of buildings – one factor which scored relatively highly for most buildings (*lighting*), and one that scored less highly (*temperatures in winter*).



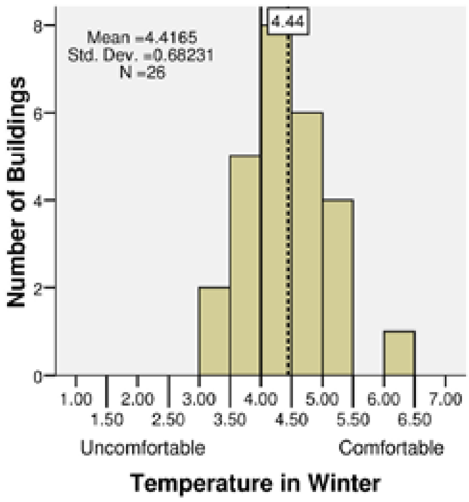


Figure 3 Lighting Overall – Average Scores *Figure 4 Temperatures in Winter Overall – Average Scores*

The mean, median and broad distributional characteristics of all the overall factors associated with comfort are presented in Table 1. Note that the mid-point of the scale is 4.00 and that 'winter time' conditions did not apply for buildings located in the tropics.

Table 1 Scoring for Key Comfort Variables

'Overall' Factor	N	Mean	SD	Median	Percentage of buildings scoring above and below particular scale values < 3.00	< 4.00	> 4.00	> 5.00
Comfort	30	4.91	0.84	4.93	-	17%	83%	40%
Lighting	31	5.15	0.73	5.24	-	10%	90%	61%
Noise	30	4.42	0.83	4.48	7%	30%	70%	27%
Temperature in Summer	31	4.32	0.97	4.42	10%	29%	71%	26%
Temperature in Winter	26	4.42	0.68	4.44	-	27%	73%	19%
Air in Summer	30	4.32	0.86	4.40	7%	33%	67%	23%
Air in Winter	26	4.44	0.61	4.38	-	27%	73%	15%

It can be seen that the mean and median scores are all greater than 4.00, with *comfort overall* approaching 5.00 and *lighting* (see also Figure 3) greater than 5.00. For the majority of these comfort factors, around 70% of the buildings score above the scale mid-point of 4.00, while in the case of *lighting* a figure of 90% is attained. Interestingly, the mean perception of *comfort overall* is higher than the average of the individual factors, possibly indicating a degree of tolerance on the part of the users (Leaman and Bordass, 2007).

4.2 The Comfort Index

The Comfort Index attempts to encapsulate, in a single figure, an overview of occupants' perceptions of the building's comfort performance. This index is formulated from the 'Z' scores for: *overall comfort, lighting, noise, summer and winter temperatures and air quality*. The formula for calculating this index can be described as follows:

$$\text{Comfort Index} = \frac{\mathbf{Z}_{\text{comfort}} + \mathbf{Z}_{\text{light}} + \mathbf{Z}_{\text{noise}} + \mathbf{Z}_{\text{temp/sum}} + \mathbf{Z}_{\text{temp/win}} + \mathbf{Z}_{\text{air/s}} + \mathbf{Z}_{\text{air/w}}}{7}$$

The Z score is derived from:

$$Z = \frac{\text{Actual - Benchmark}}{\text{Standard Deviation}}$$

The Benchmark is based on the average of the previous 50 buildings surveyed by BUS.

The Comfort Index is based on a scale of '-3' to '+3', where '+3' is considered 'best' (the mid-point lies on zero). Figure 5 illustrates how this sample of 'sustainable buildings' performs when measured on this comfort index. The majority of the buildings (24 of the 29 cases considered) were above the mid-point of the scale in terms of comfort, and 10 of these were greater than +1.00. Some 5 cases were less than the mid-point but none of these fell below -1.00.

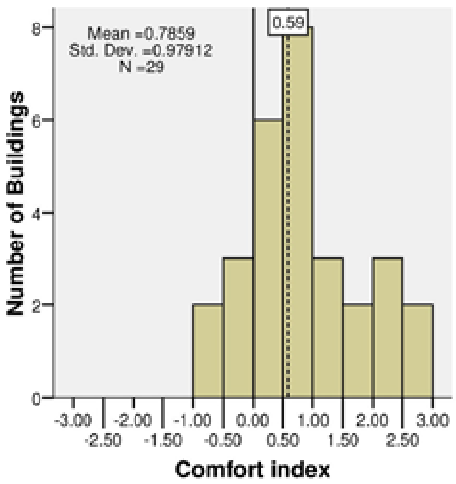

Figure 5 BUS Comfort Index

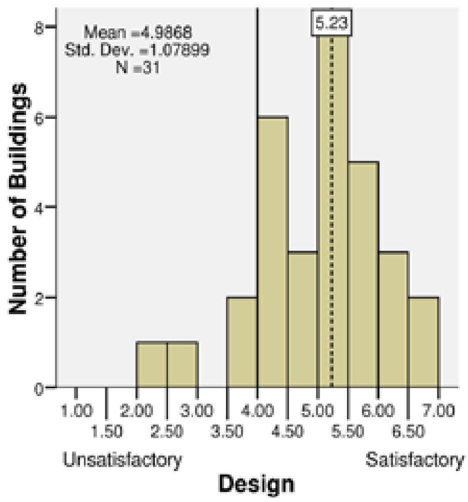
4.3 Satisfaction Scores

The variables defined as contributing to the users' perception of satisfaction were designated to be *design, needs, health* and *productivity*. The first three of these were scored on a 7-point scale where a higher value is better. In the case of *productivity* users are asked to estimate a percentage increase or decrease.

Figures 6 and 7 provide a graphical illustrations of two of these variables – *design* and *productivity*.



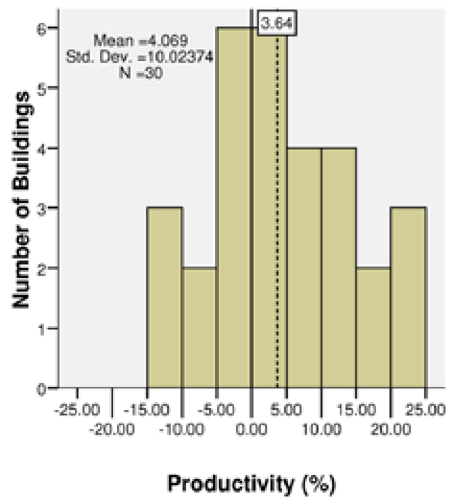


Figure 6 Building Design – Average Scores *Figure 7 Average Productivity Increase or Decrease (%)*

The mean, median and broad distributional characteristics of *design, needs*, and *health* are presented in Table 2. Note again that the mid-point of the scale is 4.00.

Table 2 Scoring for Key Satisfaction Variables

Factor	N	Mean	SD	Median	Percentage of buildings scoring above and below particular scale values < 3.00	< 4.00	> 4.00	> 5.00
Design	31	4.99	1.08	5.23	6%	13%	87%	58%
Needs	30	5.16	0.78	5.26	-	3%	97%	57%
Health	30	4.26	0.71	4.10	-	43%	57%	10%

As can be seen, this set of buildings scores particularly highly for *design* and *needs*, with around 90% above the mid-point in both cases and nearly 60% greater than 5.00. *Health* is not scored quite so highly, but still, nearly 60% made it over the mid-point

4.4 The Satisfaction Index

Similarly to the Comfort Index, the Satisfaction Index attempts to encapsulate, in a single figure, the occupants' overall satisfaction with the building. It is formulated from the 'Z' scores of the overall ratings for: *design, needs, health* and *productivity*. The formula for calculating this index can be described as follows:

$$\text{Satisfaction Index} = \frac{\mathbf{Z}\ \text{design} + \mathbf{Z}\ \text{needs} + \mathbf{Z}\ \text{health} + \mathbf{Z}\ \text{productivity}}{4}$$

The Satisfaction Index is based on a scale of '-3' to '+3' where, as with the Comfort Index, '+3' is considered 'best' (the mid-point lies on zero). As shown in Figure 8, 25 of the 29 cases were above the scale mid-point and 13 of these were greater than +1.00. Only 4 cases were less than the mid-point and again none of these dropped below -1.00. Overall these buildings were found to perform higher in terms of 'satisfaction' (mean = 1.05) than they did for 'comfort' (mean = 0.79).

4.5 Summary Index

The Summary Index is simply the arithmetical average the Comfort and Satisfaction Indices.

Figure 9 illustrates the distribution of this index which, as might be expected lies somewhere between the comfort and satisfaction distribution with a mean value of 0.92. As can be seen, 25 cases (or 86%) are above the mid-point of the scale and only 4 (or 14%) are below.

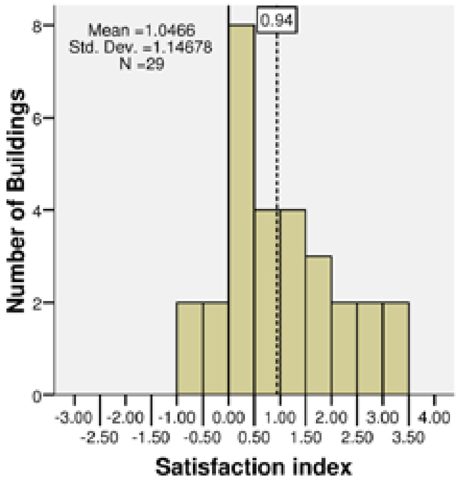

Figure 8 BUS Satisfaction Index

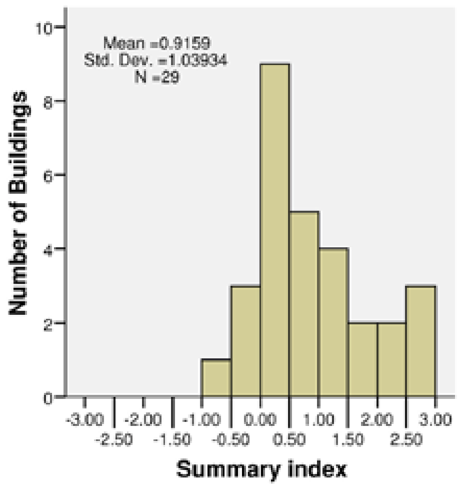

Figure 9 BUS Summary Index

5. Discussion and Conclusions

So what kinds of buildings were being scored highly overall and what design or other characteristics underlie the users' responses?

Looking first at the 7-point rating scale incorporating 10 variables, no less than 16 buildings made it into the 'Exceptional' category with a further 5 close behind in the 'Good Practice' category. 10 out of the 11 countries were represented in these 21 buildings. While most of these were in temperate climatic zones, 3 were in hot-humid climates (2 of them air conditioned). Of the 21, 10 had advanced natural ventilation, 8 were mixed-mode, and 3 were air conditioned.

Taking all 45 or so variables into account proved to be a tougher test on the 7-point rating scale for most of the buildings. The median for the group had slipped from 7 to 6 and only one building retained its 'Exceptional' status. At the other end of the spectrum the lowest rating building had moved up from 'Poor' to 'Below Average'. Overall, only 4 buildings were unchanged and 22 had gone down; 4 buildings had improved their rating – presumably factors other than those included in the 10 variable scale were scoring higher. However, in most cases the overall scores for a given variable tended to be higher than the average of its component variables resulting in lower ratings on the 45-variable scale (in the case of lighting for example, respondents scored aspects such as the amount of daylight, the amount of artificial light, the glare from sun and sky, and the glare from artificial light, as well as *lighting overall*).

The highest ranking was achieved by a building with advanced natural ventilation in a temperate climate, while the lowest had zoned mixed-mode ventilation in a hot-humid climate. Both had been designed with the intent of exploiting natural ventilation for owner-occupier clients who, while nor overtly cognisant of sustainability issues, were nevertheless interested in the long term performance of their buildings.

In terms of overall comfort, this set of buildings performed relatively well overall, with the vast majority (24 out of 29 cases or 83%) scoring above the mid-point of the -3 to +3 scale used in this instance. Of the seven factors assessed, this set of buildings had mean and median scores greater than the mid-point of the relevant 7-point scales (where 7 is best) in every case; and of these, *lighting* scored the best overall. The factors with the largest number of buildings scoring less than the mid-point of the scale were *noise, temperature in summer,* and *air quality in summer*, with around 30% each. This was borne out in connection with the 5 buildings which scored less than zero on the Comfort Index, where these factors were ones which had received relatively low scores.

For the 10 buildings whose Comfort Index was greater than 1.00, all climatic zones and all modes of ventilation were well represented. If there was a common factor it was perhaps the nature of the client organisation. In virtually every case, the client had a particular commitment to sustainability in terms of its products, its business interests, or the image it wished to portray; and in all cases planned to be the long-term owner-occupier of the building.

In terms of satisfaction, overall this set of buildings performed even better than for comfort, with a higher mean and median for the former and 23 (compared to 10 for comfort) scoring greater than 1.00 on the -3 to +3 scale. Nine of the buildings had indices greater than 1.00 for both satisfaction and comfort, though not necessarily at the same level.

Of the four factors taken into account for the Satisfaction Index, *design* and *needs* scored very well, the main exception being a zoned mixed-mode building in a hot-humid climate. As noted previously, *health* did not score quite as well as the other factors. However, with a median of 4.10 compared to recently reported medians of 3.3 and 3.7 respectively for conventional and green-intent buildings (Leaman and Bordass, 2007), this seems a reasonable figure. Finally, users' perceptions of how the buildings affected their *productivity* ranged from -13% to +23% for this group of buildings, and has been found to be highly correlated with *comfort overall* (Baird and Oosterhoff, 2008). The higher positive values appeared to emanate from buildings housing organisations with a relatively strong commitment to sustainability.

In the end, the highest values for the Summary Index were achieved by NRG Systems, the Natural Resources Defence Council, and the Torrent Research Centre (with conventional air conditioning) with indices approaching +3.00. These were closely followed by the Military Families Resource Centre, the Mathematics Statistics and Computer Science Building, St Mary's Credit Union, and the Torrent Research Centre (with passive downdraft evaporative cooling). All were owner-occupied buildings in a range of locations and climates where the client had a strong commitment to sustainability in general terms or, as in the case of the top two, in terms of their business activities.

Reassuringly, at least in terms of the choice of variables that made up the Summary Index, all of the buildings that exceeded a value of +0.5 on the -3 to +3 scale also rated highly ('Excellent' or 'Good Practice) on the 7-point rating scales

Acknowledgements

It is a pleasure to acknowledge Adrian Leaman for permission to use the Building Use Studies questionnaire under licence, to thank all the building owners and designers for their cooperation, and to express our appreciation to all the building occupants who responded to the questionnaire. Thanks are also due to Victoria University for various grants-in-aid to assist this work.

Keywords : Urban Heat Island, Mitigation Measures, Numerical Simulation

Summary

The urban heat island phenomenon is one of the most urgent urban problems in Japan as well as in the world. Various mitigation measures for heat island phenomenon have been recommended in the Sustainable Building Certification System such as LEED in U.S. or CASBEE in Japan. For example, these measures includes roof greening, site greening, high solar-reflection (albedo) painting, reduction of anthropogenic heat etc. In these certification systems, adopting each measure gives a certain credit to the building for urban heat island reduction. The weighting of this credit is usually same for all buildings in all sites. However the effects of these mitigation measures are different for the different buildings or different city blocks. Therefore, the authors have estimated the effect of various mitigation measures on the outdoor thermal environment in the two different existing city blocks in Tokyo city area using a coupled simulation of CFD (Computational Fluid Dynamics) and radiation transfer: One city block is Otemachi as a high-rise office building area and the other is Kyobashi as a middle-rise office building area. The results of this simulation would be helpful to develop the appropriate recommendation system of mitigation measures for the various city blocks.

INTRODUCTION

The heat island phenomenon has become considerably worse, and causes various other problems, such as an increase in the number of heat disorders or tropical nights. The underlying reasons behind the heat island phenomenon are considered to be the release of artificial heat, change in surface coverage due to urbanization, and a reduction in green space. Various measures to moderate the heat island phenomenon have been proposed and researched, and their effectiveness evaluated using numerical simulations. Although these effects are highly dependent on the property of each city block, insufficient comparison has been made of these effects between different city blocks. Therefore, the authors undertook coupled simulations of convection, radiation and conduction to evaluate the outdoor thermal environment over two different present urban blocks in Tokyo: Ōtemachi, as a high-rise business district, and Kyobashi, which is typified by mid-rise business district. The cases are set to compare the effects of measures such as the heat-release point and means of air-conditioning, as well as greening, high surface albedo, and traffic volume.

ANALYSIS

Analysis outline

In this study, the numerical method of coupled simulations of convection, radiation, and conduction developed by the authors (Chen H. et al. 2004) (Yoshida S. et al. 2000) was used. Figure 1 shows an analysis outline. Using input data concerning the place, weather, urban configuration, material and surface, the ground and wall surface temperatures are calculated using radiation simulation. After that, the surface temperature is used as a boundary condition for computational fluid dynamics (CFD) simulations, which are then performed.

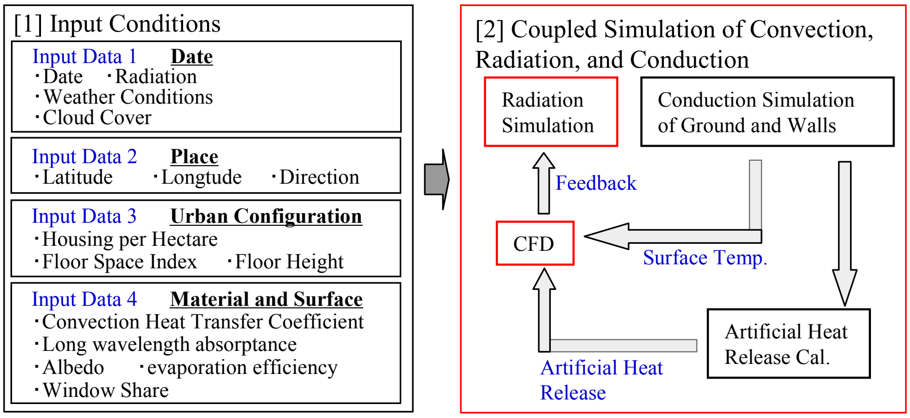

Figure 1: Analysis Outline

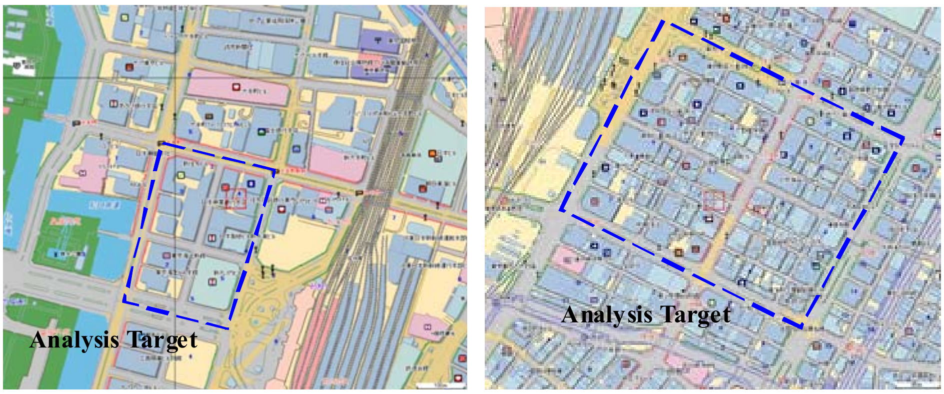
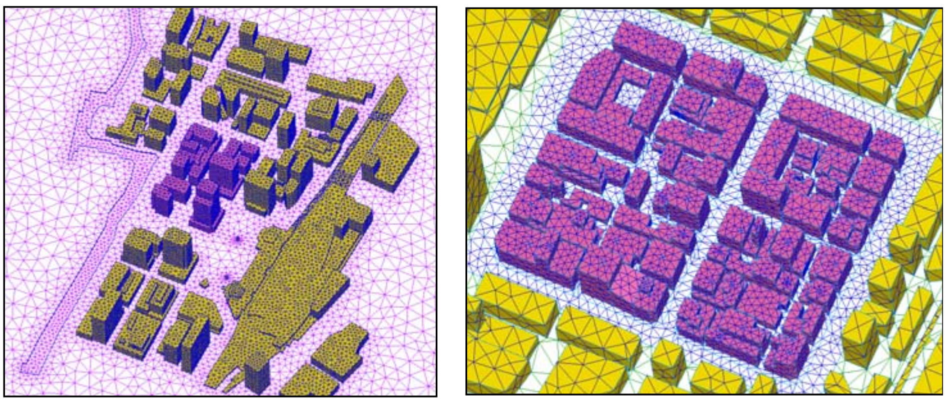


(1) Ōtemachi *(2) Kyobashi*

Figure 2: Analysis Targets



(1) Ōtemachi *(2) Kyobashi*

Figure 3: Analysis Models

Table 1: Urban Configuration of Simulation Models

	Ōtemachi	Kyobashi
Mean Gross Building Coverage	75.8%	86.9%
Mean Net Building Coverage	62.9%	71.2%
Legal Floor Space Index	900% or 1300%	600%～800%
Mean Floor Space Index	1179.0%	664.3%
Mean Building Height	67.4m	28.6m

Analysis target and model

Figure 2 shows the analysis targets. Ōtemachi represents a typical high-rise business district, while Kyobashi is a typical mid-rise business district in Tokyo. Ōtemachi and Kyobashi are located to the west and east of Tokyo station respectively. Table 1 illustrates the urban configuration of each domain, as calculated using simulation models. While Ōtemachi has wider spaces between its buildings, those in Kyobashi are crowded. Figure 3 shows the simulation analysis models based on GIS data. They incorporate an unstructured grid system. The model for Ōtemachi is 1,930 m (W) × 2,720 m (L) × 600 m (H), with 379,706 grids. The Kyobashi model is 2,460 m (W) × 3,630 m (L) × 600 m (H), with 372,000 grids. The analysis targets are set on some blocks near the center.

Analysis cases

Tables 2 and 3 show the analysis cases in Ōtemachi and Kyobashi respectively. Ten cases are adopted for Ōtemachi, and nine for Kyobashi. Cases 1-1 and 2-1 are basic cases. Cases 1-0 and 2-0 are without any artificial heat release. Cases 1-3, 1-4, 2-3 and 2-4 involve the buildings' roofs in the target area being changed to high-albedo or greening surfaces. Cases 1-5, 1-6, 1-7, 1-8 and 2-4, 2-5, 2-6 involve high-albedo, greening or water retention of the road and ground surface in the target area. Cases 1-9 and 2-8 concern the release of heat from traffic.

Table 2: Analysis Cases (Ōtemachi)

Case	Road			Ground	Building Surface		Heat Release		Release Point	Search Points

Analysis conditions

15:00 on July 23rd – a fine day weather-wise – was set for the analysis. The sun was at an attitude of 45.1º, the wind was southerly at a velocity of 3.0 m/s at a height of 74.6 m. The inflow wind velocity is set at 1/4th power profile. The air temperature was 31.6ºC, with a relative humidity of 58%. Table 4 shows the building and ground conditions. The temperature inside the building was fixed at 26ºC, and the buildings are considered to be made from concrete. The albedo and long wavelength emissivity of concrete were set to 0.2 and 0.9, respectively. Indoor convection heat transfer coefficient was 4.64 [W/m^{2}K].

The ground temperature was fixed at 26.0ºC under 0.5 m, and the ground surface was covered with asphalt. The albedo and long wavelength emissivity of asphalt were set to 0.1 and 0.95, respectively.

The Discrete Transfer Method (DTM) was used for the radiation simulation. In the CFD simulation, the turbulence model adopted was the standard k-ε model. The side and upper boundary was free slip. At the wall boundary, the wind velocity followed the generalized log law.

Table 4: Building and Ground Conditions

Building	Wall	Concrete
	Albedo	0.2
	Thickness	0.2m
	Indoor Convection Heat Transfer Coefficient	4.64 [W/m^{2}K]
	Indoor Air Temperature	26ºC
	Long Wavelength Emissivity	0.9
Ground	Ground	Asphalt
	Albedo	0.1
	Thickness	0.5m
	Long Wavelength Emissivity	0.95
	Ground Temp.	26ºC (under 0.5 m)

Setting of artificial heat release

The buildings' internal heat load was assumed using the product of the total floor area and the unit heat load intensity (Research and Exploratory Committee 2003). While all air-conditioning heat was assumed to be released from the roof in the Ōtemachi area, half of the air-conditioning heat was assumed to be released from the roof with the rest from the sides of the buildings in the Kyobashi area because the Ōtemachi urban block is composed of large buildings which have cooling towers, whereas many small buildings in the Kyobashi area have installed single-room air-conditioners.

ANALYSIS RESULTS

Ōtemachi area

Horizontal distribution of wind velocity and air temperature: Figure 4 shows the horizontal distribution of the wind velocity at a height of 1.5 m throughout Ōtemachi in order to evaluate the pedestrian area. Figure 5 illustrates the horizontal distribution of the air temperature in Case 1-1. There is a relationship in so far as that the air temperature is higher where the wind is weaker. In particular, the wind is weakened and the air temperature rises on the leeward side of the buildings.

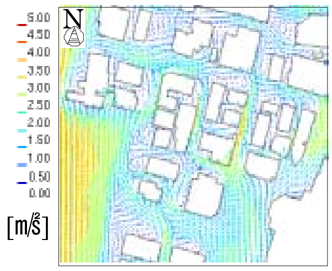

Figure 4 Horizontal Distbution of Wind Velocity in Ootemachi (Basic Case) (Height 1.5m)

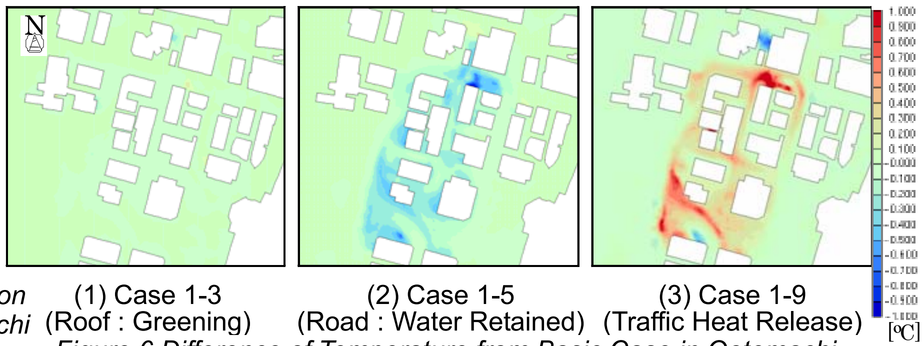

(1) Case 1-3 (Roof : Greening) (2) Case 1-5 (Road : Water Retained) (3) Case 1-9 (Traffic Heat Release)

Figure 6 Difference of Temperature from Basic Case in Ootemachi (Case 1-1) (Height 1.5m)

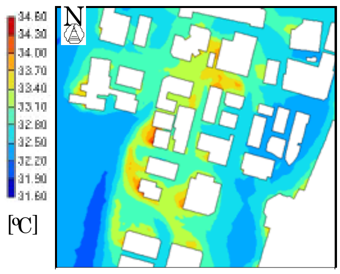

Figure 5 Horizontal Distbution of Temperature in Ootemachi (Basic Case) (Height 1.5m)

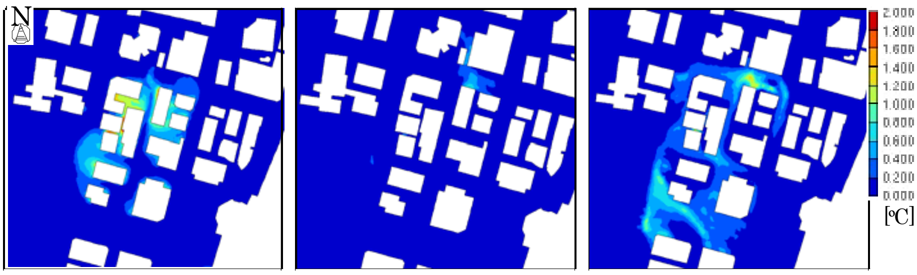

(1) Building Surface (2) Air-conditioning Heat Release (3) Traffic HeatRelease

Figure 7 Horizontal Distribution of Impact Index in Ootemachi (Height 1.5m)

Figure 6 shows the differences in air temperature from the basic case (Case 1-1) at a height of 1.5 m. Image (1) shows the result for Case 1-3, in which the roof surface is greened. In Case 1-3, there is not a large difference. Changing the roof material hardly affects the air temperature in the pedestrian area. Image (2) presents Case 1-5, in which the ground surface is changed into a water-retaining material. The air temperature broadly falls. This decrease is particularly noteworthy on the leeward side of the buildings. Image (3) presents Case 1-9, in which heat is released from traffic. The same trend as in Case 1-5 is exhibited, and the maximum increase in air temperature is more than 1ºC.

Horizontal Distribution of Impact Index: In order to compare the influence of surface temperature, air-conditioning heat release and traffic heat release, the impact index, as presented by the author [Note 1] (Chen H. et al. 2007) was calculated. Figure 7 shows the Horizontal Distribution of Impact Index at 1.5 m height. Image (1) shows the affect of a surface temperature rise of 1ºC. The surface temperature of the buildings has a substantial effect on the air temperature. Specifically, it affects the small canopy space and areas next to the buildings remarkably. Image (2) presents the air-conditioning heat release. This has no discernible effect on the air temperature in the pedestrian area. Image (3) is of the traffic heat release. Compared to the building surfaces, this affects a larger area.

Kyobashi area

Horizontal distribution of Wind velocity and air temperature: Figure 8 shows the horizontal distribution of wind velocity at a height of 1.5 m in Kyobashi to evaluate the pedestrian area. Figure 9 shows the horizontal distribution of air temperature. As in Ōtemachi, there is a relationship between the wind and air temperature. However, compared to Ōtemachi, the maximum air temperature is much higher because the buildings are crowded together and the wind has limited opportunity to exhaust the heat from the small canopies in Kyobashi.

Figure 10 shows the differences in air temperature compared to the basic case (Case 2-1) at a height of 1.5 m. Image (1) is of Case 2-4, in which the roof is greened. Image (2) shows Case 2-7, in which the ground and roads are greened or changed to water-retaining materials. While changing the roof material only cuts the air temperature a little, changing the road and ground materials sharply curtails the air temperature. As in Ōtemachi, the air temperature falls in small canopies and where the wind is weak. Image (3) concerns Case 2-9, which is of traffic heat release. The air temperature increases locally. Compared with on the road, in the small canopies, it increases considerably. The maximum increase exceeds 1ºC. There are several locations where the air temperature decreases. The reason is assumed to be that the flow field has been significantly affected by the large traffic heat release.

Horizontal Distribution of Impact Index: Figure 11 illustrates horizontal distribution of the impact index. Image (1) shows the effects of the building surfaces. These have a broad effect on the target area. The impact is especially pronounced near to the buildings and in small canopies where the wind is weak. Image (2) shows the difference from air-conditioning heat release compared to the basic case (Case 2-1). Because half of the air-conditioning heat release is from the sides of buildings in the Kyobashi area, its impact is massive and has a strong local effect. Near to any sideways release of heat generates an air temperature increase in excess of 2ºC. Image (3) concerns traffic heat release. Compared with air-conditioning heat release, its effect is primarily along the road, but it also has a local effect, such as in small canopies.

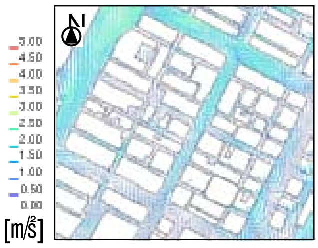

Figure 8 Horizontal Distribution of Wind Velocity in Kyobashi (Basic Case)

(1) Building (2) Air-conditioning (3) Traffic Heat

Figure 11 Horizontal Distribution of Impact Index in Kyobashi (Height: 1.5m)

COMPARISON BETWEEN ŌTEMACHI AND KYOBASHI AREAS

In order to compare the effect of urban block configurations, the mean velocity, mean air temperature, and mean impact index at 1.5 m were calculated. Table 5 shows the mean air temperature and wind velocity in the target area. In both areas, Cases 1-0 and 2-0, in which there is no heat released, the mean wind velocity decreases. Furthermore, the release of traffic heat increases the air temperature by more than 0.2ºC in both areas. In addition, the wind velocity clearly increases in Cases 1-9 and 2-8.

Table 5: Mean Air Temperature and Wind Velocity

Ōtemachi				Kyobashi		
Case	Mean Air Temperature [ºC]	Mean Wind Velocity [m/s]		Case	Mean Air Temperature [ºC]	Mean Wind Velocity [m/s]
1-0	32.96	1.47		2-0	32.99	0.90
1-1	32.96	1.51		2-1	33.19	1.19
1-2	32.96	1.49		2-2	32.97	1.10
1-3	32.96	1.49		2-3	33.07	1.26
1-4	32.96	1.49		2-4	33.20	1.16
1-5	32.82	1.45		2-5	33.18	1.15
1-6	32.93	1.48		2-6	33.05	1.17
1-7	32.86	1.49		2-7	33.07	1.25
1-8	32.82	1.48		2-8	**33.57**	**1.28**
1-9	**33.16**	**1.58**				

Table 6 shows the mean impact index. In Ōtemachi, because the buildings are high, the release of air-conditioning heat from roofs hardly has any effect. For the same reason, the roofs do not have any tangible effect although their surface temperature is high. In Kyobashi, the roofs and south-facing walls have a pronounced effect because the buildings are mid-rise types and the surface temperature of south-facing walls and roofs are higher than the other surfaces. Furthermore, the release of air-conditioning heat has a notable effect too.

Table 6: Mean Impact Index [ºC]

	Ōtemachi	**Kyobashi**
East	0.052	0.005
West	0.042	0.052
South	0.060	**0.117**
North	0.037	0.020
Roof	**0.004**	**0.108**
All Surfaces	0.195	0.303
Air-conditioning	**0.019**	**0.205**
Traffic	0.232	0.381

CONCLUSIONS

(1) In the high-rise Ōtemachi and mid-rise Kyobashi business districts, coupled simulations of conduction, radiation and convection have been performed. With cases showing changes to the heat release point and means of air-conditioning, as well as greening, high surface albedo , and traffic volume, various measures for moderating the thermal environment are quantitatively compared.
(2) In both of the Ōtemachi and Kyobashi areas, artificial heat release from traffic increases the air temperature in the overall target area at a height of 1.5 m; in particular, the leeward sides of the buildings are strongly affected. By the same token, the relaxation measures concerning the ground and road surfaces affect both areas.
(3) While the heat released from the air-conditioning systems does not increase the air temperature at a height of 1.5 m in Ōtemachi, it increases the air temperature locally; and in narrow streets with low wind velocity, the air temperature increase is especially notable. It was shown that the effectiveness of the relaxation measures differs depending on the configuration of the urban blocks.

NOTE

The impact index for outdoor thermal environment focuses on sensible heat to evaluate the influence on air temperature increases of open spaces from heat flux from building walls and the ground, and artificial heat release.
a) Impact index of sensible heat from building surface to outdoor thermal environment [ºC]

$$imp_{jw} = \left(\frac{\Delta T_{airj}}{\Delta T_{walli}}\right) \times (T_i - T_{ai}) \quad (1)$$

b) Impact index of heat release from building equipment to outdoor thermal environment [ºC]

$$imp_{jb} = (T_{jb} - T_j) \quad (2)$$

c) Impact index of traffic heat release to outdoor thermal environment [ºC]

$$imp_{jr} = \left(T_{jr} - T_j\right) \quad (3)$$

Abbreviations:

imp_{jw}: Impact index of building surface at cell j

imp_{jb}: Impact index of heat release from building equipment at cell j

imp_{jr}: Impact index of traffic heat release at cell j

ΔT_{airj}: Air temperature rise at cell j (case of high wall temperature – basic case)

ΔT_{walli}: Surface temperature rise at wall i (i: north, south, east, and west)

T_i: Surface temperature of wall i

T_{ai}: Mean air temperature of cell attached to wall

T_{jb}: Air temperature of cell j considering air-conditioning heat release

T_j: Air temperature of cell j in basic case

T_{jr}: Air temperature of cell j considering traffic heat release

Summary

The main aim of this paper is present initial outcomes from a research project investigating a Quality of Life (QoL) approach to sustainable housing in South East Queensland. Sustainable development models such as balance theory suggest that the benefit of sustainability is to integrate social, economic and environmental needs in the context of maintaining or improving the quality of life. A current report on Quality of Life in South East Queensland and the Queensland Governments State of the Environment index demonstrate a paradox - high quality of life but also increasing environmental impact. How to address this paradox is a major research question addressed in this project. Through examining examples of best practice sustainable housing it is possible to address this question. An example claimed to be best practice' is found in a new project, the Ecovillage at Currumbin on the boarder between New South Wales and Queensland. The paper will discuss research into the key factors of quality of life identified in this project and how these can assist policy makers plan for a sustainable future.

Significant strategies are identified, which bring together both the soft foundations- social and economic systems, and the hard foundation- planning, design and technology systems to create an affordable sustainable housing precinct. A biophysical system mapping methodology is used to describe the main dimensions to best practice' of the hard foundations. Performance monitoring of key quality of life indicators is also used to obtain feed back on the soft foundations.

In conclusion the paper focuses on the arguments for a nexus between planning, design and governance as a mechanism to address the current paradox and maintain quality of life whilst reducing environmental impacts.

Introduction

This project aims to evaluate quality of life and satisfaction measures of occupiers of homes specifically designed to be environmentally sustainable and set within an eco-residential precinct. Currently, the perceived high quality of life in southeast Queensland is being eroded by evidence of mounting environmental un-sustainability. Though taking different theoretical and empirical approaches, most of the quality of life or 'livability' studies conducted throughout the world have been pitched at a regional level or above. A major gap therefore exists in understanding at the level of the precinct and community.

Here, the problem is to differentiate structural and local determinants of quality and satisfaction from those operating at higher spatial scales. State and local governments, however, have been promoting Ecological Sustainable Development (ESD) at the level of individual households with subsidy and other incentive schemes, along with broader initiatives drawing on public funds. Given such expenditure, much of which has proceeded with little foregoing research, the question therefore looms as to whether residential living under ESD premises contributes to quality of life and user satisfaction as has been claimed.

Now the opportunity has arisen to investigate this question in an industry-linkage framework by reference to an incipient residential development project at Currumbin on the Gold Coast. This project is framed according to 'best practice' ESD principles with dedicated technical infrastructure, both public and private, supplied by industry and local government to monitor ongoing environmental impact.

A comparative research design is required to investigate whether this infrastructure and the ethos of the precinct contribute both tangible and intangibly to quality of life and lifestyle satisfaction among residents. More specifically, among the 144 eco-dwellings to be constructed in the next two years at Currumbin, it is proposed to form two samples for comparison with a sample of other residences developed contemporaneously in southeast Queensland but not under the same ESD provisions (the 'control' group).

Both Currumbin samples will have the same ESD infrastructure, but one will additionally receive 'extension services' from researchers and local government in the form of feedback on energy and utility demand and encouragement in the ESD lifestyle. Neither the other Currumbin sample, nor the control group will receive any special contact other than periodic attitude monitoring as part of the research project. Based on longitudinal surveys, the objective is to see how energy and utility use, quality of life estimation, and behavioural patterns vary among the three groups.

In this way, it should be possible to determine the benefit-cost effects on quality of life and ESD measures created by private and public provision of both hard (technical) and soft (extension) infrastructure within southeast Queensland. Though compiled within this region, the results should have validity in similar 'Greenfield' contexts through Australasia. The project thus offers the prospect of evaluating the efficacy or otherwise of particular types of public and private interventions with the advantage of improving existing practice where appropriate.

1. Quality of Life (QoL) research

As stated above, the main aim of this project is to investigate a Quality of Life (QOL) approach to sustainable housing in South East Queensland. Sustainable development models such as Balance Theory (Mawhinney 2002) suggest that the benefit of sustainability is to integrate social, economic and environmental needs in the context of maintaining or improving the quality of life. The argument focuses on the need to address the current paradox where high quality of life in South East Queensland is traded against high environmental impact (Stimson, R., Western J, and McCrea, R., 2003, Queensland Government, 2003. Reading the two major current reports, Stimson et al. (2003) on QoL in South East Queensland and the Queensland Government's State of the Environment Report, one is struck squarely by this paradox. A major research question therefore focuses on how to maintain or improve Quality of Life but within boundaries that limits environmental impacts. The main hypothesis advanced is that a Quality of Life model, based on sub-sectors such as housing rather than geographical regions may provide a mechanism for addressing this significant problem.

Comment [IU1]: Mawhinney, M., 2002, Sustainable development: understanding the green debates, Blackwell Science; Oxford.

The application of Balance Theory as a planning and design approach to sustainable housing has advanced in recent years with the planning and design of a number of sustainable housing projects. A second aim is therefore to examine these projects to assess the quality of life and to identify the important dimensions and priorities within the range of sustainability parameters of social, economic and environmental impact.

Assessment methodologies have advanced in recent years to accommodate a broader, more holist approach, to examining sustainable housing in the context of the Quality of Life paradigm. Whilst this paradigm has resonated at a macro national, and city-scale levels of impact reporting and policy formulation, researchers' have attempted to apply the Quality of Life approach at a meso and micro scale of local development and design, necessitating a refinement of the construct and new research methodologies. The third aim of this project is to utilise these methods, test and refine them as an ongoing support metrics for a Quality of Life approach to evidence based planning and design in South East Queensland.

The quality of life of a population is an important concern in economics and political science. These disciplines have metrics to measure both qualitative and quantitative factors to the phenomena. Quality of Life studies also called Livability studies tend to be macro in scale covering countries, regions or cities, and examine dimensions to, and satisfaction for, peoples' life style in terms of personal physiological needs and desires, and to what extent these are met by the economic and physical environment. Limitations to these studies have been advanced in terms of the lack of holism, i.e. the lack of connection between outputs and input (Luger 1999: 749). For example, it is difficult to identify the precise factors influencing the satisfaction levels found among respondents. The use of these studies at a detailed policy level whilst giving useful information about macro conditions has been questioned. Luger argued that outcomes of QoL studies might be more attributed to demographic, socio-economic and environmental factors rather than economic dimensions. Luger argues that because these factors are not tracked in a traditional QoL model it makes the studies valueless and antithetical with regard to policy formulation. New models of QoL have evolved such as that developed by the UK Government (UK Government 1999, 2005), which follows a 'principles to indicator' approach with broader set s of factors including social, economic and environmental factors (Mawhinney 2000). This approach, it is argued, qualifies as a new QoL paradigm. It offers to address the new framework of sustainability, it examines the phenomena from a range of scales - region, city and neighbourhood and also provides new methodologies for understanding the phenomena. The holistic model may offer a richer information base to facilitate policy formulation for the planning and design of particular aspects of the regional infrastructure such as neighbourhoods and precincts.

Comment [IU3]: UK Government. *A better quality of life - strategy for sustainable development for the United Kingdom* – 1999, 2005. On line. Available HTTP: <http://www.sustainable-development.gov.uk/publications> (accessed 7 April 2006).

Research in the USA has followed a different path through work by the American Institute of Architects prosing an agenda for change. This organisation has made important submissions to the US Congress to establish policy development and research in this area. Called QoL principles, they provide a planning and design research agenda for built infrastructure but this is broad based and has not been formulated into a QoL model for housing (AIA 2006). Research into QoL for housing is found in the environmental planning field through the work of authors such as Anne Beer and Cathy Higgins in the UK. They acknowledge limitations to the planning process in dealing with housing suggesting…'it is perhaps not surprising that the less quantifiable aspects such as those which influence the quality of human life have been rather neglected in the development of many housing projects' (Beer & Higgins 1997).

1.2 The absence of effective planning and design of sustainable housing

Research in the United Kingdom by the Government Department for Environment, Food and Rural Affairs (DEFRA) has addressed this problem by linking QOL and housing quality and by also identifying key barriers to improvement. In DEFRA's (2001) study of public perceptions, housing quality was ranked ninth as a very important headline quality of life issue along with factors such as climate change and wildlife. Overall, nine out of ten people thought it was fairly or very important. **Existential factors** such as money, health, crime and jobs are primary issues while **biophysical factors** such as neighbourhood, transportation and housing quality and environmental problems are rated more or less equally as second priority issues affecting QOL (DEFRA 2001).

Comment [IU6]:

Comment [IU7R6]:

Comment [IU8]: DEFRA, 2001, *e-Digest Environment Statistics, Public Attitudes*, On line. Available HTTP:<http://www.defra.gov.uk/environment/statistics/pubatt/ch3h07.htm> (accessed 7 April 2006).

1.3 Research into QoL at the sustainable housing precinct level

Research in the UK in addressing the QOL factors has been achieved through the use of demonstration projects, i.e. a project which identifies principles, processes, technologies and tools, in addressing housing quality in the context of sustainability. One notable example is the Bed ZED project - Beddington Zero Energy Development Sutton, UK (BRESCU 2002). This is a zero energy project – the onsite renewable energy generation is balanced with the energy drawn from the grid to create net zero carbon emissions. Beddington Zero also addresses environmental, social and economic issues. In the Bed ZED development, economic parameters support environmental parameters, which in turn supports social progress. For example, the use of retail units within the housing development is aimed at subsidizing the housing rental. This multi-use retail and housing strategy creates a scale effect, which supports the cogeneration energy strategy leading to the zero energy capability of the scheme. Yet, while the project aims to achieve high QoL for its residents, this claim remains largely untested (Dunster, B., 2006).

Comment [IU9]: Dunster, B., 2006, ZedFactory. On line. Available HTTP: < http://www.zedfactory.com/home.html> (accessed 7 April 2006).

The problem of how to maintain quality of life whilst reducing environmental impact is a multi dimensional and multi-disciplinary challenge that is facing South East Queensland today. The Queensland Government's State of the Environment Report (2003) shows disturbing trends in the pattern of human settlement, which cannot be solved through this project, while macro studies of quality of life show approximately 91% of Queenslanders surveyed in November 2001 said they were "satisfied" or "very satisfied" with their quality of life. Yet although most Queenslanders report being happy with their quality of life, a number of the existential factors (money, health, crime and jobs) are showing a lack of capacity in infrastructure to meet the needs of an increasing population. For example health and housing affordability are indicators, which have shown change in recent years with a sharp decline in housing affordability (Queensland Government 2003)

1.3.1 Biophysical impacts

Yet, it is the biophysical factors to QOL (neighbourhoods, transportation, housing and environmental problems), which highlight areas for concern. The rate of growth in travel is higher than the rate of population growth with the number of passenger vehicles registered in Queensland increased from 1.6 Million (0.456 cars per capita) in 1998 to 1.8 Million (0.486 cars per capita) in 2002. The average distance traveled by passenger vehicles increased from 13, 200 km in 1998 to 14, 300 km in 2002; between 1998 and 2002, total annual fuel consumption by all vehicles in Queensland increased by 22%.

It was also found that in the same period the use of public transport reduced, accounting for only 10.1% of journeys to work in southeast Queensland in 2001, down from 11.3% in 1991. The average travel times during peak periods on the main roads into the Brisbane CBD rose by over 7% between 1998 and 2000. With regard to energy, Queensland's total energy consumption rose 21 per cent from 849 petajoules (PJ) in 1994-95 to 1024 PJ in 2000-01, and the main primary energy sources were black coal (45.8% of total energy use), petroleum products (37.1%), biomass (9.0%) and gas (7.6%). Attempts to shift from fossil fuels to renewable energy seem stalled. The proportion of Queensland homes using solar hot-water systems rose from 4.8% in 1994 to 9.1% in 2001 (Queensland Government. 2003).

Water use has stabilized, with average water consumption in the fourteen major urban water authorities in Queensland rated at 220 kilolitres/capita in 2000-01, while rainwater sources depleting due to climate variability. Wastewater has increased with the volume of wastewater receiving tertiary treatment in southeast Queensland rising from 36% in 1998-99 to 48% in 2000-01. Ironically, the proportion of wastewater reused in Queensland is low – an average of 5.7% in nine major urban local government areas.

In contrast solid waste generated and sent to landfill in Queensland fell 13%. The proportion of solid waste recycled in Queensland rose from 3.9% in 1996-97 to 20.4% in 2001-02. This can be attributed to good access to household recycling programs in 2001-02. In terms of housing quality, there was a significant increase in noise complaints since 1999 with both Brisbane and greater Queensland experiencing a sharp decline in housing affordability in the period 2001-03. Urban residential densities in South East Queensland increased 5.1% between 1995 and 2001, requiring the provision of great open space and pedestrian access to parklands etc.

1.3.2 Measures to reduce biophysical impacts

Newman (2006) argues that initiatives to address these issues are found in six main areas; better governance, improved global stewardship in the use of natural resources, biophysical efficiency in settlement patterns, the creation of social capital though community, and finally improving efficiency in business through implementing a Factor 4 policy i.e. double the wealth but also double the resource efficiency (Newman 2006). The research proposed in this application examines initiatives concerning biophysical efficiency in settlement patterns and the creation of social capital though the community implementation of sustainable housing.

Comment [IU10]: Newman, P. and Kenworthy, J, 2006, *Sustainability and Cities Overcoming Automobile Dependence*. Island Press, Washington D.C.

Newman, P., 2006, *Vision and sustainabiltiy in WA*. On line. Available HTTP:<www.sustainability.dpc.wa.gov.au/pdfs> (accessed 9 April 2006).

Initiatives in SE Queensland involve efforts to address the six barriers identified by Wheeler (2003) including, disincentives in the fiscal system, perceived higher costs, lack of consumer demand, lack of investment interest by developers, no agreed standards and a planning system which does not support sustainability.

There are measures in place to provide incentives in the **fiscal systems** for sustainable housing through reduced mortgage costs for green design, subsidies for use of green technologies such as water tanks, solar hot water heaters and photovoltaic systems. It is argued that incentive such as that provided by Bendigo Bank, which provide a 0.50% per annum reduction on the Bank's Residential Variable Rate and no monthly service fee, achieve an interest saving of more than $48,000 over the life of the loan. It is argued that this is sufficient to provide equity for developers and homeowners to improve the design specifications needed to upgrade homes to meet environmental criteria. This also addresses issues identified by Wheeler concerning the **perceived additional costs** of sustainable housing.

Consumer demand is the attention of a number of Federal and State initiatives. The Australian Greenhouse office has developed the 'Your Home' marketing initiative (AGO 2006). This program targets issues such as homeowner perceptions about the quality of life improvements through owning a sustainable home. No exit studies of users of this program have been carried out to gauge the effectiveness of this marketing policy, so it remains questionable about the effectiveness of this costly exercise. In Queensland, further initiatives such as The Sustainable Homes program is a Queensland legacy of the national Year of the Built Environment 2004 (YBE) – a year that highlighted the need for our built environments to become more sustainable through improved design and function. The Sustainable Homes program aims to provide communities in Queensland with display houses that include the principles of sustainable design. Two key objectives of the initiative are to demonstrate and promote the importance of investment in sustainable design at the household and community level, and to increase the demand from homeowners, builders and developers for sustainability practice. Thirty-four homes are to be built and sold six months later. No attempts have been made to monitor or research the benefits of the design of these buildings. Discerning consumers question the value of such an exercise unless tangible benefits in quality of life are demonstrated.

Finally **barriers within the planning system and environmental standards** for sustainable housing remain. Mc Manus (2005:68) argues through what is termed SMART growth policies that the planning system has yet to embrace and gear up to sustainability. SMART growth policies are beginning to be evident in South East Queensland, which does not advocate unlimited growth but appropriate growth avoiding sprawl because of impacts on biophysical factors. It focuses on livability and quality of life and focuses on the need for quality growth (McManus 2005: 65). The planning system has been reformed to address this issue through the Integrated Planning Act, which looks to ecological protection as a key issue but is yet to be fully implemented (Queensland Government 1997 & Brindle 1999). Slack (1999) suggests problems lie in the lack of policy measures and metrics such as indicators at the Local Council level to monitor compliance and performance.

Improved metrics in the form of prescriptive and performance standards such Energy Rating tools are in place. For example BERS (Building Energy Rating Software), which are now adopted by councils to assess housing development has translated into legislation. As of 1 January 2003, minimum energy performance standards have been introduced in to the Building Code of Australia for detached and semi-detached dwellings. Since the BCA is a performance based Code, builders and designers have the option of meeting these new standards in one of two ways: by following the 'deemed to satisfy' prescriptions in the Code; or by achieving the required house energy performance rating using an accredited software tool. The stringency of this standard equates to 4 stars. Queensland has additional measures for water, which are designed to reduce water and energy use by 36 and 33 per cent respectively.

In summary, current research into QOL is seen as a macro level issue with little drilling down to community level impacts of sustainable housing. Input measures are in place to address change i.e. reducing water and energy use for new buildings but that leaves the majority of the housing stock following a business as usual approach.

Table 1 Simplistic mapping hierarchy of sustainable development in relation to available standards at three spatial scales- macro, meso and micro, and two modes of delivery- design and operations

Few output metrics are in place in South East Queensland such as monitoring the Quality of Life at a community level in terms of existential or biophysical factors. Models of the interaction of factors at a community level are largely descriptive and lack empirical validation (McManus 2005: 85.)

1.3.3 New methodologies and models

Research into new metrics to examine the sustainability of buildings and precincts is underway at The University of Sydney and the University of New South Wales and through Dr Veronica Soebarto the School of Architecture. Supported by AHURI and the Sustainable Tourism CRC, metrics have been developed for examining sustainable buildings and neighbourhoods. Initial work funded by the Australian Housing Urban Research Institute (AHURI) supported a **Triple Bottom Line monitoring survey** comparing the social, economic and environmental impacts for types of urban subdivisions. This involved developing a new methodology to measure this range of factors. Many of the factors examined issues concerning QoL but also consider the input measures, i.e. characteristics of the biophysical factors as well as existential (commonly found in QoL) and environmental factors.

Since this project, work with the Sustainable Tourism CRC has led to the development for new building design **environmental assessment systems** (BEA) such as the new Precinct Planning and Design Standard (PPDS), which can be used for examining neighbourhoods and is now completed. A keynote address by Hyde, Prasad and Blair at the International Sustainable Buildings Conference in Tokyo, 2005 presented work on these methodologies as shown in Table 1. This shows the way a variety of assessment systems and tools apply at different spatial scales and with different modes of delivery- design and operations.

2. Case Study: The Ecovillage, Currumbin, Gold Coast, Australia.

This case study is presented through first looking at the externalities to the Ecovillage and then on the internalities- the development of control measures used in the project to achieve sustainability.

2.1 Externalities- planning system

In Australia, the delivery process for housing can be fragmented. It is largely a developer led system; a developer purchases the land, forms a sub-division and then sells parcels of the land to sub-developers who can be house owners or owners of other building types such as hotels, retail and so on. Local governments either assume control of the legal title of precinct or it remains under the control of the developer and sub-developers/owners as 'community title'.

Gold Coast Council controls the process as shown in Figure 1. Development control is influences by a range of federal, state and local councils initiatives to promote sustainability. At the State level legislation is dominated by the IPA (Integrated Planning Act), which promotes ecological sustainable development through integrating State and Local Planning systems. The strategic planning and Environmental Impact Assessment process (EIA) has been replaced (Thomas 2005: 121). Local Planning responds to Desirable Environmental Outcome (DEO) statements in the form of policies and codes (Grummit 2006). Community input and environmental impacts are assessed. For example input is sort from local environmental groups such as the Gold Coast & Hinterland Environment Council (GECO). Input is also sort on the environmental principles and strategies used in a development (Grummit 2006). The methodology and procedure for assessment appears dependant on many factors, most important is its significance, that is the scale, complexity and sensitivity of the development to sustainability issues (Thomas 2005: 123).

The objective here is not to critique the planning system for its inability to deliver sustainable outcomes, clearly the IPA legislation places sustainable development on the agenda for developers, but to identify areas, which can be used to improve the level of sustainability in planning and design outcomes.

2.2 Internalities- master planning

This can be achieved by interventions at a number of levels in the system as seen in case of the Currumbin Ecovillage. This development is significant in terms of social, environmental and economic sensitivity to the area.

The Ecovillage at Currumbin, is on a 110 hectare site in the Gold Coast. The project provides for 144 eco-homes in a variety of residential configurations, together with community facilities including a small village centre. The Ecovillage incorporates a wide range of sustainability features including autonomy in water, wastewater and energy; 80 percent open space and more than 50 percent environmental reserve; negligible vegetation loss and extensive native plant regeneration; edible landscapes and permaculture and waste minimisation and recycling. The developers claim it exceeds international and Australian sustainability best practices and has been hailed by government and industry as a leading example of Ecological Sustainable Development (ESD) within the housing sector (Sunager et al 2008).

Substantiating these claims with regard to best practice, there are very different definitions of sustainability with in the international community and with in the Australia. McManus argues that ESD is a uniquely Australian definition, which is more concerned with retaining its ecological systems (McManus 2005). Whilst it is useful at one level applying this definition to urban development is hard. Hence it can be argued that IPA, which has its foundation in ESD, should be augmenting with regard to new definitions of sustainability to deal with the urban contexts and international practices. This problem with conflicts in definitions is that it finds its way into increasing the complexity and ambiguity of procedure and assessment. Thomas reports about the lack of clear procedures with re to implementing IPA. At Currumbin this caused extensive work to achieve Code compliance. The amount of documentation needed to gain planning approval was expensive time, consuming and exhaustive (Walton 2006). Adding environmental criteria such as autonomy of servicing for the site in areas of energy, water and waste means the council needs to condition a range of additional measures into the approval process. In addition a range Codes are needed to cover the biophysical aspects of designing and building houses on the development. Eco Homes are needed so that there is a reduced demand for services. Also, byelaws are need to cover social and management issues to ensure efficient use of resources and cut demand for services. The problems with procedure in this type of sustainable development that is it sits outside normal Code compliance process i.e. it is not assessable under the Planning Code, creating the need for new metrics to support the assessment procedure.

2.1.1 Lack of a common metric for both the regulatory system and the developer

Shane and Graedle (2000) and Mc Manus (2005) point to the importance of using metrics that can demonstrate environmental efficiency measures for environmental impacts assessment. It is argued that metrics cannot fulfil all the needs of planning assessment but could form one part of the process. This is argued on the basis that metrics are generic require interpretation in the local context. In the case of Currumbin a metric was created from a range of authorities such as Gold Coast Water for the water benchmarks, waste treatment from the Environmental Protection Agency. A further development that could expedite the compliance process would be to creating a common metric between regulators and developers. This would seem not only to carry forward the intent of the Integrate Planning Act but also provide simpler procedure for implementing planning approvals of sustainable development of this nature.

2.1.2 Evidenced-based planning at the precinct level

There are benefits in extending the application of the planning system at the precinct level. This can involve ‘conditioning’ measures in post construction process at the time Development Approval is given (Grummitt 2006). The reason for this is that environmental principles enshrine in international policy such as ‘continuous improvement’ can be achieved and planning measures can be validated (Hyde 2006, Hyde et al 2008). The areas of biophysical monitoring and social impacts can be measured. In conditions where both the design and management of a precinct such as the Ecovillage, it is seems imperative that planning policy is reconciled with planning reality. So impact measures can provide evidence to support planning, not as a ‘development control process’ but as ‘development evolutionary process. This quasi- research approach, derived techniques from research are available. These are tested in this research work involving biophysical monitoring and social impact study in the form of a residential satisfaction study.

3. Discussion

The paper is aimed at discussing outcomes from work on QoL of housing in South East Queensland though a case study of the Ecovillage at Currumbin. From this work it is argued that to ensure compliance with sustainability housing objectives the planning, design and operational aspects of the development process should be harnessed and integrated effectively. This has been possible at the Ecovillage, Currumbin, which uses a range of measures to reduce environmental impacts whilst also maintaining and arguably increasing QoL. QoL has been found to be useful as a surrogate indicator for sustainability since it includes social, economic and environmental factors. The **QoL residential survey** developed in the project gives feedback on residents’ issues (Wells 2008). This is status control measure can be used to enhance the development control process to an ongoing evolutional process to support Agenda 21 policy. This argues that the process of sustainability is largely evolutionary involving continued improvement of development over time. To support this view a new **standard for precinct design and planning (PPDS**) is now available to enhance this process (Hyde 2007)) and a new **Sustainable Building Code** used at Currumbin.

To examine ongoing operational performance **biophysical monitoring** has been developed to sample of data from houses. This utilises advances in electronics systems for monitoring has enable a new methodology to be developed. Although an added cost to the project it is providing useful feedback to enable residents to assess if they are meeting environmental targets.

Keywords: Sustainability; Environmental performance of buildings; Design method; Integrated Design Process.

Summary

The conventional design practice is characterized by a linear, segmented development process with isolation among design disciplines. Usually the integration between different specialties occurs late in the process, when opportunities for significant changes are very limited. In opposition, the integrated design process supposes the multidisciplinary work of all actors involved from the process outcome. Among the first steps is the discussion and definition of a consensus between client and designers regarding the objectives, methods and responsibilities to achieve the established targets. This analysis is part of a study to develop and include sustainability consideration building delivery process to be proposed to FDE. This paper aims to establish a theoretical reference, consisting of the fundamental elements that characterize integrated design processes, and to use it to analyze one case study, example of the conventional practice. It is intended (1) to identify the methodological elements used in the case study and their alignment with the theoretical reference established; and (2) to investigate the influence of these elements on the environmental performance of the building, discussing the positive results achieved as well as the opportunities that could not be seized. In the case studied, as in other schools built at the same period by the responsible state agency, there where no concerns specifically related to environmental performance issues.

Even though design goals were settled early in the process, those were mainly directed by quality issues, such as rationality, constructability and compliance to budget and schedule restrictions. The studied case revealed that even though the design process established by FDE achieved those goals, it is still distant from the ideal design integration level and lacks the means to comply with more rigorous environmental performance targets. Virtually none of the elements composing the theoretical reference defined was actually implemented in the school design process. Elements that do interfere on environmental performance were specified and built, without further evaluation of their actual contribution. The inclusion of multidisciplinary design meetings, energy, comfort or sustainability specialists and the use of simulation tools to test the design alternatives, as proposed by the integrated design process approach, on the other hand, has proven to help achieving significant reductions in energy use during buildings operation, within construction budgets comparable to buildings with similar use.

1. Introduction

It is widely acknowledged that there are serious social and environmental limitations for an economic development model based on an unrestrained growth of the productive forces. In the pursuit of more sustainable productive processes, the building industry plays a strategic role, as it represents the activity with the largest consumption of resources in the world (Berge, 2000; Silva, 2003). Raw materials sources are not always legal, and in 2001, 84% of the timber was used by the building industry, being most of it composed by native timber illegally shipped to the State of São Paulo, Brazil, as reported by Sobral et al. (2002). The emissions of the sector are also very relevant, as almost have of the municipals solid waste is produced by construction and demolition activities in Brazil (Pinto, 1999).

Within a strategy for the promotion of sustainable practices in the building industry, rating systems - either aiming at environmental assessment and/or certification of buildings - can be instruments of great help. Certification of buildings can stimulate an increased demand for corporate environmental performance demonstration and capacity building of the actors involved in building delivery (entrepreneurs, designers, contractors, suppliers, facilities managers etc). Currently, United States, Canada, Australia, Japan, Hong Kong and almost every European country have at least one evaluation system in place. Even though Silva (2003) defends that the use of other countries tools may lead to a series of distortions and it is necessary to develop a locally driven evaluation and certification system, given the absence of a Brazilian rating system, LEED[TM] certification has been pursued and an adapted version of the French system HQE has just been launched.

On the other hand, certification systems are only one among several necessary means to promote sustainability in the building sector. Increased demand for buildings with better environmental performance is already happening, but serious obstacles are perceived for the implementation of the necessary concepts in the Brazilian context. The difficulty to find reliable information and suppliers that guarantee low environmental impacts of there products are some examples. Another limitation is related to conventional design processes that lack the means to deal with the new challenges posed by sustainability.

In 2007, the first Brazilian regulation for energy efficiency was approved, to be initially implemented in a voluntary basis for commercial, services and public buildings and become mandatory after five years. This analysis is part of a study to include sustainability consideration in FDE's building delivery process to be proposed to that agency in order to, among other factors, comply with the upcoming normative requirements.

This paper aims at establishing a theoretical reference encompassing the fundamental elements that characterize integrated design processes, and use it to analyze one case study, example of the conventional practice. It is intended to: (1) identify the methodological elements used and their alignment with the theoretical reference established; and (2) investigate the influence such elements had on the environmental performance of the building, discussing the positive results achieved as well as the opportunities that could not be seized.

Integrated Design Process guides and study reports describing examples of integrated design processes where consulted for the characterization of the theoretical reference. A collection of publications produced by IEA's Task23 was the main reference used. The case study where investigated through the collection and analysis of design documents.

1.1. Integrated Design Process (IDP)

In conventional building delivery approaches, early design work is developed only by the architect, which submits the plans for the client's approval. Other design disciplines are added to the process only at design documents evolve, in particular at the construction documents stage, when the main characteristics of the building, such as site plan, volume, facade orientation and structural system, are already defined. In such format, the architect is usually responsible for ensuring design compatibility among all disciplines, but the possibility for significant changes is very limited, as it can cause great over work for the actors involved.

It is well recognized though, that possibilities for changing the building performance are great at the beginning and diminish through advancement of design development process. Melhado (1995) defends the need for the constitution of multidisciplinary design teams from early design stages, with coordination procedures methodologically established, instead of the isolation between disciplines and the sequential and non interactive design development. The author adds that a greater integration between the design and production stages is also needed, aiming for quality issues, such as attending the client's expectation, rationality and constructability of the building. In a later work (Melhado, 2001), the concept of concurrent engineering is borrowed from other industrial sectors to name the integration between multidisciplinary work and design and production stages as Concurrent Design of Product and Production (CDPP).

Terminology varies to describe processes that propose the multidisciplinary work of all actors from the design process outset. While Bill Reed defines it as Integrative Design Collaborative (Zimmerman, 2006), the LANL Sustainable Design Guide (LANL, 2002), elaborated by Los Alamos National Laboratory to guide processes of planning, designing, bidding and producing new buildings in the laboratory's campus, uses similar methodological elements under the expression Whole-Building Design.

Another concept is given by the Task23 work group, within the International Energy Agency (IEA) Solar Heating and Cooling Programme (IEA, 2003) that from 1997 to 2002, produced a set of methods and tools aiming at incorporating sustainable aspects in design processes, focusing mainly on energy efficiency. The proposed methodology was denominated Integrated Design Process (IDP), terminology that was adopted for the purposes of this text.

This approach aims for better environmental performance, mainly focusing energy efficiency. Criteria related to use, comfort, environment and costs are also considered. The following objectives are related: (1) maximum environmental (thermal, luminous, acoustic) comfort and air quality; (2) building's functionality, flexibility and adaptability; (3) minimal consumption of non-renewable resources; (4) minimal atmospheric emissions related to global warming and acidification, liquid effluents and solid wastes; (5) minimal negative impacts on the site; (6) life-cycle cost consideration (IEA, 2003). The proposed methodology includes the following fundamental elements: (1) multidisciplinary work of all actors involved from the beginning of the process; (2) discussion and definition of a consensus between client and designers regarding the relative importance of the performance issues and articulation of targets and strategies; (3) the addition of energy, comfort or sustainability and other specialists for specific problem-solving; (4) use of simulation tools to test design alternatives; (5) evaluation of budget restrictions considering the whole building, avoiding separate budgets for different building systems, as extra expenditures for one system (e.g. for sun shading devices) may reduce costs in other systems (e.g. air conditioning); and (6) insertion of a design facilitator in some cases to coordinate the process and contribute with specific information.

Examples of integrated design processes in Europe and North America reveal that each stage of the process is characterized by a series of loops, in which design alternatives are formulated, tested and reformulated until the best solution is reached (IEA, 2002). In each design loop the relevant design team members participate (Figure 1).

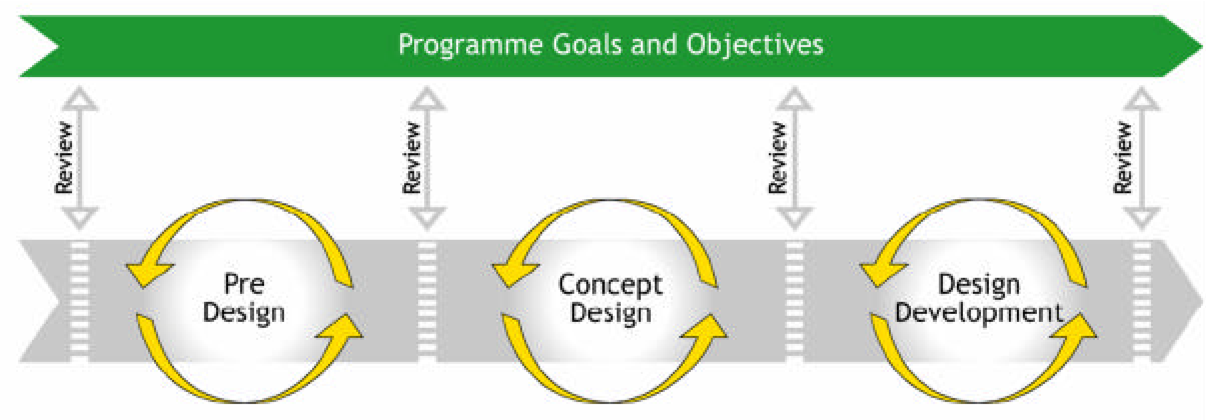

Figure 1 - Integrated Design Process (IEA, 2003)

2. Case Study

The Jardim Dom Angélico II State School (Figure 2 and Figure 3) was built in a poor east side suburban area in the city of São Paulo, Brazil, to substitute a provisory facility consisted of metallic container-like modules, which functioned as school. A small site (approximately 1200 square meters) was selected given the lack of alternative areas in the surroundings (FDE, 2006). The result was a compact three-storey building, arranging the building programme within a built area of 1616 m^2. The design and construction process occurred between 2003 and 2005. The architecture design was developed by the architect Pedro Mendes da Rocha and the structural design was developed by the Kurkdjian e Fruchtengarten office.

Figure 2 - Jardim Dom Angélico II State School (Photos by Nelson Kon)

The Foundation for the Development of Education (Fundação para o Desenvolvimento da Educação FDE), created in 1987, is the public institution responsible for building and administrating schools included in the educational system of the state of São Paulo. According to FDE (2006) schools built after 2003 aim mainly at increased quality and cost reduction, through greater rationality and constructability of projects.

To achieve these goals, the design of new schools is assisted by program elements, building components and construction procedures catalogues, which facilitate the development of projects and quantifications, by providing standard information. These catalogues are permanently updated, being adapted to technology, building materials, standards and legislation changes.

Since 2003, new guidelines have been incorporated by FDE, such as the adoption of industrialized structural systems and of a process management model in which the contractor was in charge of hiring and managing design products at the construction documents stage, resulting in a better integration at that moment.

2.1. FDE's usual design process

FDE is responsible for the building site selection and all technical support for new schools to be built, from the definition of the architectural program to the allocation of financial resources (FDE, 2006). After the site is selected, topographic and soil resistance analysis are carried out. Then an architect is hired to elaborate the concept design and once it is approved by FDE, the design development stage is carried out. Consultation with a structural engineer is made and additional information related to mechanical and electrical systems are provided by FDE. The bidding process is then held based on the documents produced at this design stage.

After bidding, the contractor is responsible for hiring and managing the projects at the construction documents stage. The mechanical and electrical engineers are then included in the process, and meetings for design compatibility verification are realized under the contractor's project manager supervision.

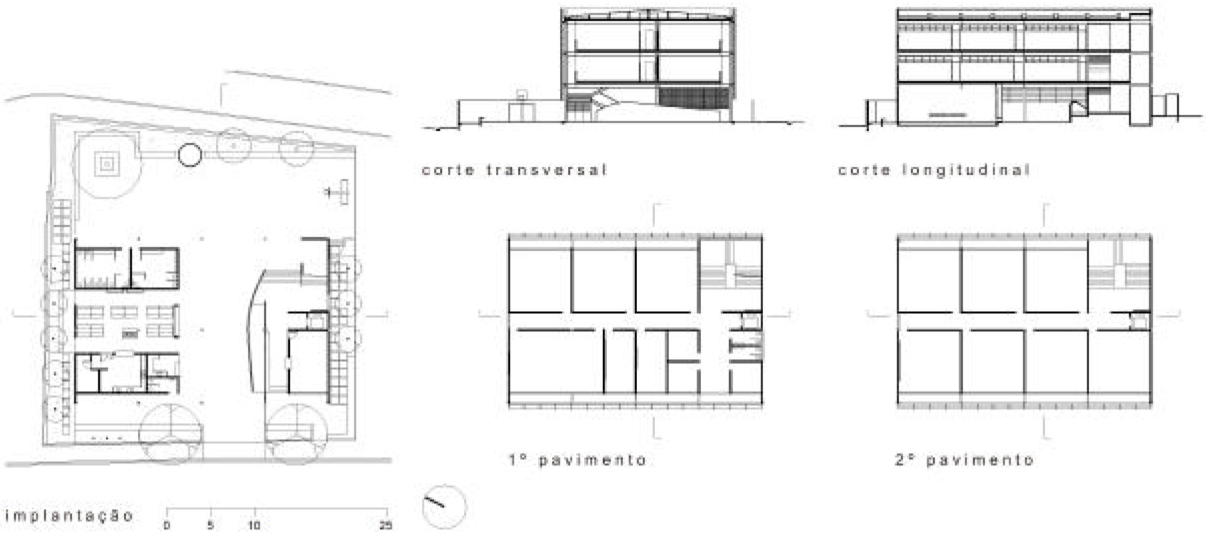

Figure 3 - Architectural drawings for Jardim Dom Angélico II State School.

Even though industrialized concrete structural systems adopted in schools built at the same period, resulted in lower construction costs, a steel frame was applied for greater rationality and constructability of this specific building, reducing the construction schedule while providing higher quality (FDE, 2006).

Environmental performance issues were not among the objectives at the outset of the design process, although some generic guidelines are commonly adopted by FDE to improve users' comfort. External fenestrations comply with current standards and legislation regarding day lighting and natural ventilation. In addition, operable windows between classrooms and circulation spaces enable cross ventilation across the building. Particularly, in this case study, site limitations did not allow for a better orientation, and main facades resulted northeast and southwest. This fact made necessary the specification of shading devices, composed by hollow concrete blocks, which contributed for a better thermal comfort in the classrooms. However, no comfort analysis or simulation tools where used to evaluate the performance of the specified solution. Neither a post-occupancy evaluation was carried out to verify actual comfort and energy efficiency levels of the building in use.

3. Alignment with the adopted theoretical reference

The six key elements identified in section 1.1 for fully integrated design processes refer to team composition aspects, and process development and instrumentation. Considering that, the following observations apply:

- Discussion and definition of consensual basis of design (BOD)

  The goals of greater rationality and constructability have been settled before the design process started by the client, without further discussion and definition of a consensus with designers regarding the relative importance of the performance issues and the articulation of targets and strategies. In this case, there was no environmental performance targets established that could motivate the adoption of methodological guidelines alternative to conventional practice.

- Multidisciplinary work from process outcome

  Figure 4 describes interaction among actors and methods and design aids involved in each design phase. It also reveals that apart from structural design, in the case studied integration among design disciplines occurred only at the construction documents stage, after the building bidding, when significant changes could not be implemented anymore.

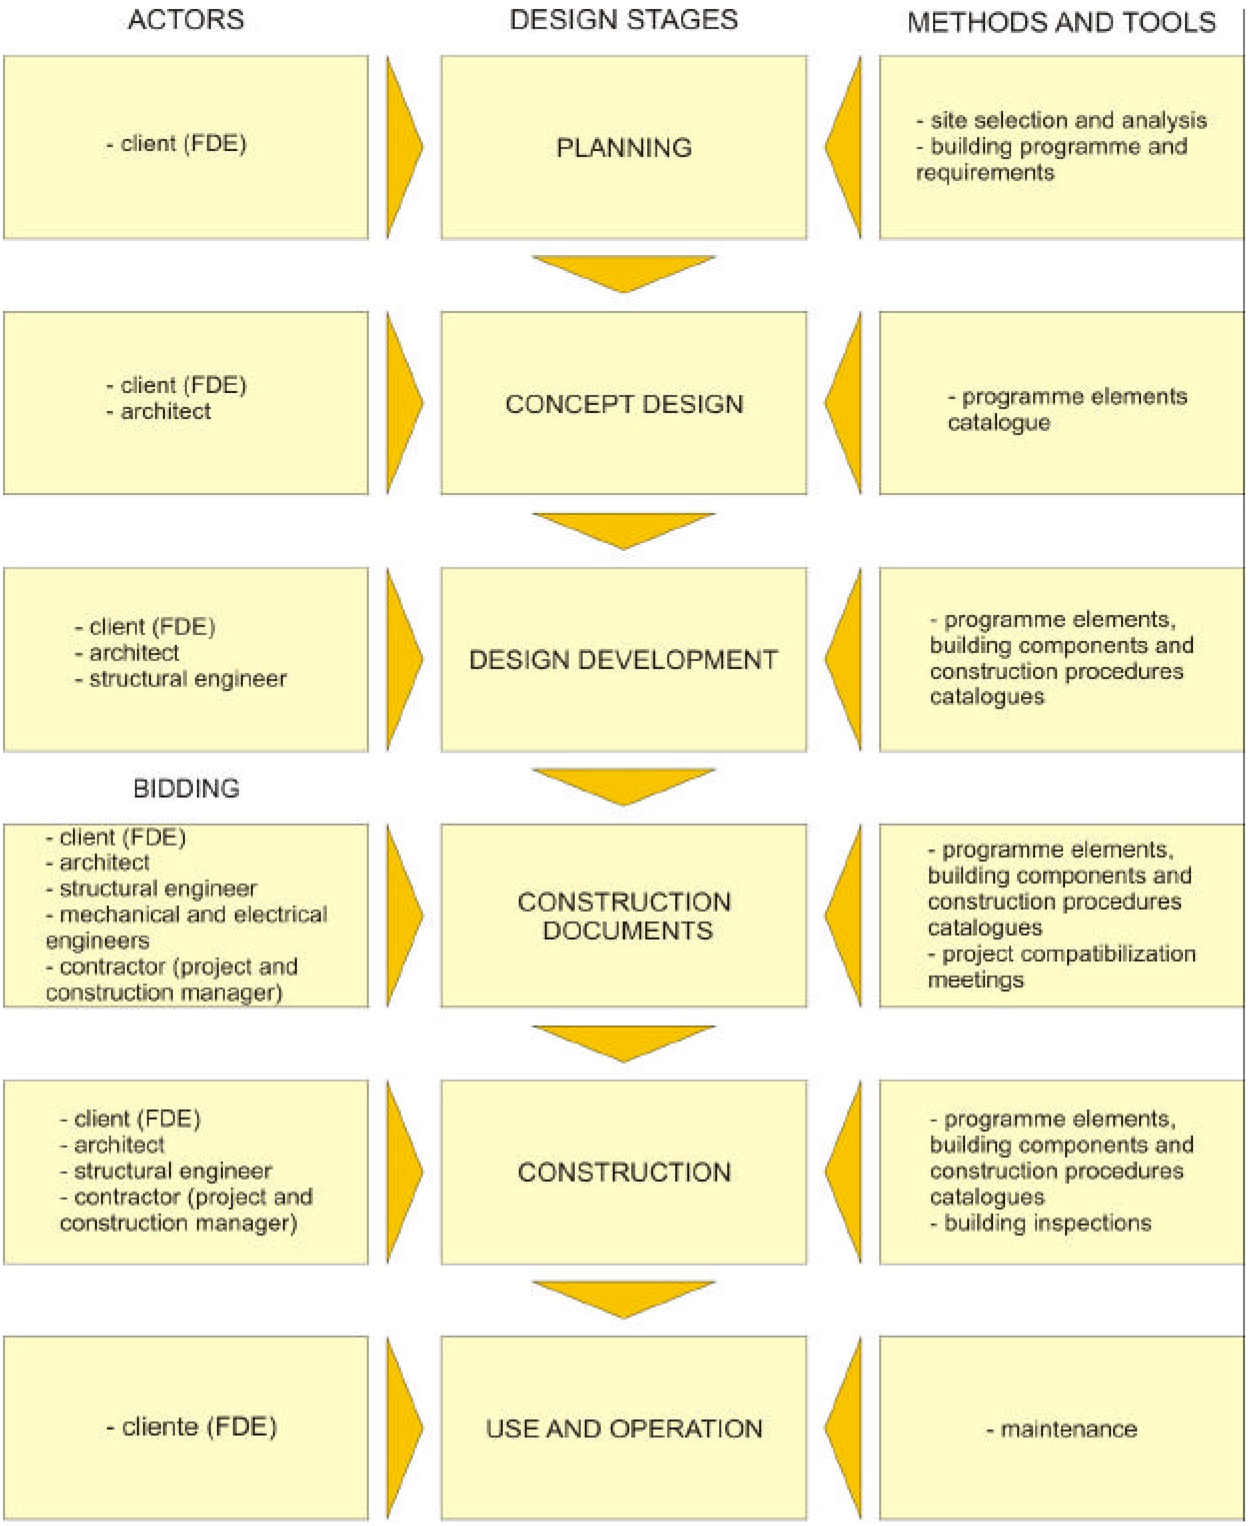

Figure 4 - Design Process of Jardim Dom Angélico II State School.

- Evaluation of budget restrictions considering the whole building

Cost assessment was carried out on a system-by-system basis, without proper consideration of possible synergic contributions that certain expenditure could have on the overall building performance.

- Addition of energy, comfort or sustainability and other specialists, use of simulation tools and insertion of a design facilitator to coordinate the process and contribute with specific information.

Differently from encouraged by integrated design approaches, in the studied process there was no significant concern with the stages before (planning) and after (use and operation) design and construction phases. In examples of Integrated Design Process, such as the Zion National Park Visitors Center (ZNPVC), the multidisciplinary work, the climatic analysis and the use of a simulation tool at the planning stage, enabled the integration between the set of solutions, a fundamental aspect for the achievement of the settled goals (Torcellini et. al., 2005). In the ZNPVC case, an energy performance evaluation carried across the use and operation stage allowed for the correction of some aspects that did not function as originally expected, and results documentation to close the cycle serve as reference for future designs.

FDE provides designers with a robust design handbook, which lists and describes program elements and defines in detail requisites from both the client and the expected user. This handbook so far does not include energy or sustainability performance requirements.

Energy, comfort or sustainability specialists where therefore not included in the process and no simulation tools to test the design alternatives were used. The shading device, specified and detailed in the construction documents, was based on an assembly of hollow-core concrete blocks actually determined by budget restrictions that prevented that the original system, constituted of horizontal metallic elements, was implemented. No evaluation could be made to determine the impact this substitution had on the thermal and luminous performance.

4. Conclusions

In 2007, the first Brazilian regulation for energy efficiency was approved, to be initially implemented in a voluntary basis for commercial, services and public buildings and become mandatory after five years. This analysis is part of a study to include sustainability consideration in FDE's building delivery process to be proposed to that agency in order to, among other factors, comply with the upcoming normative requirements.

In Jardim Dom Angélico II State School's design process, as in other schools built at the same period by FDE in the state of São Paulo, there where no concerns specifically related to environmental performance issues. Even though the design goals were settled early in the process, they were mainly directed by quality issues, such as rationality, constructability and compliance to budget and schedule restrictions. The studied case revealed that even though the design process established by FDE achieved those goals, it is still distant from the ideal design integration level and lacks the means to comply with more rigorous environmental performance targets.

Apart of that, virtually none of the elements composing the theoretical reference defined was actually implemented in the school design process. Elements that do interfere on environmental performance were specified and built, without further evaluation of their actual contribution. The inclusion of multidisciplinary design meetings, energy, comfort or sustainability specialists and the use of simulation tools to test the design alternatives, as proposed by the integrated design process approach, on the other hand, has proven to help achieving significant reductions in energy use during buildings operation, within construction budgets comparable to buildings with similar use.

URBAN VEGETATION AS A TOOL FOR CLIMATE ADAPTATION

Annika KRUUSE AF VERCHOU PhD[1]
Trevor Graham[1]

[1] Environmental Department, City of Malmo, Malmo, Sweden

Keywords: climate change, microclimate, urban, vegetation, green roofs

Summary

Climate change already has a large impact on urban areas throughout the world. The effect will increase in the future, even if we manage to keep emissions at today's level. The impact looks different in different regions, but hotter and longer heatwaves, and local flooding caused by heavy storms, are two severe problems already increasing in Europe and other regions. Societies will need to adapt to a changing climate in many ways. One means of adaptation is increased use of urban vegetation. Competition for urban space will make increased urban park areas unlikely, but cities can be greener by utilizing streets, rooftops, and walls. Large scale city greening, by e.g. greening rooftops, increasing the number of street trees and using climbing plants on walls, can significantly cool the local climate by evapotranspiration. The urban heat island effect and heavy storms caused by large temperature differences between cities and their surroundings, are therefore reduced. Climbing plants can cool buildings during the growing season through shading. Green roofs can cool buildings with poor insulation during the warm season due to evapotranspiration. Urban vegetation will also reduce local flooding by its water uptake during the growing season. Green roofs have a water uptake of at least 50% of the precipitation, on a yearly base, in the temperate region. Local storm water management means that rain water is treated locally to as large extent as possible. Water is retained in ponds, and lead through ditches and swales, which all are more efficient if vegetated. Compared to conventional storm water management in pipes, local storm water management can decrease the risk of local flooding drastically. These measures can together help make our cities more robust and resilient to the impacts of an inevitably changing climate, can in themselves contribute to decreased energy demand and climate impact, and not least contribute to a more attractive and liveable urban environment.

In this paper, different examples and practical experiences of city greening for climate adaptation are presented, and city planning strategies and building sector possibilities are discussed.

1. Introduction

Climate change is already here, and will increase in the future, even if we manage to decrease or keep greenhouse gas emissions at today's level. It's impact is different in different parts of the world, but hotter and longer heat waves, and local flooding caused by increased precipitation and storm frequency, are two severe problems already increasing in Europe and other regions. Societies will need to adapt to a changing climate in many ways. Climate adaptation appears as a needed policy complement to approaches aimed at mitigation climate change under any scenario produced by the Intergovernmental Panel for Climate Change (IPCC), and is increasingly seen as important in the international and national arenas in both developed and developing countries (IPCC, 2007, IPCC, 2001, Storbjörk, 2007). Adaptation is here defined as 'adjustments in natural and human systems in response to actual or expected climatic stimuli or their effects, which moderates harm or exploits beneficial opportunities' (IPCC, 2001). Taking anticipatory actions well before 2050 results in less total adaptation and impact costs than taking no actions (Kirshen et al. 2008).

In the city, impervious built surfaces replace vegetated surfaces, which provide shading, evaporative cooling, and rainwater interception, storage and infiltration functions. As a result, energy exchanges are modified to create an urban heat island, where air temperatures may be several degrees warmer than in the countryside. Also, the rate and volume of surface runoff of rainwater are larger in cities than in surrounding rural areas. In combination with the urban concentration of population, infrastructure and socioeconomic values, climate change impacts are likely to be more severe in urban areas than elsewhere. The seriousness of the possible impact on the population is illustrated by the estimation that the European summer heat wave in 2003 claimed 35,000 lives (Larsen, 2003)

This paper addresses the question of reducing the increase in future urban summer temperatures and local flooding by adding urban greenery, as well as managing storm water run-off in local, ecological systems.

2. Greening cities

2.1 Cooling

Several studies in recent years have shown that increasing vegetation in the urban context can be an effective way of mitigation the heat island, and benefit urban centres (Dimoudi & Nikolopoulou, 2003, Gill et al. 2006, Alexandri & Jones, 2008). The maximum surface temperature is very dependent on the proportion of green cover; this will become increasingly important in the future (Gill et al. 2006). Adding 10 per cent green cover to areas with little green, such as town centre and high-density residential areas keeps maximum surface temperatures at or below today's levels, even under scenarios of a temperature increase of almost 4°C, according to modelling of Manchester by Gill et al. 2006. On the other hand, if 10 per cent green cover is removed maximum surface temperatures are up to 8°C higher by the year 2080 (Gill et al. 2006). Green roofs are a smart solution for adding urban greenery. A green roof can be everything from a 4-5 centimetre thick mat of drought resistant plants and their substrate, up to a construction with a 10-100 centimetres thick substrate with varied vegetation and/or horticultural possibilities. The thinner roofs have the advantage of being enough light-weight to suit almost all kind of roofs with a slope less than 30 degrees. A thicker roof is heavier and demands a stronger roof construction, but the thicker roof have larger cooling capacity, and absorb larger amounts of rain water. Adding green roofs to <u>all</u> buildings would keep temperatures below today's values in a high emission scenario for 2080 in Manchester (Gill et al. 2006). Alexandri & Jones (2008) modelled air temperature in the canyon between buildings. Temperatures decreased drastically on a warm summer day, when both roofs and walls were covered with vegetation. The decrease varied from -3,5 °C in Moscow to -11 °C in Riyadh, with the cities of Athens, Beijing, Brasilia, HongKong, London, Montreal, and Mumbai in between. Greening every roof in an existing city is perhaps not a very likely scenario. But in the city of Basel, Switzerland, a local regulation states that all flat roofs on new buildings have to be green. Combining the urban vegetation with local storm water management, or bioretention, can even more efficiently reduce urban temperatures, as more available water will increase evapotranspiration (Endreny, 2008). The significant increase in the duration of summer droughts with climate change, calls for a consideration of ensure that urban green areas have an adequate water supply. This could be in part through rainwater harvesting, the re-use of grey water or other solutions (Gill et al. 2006). Rainwater collection on the roofs for irrigation of green roofs is also a possibility. If the question of irrigation is not solved, much of the cooling effects of grass areas and green roofs are lost during hot and dry periods. Trees, if draught resistant species are chosen, can keep the cooling ability for longer periods of draught. Trees have also the additional cooling effect of shading, a factor not included in the model of Gill et al. 2006.

2.2 Decreased risk of flooding

In many parts of the world, climate change will lead to increased precipitation, and increased proportion of the precipitation in the form of storms, which will both increase the rainwater run-off (IPCC,2007). In northern Europe, precipitation pattern changes are already well under way, as a Danish study by Arnbjerg-Nielsen (2006) shows. Grum et al. (2006) states from measured and modelled changes in precipitation, that changed rainfall patterns will require rethinking of current design criteria relating design not only to the traditional drainage system, but that we will see the need to incorporate roads and parks into the active urban drainage system. While urban greenery captures a large share of the storm water, greenery alone is not enough to manage the increased run-off. An effective way of managing storm water is called bioretention, and is a combination of living trees and other vegetation, soil and shallow, short-term ponding Successful, ecologically based designs of novel urban aquatic ecosystems are becoming more common and exemplify stream-floodplain protection, retrofitting of neighbourhood stormwater flowpaths and use of low-impact stormwater/water capture systems as creative solutions to urban storm water management (Grimm et al., 2008). Many cities include the building of local, ecological storm water systems in the development of new areas. That it is possible to retrofit such systems is shown by the examples of Malmo, Sweden, and Freiburg, Germany. In Malmo, a local storm water system was built in Augustenborg, a housing district from the 1950s. The system is made up of swales, ditches, and ponds with regional wetland vegetation, and since it was built in the late 1990s no run-off water has left the area and the former frequent floods are no more.

2.3 Other benefits of greener cities

Adding urban greenery could decrease the need for air-condition and therefore the emission of green house gases. About 3 to 8% of electricity demand in the United States was estimated to be used to compensate for Urban Heat Island effects (Grimm et al., 2008). The greenery, especially trees, is also carbon sequestering and using urban tree planting for CO2 sequestration can be a cost effective means of climate change mitigation (MdHale et al. 2007). Greening cities is thus a good example of synergy between mitigation and adaptation of climate change that is proposed by Swart and Raes (2007). City greening is a way of improving local air quality; city trees remove large amounts of air pollutants, especially ozone and PM10 (McPherson et al. 1997). Green surroundings have a beneficial impact on health and well-being, and gives fast recovery from stress reactions (e.g. Ulrich, 1984, Ulrich et al. 1991). Greener cities will also be of benefit for urban biodiversity, especially if designs aimed at biodiversity amendment are used.

2.4 Green city planning

Cities need to be compact to avoid unnecessary use of productive land. Land for production of food, fuel and building material, is a limited resource that is scarcer than ever (Haber, 2007). Compact cities are also a condition for an effective transport system and are good for regional air quality. For example, Stone et al. (2007) found a 10% increase in population density to be associated with a 3.5% reduction in household vehicle travel and emissions. Dense cities are also a prerequisite for an exciting and attractive urban life that is the goal of a modern urban planner. The challenge lies in making cities greener without them losing their density. Green roofs and climbing plants are efficient in urban climate mitigation, and are important components in making cities greener. Also, all surfaces that do not have to be impervious out of some specific reason should be green. Large trees should be planted in streets, school yards, parks, yards and gardens. A planning instrument called ‘green space factor’ is being used in new housing developments in Western Harbour, Malmo, Sweden. It was first developed in Germany, and is used in many German cities, and is a tool for achieving a certain amount of greenery in the housing districts, including green roofs, climbing plants and large trees.

2.5 Building sector possibilities

The view of many of these issues has changed dramatically over recent years and we are now seeing the emergence of the environmental technology sector as a major growth sector and an important contributor to economic development, whilst also tackling important challenges. The growth of the green roof industry in Germany, Switzerland and Austria has been witness to the potential to build new economies around ecological service solutions in the built environment and many similar developments are in the pipeline and under development. With the political and scientific consensus emerging around the climate challenge, risk capitalists feel increasingly secure to invest in emerging technologies and the climate-related market generating a virtuous spiral for innovators and entrepreneurs to commercialise their ideas and mainstream their pilot projects. The demand for knowledge and technologies for climate adaptation will grow enormously and green and blue solutions have the opportunity to offer cost-effective solutions that not only tackle problems, but are welcomed by urban dwellers as positive enhancements to their everyday environment.

3. Conclusions

The role of the green and blue infrastructure of cities in climate change adaptation, and other ecological benefits for the urban environment, calls for a change of paradigm regarding green planning. On different levels, from the single house, street, housing district and industrial area to the whole city, the green and blue infrastructure should be optimized to fulfil different ecological services of which cooling the city and harvesting of rainwater run-off are two of the most important. Researchers and practitioners in the field of city green planning, storm water management and landscaping should aim at developing the green and blue infrastructure to find solutions for different city types and different climatic regions. One of the questions that remains to be solved is that of rain water harvesting, and possibly reuse of grey water, for irrigation.

BUILDING INFORMATION MODELS AND INNOVATIVE SUSTAINABLE HOUSING

Pekka HUOVILA M.Sc.(Tech)[1]

[1] VTT Technical Research Centre of Finland, Espoo, Finland, pekka.huovila@vtt.fi

Keywords: performance in use, requirements management, sustainable housing, innovative housing, building information models

Summary

This paper presents findings from the STAND-INN project that describes how standards support innovative sustainable housing that meets user needs and performance requirements with managed environmental and economic impacts during the life span of buildings. The performance approach and tools supporting this approach are described in relation with building information models. The technical aspects of current IFC specification (IFC 2x3) are discussed and explained how sustainability aspects can be modeled. Findings from good examples of innovative sustainable housing are summarized. Experiences from the use of building information models are shared, and an approach to value creation is presented.

1. Introduction

1.1 Innovative sustainable housing in the STAND-INN project

Integration of performance based building standards into business processes using IFC standards to enhance innovation and sustainable development (STAND-INN 2006-08) is an ongoing research project funded in the 6th Framework Programme of the European Commission. It focuses on facilitation of the integration of open standards into business processes, and stimulation of innovation through reference to standards in public procurement. This two year project with 28 members from 11 European countries, five European-wide networks and two Chinese partners will be accomplished by late 2008. (Haagenrud et al. 2008)

1.2 Vision 2030 by the European construction industry

The European Construction Technology Platform Strategic Research Agenda (ECTP 2005b), based on its Vision 2030 (ECTP 2005a), addresses the following key points to be developed

Meeting Clients/User Requirements

- providing a healthy and comfortable habitat for all
- promoting new image of European cities
- developing underground transport to free surface space
- developing mobility and supply through efficient networks

Becoming Sustainable

- reducing resources consumption (energy, materials, water)
- reducing the environmental impact of human activities
- maintaining efficient transport and utility networks
- enhancing our cultural heritage
- improving safety and security

Transforming the Construction Sector

- developing a knowledge-based, client driven construction process
- supported by ICT, automation, high added value construction materials
- making construction workplaces attractive.

In ECTP's Implementation and Action Plan (2007) the two first objectives: meeting user requirements and becoming sustainable should be achieved with the help of the third one: transforming the construction sector. These ECTP objectives to meet client requirements in a sustainable way reflect well the innovative sustainable housing task in STAND-INN that this paper deals with.

1.3 Scope of this paper

This paper presents results from a STAND-INN task addressing IFC and sustainability standards and innovative sustainable housing. Sustainability in this context was defined as **responsible supply, operation and maintenance of buildings that meet the needs of their owners and users over the life span with minimal unfavourable environmental impacts whilst encouraging economic, social and cultural progress**. This paper focuses on the first part of the definition: how to deliver sustainable housing **performance that meets the needs of owners and users** over the life span.

2. Performance in use

2.1 Meeting client requirements

To be able to meet client requirements one should know what these requirements are. In case the requirements remain unexpressed the clients' needs behind these requirements should be captured. Kiviniemi (2005) did some empirical studies in his PhD work at Stanford to find out how the requirements can be traced in the building process. In his interview the replies were "it would be very laborious task to go through the meeting minutes trying to find out the requirements for any specific space or building element" or "the only documents where this could be found are the meeting minutes, but they don't cover all issues". In other words, the requirements are not often documented in the form of requirements. Instead, technical solutions are documented and their conformity is assessed instead of validating the solutions against performance requirements, or original user needs. One approach to meet client requirements is the performance concept.

2.2 Managing the conformity of technical solutions in the building process

Gielingh (1988) defined a General AEC Reference Model (GARM) showing the building process as series of "hamburgers" where performance requirements (FC) are met by technical solutions (SC). The technical solutions, in return, are interpreted as performance requirements at a lower level, and met by more detailed technical solutions. The process continues into a lowest needed level, and conformity should be validated in every phase. This approach should lead to meeting client requirements as long as they have been successfully captured. The solutions that don't meet the requirements can also be accepted if so desired but that decision should be made knowingly, and requirements then changed accordingly. It is important to communicate the consequences of such a decision to the client, since from that on the original requirements aren't valid any longer. Spekkink (2005) has presented the old GARM model twenty years later in a slightly improved form (at right of the figure below).

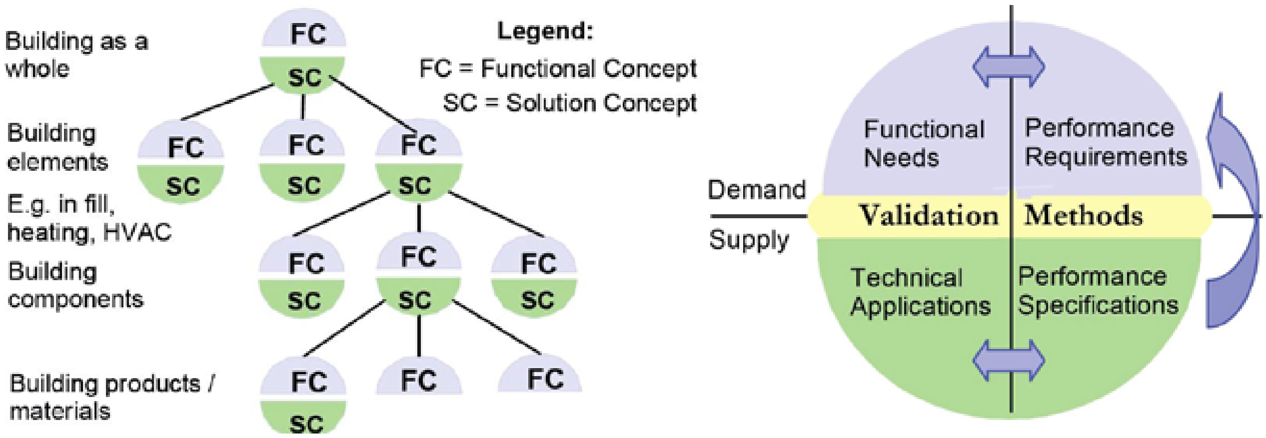

Figure 1 Technical solutions meet performance requirements in a continuous process, and the conformity should be validated in every phase.

2.3 Performance management methods and tools

Various standards and check lists have been developed to help identifying performance requirements and their validation, such as

- ISO6241 Performance Standards for Buildings (1984)
- different versions of CIB Master lists (1964, 1972, 1983, 1993)
- the CIB Compendium of Performance Based Building Models
- Standards on Whole Building Functionality and Serviceability (ASTM 2000)
- FiSIAQ (2001) Classification of Indoor Climate
- ASHRAE (2005) the Commissioning Process.

Different tools that support systematic performance management have been described e.g. in Huovila (2005).

Lützkendorf et al. (2005) surveyed performance tools, standards, checklists and sets of instruments and indicated in which areas they can be best applied. It is worthwhile noticing that these instruments have often been developed for a specific use at first, with more functions and applications pursued later.

Application / Instruments / Tools	A: Performance Requirements[A]	B: Performance Measurement[B] New Build.	B: Existing Build.	C: Performance Assessment[C]	D: Performance Communication[D] Non-rated	D: Rated
1a. Codes and Regulations[a]	Building Decree[1]					
	CPD (93/68/EEC)[2]					
1b. Standards[b]	ASTM standards[3]					
		NOPA M/S[4]				
2. Checklists / guide lines	Healthy Office[5]					
	SIA 112/1[6]					
	Guideline SusCon.[7]					
3. Calculations / algorithms[c]		LCA-Tools[8]

			SAP 2001[10]			
4. Measurements[d]			Accounts[11]			
5. Questionnaires[e]			CBE (IEQ)[12]			
	DQI[13]					
6. Building descript./passport[f]					Build. File[14]	
7. Labels / Certificates				ECOHomes[15]		
8. Integrated Tools[g]		EcoProP[16]				
		LEGEP[17]				

Index: fully applicable | partly applicable | not applicable

Figure 2 Typology of selected performance instruments and tools. (Lützkendorf et al. 2005)

One of those integrated performance management tools, EcoProP, contains a pre-set database using the VTT ProP® classification. It differentiates the output (value, performance, quality) and input (cost impacts and environmental impacts). The numerator contains location specific and building performance specific aspects separately. A similar approach with building environmental quality and performance vs. building performance loadings has been adapted in CASBEE, the Japanese assessment tool as shown below.

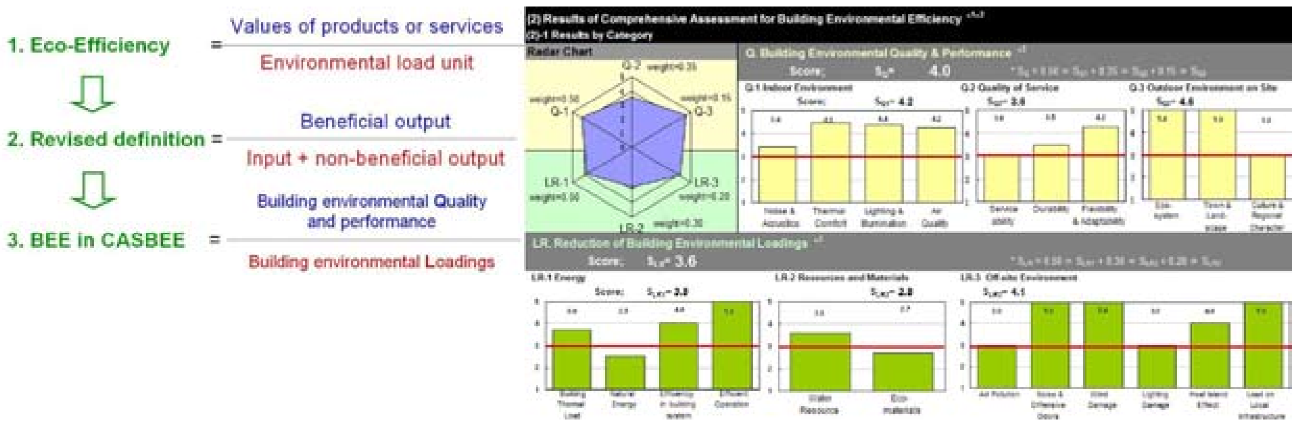

Figure 3 CASBEE environmental rating tool. (Iwamura 2005)

2.4 Requirements model and other Building Information Models

Karud (2007) concluded in STAND-INN that the IFC and use of BIM have great potential for value creation during the whole life of buildings at least in the following areas

1. Focus on customer and end-user requirements and sustainability within the building process and life cycle phases
2. Increasing transparency in the decision-making process and re-engineering the building process with new business opportunities for new and existing actors
3. Cost saving to all actors and a better project economy

4. Improved possibilities for early stage analysis about: best practice design, construction cost, energy consumptions, environmental impacts, lifecycle cost, performance in use, flexibility, adaptability, indoor climate, usability and maintainability
5. A comprehensive and common international knowledge model database with standardized ICT tools, objects and communication rules and available best practices examples.

The following figure tries to illustrate some of these value aspects with the focus on two first ones: end-user requirements, and transparency in decision-making. The content is shortly represented in different phases of the building process. Even though the BIMs are depicted here as separate models, it must be noted that the information exchange standard ensures the interoperability between different information models. In practice, some of these models may be as one model.

	REQUIRED	DESIGNED	CONSTRUCTED	DELIVERED	ACHIEVED
PERFORMANCE IN USE	• user requirements • desired performance in use	• designed technical solutions • estimated performance	• constructed building	• validated conformity	• user satisfaction • performance in use
ENVIRONMENTAL IMPACTS	• targeted environmental impacts over the life cycle	• estimated environmental impacts over the life cycle	• environmental impacts during construction	• estimated environmental impacts in use	• environmental impacts of building and its use
ECONOMIC IMPACTS	• targeted whole life costs • targeted business impacts and value of the facility	• estimated whole life costs	• construction costs	• estimated running costs	• running, maintenance and refurbishment costs, recycling, reuse, demolition and waste disposal costs • value of facility
OTHER	• targeted social, cultural and institutional impacts		• construction safety • construction ethics		• social impacts in the neighbourhood • impacts to cultural heritage

Figure 4 Building Information Models.

Hyvärinen states (in Huovila et al. 2007) that the IFC specification IFC2x3 includes a generic mechanism for expressing requirements as controls (IfcControl), or constraints (IfcConstraint), or merely as property sets. Some explicit entity type and property set definitions exist for requirements capture: e.g. for most typical building space (programming) requirements there is the IfcSpaceProgram entity type (subtype of IfcControl) and its associated Pset_SpaceProgramCommon, as well as a number of property sets directly associated to spaces (IfcSpace or IfcZone), e.g. Pset_SpaceThermalRequirements. However, in general there are no comprehensive and consistent sets of performance indicators organised in accordance to standard building performance classifications (e.g. indoor climate parameters as listed earlier). IFC software support for requirements management is still at an experimental phase.

3. Sustainability over life cycle

3.1 Environmental impacts

Different approaches are applied to manage the environmental impacts of buildings. Häkkinen describes the following ones (in Huovila et al. 2007)

- Life Cycle Assessment for the environmental impacts (ISO 14040 2006)
- environmental declarations (ISO 14020 2000)
- standards for life-cycle management of buildings (CEN/TC350)
- national environmental assessment and classification methods for buildings and building products
- a framework for sustainability indicators of buildings (ISO/TS 21929 2006)
- standards and methods for service life management of buildings (ISO 15686 2006)
- standards for the management of energy efficiency.

A recent EC project Methodology Development towards a Label for Environmental, Social and Economic Buildings (LEnSE) was by the EC to develop a sustainability assessment framework. Its structure is shown in the following figure in three main categories. 36 of their 57 sub issues have been developed and tested on ten pilot buildings.

Figure 5 A sustainability assessment framework (LEnSE 2008).

At present the environmental rating seems to be a burning topic in Europe. In some cases the same buildings are assessed two, or even three times, because in an international market the applicability for a single national rating doesn't always seem to be sufficient.

3.2 Economic impacts

Pulakka (2005) states that life-cycle values are mainly caused by combination of location and most significant characteristics of the facility. Life-cycle economical, energy-saving, eco-efficient, healthy and social facilities are quite similar: durable enough and desirable with functional, change-flexible and unrestricted spaces as well as reliable, advantageous and undamaged systems and other products and materials.

RAE (1998) has published a paper on the long term costs of owning and using buildings. A key point in that paper is that buildings designed for the accommodation of people generating wealth, or people providing a service, must create and environment where people will give their best. The cost of ownership and maintenance of a building is typically about 3 % of the overall costs of the people working in the building.

3.3 Social, cultural and institutional impacts

Sustainable construction is often divided into three dimensions: environmental, economic and social. Sometimes the third category is called as social and cultural to emphasize the cultural heritage aspects of the built environment. When the international work on sustainable development indicators was started, four categories were used: environmental, economic, social and institutional. Over time, the institutional category has mainly been merged into the social one in the context of sustainable construction.

Social aspects in the built environment are much more in focus in the neighbourhood, or at a city level, than in individual buildings. There isn’t clear agreement where the health and safety issues belong to. The indoor climate aspects clearly belong to the building performance category. At the same time its impacts to human health are dealt as environmental loads in the building environmental rating tools. In city indicator systems, health is typically treated as a social element.

Social aspects are present in Corporate Social Responsibility (CSR) strategies by enterprises that may use triple bottomline (economic, environmental, social) reporting. Earlier, many companies published their environmental reports apart to the economic balance sheet. CSR combines separate reports into one. Sustainability Reporting Guidelines is an example of such a system providing a structure also to social aspects that may be relevant to sustainable construction (GRI, 2006).

4. STAND-INN Case studies

4.1 Good practice examples of innovative sustainable housing

STAND-INN D9 collected seventeen good practice examples of innovative sustainable housing from eight countries. They demonstrated the rich nature of innovative sustainable housing from different perspectives covering

- climatic and cultural regions from North to South and Central of Europe
- both new construction and refurbishment
- detached houses and blocks of flats
- individual buildings and neighbourhood scale development
- various forms of ownership: rented flats and owner occupied or tenant right dwellings
- types of sustainability standards as defined in this context (ISO/CEN, guidelines, concepts, tools etc.)
- time scales from ongoing or recently completed projects to the development in the 1990s representing also older technologies
- different aspects to improve end product performance, to minimize environmental impacts and to encourage economic, social and cultural progress.

The objective was to study the use of sustainability standards in those cases. In addition to some ISO or CEN standards, mainly voluntary guidelines (FiSIAQ, IEA Task 13), concepts (Passive House, Zero Carbon) and tools (Ecoprofile, HQE, LiderA, PromisE) were included in the compilation. Thus a broader sample was obtained to complete the picture of endeavours towards innovative sustainable housing. Those good examples were viewed in three main categories that contained each at least five examples from three countries. The categories were detached houses, blocks of flats and groups of buildings, and mixed development, refurbishment, neighbourhood scale and process issues.

The selected examples showed successfully realized features of innovative sustainable housing that address these categories. Considerable improvement was justified in detached houses by implementing the state-of-the-art technologies. The development motivation in those examples varied from private interest of individual experts (architects or thermal designers becoming future owners and users of these houses) to publicity (housing fair, IEA showcase). Reported obstacles did not relate that much with standardization issues. Instead, lack of craftsmanship amongst professionals and resistance to change the traditional way of doing things were mentioned as hindrance. Also in blocks of flats, considerable progress was achieved that reduced environmental impacts and simultaneously enhanced the indoor performance of flats. Measured results of 70 % reduction in space heating (with only 1,7 % increase in construction costs and estimated 5 to 7 years pay back time) and 50 % reduction of total energy use (and 4 % additional building costs with 10 to 12 years pay back time) were obtained.

Neighbourhood development examples raised the importance of social issues as part of the sustainability concept. Sustainable process contained, in addition to resource management, also participatory aspects and focused diversity and integration of the inhabitants. Besides meeting the environmental sustainability objectives the successful cases were reported to be beneficial both to the developers and buyers. Improved comfort level can be seen as a positive side effect of meeting ambitious environmental targets. Some cases influenced in further development of the guidelines, concepts or rating tools, which were considered as "standards" in those good examples.

These case studies show that individual examples of innovative sustainable housing have been successfully realized in many European countries using existing knowledge, tools, standards and guidelines. Since the built environment is the major contributor to sustainability, in addition to occasional showcases, the mainstream practice in housing design, construction, refurbishment, operation and maintenance should be transformed into a sustainable path. Relevant standards and building information models provide a natural vehicle to strive towards that objective which should be beneficial to all, especially the future generations.

4.2 Building Information Models applied by Senate Properties

Senate Properties' is an advanced building owner whose product modeling requirements in 2007 provide an example of technical aspects of the use of IFC. Senate Properties has carried out a number of pilot projects since 2001 to develop and study the use of product models. Based on feedback from these, they have assessed product model technology to be sufficiently ready for putting to use in ordinary project work, and the company decided to require models meeting the IFC standard in its projects as of 1 October 2007.

The modeling of projects is not an end in itself. Instead, its main aim is to ensure that the scope, cost and practicality of the project conform to the objectives. In the first phase, models are required in ordinary projects and only for some of the design jobs of the project. The modeling requirement applies both to construction and to renovation projects. The only projects excluded are those for which no significant advantages are seen in modeling. In the first stage, tens of projects will be modeled, the total volume of which is estimated at hundreds of millions of euros.

The obligatory part is limited to modeling and visualization of the starting scenario and architectural design as well as to the monitoring of the scope and costs performed on the basis of the models. In the architectural design, modeling will be applied throughout the process, starting with the presentation of alternatives based on space models and ending with the tender documents for the contracting stage. In the project planning stage, the main emphasis for modeling will be on supporting the investment decision by comparing alternatives' scope, costs and lifecycle attributes. To facilitate cost control, type data in conformity with the room schedule for spaces will be added to the model. The quantity and scope data obtained from the model in the draft stage will be used to support the production of the building element estimate. Efforts will be made to secure the energy budget of properties by simulating the building's energy consumption before major decisions and by harnessing these results in monitoring the energy consumption of the building during its occupation stage. Efforts will be made to model structural and HEPAC systems in the detail design stage, but the requirement for these models will be decided on a case-by-case basis. The use and data content of the models will be binding requirements in design agreements.

The level of modeling required from 1 October 2007 is just the first step in going over to the broader use of models. Senate Properties will develop modeling requirements together with property owners in the Nordic countries, the USA and the Netherlands. The aim is to go over to all-embracing, integrated model-based operations in designing, building, and property servicing and maintenance in the next few years.

Senate Properties' modeling guidelines specify the data content requirements for models to the participants in the project at each stage of the design. The guidelines comply with the main lines applied to decisions to be made in Senate Properties' investment process. In the first phase, all design software packages which have passed IFC 2x3 certification may be used for modeling.

4.3 Value creation in VTT's Digitalo owned by Senate Properties

VTT's goal is to provide modern work spaces that support interactive collaboration and innovative ways of working for its employees. Digitalo is an example of systematic requirements management procedure where an active end user strives towards an optimum value in the process.

According to Senior Vice President Jyrki Kalavainen at VTT Real Estates

- instead of defining needed room spaces, it is important to identify the user needs with help of understanding the ways of working

- in Digitalo project, VTT wanted the representatives of the real users of the building to be involved in the process from the very beginning
- the process started with studying the ways of working of the planned users of the building and the distribution of working time between different kinds of tasks
- the architectural and real estate consultancy company Evata defined alternative concepts for the spaces based on identified user needs
- the needs for spaces that support interactive ways of working were emphasized by VTT
- on the basis of the process, VTT and Senate Properties were able to formulate a building plan, which does not fix the room spaces but describes the needed quality of the spaces. In addition, requirements were also set to energy-efficiency and life-cycle management of the building
- continuous management of efficient use of spaces and space costs was monitored and various situations could be affected.

VTT’s strategic goals were taken as a starting point for the design of Digitalo. VTT's strategy characterizes VTT as a technology intensive innovation organization. The primary objective is to strengthen interactive ways of working and to promote innovation processes. Interaction is believed to improve communication and transfer of tacit knowledge. The efficient use of ICT is in central role. The desired ways of working can be characterized with the help of four areas of strength: cooperation, knowledge, creativity, and efficiency.

The project sought to create a modern work space in an office building that supports interactive and innovative ways of working, communicates VTT's brand and image as a high-end technology solution provider, and is in accordance with sustainable building principles, especially in terms of energy-efficiency and life-cycle costs, adaptability, indoor conditions and service life.

Senate Properties see the benefits of the use of BIM as follows

- improved management of investment costs (especially the extent of design based on space models and space group models)
- better focus on life cycle costs (in addition to investment costs)
- validating the conformity of performance objectives
- amelioration of communication especially towards the customer, and between the design team
- in addition to management of the performance of the building, monitoring of environmental impacts will become extremely important (e.g. energy consumption will be simulated in modeling and measured and followed-up in use)
- early analysis of alternative solutions aims at an overall optimal solution in regard with all objectives.

The first steps are to model architectural design. Models in other domains will be decided case specifically. Along with time, increased interest and improved skills will most likely lead into a state where all actors volunteer to work with BIMs without request.

5. Conclusions

The policy and process related problems connected with the efficient implementation of sustainable building technologies affiliate also with the deficiency of business models of the sector. The building and real estate sector has acknowledged the importance of customer orientation, but this does really affect the business processes. Eco-efficient building calls for demanding and conscious customers, functioning value chains and capabilities to make use of sustainable building knowledge in marketing and efforts of exportation. Effective business models of sustainable building from the viewpoints of demand, value chains and competitiveness should be investigated and analyzed. The problem is also related to the possibilities and importance of business image and brand building.

Although the level of knowledge of sustainable building technologies is high in some European countries, this knowledge is diverged into separate solutions of materials, products, building services and methods of information management. In order to proceed we should develop

- ways to capture and formalize end-user needs and tools for requirement management
- integrated design methods, tools and practices
- comprehensive concepts of eco-efficient building (e.g. local/national Passive Houses)
- interoperable Building Information Models to cover the whole life cycle.

Keywords: sustainable building, building information modelling, information management, environmental assessment tools

Summary

Aspects of sustainable building include the aspects of building performance, environmental, economic, and social impacts. Sustainable design and life cycle (LC) management of buildings need new type of information compared to traditional building processes. Because of the abundance of required information, efficient information-technological solutions are needed. Building Information Modelling (BIM) is becoming momentous in AEC industry and real estate sector to share and exchange information among stakeholders, and the use of BIM is currently emerging around the world. BIM should also be able to support the supply, integration and management of information throughout the building LC. LC information can be given in terms of product data and different kinds of assessment and simulation models. With help of this information, aspects of energy, indoor environment, environmental impacts, LC costs and service life should be able to be considered in design and maintenance. BIM in its different stages should be provided with all initial information that is needed in the implementation of LC methods. Additionally, the results of assessments should be integrated with the different stages of BIMs in terms of indicators and guidelines. The paper discusses some of the problems of integrating LC information with BIM and highlights the expected benefits.

1. Sustainable building

According ISO TS 21929 (ISO 2006a), sustainable construction brings about the required performance with the least unfavourable environmental impact, while encouraging economic, social and cultural improvement at a local, regional and global level. The concept of sustainable building is wide. As summarised by Shelborn et al. (2006), one of the key issues in making construction projects more sustainable is overcoming the obstacles of capturing and managing the knowledge needed by project teams to affect such change. There is still a need for a structured approach for the implementation of sustainability practices and methods within construction projects. Indicators, checklists and assessment tools for sustainability in construction are available, but these do not provide a comprehensive solution.

Design tools for sustainable building should be able to simultaneously address a number of performance aspects and integrate the information into the design environment. Kohler and Lützkendorf (2002) mention six criteria for integrated building life-cycle assessment: 1) adaptability to building life cycles, different actors and decision levels, 2) adaptability to different types of impacts, 3) consideration of absolute and relative targets, 4) relying on explicit physical framework, 5) linkage of needed data with normal professional working environment, 6) scaling of needed data with process phases and availability of accurate information.

An important approach to seek solutions for the problems of sustainable building is with help of information management, and there integrated Building Information Modelling (BIM) offers a potential. The scope of this paper is to study the management of sustainable building with help of BIM from the view point of:

- Assessment of environmental impacts
- Assessment of energy consumption
- Service life design
- Maintenance manual
- Optimization of building refurbishment
- Sustainability rating of buildings

The starting point for this paper is that life cycle assessment methods and sustainability indicators are able to support sustainable building and construction in requirement setting and design for required performance and life cycle. Sustainable building assessment methods are believed to support sustainable building, because those enable the comparison of alternative solutions and thus enable the consideration of sustainability aspects in decision making. However, the use of these methods in building planning and in design for sustainable buildings is problematic, because a lot of data is needed in order to be able to assess alternative solutions. Thus the assessment is often done only for the final solution instead of collecting data for design options. Design for sustainable buildings needs integrated methods which should provide the process with easy-to-use and comprehensive product information and integrated calculation and simulation facilities that enable the comparison of design options and the effect of changes automatically or with reasonable extra work (Häkkinen & Pulakka 2007).

Furthermore, even more problematic is to understand, how sustainability aspects could be considered already in the preliminary planning process where decisive decisions are already done. It would be important to integrate environmental indicators and data to the design process in order to rationalise assessment and thus also to support planning and design for sustainable building. The premise of this paper is that this can be done with help of BIM.

Integrated building information modelling is becoming very important in AEC industry and real estate sector and the use of BIM is currently emerging around the world (GSA 2007, NBIMS 2007, Senate Properties 2007, Statsbygg 2007).

2. Building Information Models

BIM denotes the creation and use of coordinated, consistent, computable information about a building project during design, construction and building operation and management. BIM can also be defined as the collection of objects that describe a building (Lima and Hans 2007). Software applications of BIM work with 'objects', which represent all elements of building construction including physical components, spaces, processes, actors involved, and relationships between these objects. In most cases the complete design information of a building consists of several domain specific design BIMs, such as architectural, structural. HVAC, and electrical BIM. Integrated BIM is a combination of these individual BIMs. In this paper the term BIM is used to describe the integrated BIM; total repository of all BIMs containing the information of a building. BIM covers not only geometry, spatial relationships and geographic information and quantities, but also properties of building components. Quantities and shared properties of materials can be extracted. It can be used as the source of information for the analyses of the solution as well as to store the results of analyses. BIM can be used to represent the entire life cycle of the building including the processes of construction and facility operation.

Because of enabling the sharing of information and because of working with objects, BIM could significantly support the management of information needed in design for sustainable building. Important questions are how to integrate and what is the degree of linkage or inclusion of different data bases and tools with domain specific BIMs. In most cases, the BIM should offer a framework and the source of information concerning the design solution, while the specific assessment and simulation models and the needed background data (for example the environmental data of products) are not embedded but linked with help of identities and interfaces (Häkkinen 2007).

The usage of BIM in sustainable building and construction depends on the implementation of BIM and this varies in different countries. The Finnish Senate Properties is one of the forerunners in mobilizing BIM, and this paper refers to the guidelines "BIM Requirements 2007 in different phases of the design and construction process" adopted by Senate Properties. The guidelines have been formulated by Kiviniemi et al. (2007). Senate Properties is a government owned enterprise that is responsible for managing the Finnish state's property assets and for letting premises. The building stock comprises university, office, research, cultural and other buildings (Senate Properties 2008).

According to the Senate Properties guidelines, the different phases of construction projects and related BIMs are the following:

- Analysis of needs and objectives
  Requirement model: Project requirements and requirements of the authorities
- Design of alternatives
  Alternative mass and spatial models
- Early design
  Architectural model, structural model, HVAC model, Electrical model
- Detailed design
  Architectural model, structural model, HVAC model, Electrical model
- Bidding phase
  Approved detailed design and Construction model
- Construction and commissioning
  Construction model and As-built model
- Facility management and maintenance
  Maintenance model

3. Sustainable building standardisation

Standardisation of sustainable building methodologies is necessary in order to integrate sustainable building aspects with BIM processes. It is necessary to standardise the definitions and semantics of this information.

The general principles on life cycle assessment of products and services have been agreed upon and made public with help of ISO standardization. In addition to general methodologies, applied methods for building products are being standardized by ISO. There is also a European process going on, which aims at the development of harmonized life-cycle standards for buildings and building products. ISO TC 59 SC 17 "sustainability in building construction" is working on several documents:

- IS0 CD 15932-2 General Principles;
- IS0/PTR 21932 Terminology;
- IS0 /TS 21929-1Sustainability indicators Part 1: framework for the development of indicators for buildings;
- ISO DIS 21930 Environmental declarations of building products; and
- ISO DTS 21931-1 Environmental performance of construction works Part 1- Buildings.

ISO has also leaded the process of developing standards for service life planning. ISO 15686-1 (ISO 2000), ISO 15686-2 (ISO 2001) and ISO/DIS 15686-8.2 (ISO 2006b) give general principles for service life planning, describe service life prediction procedures and give guidelines for reference service life. Standard ISO 15686-1 presents a basic methodology in the area of service life design, but the methodology requires considerable knowledge about the age and degradation of components and materials.

From the view point of information management, the above mentioned standards rather work with principle methodologies. In order to enable integration of sustainable building methodologies with BIM, the definitions of information contents should be further developed. Also the specifications for data representations that have exact representation syntax which could be made use by software are missing.

Sustainability in construction is also studied at European level within the CEN TC 350 "Sustainability of construction work". This TC deals with the aspects of sustainability at the levels of products and buildings. Aspects especially considered include environment, health and comfort, and life cycle cost. CEN/TC 350 will develop voluntary horizontal standardised methods for the assessment of the environmental performance of new and existing buildings and for the environmental product declaration of construction products, in the framework of the integrated performance of buildings. The becoming standards will be relevant for the assessment of buildings over its life cycle. The results from the standards mandated by the M/330 (energy performance directive) will be integrated into the assessment of the environmental performance of buildings in the framework of integrated performance of buildings.

On the basis of the EC standardisation mandate M/330 EN CEN is developing methodologies for the calculation of the energy uses and losses for heating and cooling, ventilation, domestic hot water, lighting, natural lighting, passive solar systems, passive cooling, position and orientation, automation and controls of buildings, and auxiliary installations necessary for maintaining a comfortable indoor environment of buildings.

4. IFC

IFCs (abbreviation is originally based on the terms Industry Foundation Classes) aim at providing an open definition for data structures to capture and exchange information (IFC 2007). The development, maintenance and implementation of IFC include to the purposes of the buildingSMART initiative of the International Alliance for Interoperability (IAI). The purpose of IFC within buildingSMART is "enabling interoperability between AEC/FM software applications" (International Council of the IAI in November 2006). IFCs express common agreements on the content, structure and constraints of information to be shared and exchanged by several participants in construction and facility management projects using different software applications. The result is a single, integrated schema representing the common exchange requirements among software applications used in construction and facility management processes (Lima and Hans 2007).

Although sustainable building related information has not yet been agreed on the level of IFCs, the use of BIM could strengthen and rationalize the management of sustainable building. IFC incorporates a mechanism called Property Sets which allows information publisher to allocate new properties to an object. This enables IFC to be used for representing also product specific information. For example the environmental assessment of a design solution can be supported with help of BIM by attaching environmental information to BIM objects (defined by IFCs) via the Property set mechanism or simply with linking the object to external data bases, whereas the existing sustainability standards can be made use of. This is further discussed in sections 5.3 and 5.4.

5. Integration of sustainable building tasks with BIMs

5.1 Introduction

There are different solutions for integrating life-cycle analysis software and BIM. These include separate software solutions that are able to use file exchange with BIM or that can be integrated with a BIM server using a specific API. The analysis software can then have its own library for those pieces of information that are not included in BIM. The analysis software could also be implemented by programming new functionality to BIM software. An intermediate solution for these is the integration with help of parametric formats (e.g. GDL) that allow representing not only product information but also calculations used in analyses (Siltanen et al. 2008). This paper deals with the needed contents of product information assuming that a separate software solution connected to BIM is the most likely in terms of easiness to realise and use. VTT has also developed a prototype software solution which uses design information represented by IFC together with separate product information represented in PMO ontology and calculates environmental results by combining the effects of different building elements (Siltanen et al. 2008).

5.2 Service life design

Service life design needs information about the age behaviour of building elements and components. As defined by ISO 15686, this is information about the effect of different parameters on service life; these parameters include for example the quality of workmanship, quality of materials, building structure and details, environmental conditions, user conditions and quality of care and maintenance.

Service life prediction methods have been developed for construction products which are exposed to weather conditions (for example Shohet et al. (2002) and ENNUS (2006)). There is a growing awareness worldwide about the importance of the maintenance of constructed facilities as shown by Shohet et al. (2002) and about the significance of maintenance from the view point of sustainable building as summarised by Häkkinen, Vesikari and Pulakka (2007). One of the most important parameters affecting the efficiency of maintenance management is the precision and the reliability of the predicted service life of building components.

ENNUS®-programmes support service life assessment of building structures (Nilsson, Vares and Vesikari 2007). The programmes help designers to determine parameters that affect the service life of a building structure and to predict service life in accordance with the factor method presented in ISO 15686-1. These parameters include materials, details, assembling, outdoor and indoor conditions, use conditions, and care and maintenance.

Service life assessment methods support the design for required service life the better the more simultaneously the assessment can be done with the very design process. This can be supported by BIM. When integrating service life assessment with BIM, the initial data needed for defining the values of parameters should be available through the properties of the model or with help of integrated databases. Part of the needed data could be made available with help of an integrated database; this may concern for example material properties. However, also the design solution itself affects service life. Thus for example the structural model should include all information about the quality of structures that is needed as initial information for the service life assessment of structures. The structural model software should support the designer to define the structural parameters needed in the assessment of service life.

The assessment software itself can remain a separate tool that is compatible with the model. The interfaces can be made by converting native data formats into IFC representations. In the case of ENNUS® software described in (Häkkinen and Vares 2007) the integration of the ENNUS® tool with BIM was done by converting XML file produced by standard Excel methods to IFC (Fig. 1 and 2). The results of the assessment for different building parts and systems should be imported as service life indicators to BIM. The formats of information should follow the definitions given in standards dealing with service life planning. Even applications using relatively simple data structures (e.g., service life assessment tool ENNUS is a simple Excel spreadsheet) benefit from the ability to utilise BIM. BIM can be used in this case for transferring data between life cycle phases, as well as getting initial information from the building information model.

5.3 Environmental assessment

The basic principles and declaration formats of environmental assessment in terms of LCI or LCA have been agreed upon with help of standardisation processes. The environmental standards provide the needed definitions for the contents of environmental information. The building level assessment can be done by summing up the product level environmental profiles and by considering the bill of quantities.

Information needed from BIM includes data about properties and quantities of different components and elements. In order to make the environmental assessment for a design or for a part of a design, this information should be linked to a database that includes the environmental profiles of building components and elements. The environmental assessment of a building can be integrated to BIM similarly as cost assessment is already done at present. The integration requires that product specific and energy related environmental profiles are available, for example, in the form of an XML database.

The final result from assessment should be enclosed as environmental impact indicators to BIM (design model). According to ISO TS 21929 an environmental indicator of a building addresses an environmental aspect either in terms of loadings or impacts. Environmental loadings are the use of resources and the production of waste, odours, noise and harmful emissions to land, water and air.

Different kind of environmental information is needed in different stages of the process. During the design phase relevant generic environmental information should be available. This information should describe the average environmental performance of products without being producer specific information. Generic information should be replaced by product and producer specific information in building construction phase, when the contractor wants to analyse the importance of individual product choices and store the environmental indicators to the as-built model.

Environmental information may also include instructions for the building use and final disposal. This includes information about indoor emissions of building products and instructions for recycling. The integration of this information with BIM can be dealt with similarly as the care and maintenance information presented in section 5.5.

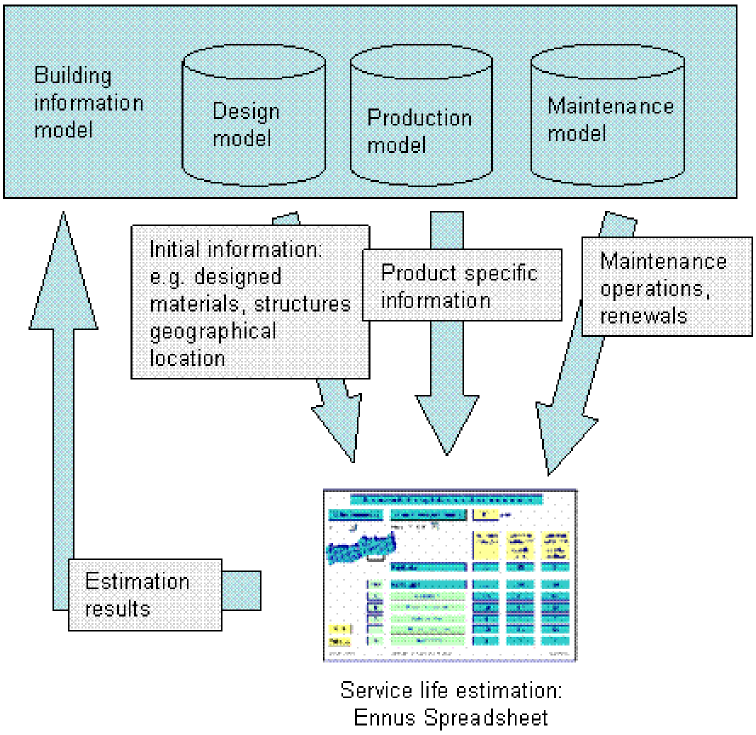

Figure 1 Information flows between ENNUS Spreadsheet and BIM.

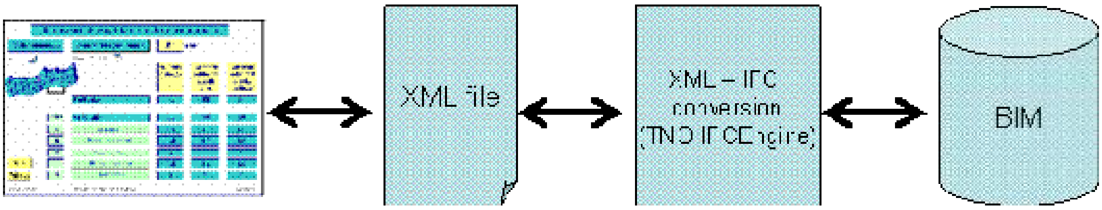

Figure 2 Implementation of the interface between building information models and ENNUS.

5.4 Energy consumption estimate

The initial data needed in design for energy efficiency includes information about local environmental conditions, technical performance and capacity of building elements and HVAC units and systems, position of the building in the building lot, spaces, arrangement of spaces, and intended user profiles. Depending on the complexity of the design and the needed level of accuracy of the assessment, the amount of data needed may be extensive.

Different kinds of assessment and simulation methods and tools are available for the assessment of energy consumption of buildings. In order to enable the energy consumption assessment with help of BIM, 1) the model should provide all data needed in the calculations and 2) there should be a suitable interface between the model and the assessment software.

The product related information needed in calculations does not need to be included in the model (as attribute data of objects) but it can be integrated data collected into a compatible database and linked with the model. Probably the best solution is that the assessment is not done within the model but with help of a software solution that is compatible with the model. The results of the assessment should be imported as energy-efficiency indicators of the design model and correspondingly later as indicators of the later stages of BIM. These indicators should follow the formats and expressions (units etc.) agreed upon in standardisation.

Similar conclusions have also been done by Morrissey et al (2004) when they analyse the assessment of building performance within BIM. Analysis will be achieved by querying an archive of performance objectives and performance metrics that are programmed within the BIM. Once the user has selected the performance metrics, a critical analysis may be preformed for all related design decisions and management operations. This leads to large sets of data that must be elicited at various stages and from various sources. Storage in a single IFC database would lead to a model that would be oversized and unmanageable. Performance metric data should be separated from the main model with storage occurring in XML files. The XML files should be referenced within the BIM and their associated sets of data may be elicited from a database in order to analyse the performance of the building.

5.5 Maintenance manual

Building maintenance needs system-specifically grouped and scheduled information of all care and maintenance measures. This information should be given in terms of recommendations and instructions and formulated during design and construction. For example the Finnish building regulations require the provision of care and maintenance information in all significant building projects. In order to support maintenance management, this information should also be updated during the use and maintenance phases of the building.

Building refurbishment needs information on realised building solutions and information about the requirements concerning the handling and treatment of products to be demolished, surface treated etc. When the optimum maintenance and refurbishment processes (both in terms of quality of measures and scheduling of those measures) are sought, same kind of information about the age behaviour of different building elements is needed as within service-life design. Additionally, information about costs of alternative measures is required.

VTT have proposed simple methods for sharing and integrating product-specific instructions-type-of-information with BIM (Siltanen in Häkkinen et al. 2004 and Heinonen in Häkkinen et all. 2007). A framework for a web browser (Fig. 3) based database was created where manufacturers can store all product specific service life information. The service life information was defined with using XML description language.

The project suggested that the process could operate in such a way that the concept-developer requires all the suppliers of the concept to include service life information into the database with help of which the compiler of the maintenance information collects and arranges the building information to form an organised and scheduled product information set for care and maintenance. The maintenance model should be provided with methods and tools with help of which product specific maintenance information can be arranged and collected as building system specific information. The contents of this information should enable the effective implementation of maintenance considering the different periods and types of inspections, care, repair and renewals.

Figure 3 LifePlan database system.

5.6 Optimization on building refurbishment

Especially the managers of municipal and state infrastructure are realising the need for effective tools to manage the large asset base. Decision support tools are needed in order to support understanding and decisions on its value, condition, remaining service life, needed maintenance and optimal scheduling of operations. For example Söderqvist and Vesikari (2006), Bucher and Frangopol (2006) and Vanier (2001) have introduced methods for the optimisation of lifetime maintenance of buildings. MaintenanceMan is a tool, which supports the optimization of building refurbishment measures (Vesikari 2008). The tool uses service life models with help of which it is possible to predict the service life of the modules. The tool allows studies at different risk levels. The optimization criteria are life cycle costs (LCC) and environmental impacts. MaintenaceMan works on modular basis so that the building is divided into structural parts or modules.

In order to rationalize the use of these kinds of tools in the design of refurbishment options, the maintenance model should include the needed initial data, and correspondingly the design model software and the construction model software should support the designers to provide all needed initial data to the model. This includes information about materials, structures and environmental conditions. Additionally, the maintenance model should support the maintenance managers to update this information. The optimization also needs information about LCCs. This should be available through a separate integrated database, because it is both product specific and user specific information. If the results of optimization (the favourable maintenance and refurbishment strategies and their life cycle costs) were wished to be used as guidelines for future measures, this information should be imported to the maintenance model.

5.7 Sustainable building rating systems and their relation to BIM

Sustainable building rating systems have been developed in international cooperation and nationally in a number of countries all over the world. The majority of the existing environmental assessment methods of buildings evaluate environmental performance of buildings relative to explicitly declared or implicit benchmarks (Cole 2005). Typically, the environmental performance is described with help of indicators which try to express both the environmental impacts as well as other performance aspects such as indoor conditions. Methods which are widely well-known are for example the BREEAM (2008) (UK), LEED (2008) (USA) and GB Tool (Kimberly et al. 2006). The point of view has gradually widened from sole environmental assessment to overall assessment of sustainability aspects of buildings.

LCI/LCA approaches are partly being adopted into the environmental rating systems (for example in the German (Schminke 2008), Finnish (PromisE 2008) and Australian systems (GREEN STAR 2008)) to deal with the environmental impacts of buildings. However, the overall sustainability of a building does not only depend on the direct environmental loadings induced by the building and its use, but also on the quality of the building as a place to live and work, accessibility and interface with surroundings, quality of process (for example the participation of all concerned, probability of non-desired risks).

The potential of rating systems to support sustainable building design and sustainable refurbishment of buildings would be improved, if the systems were integrated with BIMs. This would require that the BIM processes supported the determination of the building specific values for the indicators and calculation of the final results with reference to given benchmarks. With regard to LCI/LCA related indicators and indicators that are based on the characteristics of building products and energy-efficiency indicators, the determination of indicators' values can be based on the principles described in sections 5.3 and 5.4. However, with regard to some indicators - like accessibility, adaptability - the development of a specific model-checking software solution might be the best solution.

6. Conclusions

Tools of LCI/LCA assessment, energy consumption assessment, service life assessment, maintenance manual, optimization of refurbishment and sustainability rating are important methods in design for sustainable buildings and in sustainable use and refurbishment of buildings. The use of these methods requires the availability of tools and a lot of additional information compared to a traditional building process. In order to rationalize the use of these methods and to support the use of methods during the design processes, the methods should be integrated with BIM processes. This paper describes the data contents related to different assessment methods and discusses the principal solutions how to integrate the methods and the required data with BIM in the different stages of building process.

Keywords: Green Mark, green buildings, sustainability, sustainable construction

Summary

Construction has been accused of causing environmental problems through excessive consumption of global resources from building and construction activities. There have been research on green building design and green materials to minimize environmental impacts. Rating tools such as the BREEAM in the UK, the LEED in the US and the GreenStar in Australia allow for benchmarking and rating building performance in energy efficiency to promote sustainable development and reduce greenhouse gas emissions. In Singapore the Green Mark assessment scheme was introduced in January 2005 by the Building and Construction Authority. It is a government initiative to promote environmental sustainability in buildings in Singapore. It was initially a voluntary programme for new and existing buildings but was made mandatory on 15 April 2008. This paper discusses the introduction of the scheme as the first government-implemented environmental assessment scheme in Singapore. This paper is based on an online questionnaire survey undertaken in January 2008 to examine the impact of the scheme in the construction industry since its introduction. It also provides an overview of the principles of the scheme in enhancing sustainability awareness in construction and presents the survey results, recommendations and direction for future research.

1. Introduction

Building, together with the transport sector, are the key industries in most countries with the greatest impact on urban environment (Ng & Hirota, 2007) and environmental building assessment methods are growing in importance in improving sustainability of the built environment (Ding, 2008). Eliminating or reducing environmental impacts through design of environmentally certified buildings is the primary purpose of building assessment tools (Chau et al., 2000; Seo et al., 2005; Ding, 2008). Secondly, it aims at providing the means for stakeholders to make property investment decisions based on environmental performance of buildings (Shiers, 2000; von Paumgartten, 2003). Finally, it aims to achieve the goal of improving quality of life for building occupants (Ding, 2005; Ha¨kkinen & Nuutinen, 2007).

In January 2005, the Singapore government, through the Building and Construction Authority (BCA), made a commitment to reduce environmental impacts by introducing the Green Mark assessment scheme. It is an initiative to guide the construction industry to move towards more environmentally friendly buildings. So far, over 60 buildings have received Green Mark certification by BCA, ranging from public sector institutional projects to private sector projects (BCA, 2008a).

This paper provides an overview of the Green Mark scheme as the first government-implemented environmental assessment tool in Singapore. This paper is based on an online questionnaire survey undertaken in January 2008 to review the impact of Green Mark scheme in the construction industry since its introduction in 2005. The survey seeks to examine whether there is an uneven uptake of environmental consideration across all the stakeholders in the development process and the increase in market awareness of the benefits of green buildings. This paper also discusses the principles of Green Mark, its implementation and its impact on sustainable buildings in Singapore.

2. The Green Mark Scheme – An overview

Green Mark is a credit award scheme that aims at promoting sustainability in the built environment. In particular the main objectives of the Green Mark scheme are (BCA, 2008a):

a. to promote sustainable development by improving environmental performance of buildings;
b. to employ market forces to bring about environmental awareness and to improve quality of life for occupants;
c. to raise awareness of developers, facility managers and occupants of the benefits of green building;

d. to encourage the best environmental practice in building design, operation, management and maintenance; and

e. to establish key performance indicators for benchmarking green building performance.

The Green Mark scheme attempts to combine features from three major green building rating systems to evaluate environmental performance of buildings and to improve quality of life. They are the Building Research Establishment Environmental Assessment Methods (BREEAM) in the UK, the Leadership in Energy and Environmental Design (LEED) in the US and the GreenStar in Australia. The Green Mark scheme, similar to BREEAM, LEED and GreenStar, gives outcomes as a certificate awarded to individual building based on credits for a set of pre-determined performance criteria.

The assessment classification is based on the total number of credits. This certificate provides recognition for the building environmental performance. The classification rankings in Green Mark are Green Mark Certified (scores 50 to <70), Gold (scores 70 to<80), Gold^{PLUS} (scores 80 to <85) and Platinum (scores 85 and above). Assessment method and certification process provide means of distinguishing green buildings and promoting their uses. The documentation format, third party assessment and post-occupancy evaluation provide a systematic approach to the certification process.

Based on the structure of BREEAM, LEED and GreenStar, six assessment criteria were identified. These assessment criteria contribute to the credibility of Green Mark by ensuring that green building environmental performance goals match up to the desired international rating standards in a transparent manner (Fowler & Rauch, 2006). Other credibility concerns include measurement of environmental impact, market transformation, quality of life, and a track record of accomplishment through post-occupancy evaluation (Lutzendorf & Lorenz, 2006).

Table 1 - Comparison of performance scores for BREEAM, LEED, GreenStar and Green Mark

MAIN ASSESSMENT CATEGORIES	BREEAM '98		LEED 2.1		GREEN STAR v.2		GREEN MARK	
	Points	% of total points	Points	% of total points	Points	% of total points	Points	% of total points
Site/Project development & ecology	128	11	14	20	8	6	10	10
Energy efficiency & atmosphere	208	17	17	25	24	18	30	30
Water efficiency	48	4	5	7	13	10	20	20
Indoor environment quality & environmental protection			15	22	27	20	15	15
Innovation & design			5	7	5	4	15	15
Materials & resources	104	9	13	19	20	15		
Transport	240	20			11	8		
Pollution & emissions	154	13			14	10		
Health & Comfort	150	13						
Management	150	13			12	9	10	10
TOTAL	**1182**	**100%**	**69**	**100%**	**134**	**100%**	**100**	**100%**

The Green Mark assessment scheme covers a wide range of green building issues, environmental impact, resource exhaustion, emissions to environment, indoor environmental quality, and management quality as well as other social aspects in Table 1. The table provides a comparison of assessment criteria between Green Mark and the BREEAM '98, LEED 2.1 and GreenStar v2. Green Mark places a lot of emphasis on energy and water efficiency which are the two main areas of concern in Singapore.

The intention of the Green Mark assessment scheme is to evaluate environmental impact of new and upgraded buildings using locally developed benchmarks and weighs established for each criterion. The values for benchmarks were classified into two main types: numerical and text based. The numerical values reflected the scores achieved and the text scores reflected the building performance grade. The numerical sore range from 0 to 100 and the five text scales represent minimum acceptable scale, average, good, excellent and outstanding performance achieved using best available technology and affordable cost.

In order to accelerate the Green Mark scheme in construction the government launched a Green Mark Incentive Scheme (GMIS) to encourage the adoption of green building design, technologies and practices. GMIS provides developers and building owners with financial incentives for buildings with Green Mark Gold rating or higher in new constructions or retrofitting of existing buildings.

3. Assessing the impact of Green Mark Scheme

3.1 Research method

Green Mark has been a voluntary requirement for the design and construction of projects in Singapore for about three year. In order to examine the impact of Green Mark in promoting sustainability in the construction industry, an online questionnaire survey was developed to investigate its role and impact. The survey was designed and distributed online so that it could obtain a wider coverage and provide a quick and easy platform for the return of the completed survey. The purposes of the survey were to examine the level of acceptance of Green Mark since its introduction in January 2005 and to explore the role of Green Mark in the construction industry in enhancing sustainability in construction projects. The survey also assesses the impact of its implementation as voluntary to the design and construction for buildings.

The questionnaire was divided into three parts. The first part was intended to obtain general details of the respondents and contained eight questions. Information about the demographics of respondents and details of their professions and organizations were the focus of this part. Part two was intended to examine the viewpoint of respondents in respect to their understanding and acceptance of the green buildings, and it contained 12 questions. Some of the questions were designed as a standard Likert scale where respondents were asked to rate each questions from low to high or from strongly disagree to strongly agree. Part three contained eight questions and was designed to identify the level of expertise the respondents have in the operation of the Green Mark scheme.

The online survey was assisted by the Royal Institution of Chartered Survey (RICS), the Chartered Institute of Building (CIOB) and the Singapore Institute of Architects (SIA) in distributing the survey to their members. The anonymous questionnaire was sent to members of RICS, CIOB and SIA as well as to 150 practitioners in the construction industry in Singapore via email with a URL containing the online survey in January 2008. Many participants also forwarded it to URLs of other practitioners in the industry. Therefore it was difficult to determine the exact response rate. Completed questionnaire were received via online and the survey was concluded in mid March 2008.

3.2 General Information

In mid March 52 completed questionnaires were received and analyzed. Of the returned survey 74% were from male respondents whereas female respondents contributed 26%. The survey respondents came from a variety of backgrounds and details are included in Figure 1. Project managers, Architects and quantity surveyors made up of the majority of the respondents and contributed 18%, 24% and 25% respectively to the total returned surveys whilst the rest was distributed among property managers, developers, engineers and others. Figure 2 presents the survey by age group. The age distribution of the respondents was evenly distributed. Regarding work experience 48% have less than 15 years, 44% have between 16 to 35 years and 8% have more than 35 years respectively. The majority of the respondents, about 49%, work for large companies with staff over 100 and have been established over 40 years in the construction industry.

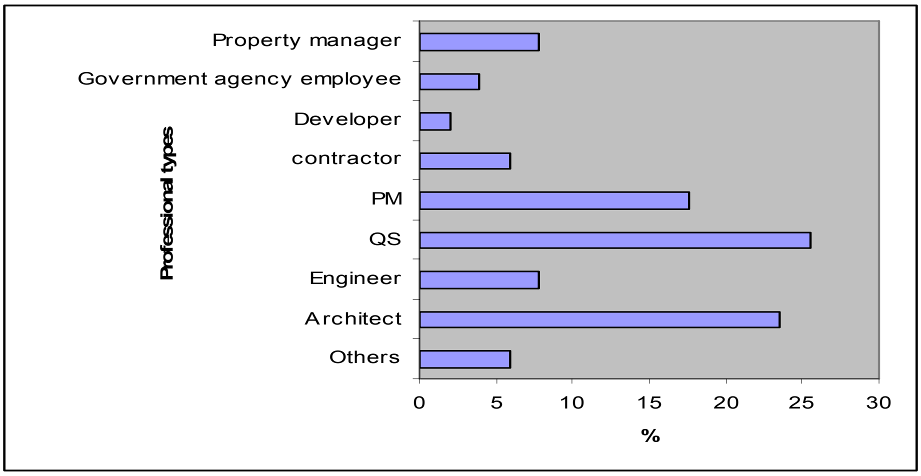

Figure 1 Summary of respondents by professional

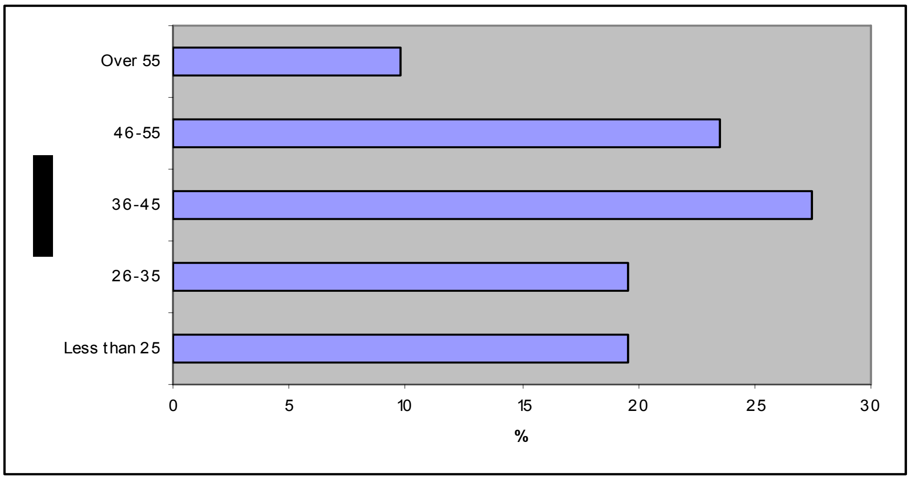

Figure 2 Summary of respondents by age

3.3 Greening the construction industry

The survey indicated that the majority of respondents are well aware of the environmental issues in the construction industry. Approximately 95% have expressed their concern about the environment and 59% have work experience in environmentally related projects. Of the 59% respondents having work experience in environmentally related projects about 50% are engaged in the design whilst 29% are involved in the construction and the rest in maintenance and assessment. Regarding work experience in environmentally related project approximately 82% have only two years work experience in about five projects. About 18% have up to 15 environmental projects with about ten years of such work experience.

In Part II survey respondents were asked to provide their opinions on greening the construction industry in Singapore. The questions were designed using a standard Likert scales, ranging from strongly disagree to strongly agree. The results indicate that over 90% of respondents agreed that environmental issues are important and should be incorporated in the design and construction of projects. About 90% believed that the demands for green buildings in the society will continue to grow and will eventually become an important source of workload in construction.

The respondents were asked to comment on whether research and development in green buildings in the construction industry is sufficient in Singapore. However only 12% agree that the construction industry has done enough to protect the environment whilst 66% disagree and 22% having no opinion. Some propose that the government needs to re-evaluate current regulations and policies in order to develop new directions and guidance for improving sustainability in construction. Some suggest that more grants and funding should be used to encourage research and development in renewable energy development, green technologies and materials, and so forth.

Concerning protection of the environment some suggested using severe legislations, regulations and by-laws as means to protect the environment. Approximately 74% believed that the laws and regulations will become more demanding in construction in the next few years. They recommend on one hand heavy penalties or taxes be imposed on those who pollute the environment. On the other, encouragement may be given by the government to those who pursue environmentally friendly projects through tax incentives or financial benefits.

3.4 Impact of Green Mark Scheme in construction

The Green Mark scheme was introduced in January 2005 as an initiative to raise environmental awareness among construction professionals in the design and construction of projects. However the long-term impact of Green Mark is yet to be reviewed. From the survey 45% of respondents have used Green Mark before of which 81% have used it for less than 5 projects whilst 19% used it for between 6 to 15 projects. Of those who had used the Green Mark before, about 65% used it as a design tool whilst 35% used it just for marketing purposes.

In assessing the impact of Green Mark in the construction industry respondents were asked to rate questions that were designed on a standard Likert scale from strongly disagree to strongly agree. The results are summarized in Table 2. Based on the returned surveys, professionals in the construction industry are generally well aware the importance of Green Mark in construction. The survey results indicated that 70% agree that the scheme is useful in assessing environmental performance of buildings. Green Mark is reasonably user friendly and 54% agreed that the information on the website is sufficient. With regards to assessment criteria 63% believe that Green Mark can help to provide better sustainability outcomes in construction. About 74% of respondents found the assessment criteria achievable.

Table 2 Summary in the use of Green Mark in the construction industry

Proposition	Responses (%)				
	Strongly Disagree	Disagree	No Opinion	Agree	Strongly Agree
The Scheme is useful in assessing environmental performance of buildings	4	4	22	59	11
The information on the website is sufficient	4	15	27	46	8
The criteria set in the Scheme are achievable	4	0	22	67	7
The Scheme will help to provide better sustainability outcomes of buildings	4	4	22	59	11
The assessment criteria are sufficient to cover the environmental aspects promoting green buildings	4	11	22	44	19
The cost of building green under the Scheme will be more expensive than traditional developments	4	7	22	37	30
The duration of building green under Scheme will be longer than traditional development	4	30	26	26	15
The Scheme should be used by all types of projects in the construction industry	4	0	19	62	15

Since the introduction of the Green Mark scheme there have been substantial discussions on increased construction cost and time due to compliance with the scheme. The use of Green Mark may have impacted on the overall construction cost due to incorporation of green features in buildings. Some have raised concern that compliance to Green Mark will escalate the overall budget which will impact on financial return. Approximately 67% of the respondents agree that the implementation of Green Mark has increased the overall construction cost but only 41% agree that Green Mark may increase the overall construction duration. In accordance with a preliminary study undertaken by the BCA the Green Mark certified buildings have a cost premium between 0.3% to 8% depending on the awards and building types (BCA, 2008b). The Green Mark Certified buildings are at the lower end of the range whilst Gold Platinum has the highest costs premium of up to 8% due to higher performance designs. The higher cost premium of green buildings is recovered from long-term energy and water cost savings.

There is no great disparity in the payback periods for the Green Mark certified buildings ranging from 2 years to 8 years (BCA, 2008b). However it is hard to ascertain whether Green Mark has increased the construction cost and time and further research is needed. About 77% of respondents agree that Green Mark should be applied to all types of construction. However many believe that the scheme needs further development to improve it usefulness. There is no indication of the details of improvement that needs to be made in Green Mark.

The respondents were also asked to comment on the limitations of the scheme in enhancing sustainability performance of buildings. They raised the issue that some developers may like to get the certificate at the lowest pre-determined costs. Developers in Singapore are not likely to spend more than the construction budget if there are no real benefits of green features such as solar, rainwater storage and so forth. Unfortunately wind tunnel tests or acoustic design are usually last on the list as they have initial costs which may lead to other costs. Too much emphasis on green features will lead to the presumption that green buildings are expensive and thus lessen the motivation to building green. They believe that in order to make Green Mark more successful team work and team participation from all construction professionals are important. The government can make Green Mark a requirement for the approval of building plans. They also suggest that sufficient information on green buildings should be made available through the development of a vibrant database that has information of all green innovations in the world as reference materials.

Some raise concerns that Green Mark, like other environmental building assessment methods such as BREEAM, focuses on the evaluation of design against a set of sustainability indices. The scheme includes six main areas (refer to Table 1) but does not include financial matters in the evaluation framework. This may contradict the ultimate principle of a development, as financial return is fundamental to all projects. It is important to include economic analysis in the framework and to emphasize potential long-term savings in order to convince people to adopt sustainable practices when building,

In addition, building life cycle has not been incorporated in the evaluation process in the Green Mark scheme. As Curwell (1996) states, life-cycle analysis is important in environmental assessment of buildings as it gives a balanced assessment between a development and the environment. Therefore, a whole-of-life approach is an essential method to evaluate and integrate the costs and benefits associated with sustainable construction. Kats (2003), states that the lack of life cycle costing is one of the obstacles to sustainable buildings. Therefore the ongoing maintenance, repair and replacement of the building should also be included in the evaluation process.

Further, embodied energy has not been included in the evaluation process although it is growing in importance. Construction consumes energy in two principal ways. Firstly, it consumes energy through the construction of buildings and related facilities. In general the energy is used to produce building materials and their subsequent on-site assembly at their final destination. Secondly, it consumes energy in the later use of the building and related facilities in the form of heating, ventilation and cooling, lighting, hot water, and appliances and equipment. It is important to assess the building's entire life cycle on the environment including energy consumption embodied in the process of recovery of raw materials and the manufacturing process. Therefore using low embodied energy materials and recyclable materials have become extremely important (Weir & Muneer 1998). The energy embodied in construction can represent up to one-fifth of national energy consumption (Treloar et al 2001) and it is significant because it occurs immediately and the total energy consumed in the production of building materials can be equal, over the life cycle of a building, to the requirements for operational energy (Pullen 2000).

4. Conclusion

The literature review of existing assessment tools and design methodologies has shown a plethora of environmental issues addressed. Study revealed that not all tools have taken account of economic and social parameters. It is evident that a more holistic approach would result in a more pragmatic and operational outcome. It seems that intentions behind the design of these assessment tools are to be guidelines during the design process and as general green assessment rather than as a specific architectural evaluation tool of building performance.

Construction is one of the largest users of environmental resources and one of the largest polluters of the man-made and natural environment. The improvement in the performance of buildings with regards to the environment will indeed encourage greater environmental responsibility and place greater value on the welfare of future generations. There is no doubt that Green Mark contributes significantly to achieving the goal of sustainable development within construction. On one hand, it provides a methodological framework to measure and monitor environmental performance of buildings, whilst on the other it alerts the building profession to the importance of sustainable development.

The questionnaire survey has provided a preliminary investigation on the impact of Green Mark scheme as introduced by the BCA in January 2005. However, Green Mark has limitations as examined in this paper reducing its effectiveness and usefulness. There is a requirement for greater communication, interaction and recognition between members of the design team and various sectors in the industry to improve and promote the use of the scheme. In considering the advantages and disadvantages that the Green Mark Scheme may have, it has come into effect quite smoothly and with continued improvement and updating, it could become one of the most important planning and design tools in the construction industry.

Summary

The increasing concern regarding climate change and the future of the planet has led to the adoption of sustainable construction principles being a globally attractive alternative. Almost every developed country has its own method for environmental assessment of buildings; developing countries have more recently started to follow a similar track. The main objective of this paper is to present a proposal for a sustainable building assessment tool for office buildings applicable from the design stage. To achieve this objective, a checklist was drawn up based on existing environmental assessment methods for office buildings and complementary references. The checklist includes six categories: Land use and occupation; Water; Energy; Materials and resources; Transport and accessibility; and Indoor environmental quality and health. It was evaluated by specialists regarding its adequacy and relevance to the Brazilian context. The checklist was applied to 17 office buildings in a data survey and these data resulted in benchmarks that were used as the basis for the proposed method to evaluate sustainability of Brazilian office projects at design stage. The results were: validation of requisites for building sustainability assessment; evaluation of office buildings located in Florianópolis-SC, southern Brazil; benchmark definition; tool to guide designers towards more sustainable approaches; and methodology to evaluate sustainable office building design.

1. Introduction

Data from the Fourth Intergovernmental Panel on Climate Change Report (IPCC, 2007) show the alterations in the global climate due to human intervention and a projection of what is to come due to the increase in the global greenhouse gas emissions. Among the short and mid-term options the report classifies, with a high degree of certainty, that efficient buildings and a change in lifestyle and population consumption standards can considerably reduce climate change. This highlights the importance of the application of the sustainable development concept to the civil construction industry, since the way in which constructions are designed, constructed and operated directly influences the consumption of natural resources and the comfort and health of the building users. Buildings and civil workplaces are considered the physical products with the greatest useful life that society produces. They modify the nature, function and appearance of urban and agricultural areas. Housing and the infrastructure required for transport, water supply, sewage systems and energy to support the necessities of the increasing world population present a considerable challenge in terms of sustainable construction.

The impact of the construction industry on the environment is well documented (UNEP, 2003; USEPA, 2004; WINES, 2000; JOHN, 2000; IPCC, 2007) and it is clear that this industry is addressing the situation. This impact occurs throughout the production chain: from the conception of a building until its demolition. Design decisions, such as the location of the building, its orientation on the land and the specification of materials and components directly affect the consumption of natural resources and energy, the optimization or not of the building construction and the effect on its neighborhood. Added to this, raw materials are *per si* great consumers of natural resources and energy. Construction generates a great amount of residues, aggravated by the losses in the processes which are not optimized. In the operation and maintenance of a building, there is a high consumption of water and energy and considerable generation of residues. Finally, in the demolition stage more residues are generated in great volumes.

Within this perspective lie the proposals for sustainable constructions, conceived to make rational use of natural resources (materials, water and energy), to provide user comfort, to reduce the costs during the useful life of the building and to modify as little as possible the environment into which the building is inserted. The first point to consider in the search for this type of construction is that the concerns must start at the initial stages of planning and design, continue during the construction and participate in the operation and maintenance stage. The building design (conception) appears as the basic stage, where the agents involved must achieve integrated solutions to reach a high performance of the building during its useful life, considering environmental, social and economic aspects. In this context, the introduction of mechanisms to manage sustainable requisites during the design process represents an important means by which to improve the performance of the building construction sector.

To achieve sustainable constructions, it is necessary firstly to define a reference to establish the criteria used to analyze the inclusion of environmental, social and economic concerns into the conception and execution of the constructions. Currently, almost all developed countries have their own environmental performance assessment system. More recently, some developing countries have also initiated the elaboration of proper methodologies, with the focus on sustainability, that is, weighing up the balance between environmental, social and economic aspects. These include initiatives in South Africa (GROBLER; SINGH, 1999; GIBBERD, 2002), Brazil (SILVA, 2003), Chile (CARVAJAL, 2005), China (LIU *et al.*; 2006) and India (IGBC, 2007).

Despite the existence of several models, Silva (2003) confirms the hypothesis that the existing international models for environmental assessment of office buildings are not suitable for application in Brazil, it not being feasible to simply copy, translate or apply a foreign method in the Brazilian context (or in any another country other than the country where it was developed). Even though the success of foreign methodologies has been verified, the unsuitability of their evaluations to application in Brazil goes beyond the withdrawal or inclusion of requisites, and adaptations are therefore very different from the original methods. This is partly because the majority of the aspects are evaluated on the basis of standards and legislation from the original country. The risks of the homogenization and consequence loss of the regional characteristics of the countries, in these cases, are always present. Therefore, the importation of methods can be detrimental to the environmental progress of the countries where they are being applied, since the methods are inevitably based on the implicit cultural and construction traditions of their original country (COLE, 2005).

Another drawback in this regard is the lack of standards and references related to sustainability in the Brazilian construction industry. The sustainability concept - not always addressed in an objective way – is often used only as marketing instrument. Initiatives that clearly define the performance criteria and parameters of the constructions can raise the sustainable development of a subjective plan to a more effective and realistic level, enabling, from the conception of the project, a reduction in the energy and water consumption, production of residues, and costs during the useful life of the building, along with improved user welfare. Additionally, through the formalization of a sustainable building evaluation methodology it is possible to: a) establish measures of sustainability for requisites in the Brazilian context; b) define sustainable building by the establishment of measured standards; c) seek the integration of all construction designs; d) enhance discussion between engineers and designers in the preliminary stage of the project conception; e) recognize sustainable initiatives in the construction industry; f) increase the perception of the consumers regarding the benefits of sustainable constructions; g) stimulate competition between companies; h) identify wasteful focuses and techniques to eliminate or to minimize them; i) improve the reputation of and confidence in companies that demonstrate responsible actions; and j) eliminate expensive options and reduce the costs of reforms.

2. Objective

The main objective of this article is to present a proposal for a methodology to evaluate the design of sustainable office buildings in Brazil, based on the case of Florianópolis, SC.

3. Methodology

3.1 Analysis of environmental assessment methods for office buildings

Existing methodologies for office building assessment were analyzed, with an emphasis on the design stage, for the identification of its arrangement and the requisites considered. The selected models were:

1. BREEAM - Building Research Establishment Environmental Assessment Method; United Kingdom (BRE, 2006): the first system of environmental evaluation of buildings which served of a basis for other systems;

2. GBTool – Green Building Tool; international consortium (IISBE, 2005): a second-generation environmental performance assessment system for buildings, based on research;
3. LEED - Leadership in Energy and Environmental Design; United States (USGBC, 2006): currently the method with greatest growth potential due to the massive investment that is being made to promote its dissemination and improvement;
4. CASBEE - Comprehensive Assessment System for Building Environmental Efficiency; Japão (JSBC, 2006): inspired on GBTool and based on new concepts such as Building Environmental Efficiency (BEE);
5. Green Star Office Design; Australia (GBCA, 2005): based on existing methodologies such as BREEAM and LEED;
6. NF *Bâtiments Tertiaires - Démarche HQE Bureau et Einseignement*, France (CSTB, 2005): differentiated methodology where the whole project is managed, providing the possibility to adapt the evaluation of the environmental performance to the context of each project, allowing the designs to focus on specific realities and priorities separately from those of the entrepreneurs;
7. SBAT - Sustainable Building Assessment Tool; South Africa (GIBBERD, 2002): first initiative for development of systems for building sustainability evaluation in developing countries;
8. Model considered by Silva (2003); Brazil, that pioneered the work on sustainability evaluation of Brazilian office buildings throughout their lifecycle[1].

3.2 Determination of Sustainable Requisites to Evaluate

Definition of sustainability requirements to be assessed at design stage was based on the analysis of the requisites which constantly appear in existing methodologies (cited in the previous item) and in complementary documents such as standards, legislation, regulations, theses and other Brazilian publications. Such documents were analyzed for identification of the requisites applicable to the Brazilian context, seeking to include environmental, social and economic aspects affected by implementation of a new building development. Requisites were structured in a checklist format for each of the following six categories: 1) Land use and occupation; 2) Water; 3) Materials and resources; 4) Transport and accessibility; 5) Energy; and 6) Indoor environmental quality and health.

3.2.1 Consultation to a panel of experts

To evaluate whether the selected requisites were pertinent to the Brazilian context, Brazilian academics and other stakeholders (architects and engineers), specialists in each category, were approached. All the professionals are involved with the subject of sustainable construction and participate or have previously participated in a design project following LEED specifications[2]. Experts on each category were requested to give an evaluation that consisted of following items:

- Would you include any requisite not covered by the checklist?
- Would you exclude any requisite that, in your view, is not applicable to the Brazilian reality or that does not differentiate a sustainable construction from a non sustainable one?
- Does the measurement form provide an adequate survey of the necessary data?
- Is the standard/reference material appropriate or would you use a different data/info source?

Academic specialists were consulted first, to best calibrate the checklist and proposed metrics and data sources. In case significant changes were proposed, checklists could be updated prior to consultation with technician/market specialists. No great alterations were required though, and the original checklist was sent to the technician specialists. This survey was limited to 16 specialists and, in these authors opinion, the views were very optimistic (the great majority of the requisites were kept).

---

[1] Although already exists this initiative to assess Brazilian buildings, the limits of the system were defined in order to include the construction stage and the building use (some aspects of planning and design are considered, but not in the same level of detail), as well as the evaluation of the agents involved in the process, initiated by the construction company. The suggested model is for application to buildings with occupation above 80% and time of use between 1 and 3 years.

[2] At the time this study was carried out, LEED was the only environmental certification system used in the Brazilian market.

3.3 Data collection for Benchmark Definition

After the inclusion of the considerations from specialists, the final checklist was used for the data survey on the buildings in Florianópolis. Florianópolis is the capital of Santa Catarina state, located in Southern Brazil, at latitude 27°40' south and longitude 48°33' west. The results of the survey served as the basis for benchmarks definition.

3.3.1 Office building sample

Sample definition criteria included typology (office building projects), period of approval (between 2000 and 2005), and size (3 or more storeys, and one or more garage levels). Such criteria were used to screen a report of design approvals issued by Florianópolis Urban and Public Services Secretariat (*Secretaria Municipal de Urbanismo e Serviços Públicos* - SUSP). The resulting sample included 17 buildings and encompassed 11 from the largest construction firms in Florianópolis.

3.3.2 Data collection

Checklists of each category guided data collection. Table 1 shows an example of the requisites included in the Water category.

Table 1 - Example of requisite included in the checklist for the Water category

Req	Requisite	What to evaluate	How to evaluate	How to get the information
Water				
A-1	Potable water reduction	**1.1.** Reduction in potable water used for irrigation	To verify whether landscaped areas are present. To verify the existence of efficient irrigation technologies; usage of rainwater or graywater for irrigation; lack of permanent installed irrigation system. If applicable, calculate the percentage reduction in the use of potable water for irrigation.	Design analyses/ on-site verification

Data collection consisted of: design analyses, interviews with designers, constructors and buildings managers, calculation and recording of variables. Obtained data were recorded on auxiliary spreadsheets, carefully designed so that all information required to evaluate the requisite was identified and registered (Table 2).

Table 2 - Example of checklist auxiliary spreadsheet to record collected data

WATER

A-1. Potable water reduction

A-1.1. Reduction in potable water used for irrigation

Are there landscaped areas on site?			Yes ( )	No ( )
If affirmative:	Are they native landscapes?		Yes ( )	No ( )
	Are there irrigation systems installed?		Yes ( )	No ( )
	If affirmative:	Is high-efficiency irrigation technology in use?	Yes ( )	No ( )
		Describe:		
	Is there on-site rainwater collection for irrigation?		Yes ( )	No ( )
	Is there on-site water recycling for irrigation?		Yes ( )	No ( )
	If irrigation is carried out using rainwater or recycled water, calculate the percentage of potable water reduction for irrigation:			

3.3.3 Analysis of results and benchmarks definition

On analyzing the data collected through application of the checklist it was possible to observe the requisites that already constitute market practices, those that were recently added to some buildings and those not addressed by any of the studied cases. According to the assessed requisites, building performance was classified according to three levels:

B – Good, current practice or minimum performance required for a sustainable construction;

I - Intermediate performance;

S - Advanced performance in relation to current practices, which can be achieved using existing practices and technologies.

In this work, authors decided to experience a three-level performance scale for benchmarks (similar to HQE) as the definition of a more detailed performance scale (as in GBTool and CASBEE) would be more complex and require higher amount of data, unavailable at the moment.

From the data collection results, and researching standards, legislation and specific literature, benchmarks were then defined. Due to the lack or outdating of some standards, and in the absence of local or national parameters, benchmarks recommended by the international methodologies analyzed were applied.

Besides the evaluation criteria that defined levels B, I and S, mandatory criterion were determined, in relation to legislation and standards currently enforced. Such criteria are mandatory in any building, but were included as sustainability criteria and the results of the data collection showed that they were often ignored or disrespected.

3.4 Proposal for the Evaluation Methodology for Sustainable Office Building Design

The presentation structure of the proposed methodology is summarized in Table 3:

Table 3 - Sample for presentation of the proposed methodology

X. CATEGORY		**Level**		
		B	**I**	**S**
X.1 SUBCATEGORY				
X.1.1 Performance requisite				
indicator	level B criterion	**B**		
	level I criterion		**I**	
	level S criterion			**S**

The mandatory criteria are presented according to the example in Table 4.

Table 4 – Sample for mandatory criteria presentation

X. CATEGORY	
X.1 SUBCATEGORY	
X.1.1 Performance requisite	**Mandatory**
mandatory criterion	

To complete the methodology, factor like target for application, evaluation timing and results presentation format were defined.

4 Results

4.1 Definition of Requisites for Evaluation of Sustainable Office Building Design in Brazil

The set of requisites defined for data collection was sufficient to cover, if not all, most main questions related to sustainable constructions. Definition of the requisites and their validation by the specialists resulted in checklists and auxiliary spreadsheets for data collection. Such tools are expected to allow for good repeatability of the method used in this study when applied in other evaluation contexts, either at whole building level or at specific aspects. Development of a reproducible method, besides facilitating other data collection ventures, will assist in the definition of new performance parameters and the recognition of the particular characteristics of each region, allowing the definition of performance parameters that better represent the national reality.

4.2 Implementation and Validation of the Requisites in Data Collection

The data collection carried out for 17 office buildings allowed the validation of the essential requisites for sustainable office constructions. From evaluated requisites, energy efficiency should be highlighted as this study applied for the first time the methodology of the Regulation for Energy Efficiency Level of Commercial, Service and Public Buildings (BRAZIL, 2007) and tested its ease of application. In a general way, it was verified that interpretation and application of the Regulation's text was sufficiently clear. Results from this experience based updating of the regulatory text.

4.3 Evaluation of the Panorama of Florianópolis Office Buildings regarding Sustainability

Data collection results provided a current panorama of office buildings in Florianópolis regarding sustainability. In a general way, it could be perceived that the constructions fell short from the performance expected. Even mandatory requisites are, in some cases, disregarded. Resolution 307/02 of CONAMA (regarding disposal of the construction and demolition waste), Resolution 09 from ANVISA (that fixes the indoor air parameters in mechanically ventilated buildings) and Standards NBR 9,050/04 and NBR 13,994/00 (regarding accessible design), for example, are generally disregarded, even though they are basic requisites for any construction.

It was found that some requisites, although their positive impact on the environment is public knowledge, is still not market practice and was not taken into consideration by any of the studied buildings, for example, the existence of facilities for the adequate collection and storage of recyclable materials. Moreover: some requisites were actually applied not because of their environmental or social impact, but rather due to low cost or availability of specific items and materials in the marketplace..

Requisites such as the organization and protection of water systems, the use of water-saving devices, specification of materials in conformity with technical standards and use of certified wood had been incorporated into the local construction business.

Some good examples were also observed, representing performance practices superior to the typical construction market in Florianópolis. Amongst them can be cited the development of a Study of Neighborhood Impacts; the use of the rainwater for sanitary flushing and the analysis of suppliers for specification of environmental-friendly materials.

4.4 Definition of Performance Parameters to be achieved in Sustainable Buildings

The results obtained in the Florianópolis office building evaluations were the main reference for the definition of the performance parameters. In cases where the results of the data collection were not sufficient for the basis of a definition, additional information was obtained from specialists, standards, Brazilian publications and benchmarks used in international methodologies which fitted the Brazilian reality.

Silva (2007) states that the creation of a benchmark database for each indicator is fundamental in order to provide meaningful evaluations and to mark out the limits for the establishment and updating of sustainability goals. Benchmarks reflect local construction standards and can vary according to the regional context. Therefore, to obtain national indicators, data collection must be carried out in several locations in order to identify the regional differences and suitability of the performance parameters of each requisite for the context into which they are inserted. The definition of benchmarks in this study contributes to filling the gaps in Brazilian research, to be complemented by a collective, coherent and constant research effort to keep it disclosed and up-to-date..

4.5 Establishment of Criteria for a Tool to guide Designers in the Development of Sustainable Design

During the interviews it could be noted that some constructors and designers are unaware of certain requisites related to sustainable construction and the reason for their inclusion. Moreover, it was observed that, either due to misinformation or opportunism, some constructions address one or another requisite in order to appeal to the marketing of "environmentally responsible constructions". One positive point observed is that all the interviewees demonstrated great interest in the subject of the research and requested feedback at the end of this study. Thus, it can be concluded that the clear definition of sustainable requisites will provide an important guide to aid constructors and designers to incorporate them into projects and will define objectively what a construction must achieve in order to be considered sustainable.

4.6 Proposal of a Methodology for Evaluation of Sustainability of New Office Building Designs in Brazil

The main objective of the study was achieved with the proposal of a methodology to evaluate the sustainability of new office building designs in Brazilian, whose benchmarks are suited to Florianópolis, SC. The method here considered illustrates in a sufficiently clear and representative way the building performance achieved.

The structure chosen – inspired by the French HQE approach - and the criteria based on performance levels - where all the constructions must present at least one basic performance - were adjusted to the Brazilian reality. Due to the number and wide-ranging particularities considered by the French methodology, the authors believe that, from the models currently available in the Brazilian market, this model could provide a more appropriate assessment of sustainability performance of buildings. Suitability of such approach is also being investigated for residential constructions.

In order to demonstrate the application of the proposed methodology, the performance obtained for three of the evaluated buildings is presented in Fossati (2008). In that work, all the guidelines for methodology implementation were traced, from the application target to the presentation format of the final evaluation results.

5 Conclusions

In the carrying out of this study it could be noted that a reduction in the impact of the civil construction industry and the achieving of more sustainable buildings are not simple tasks and require agreed and simultaneous actions covering diverse topics. However, the authors believe that, in a near future, the consideration of sustainability will be a primary requisite for engineers and architects, as are other technician requisites such as structural, fire and user safety, for which the majority of standards guide the designers in the generation of adequate solutions.

Concerning initiatives related to sustainable constructions in Brazil, this has been summarized by Silva (2007) who states that Brazil has already made some effort to establish sustainable indicators; however, these vary widely and are defined by criteria and methodologies which are not necessarily replicable, and that for the country to advance in the development of sustainable indicators it is necessary to: define a consensual methodology to structuralize indicators; collect data; define national indicators, and become aligned with international trends, as well as produce a block of local indicators in each case; to measure or to attribute values; and to interpret and, eventually, add indicators. A robust database must be created and kept up-to-date and be widely accessible.

The research presented in this paper offers an important contribution in the development of sustainable constructions in Brazil, presenting a replicable methodology; carrying out of data collection; defining requisites aligned with international methodologies and initiating the formation of a database. It can also contribute to other developing countries in the development of their own research and reproductability of the method can facilitate data collection needed for the definition of performance parameters and recognition of the particular characteristics of each region.

Keywords: Sustainability Assessment, DesignBuild Procurement, Decision-making

Summary

There is now widespread popular awareness that on local, national and global scales buildings have very significant and increasing environmental impacts. In response, industry stakeholders are seeking to adopt sustainability decision-support tools that are needed from early project initiation, concept design to detail design, construction and post occupancy. But even with new advanced tools emerging it is still very difficult to deliver the technical as well as practical information needed to support cost effective holistic decisions. There are a broad range of stakeholders involved and an industry sector cultural resistance to advanced information and communication technology.

The Australian Cooperative Research Centre for Construction Innovation has developed and trialled novel decision-support tools for Architectural, Engineering, Construction Property and Building practitioners. One such tool LCADesign, with a rapid take off from 3D Computer Aided Drafting models was developed to automate assessment of building environmental costs. While LCADesign has been tested in Australia, Holland California and Germany the focus of this paper is to describe lessons learned in 2 trials in Holland including on the new KPMG Commercial Office building Slavenburg BV delivered in Rotterdam.

The paper outlines how this tool works and has been applied in Dutch pilots along with DesignBuild procurement strategies applied to integrate effort to deliver more sustainable building. Issues met, new approaches tested and lessons learned in these pilots are discussed and recommendations for future management approaches are presented.

1 Introduction

Along with community concern about induced climate change, biodiversity and habitat loss stringent government environmental legislation on development applies in most modern jurisdictions worldwide. The Intergovernmental Panel on Climate Change (IPCC) (2007) attributed the world's hottest climate on record this last decade to greenhouse gas generation mostly from fuel use in operations to generate electrical energy. Countries reliant on fossil fuels in electrical power generation are major contributors to such climate change especially from buildings. Building operations, for example, account for;

- 40% of all energy consumed in Europe according to S Sattery (2005);
- 35% in America (Organisation for Economic Cooperation and Development (OECD) (2003)
- 25% in Japan according to the United Nations Environment Program (UNEP) (2003).

The World Business Council for Sustainable development (WBCSD) 2007) has stressed that delivery of more sustainable outcomes is driving uptake of new Architecture, Engineering, Construction (AEC) Property and Building solutions. Brandon and Hampson (2004) reported that the top global trend identified by AEC stakeholders was sensitivity to sustainable development which will be enabled by uptake of advanced information and communications technology (ICT). Scuderi, Jones and Watson (2005) also found a broad spectrum of stakeholders seek more user-friendly and integrated eco-profiling tools.

To equip industry moves toward sustainable development and uptake of enabling ICT, the Australian Cooperative Centre for Construction Innovation (CRC CI) initiated development of novel building eco-profiling software reported in Tucker et al (2003). To leverage uptake of sustainable development improved project contracting and management practice solutions are also emerging.

The purpose of this paper is to discuss a Dutch pilot of automate building environmental assessment software. It seeks to show LCADesign (Life Cycle Assessment of Computer Aided Design) software capabilities along with approaches to integrate effort and facilitate such ICT adoption in project delivery and to discuss market research related to uptake of LCADesign.

2 Green Building Market Strategic Analysis

2.1 Demand Trends

Five years ago, the OECD (2003) reported that many global industry groups were calling for more integrated sustainable energy responses. The Australian Environmental Labelling Association (AELA) (2004) then reported 80% of people buying environmentally preferred products. According to AELA (2004) Government and consumer preference for minimum energy, water and pollution was driving demand for green building benchmarks in Australia.

AELA (2004) and Scuderi et al (2005) both found that despite a lack of objective information consumer demand was forcing greener market responses. Scuderi et al (2005) also argued that instruments in government environmental policy and regulation were increasingly strong market influencers.

Jones et al (2006) found consumer demand for more sustainable development initiatives coupled with the buying-power of Government and Community green procurement initiatives constituted the main market influencers in Australia. Now the IPCC (2007) climate change warn there is an urgent global need for much more sustainable development of stationary and transportation energy infrastructure. And the WBCSD (2007) reports that client demand for increased renewable content in energy supply is increasingly high globally.

As to the key green building market drivers on a global scale the UNEP (2003) pointed to alliances of local Governments working on the United Nations Agenda 21 while the WBCSD (2007) points to the work of the International Green Building Council (GBC).

2.2 Barriers to Building LCA

Sarja (2002) found very significant building environmental impacts are common on internal, local and global scales and LCA was the best method to asses them. He concluded that delivery of more sustainable buildings required timely, cost-effective LCA for whole of building life decision-making.

Grant (2004) found lead industry players recognise that LCA was needed to provide quantitative eco-profiles to inform decision-makers in supply, design and procurement. However, despite the many green design tools Watson et al (2004) found few AEC practitioners use them routinely as most fail to deliver relevant information needed to support broad stakeholder engagement essential for more sustainable project delivery. They also argue that conventional ICT for building LCA has severe time and cost limitations as most are reliant on:

- subjective rather than objective, transparent or quantitative measurement (Seo 2002);
- no data input from or interactivity with Computer Aided Design (CAD) (Tucker *et al* 2003);
- tedious manual data entry to calculate outcomes in spreadsheets (Grant 2004);
- incorporation of subjective and often contentious or poor information (Mitchell et al 2005) and
- much new technical language for project teams to assimilate (Huysmans *et al* 2007).

Huysmans et al (2007) recently reported that stakeholders need capacity to deliver rapid, comparative quantitative building assessments of "what if" scenarios to assist decision-making.

3 Advanced ICT for Automated LCA

Advanced ICT now used in all modern CAD tools offer users very significant time, cost advantages (Watson et al (2004)). The CRC CI exploited such ICT to deliver novel building software to meet core market demand for real-time, cost-effective LCA for building environmental appraisal from concept to detail design. The main aim of this LCADesign software was to avoid manual transcription of data in assessments reliant on ISO 14000 Environmental Management Series (EMS) methods for LCA, Life Cycle Inventory (LCI) and Life Cycle Impact Assessment (LCIA).

The software uses industry foundation class (IFC) global data transfer protocols to access and view element volumetric, spatial and specification data embedded in three dimensional (3D) CAD files. In addition to automated take-off from BIMs IFC protocols allow software interoperability as e.g. in other CRC CI developed software tools to automate planning, scheduling, quantity survey, checking and specification applications. Automated take-off from such building information models (BIM) files allows LCADesign users to quickly conduct whole building LCA (Tobias and Haymaker 2007).

The CRC CI has trialled LCADesign in real world pilot projects in Australia, The Netherland, California and Germany in partnership with commercial providers, since 2005. The Dutch pilot tested an LCADesign prototype that accounted for resources, energy and pollution associated with operations from acquisition, refining, manufacture, transport and assembly to construction plus maintenance and replacement phases considering renewal schedules. The new version commercialise late in 2007 conducts operational energy and water LCA as well.

3.1 What LCADesign Does

LCADesign integrates outputs of global standard:

- BIMs used in modern design documentation practice;
- life cycle costing for economic prices and schedules considering service life;
- ISO 14000 EMS LCA methods for improvement assessment;
- LCI databases of national building industry supply chains and
- EcoIndicator-99 LCIA methods to calculate mid-point damages and impacts.

The software factors BIM volumetric data with rules defining design element compositions and densities, LCI results and LCIA algorithms to produce a 4^{th} D, an ecoprofiling dimension: via LCA of building models. Results can be as LCI, EcoIndicator-99 defined damages and impacts as well as single point scores. Users may choose standard and eco-preferred selections or develop new rules linked to extensive LCI datasets. Figure 1 depicts how it works as users:

1. create and import a CAD mode saved as an IFC file into LCADesign;
2. tag objects by group type and apply reasoning rules to link tags with material inventory;
3. select metrics to calculate LCA results and display environmental impact
4. compare selected and eco-preferred options to show improvements.

LCADesign produces eco-profiles in charts of relative intensity per square metre floor area (M2) for e.g. walling and fenestration to compare intensities of resource input and pollution output LCI, plus carcinogens, climate change and fossil fuel impacts as well as damages to human health, ecosystem quality and resource depletion. It also calculates an eco-point score normalised to average per capita annual impact. With such indicators users can view and apply changes to reduce particular or total score or drill down through breakdowns of results in exportable tables and charts.

For example Figure 1.4 shows LCADesign of 35 year old 7668 m2 offices in Melbourne, Australia made of reinforced concrete slabs, beams and encased steel columns with steel edge beams (Seo et al 2004). The column chart shows floor finishes associated with highest embodied resource depletion. This was from four new installations of renewable sheep wool pile jute fibre hessian-backed carpet over 35 years but with carbon sequestration completely offsetting the building shell’s climate change impact.

4 Dutch LCADesign Pilot

Slavenburg BV, a Dutch company piloted LCADesign in the Netherlands on a new 25,000 m^2 gross floor area office building with a 13,000 m^2 semi-basement car park for 1000 office workers in Rotterdam. The client for this pilot was KPMG, an international audit, tax and advisory services company. To deliver the best value proposition for budget and add value from integrating design & construction disciplines KPMG applied a new procurement strategy using a DesignBuild rather than traditional tendering.

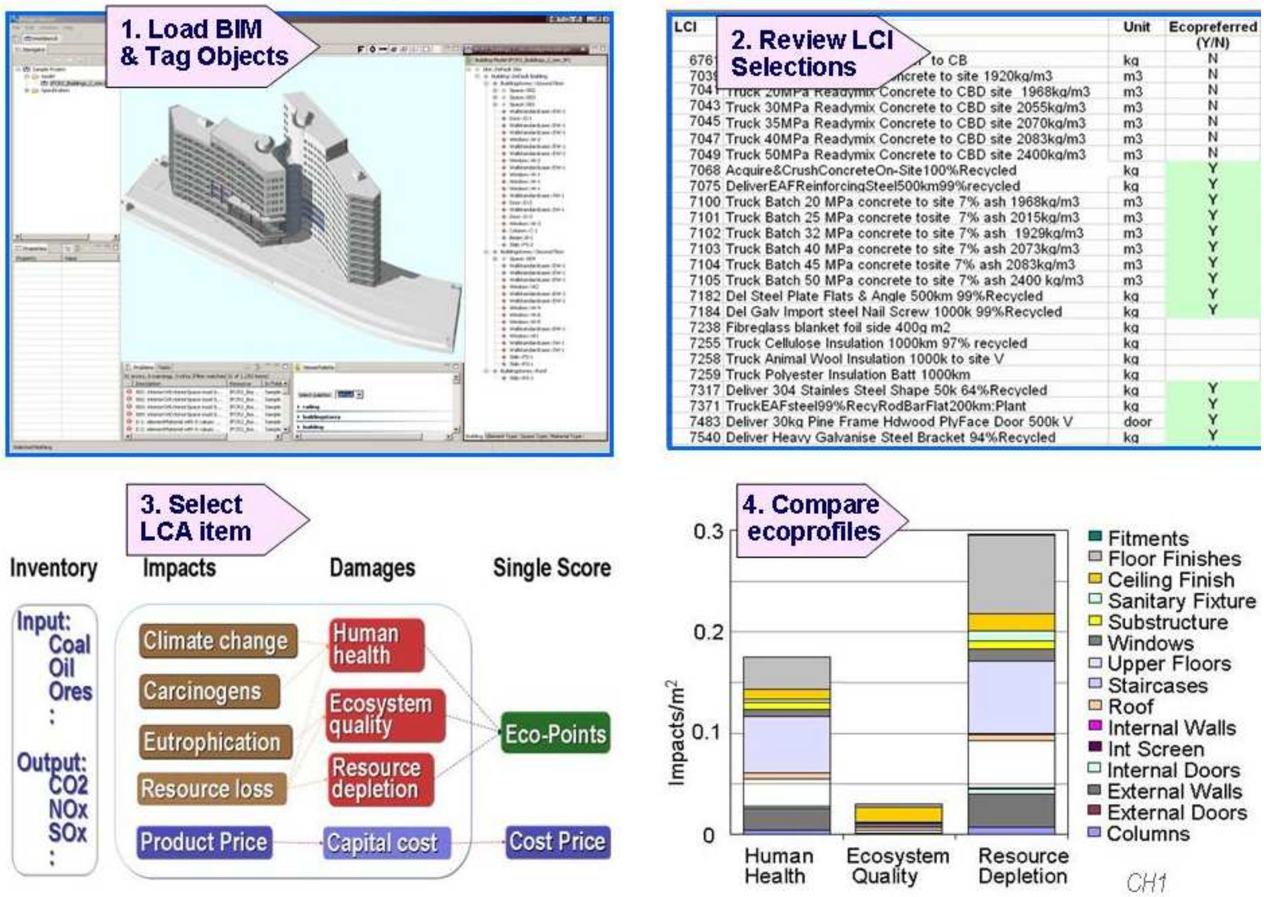

Figure 1 Four steps in LCADesign

4.1 Procurement: Design Build Versus Traditional

Traditionally design and construction are distinctly separate stages when a client's architect designs and documents a brief and tenders for a contractor whose bid is selected usually on price. In DesignBuild projects are tendered on preliminary design with room for bidding parties to add value to the proposition. For sustainable building it contractually provides one point of responsibility for project delivery plus integrated:

- project management of otherwise fragmented processes, and
- decision-making to leverage economic and environmental cost savings.

Another advantage is that with such contracts contractors can apply their sustainable building knowledge to integrate effort from design concept and detailing through construction scheduling and BIM applicable in Facility Management and disposition. While WBCSD (2007) reports stakeholder consider investment in sustainable building is too expensive, Huysmans et al (2007) argue that integration can save costs when contractors invest in sustainability measures right from project initiation through building delivery to handover.

4.2 Pilot Analysis Results

At the time of the pilot the Dutch real estate market was not strongly driven to conduct full building LCA as it was considered a research tool rather than a building tool. In fostering innovation, it was more feasible for Slavenburg BV to conduct an LCADesign Pilot. as they lead the KPMG project and could integrated effort fully throughout the project. The pilot compared a Dutch-developed GreenCalc spreadsheet tool against the Dutch version of LCADesign with GreenCalc analysis on three Dutch reference buildings by TU Delft compared to LCADesign of substructure, structure and inner floors and walls.

In the KPMG project pilot the building shell and interior structural elements from underground garage to level 14 were analysed by level. Figure 2a show level 1 with highest damages to resource depletion, ecosystem quality and human health from in situ slab and beam cast concrete floor elements. Had >95% recycled steel electric arc furnace rather than basic oxygen furnace steelmaking route 8% scrap steel been available for this high strength low alloy steel application it would avoid the extra damage.

Figure 2b shows contributions of embodied water and greenhouse gas to the Eco-Indicator 99 point score where inner upper floors have higher embodied water and greenhouse gas. Roofing had high embodied water from steel coil rolling, quenching and finishing operations.

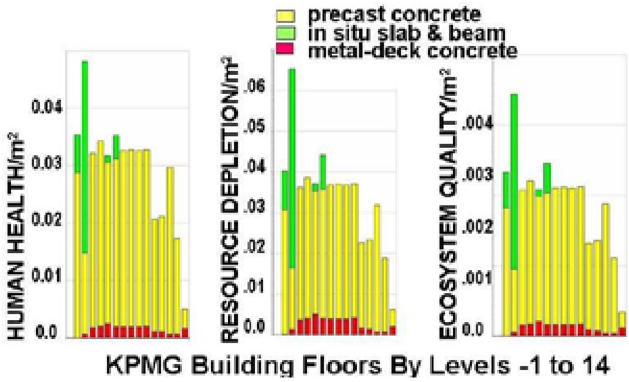

Figure 2a Shell Concrete Impacts by Level

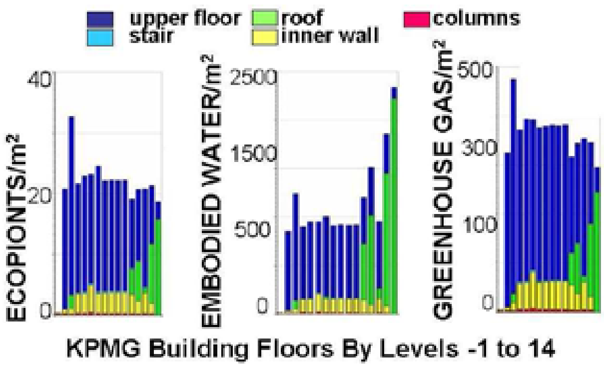

Figure 2b Internal Element Impacts by Level

4.3 Issues Arising during the Dutch Pilot

Slavenburg was responsible for building design, production and delivery so once the commitment was made it was feasible to produce a BIM. Producing one entails more effort in the earliest design stage to derive many benefits later in concurrent engineering, 4D construction modelling and in facility management phases (Huysmans et al 2007).

Traditionally with different partners responsible for different parts of the whole construction process, it is most difficult to develop and apply such integrated tools. From the outset of the pilot the Dutch construction sector was found to be underdeveloped in BIM capability to support design and construction companies in Architecture, BIM development as well as Scheduling.

Because Dutch architects are rarely given the time and money to produce elaborate models was one reason why Slavenburg found lacked experience in producing BIMs for the LCADesign pilot. Nevertheless a new BIM was produced from scratch separately by an architect in Melbourne Australia. So the dominant and traditionally fragmented procurement approach with different liabilities and responsibilities had created an adverse climate for BIM development.

During BIM development barriers arose including stakeholder aversions to advanced ICT, iterative processes and client involvement. There was scepticism that advanced ICT could be reliable, accurate and add value to project delivery processes, communications or workflow.

Project partners prefer not to handover preliminary designs and have them resurface later as the architect responsible and liable for detailed design models strictly control exposures. But a good LCA in design development depends on being able to change it on lessons learned. So project partners need to anticipate, enable and control an iterative process. The LCADesign pilot was a very ‘open’ and ‘honest’ way to assess design on environmental impacts but project teams fear openness as clients may make more changes that interfere with and delay schedules.

4.4 Key Learnings

From the inexperience, delays and aversions the project partners determined that the local industry needed to learn more about and adapt to BIM development. They also suggest that in future project partners needed to become more confident about increasing reliance on ICT where the program does the work. Delays in developing the BIM meant LCADesign analysis was already too late to influence most design decisions.

Nevertheless the pilot study showed the partners how to further improve building performance and Slavenburg has since completed a second LCADesign pilot on another new building in design development.

5 Global BIM Drivers, Obstacles and Advantages

Jones et al (2006) BIM find uptake is set to increase building design, construction and management productivity and quality. Building information modelling delivers a continuous flow of high quality, reliable, integrated and fully coordinated information on project design scope, schedule and cost concerns with:

- Valuable design information and data in digital easy to update, share formats;
- Consistent real-time relationships between digital design data and parametric models.
- Models exploited throughout design, construction and management of building lifecycles.

An Autodesk (2004) poll found ICT was changing business and professional practice with.

- More clients expecting more sustainable intelligent integrated buildings, automated performance and more advanced professional service delivery.
- A shift toward design-build and integrated service delivery with speedier collaboration, virtual project teams and management, stronger collaboration creating more sophisticated service delivery.
- Calls for simultaneous rather than sequential decision-making processes with collaborative services and new design authoring tools focused on enhancing process.

Significant leadership challenges are presented with significant change required to shift entrenched thinking and behavioural patterns in industry providers. Multidisciplinary providers in architecture, construction and real estate organisations and champions are to drive these changes forward. Building owners, however, may become primary drivers of change to recoup advantages in intelligent facilities (Jones et al (2006)).

As a design, delivery, and management approach BIM offers new data-driven models and building lifecycle management solutions facilitating a design firm’s capacity to do building and sustainability performance analyses in-house. Benefits include:

- Provision of integrated coordinated models and visualisation of the end product in 3-D,
- Helping clients visualise future buildings and scheduling in project delivery,
- Interference detection prior to construction which reduces waste and errors, and
- Accessible information for more-accurate early-pricing and better management (Jones et al (2006)).

Owners are increasingly demanding and paying for digital models. When models are used effectively, architects can employ a project's digital design data to provide new services including move management, energy analysis, digitally integrated cost estimating and renovation phase planning for additional fees and gain new sources of income.

5.1 Technologies Involved

In modern design and documentation software BIM is established and used to simulate building elements as 3D objects volume and space in a geometric building modelling environment, to generate 2D documentation and extract object data to provide information about element quantities and properties. LCADesign requires such an object model of drawn objects, tagging of element functions, attribution of accurate quantities to objects and application of generic or creation of new formulas and rules that define all groups of objects and composition of all product types in the building that are to be analysed.

BIM technology helps coordinate various building representations in documentation and as it is data-rich data its functionality can extend into building information modelling. Being CAD-based it can be easy to implement and yield immediate benefits with little or no process change. Effectiveness is contingent on user discipline and reliability and it cannot ensure high-quality, reliable, integrated and fully coordinated information needed for highest levels of building information modelling benefits (Jones et al (2006)).

5.2 Benefits In Design, Construction And Management In Use

In the traditional design phase untimely changes to work scope, schedule and costs waste time and money during a project. With building information modelling more critical information is immediately on-hand so decisions can be made more quickly and effectively. Project teams are able to:

- Make changes in design or documentation without re-coordination and manual checking;
- Do all design and documentation work concurrently;
- Automatically coordinate change consequences to eliminate mistakes and improve work, and
- Create visualisations and regulatory approval documents for faster better work outcomes.

In the construction phase by exploiting building information modelling then data on quality, schedule, and cost is concurrently available. The builder can accelerate quantification of building elements and activities for estimating and value-engineering purposes and update estimates and schedules.

The consequences of proposed or procured products can be more easily studied and understood, so the builder can quickly prepare plans showing site use or renovation phasing for the owner which communicates and minimises the impact of construction operations on the owner's operations. Better document quality and construction planning also means that less time and money is spent on construction process and administration issues and more of the owner's construction dollar goes into the building than into administrative and overhead costs.

In the management in-use phase such building information modelling can deliver concurrent information on building usage, performance; occupancy, contents, performance life and financial aspects over future times including:

- Digital records of renovations and improve move planning and management.
- Acceleration and adaptation of standard prototypes to site conditions in large estates.
- Physical data on finishes, tenancy assignments, furniture and equipment inventory.
- Financial data on lease-able areas, rental income, cost allocations for management.
- Consistent access to information to improve revenues and cost management (Jones et al (2006)).

6 Green Development

From 2008 new EU legislation on building energy use will apply an Environmental Product Data Management (EPDM) standard to assess the energy-use of buildings. With the current Dutch EPDM standard most new buildings built under current legislation will get the highest score 'A' rating so it will only improve building sustainability if partners go beyond 'A' ratings. To improve such outcomes one imperative is to further develop and exploit the sustainable building business case facilitated by tools like LCADesign. Mapping LCADesign to ratings such as the Australian GBC GreenStar USA GBC LEED systems is underway. Members of the Dutch and Australian construction industry also need to make the different quality of more sustainable buildings transparent and to pressure developers, contractors, architects and investors to show stronger progress.

7 Conclusions

The paper discussed a Dutch pilot of LCADesign, new CRC CI software that automates building environmental assessment. Experiences were discussed from a Dutch DesignBuild procurement strategy to integrate effort and pilot novel approaches to support practitioner decision-making for sustainable building. Barriers found included some aversions to ICT, iterative processes and client involvement. The Dutch construction sector was found to be underdeveloped in ICT to support the business and partners found industry needs to adapt to BIM development.

The authors discussed how LCADesign can provide quantitative dimensionally relevant building environmental assessment effectively, quickly and cost effectively. The paper also outlined an emerging business case for adoption of LCADesign based on meeting the need for fast country-specific user-friendly quantitative eco-profiling software to assess specification, procurement and design. The main benefit of LCADesign is the ease of deriving dimensionally relevant eco-profiles without re-entry of data as it allows:

- rapid analysis with data already in the software used to calculate eco-profiles;
- users to almost eliminate error from manual data entry, and
- re-analysis of altered designs to optimise eco-efficiency.

In striving for a more environmentally sustainable construction industry, ratings and real estate it is important to adopt new approaches to facilitate integrated project management and ICT so developers, contractors, architects and investors can better work together. Recommendations for further industry development include that procurement and design should increasing specify delivery of building information model with industry foundation class software to uptake the advantages from BIM.

Keywords: assessment, building performance, energy, economics.

Summary

ITC-CNR carried out a specific energy retrofit case-study which includes the assessment of the environmental and energy sustainability of a building and the support to the definition of construction and technological solutions with low environmental impact involving the application of RES systems integrated into the building.

This case-study consists in the assessment of the energy, environmental and economic performances of a residential/commercial building design located in Northern Italy, conducted by ad hoc assessment tools, such as SBTool (assessment in a holistic approach), PHPP (energy analysis) and RetScreen (RES application feasibility study), aimed at pursuing the "best practice" solutions in a specifically defined performance scale, supporting designer's activities.

Costs analysis were also lead in order to prove that the solutions presented affordable investment costs and remarkable advantages on the energy efficiency and indoor comfort. The developed analysis related to the extent of the main renovation interventions investments on the envelope and systems, the relative simple payback times, the externality costs of the interventions and the LCC analysis of the applied technological and constructive solutions.

The case study allowed to verify the possibility of bringing a zero level building close to the best practice level by applying efficient technical and economic solutions.

1. Methodological approach

The energy-environmental performances of the building design were assessed by means of SBTool (the GBC system tool). The assessment was based on the calculation of a certain number of performance indicators relative to the building, divided into categories and assessment areas, which were assigned a score.

Each score was calculated according to laws and regulations in force or to the methods described in the technical-scientific literature, at times with the help of ad hoc calculation programs such as PHPP [3], for the heating primary energy requirement and RETSCREEN [4] for the energy contribution from renewable resources; scores were assigned by comparing the calculated indicator values with those of the relative performance scales, defined in advance. Once the building was evaluated, the analysis of the performance indicators scores led to hypothesize improving interventions aimed at enhancing its energy-environmental performances with better regard to the criteria which have recorded the worst scores. After bringing about the foreseen modifications, the energy-environmental performances of the new building design were newly assessed to demonstrate they had improved: in fact the objective of the interventions was to bring the building sustainability level to the "best practice" score (level "3").

1.1 SBTool

SBTool was contextualised for the verification of the environmental sustainability of a building (or a project) through a series of steps listed as follows:

1) <u>Definition of the "assessment checklist":</u> selection of the criteria for the energy-environmental assessment of the building. Regarding typology, intended use and life-cycle of the building the most convenient criteria are chosen in order to determine and assess its energy-environmental performances (SBTool

suggests a maximum number of 145 criteria but the person in charge of the assessment can modify the system by choosing the number of criteria that best suit his needs).

2) "Weighting": assignment of relative weights to the single criteria. In consequence of the evaluation of building construction type and general context (State, Region, location…), the criteria are assigned different important degrees so that they can contribute to different extents to the definition of the final result.
3) "Benchmarking": definition of performance values scale (benchmarks) for each performance indicator. The benchmark scale is defined relating to the building energy-environmental performance criteria from a base level to a best practice level, to which compare the different technological and construction solutions of the building to be assessed.
4) "Assessment": assessment of the design solutions with respect to the pre-defined benchmark levels. Each criterion gets a score by comparing the performances of the building that has been assessed with the formerly defined benchmark values.
5) "Rating": final score calculation of the building environmental sustainability level by aggregating and weighing the single criteria assessment scores.

SBTool is composed of six connected files in worksheet format, each of which has to be filled in by the actor concerned. The assessment involved the following three actors:

- designer: his task is to derive and enter the design input data into the tool in order to proceed with its sustainability assessment;
- person in charge of the assessment: his task is to check the input data accuracy and adjust criteria weights according to the design typology;
- third party (i.e. public administrator): his task is to fix the benchmark values and all the parameters which concern the intervention context (i.e. weather data location).

The design assessment is based on the weight of the different parameters which are ordered in groups and characterized by a progressive subordination relation one another: criteria, categories and assessment areas. At each level the assessment scores vary in a range from –1 to a maximum of 5, defined as follows:

-1 represents a performance below the standard and the current practice;
0 represents the minimum acceptable performance level defined by laws and regulations in force, or if no reference standard applies, it represents the current practice;
3 represents a significant improvement over current standards and practice, it's considered as the best current practice;
5 represents an experimental considerable improvement with respect to the best current practice

The scores assigned to each criterion are weighted and aggregated to define the scores of the categories which are in turn weighted and aggregated to define the scores of the assessment areas; the weighting and aggregation of these last scores give the building final score.

2. Description of the case study

The design to be evaluated with the assessment tool formerly described is the executive design of a building, named Porta Mulina, located in a sub-urban area in the North-west of the city of Mantova, in Northern Italy. It is a three-floor building with different intended uses: car park (in the basement – below grade), commercial area and dwellings for families and students.

It is located in a developing suburban area characterised by an intensive building trade and with the following features:

- presence of a lake;
- presence of historical value buildings together with new service building complexes (university, hospital, etc);
- location in a village on the outskirts of the city and linked to it.

The building has a net surface of 2,457 m^2 (excluding car park) composed of a commercial area located on the ground floor and a residential area of 24 housings located on the three above-ground floors; this last area is basically divided into two parts: the Northern side where the family dwellings are located and the Southern side dedicated to students housings.

It is also provided with a basement car park (below grade) and an external parking area, which is going to be integrated with green areas.The building is fitted with a gas-powered heating system which supplies heat through steel baseboards. The number and disposition of hot-water and heating boilers can vary depending on to the building intended use: in the students dwellings there are two boilers on each floor (one every three housings), the family dwellings have an independent heating system while the commercial area has a central heating system.

Figure 1 First floor plan

Figure 2 West prospect

2.1 Building design assessment

The building environmental sustainability assessment was led with SBTool considering the following assessment areas: Site Selection, Project Planning and Development, Energy and Resource Consumption, Environmental Loadings, Indoor Environmental Quality, Service Quality, Social and Economic Aspects.
The six assessment areas were chosen among the seven areas proposed by SBTool: areas B, C and D are compulsory to perform the assessment while the others can even not be included in the evaluation. Weights were assigned basically by adopting the default values suggested by SBTool and adapting them, where necessary, according to the design needs. Each area is divided into categories and each category into criteria. For the purpose of the case-study twenty criteria were examined; they are listed in the following table together with their relative weights. Criteria can be quantitative, then associated to a numeric indicator, or qualitative, then related to a scenario.

The benchmark values of the performance scales relating to which scores are assigned to criteria, categories, assessment areas and to the building, were defined according to certified and recognized methods referring to laws and regulations in force or, if lacking, to updated specialized publications. In some cases SBTool default values were used.

Table 1 Evaluation criteria

	CRITERIA		WEIGHTS within group
A	**Site Selection, Project Planning and Development**		**4.8%**
A1	Site Selection		0.0%
A2	Project Planning		50.0%
	A2.1	Feasibility of use of renewables	60.0%
	A2.7	Collection and recycling of solid wastes in the community or project	40.0%
A3	Urban Design and Site Development		50.0%
	A3.3	Encouragement of walking	60.0%
	A3.4	Support for bicycle use	40.0%
B	**Energy and Resource Consumption**		**23.8%**
B1	Total Life Cycle Non-Renewable Energy		38.5%
	B1.1	Annualized non-renewable primary energy embodied in construction materials	25.0%
	B1.2	Annual non-renewable primary energy used for facility operations	75.0%
B2	Electrical peak demand for facility operations		0.0%
B3	Renewable Energy		38.5%
	B3.2	Provision of on-site renewable energy systems	100%
B4	Materials		0.0%
B5	Potable Water		23.0%
	B5.2	Use of potable water for occupancy needs	0.0%

C	**Environmental Loadings**		**23.8%**
C1	Greenhouse Gas Emissions		100%
	C1.2	Annual GHG emissions from all energy used for facility operations	100%
C2	Other Atmospheric Emissions		0.0%
C3	Solid Wastes		0.0%
C4	Rainwater, Stormwater and Wastewater		0.0%
C5	Impacts on Site		0.0%
C6	Other Local and Regional Impacts		0.0%
D	**Indoor Environmental Quality**		**23.8%**
D1	Indoor Air Quality		25.0%
	D1.3	Off-gassing of pollutants from interior finish materials	33.3%
	D1.8	IAQ monitoring during project operations	66.7%
D2	Ventilation		25.0%
	D2.1	Effectiveness of ventilation in naturally ventilated occupancies	100%
D3	Air Temperature and Relative Humidity		25.0%
	D3.2	Air temperature in naturally ventilated occupancies	100%
D4	Daylighting and Illumination		25.0%
	D4.1	Daylighting in primary occupancy areas	100%
D5	Noise and Acoustics		0.0%
E	**Service Quality**		**9.5%**
E1	Safety and Security During Operations		0.0%
E2	Functionality and efficiency		37.5%
	E2.5	Spatial efficiency	50.0%
	E2.6	Volumetric efficiency	50.0%
E3	Controllability		37.5%
	E3.4	Degree of personal control of technical systems by occupants	100%
E4	Flexibility and Adaptability		0.0%
E5	Commissioning of facility systems		0.0%
E6	Maintenance of Operating Performance		25%
	E6.3	Development and implementation of a maintenance management plan	100%
F	**Social and Economic aspects**		**14.3%**
F1	Social Aspects		100.0%
	F1.2	Access for physically handicapped persons	50.0%
	F1.3	Access to direct sunlight from living areas of dwelling units	50.0%

Once all the indicators have been calculated and all the scenarios hypothesized and after comparing them with the benchmark values, each criterion is assigned a score. These scores, weighted and aggregated, provide the category scores and the assessment area scores. The final building score results from the weighting and aggregation of these last ones. The building design calculated score was equal to 0.0, which corresponds to a barely acceptable sustainability level. Four assessment areas out of six got a higher score, although not significantly higher, but the two areas with a negative score are those with the greater weight and therefore they weigh on the final score of the building.

2.2 Improving interventions

The building design was subjected to some improving interventions in order to bring its sustainability level form the minimum value to the "best practice" one. The adopted solutions can be grouped in the following design actions:

- integration of systems using energy from renewable sources
- modification of façades
- modification of the internal and external distribution of housing units
- three-dimensional development of the ground-floor
- modification of opaque and transparent partitions
- modification HVAC and electric systems
- preparation of a maintenance plan

Each action affected one or more assessment indicators thus modifying the score resulting from the corresponding criteria evaluation. The adopted operational design actions aimed at improving the energy-environmental performances of the building design are listed as follows and grouped according to the criteria they have influenced (if an action is listed more than once it is because it affected more than one criterion).

Table 2 Assessment area A: Site Selection, Project Planning and Development

criterion	Improving actions
A.2.1	- solar PV and solar thermal system analysis led with RetScreen software - design of a solar PV on-grid system - design of a solar thermal system for district hot water with RetScreen software

A.2.7	- setup of an inorganic waste disposal plan
	- arrangement of areas for separate collection of rubbish
A.3.3	- creation of outdoor green areas and parking areas; vehicle admittance is restricted to residents
	- arrangement of facilities for disabled people connecting the raised square to the sidewalks
A.3.4	- creation of bicycle parking areas in the basement of private housings
	- arrangement of a bicycle parking area inside the building for special housings
	- arrangement of bicycle parking areas in the roofed parking area for commercial area users

Table 3 Assessment area B: Energy and Resource Consumption

criterion	Improving actions
B.1.1	- replacement of all the insulating synthetic materials with non-toxic and wood-fibre materials
	- replacement of wooden door and window frames with PVC frames
B.1.2	- decrease in the thermal transmittance value of roofs, walls and floors towards non-heated zones
	- use of low-emission glasses and certified PVC frames
	- modification of the East prospect and creation of overhangs projecting from the wall's plumb-line and full-height corner windows
	- ad hoc insulation for all shape and material discontinuity points (except for the landing)
	- modification of the hot water supply system
	- modification of the number of building boilers and of hot water delivery and return pipes
	- modification of the heating system typology
	- use of low consumption lighting devices
B.3.2	- design of a solar PV on-grid system
	- efficiency and productivity analysis of the PV system
	- design of a solar thermal system for district hot-water
B.5.2	- use of low water flushing systems for WCs
	- use of taps and fittings for the commercial area with controlled delivery

Table 4 Assessment area C: Environmental Loadings

criterion	Improving actions
C.1.2	- decrease in the thermal transmittance value of roofs, walls and floors towards non-heated zones
	- use of low-emission glasses and certified PVC frames
	- ad hoc insulation for all shape and material discontinuity points (except for the landing)
	- modification of the hot water supply system
	- modification of the number of building boilers and of hot water delivery and return pipes
	- modification of the heating system typology
	- use of low consumption lighting devices

Table 5 Assessment area D: Indoor Environmental Quality

criterion	Improving actions
D.1.3	- replacement of all the insulating synthetic materials with non-toxic and wood-fibre materials
	- replacement of all the used materials with equivalent ones holding a certificate of non-toxicity
	- use of non-toxic photocatalytic paints
D.1.8	- setup of an annual plan of indoor environment monitoring
D.2.1	- design of family dwellings living rooms with window openings on different sides
	- design of family dwellings bedrooms with window openings on different sides
	- use of mobile partition walls between living room and study area in the students housings
	- use of open space partitions in the commercial area between utility rooms and exposition rooms
	- openings on the different sides of the housing units located at the corners of the building
D.3.2	- decrease in the thermal transmittance value of roofs, walls and floors towards non-heated zones
	- use of heating radiant floors in order to maintain an even indoor temperature
D.4.1	- modification of the window opening size
	- modification of the type of window frame
	- use of wall-embedded subframes instead of internal flush subframes
	- use of low-emission glasses with a high lighting transmission factor

Table 6 Assessment area E: Service Quality

criterion	Improving actions
E.2.5	-
E.2.6	-
E.3.4	- installation of separate counters for heating and hot water supply systems
	- installation of on/off devices for water supply within commercial and dwelling areas
	- arrangement of a radiant floor heating system with independent take-off branches for each heated zone
	- monitoring system of zone temperatures (thermostats), independent for each heated zone
	- installation of on/off devices for heating supply within commercial and dwelling areas
E.6.3	- setup of a 25-year maintenance plan

Table 7 Assessment area F: Social and Economic aspects

criterion	Influencing actions
F.1.2	- arrangement of a students apartment accessible to disabled people on each floor
	- arrangement of a bathroom accessible to disabled people in each housing unit
	- arrangement of a bathroom accessible to disabled people in each commercial unit

	- arrangement of 14 car-parks reserved to disabled people within the roofed parking - design of external driving ramps to connect different levels that can be used by disabled people (max slope 8%, intermediate landings every 10 m, continuous handrail 70 cm high), except for the driving ramp
F.1.3	- modification of the East prospect involving the creation of overhangs projecting from the wall's plumb-line and corner south-facing windows in order to facilitate sun penetration in high-occupancy areas (living room areas for family dwellings, study areas for students dwellings)

The new building design was assessed with SBTool and was assigned a new score. The following tables and graph synthesize and represent graphically each assessment area score and the building final score before and a after the improving intervention; some absolute calculated results referring to significant criteria and representative of the building energy performance are listed too.

Figure 3 Comparison between the graphs of weighted scores of the existing building and the improved one

Table 8 Comparison between the weighted scores of the two cases-study

			Existing building	Improved building
A	Site Selection, Project Planning and Development	5%	**0.2**	**3.1**
B	Energy and Resource Consumption	24%	**-0.3**	**3.0**
C	Environmental Loadings	24%	**-0.2**	**2.7**
D	Indoor Environmental Quality	24%	**0.1**	**2.6**
E	Service Quality	10%	**0.5**	**1.9**
F	Social and Economic aspects	14%	**0.4**	**3.7**
	Total weighted building score		**0.0**	**2.8**

Table 8 Comparison between the absolute performances of the two cases-study

		Existing building	Improved building
1	Total net consumption of primary embodied energy for structure and envelope, GJ/m2	37.8	32.1
2	Net annualized consumption of embodied energy for envelope and structure, MJ/m2*yr.	378	321
3	Net annual consumption of delivered energy for building operations, MJ/m2*year	476	176
4	Net annual consumption of primary non-renewable energy for building operations, MJ/m2*yr.	478	181
5	Net annualized primary embodied energy and annual operating primary energy, MJ/m2*yr.	856	503
6	Total on-site renewable energy used for operations, MJ/m2*yr.	0.0	21.6

The hypothesized design variation for the arrangement of Porta Mulina led the building to score a total of 2.8, just a bit less than the best practice sustainability level. By analysing each assessment area scores it seems evident that only one area (E: service quality) got a lower-intermediate sustainability level, lower than 2, whereas all the others got high scores in almost all criteria.

The energy-environmental performances of the building have globally improved (in fact the ones that remained on constant values were already referring to well scored criteria): it means that it is possible to apply retrofit actions to improve the energy-environmental sustainability of a zero level building improving its weak points and without worsening its initial positive performances.

2.3 Is the investment convenient?

In order to assess if the future stream of benefits can justify the costs of the above mentioned interventions, a cost benefit analysis was lead. It involved a comprehensive economic evaluation of all the costs and benefits associated with the proposed project options, including financial, environmental and social ones. The objective was to determine the most economical use of resources.

The first step was to quantify costs and benefits: in this case study cost inputs included the cost of the improving interventions and external costs, such as the CO_2 emissions[1]. Besides benefit inputs included energy-savings and emissions avoided. In order to check if the present value of all the benefits exceeded the present value of all the costs the Net Present Value (NPV) was calculated together with the Internal Rate of Return (IRR) of the two options: the existing building and the improved one.

The cost of the interventions was calculated by using the Work Breakdown Structure (WBS), that is a referenced project tool[2]. The WBS comprises discrete work packages, called elements, that describe a specific item. By descending levels of the WBS, elements get greater and greater detail. The number of levels of the WBS depends on the size and complexity of the project. In this work, the decomposition was carried out at the level of individual elements. The following table show the costs difference for each major group of building elements.

		Existing building		Improved building	
	Total cost (€)	**1.836.179**		**2.094.611**	
00	Site works	137.882	7,5%	149.515	7,1%
01	Structures	373.263	20,3%	499.196	23,8%
02	Closures	485.947	26,5%	508.560	24,3%
03	Interior partition	434.431	23,7%	463.136	22,1%
04	Exterior partition	43.237	2,4%	19.213	0,9%
05	Energy systems	213.664	11,6%	349.430	16,7%
06	Other plants	104.716	5,7%	105.562	5,0%

Figure 4 Comparison between the costs of construction of the existing building and the improved one (%)

The total cost of the improved project resulted bigger than the existing one (+ 14,07%). The group of elements that affected more this increase was the energy systems one (from 11,6% to 16,7%). According to this result, it was very meaningful to verify whether the investment was convenient, considering its benefits spread over many years.
Costs and benefits were discounted using a discount rate of 8% during a period of 30 years in order to not calculate the costs of special maintenance interventions[3].

The investment performance criteria considered were Net Present Value (NPV) and IRR (Internal Rate of Return), including both the financial analysis and the economic one. Even if these indicators were applied just to the buildings and not to the whole territorial system, interesting outcomes emerged. The NPV of the investment concerning the existing building resulted positive (€ 7.000) and the IRR was equal to the discount rate (8%). It means that was quite indifferent to carry out the investment or not. Considering the benefits rising from the environmental strategies adopted by accounting the externalities (reduction of general environmental costs), the NPV resulted more than twice the NPV of the existing building (€ 16.000) and the IRR was a little higher than the discount rate (8,1%). In this case benefits were double: private benefits concerning the cut of energy costs and public ones regarding the reduction of CO_2 emissions.

The conclusion is that it is important to get incentives from local governments both in term of promoting the use of energy efficiency measures and in term of direct subsidies. Furthermore, incentive policies would allow an increase of demand of such technologies and the consequent reduction in prices according to the market laws.

It is also meaningful to underline that the Cost Benefit Analysis should be applied in two different steps of the investment project: *ex-ante* (before designing) in order to evaluate different options and *ex-post* (after designing) with the aim of monitoring the outcomes of the investment.

3. Conclusions

The described analysis underlined the importance and utility of multicriteria approach tools, like SBTool, to design energy efficient and environmental sustainable buildings both in the primary design phase (ex novo or retrofit) as a support to design, and at the end of the project, for the global building assessment. This

[1] The costs of CO_2 emissions were calculated with according to the methodology proposed by the ExternE Project (see References).
[2] A Work Breakdown Structure is a results-oriented family tree that captures all the work of a project in an organized way. Considerable thought and planning should be given to its development and implementation so that subsequent changes are minimized.
[3] The cost of usual maintenance interventions was the only one took into account.

analysis focused on the former aspect in order to verify whether the improving actions hypothesized for a building design could actually improve its energy-environmental sustainability level.

A preliminary assessment of the building is important because the choice of efficient envelope and technological systems solutions, with a low impact on the environment, can be already addressed in the first design phases, by setting as targets the specified best practice indicators in the criteria performance scales. Also, when there are big gaps between targets and building performances, it is possible to correct them by acting on its envelope and systems features, in order to obtain a globally positive assessment. Obviously the use of tools and approaches which innovate the current design practice may make it necessary to develop new professionals able on the one hand to plan and manage an integrated design approach, where the different involved professionals interact, and on the other hand to support the designer regarding highly specific subjects related to the energy efficiency of the building, indoor comfort, environmental impact and so on.

Costs analysis were also lead in order to prove that the hypothesized solutions presented affordable investment costs and remarkable advantages on the energy efficiency of the buildings.
Energy and environmental issues on a global scale and the higher and higher performance requirements of final users show how topical is the need of objective and referenced assessment tools. They should be used together with costs-benefits analysis tools in order to prove the economical sustainability of the project.

The developed analysis intended to test the actual resources needed for this innovative approach on a real study case, with expected positive results for all the involved stakeholders: the case study management allowed to verify the possibility of bringing a zero level building close to the best practice level by applying efficient and effective technical and economic solutions.

Keywords: low-energy building, solar energy, building design, building integrated photovoltaics

Summary

In the first part, the paper summarizes basic information about solar energy under local condition of the Czech Republic and brings general ideas about possible way of expressing the energy performance of a building. It is suggested to create an energy matrix with information about energy needs and energy used by different energy carrier, considering the energy savings due to better energy standard in the same way. The second part of the paper informs about new development of residential area consisting of 13 passive houses. The priorities (renewable materials, renewable energy) and overall design approach are discussed. The final results are presented. The PV-systems are used at two houses, the first one is equipped by 8,45 kWp on-grid system, roof integrated. This house reached the level of zero-energy house, considering the energy demand and production within one year. The design of the second house was focused on energy security: a back-up system is combined here with PV in order to guarantee grid independent operation for 24 hours. The residential area is in operation since 2007. The zero-energy house serves as an information and educational centre. Long-time monitoring of energy parameters and indoor quality are running.

1. Solar energy use under real local condition

Solar irradiation can be understood as a significant energy source for buildings and especially low-energy and passive buidlings are known for its broad utilization. However, unlike convectional energy sources, solar energy can vary considerably with geographical location as well as in time. Furthermore, the amount of incident solar radiation can be decreased for many reasons, as for example by local shading, elevated horizon, pollution or high water vapor content in the atmosphere and others. Therefore it is crucial to perform a detailed study of really available solar energy before designing elements and devices for its active or passive use in buildings.

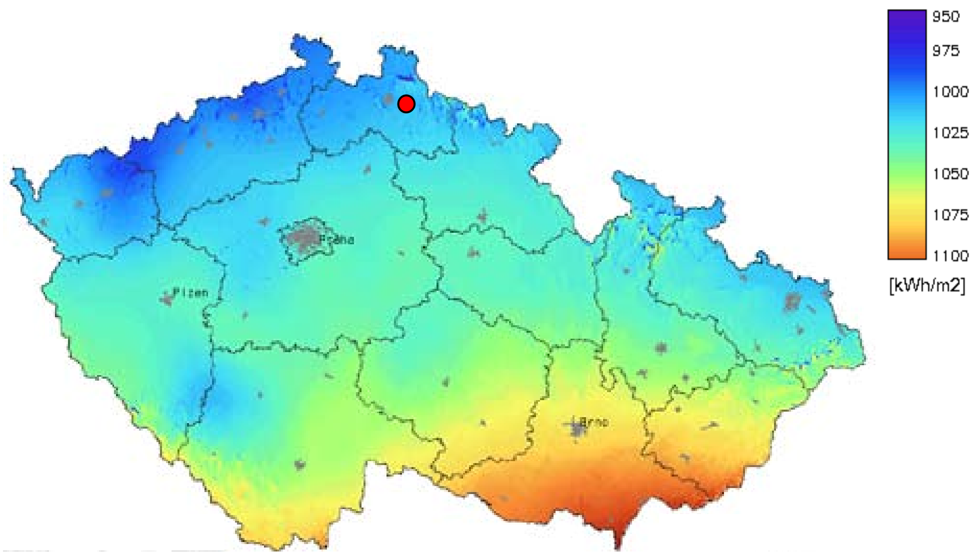

Figure 1 Solar map of the Czech Republic showing yearly sum of global irradiation on horizontal surface in kWh/(m2.a) [PVGIS]. The location of interest (Koberovy) is marked by a red dot.

Solar data for the location of interest are usually obtained from a meteorological database and common tools (Meteonorm, PVGIS) allow the user to get desired solar information based on selected slope, orientation and other parameters. The building designer then proceeds with more detailed analysis and optimizes solar energy use to match the overall building design.

In general, solar energy in the built environment can be used for passive and/or active solar heating, hot water preparation, cooling and electricity generation. As an example of solar energy utilization in passive house design, the Koberovy project is presented here. The Koberovy project consists of 13 passive houses located in the northern part of the Czech Republic (see Figure 1). The available solar radiation at the location was studied using Meteonorm hourly data. The total annual amount of solar radiation on horizontal plane is 1 030 kWh/m^2 from which 41 % comes as direct radiation and 59 % as diffuse radiation. Furthermore, 33 % can be expected in spring, 42 % during summer, 17 % in autumn and only 8 % in winter. From the very first stage of the design process it was assumed that a large-scale on-grid PV system and a solar thermal system for hot water preparation would be placed on a south facing 45° sloped roof. A standard analysis based on solar geometry and Perez model of diffuse radiation was performed in order to calculate the optimum position for each system based on the following strategy: The on-grid PV system would generate most electricity when placed in optimum position for year-long period. On the other hand, the solar thermal system providing hot water is most effective when generating heat evenly during the year, not exceeding the needs of the house in summer to an undesirable level. It was concluded that the optimum position for an on-grid PV system is at 35° south-oriented where 1 215 kWh/m^2 of available solar radiation can be expected (see Figure 2, left). Systems for hot water preparation should be optimized for April and September (100 % coverage, recommendation for central European conditions) resulting in the optimum of 50° south-orient ed which usually means coverage of 60 % to 70 % of annual energy need for hot water preparation. Furthermore, it was in question whether the solar thermal system can actively support heating. In this case the optimum position would be 60° south-oriented, c alculated for winter season. However, during this period only 145 kWh/m^2 of available solar radiation can be expected (see Figure 2, right), which would lead to ineffective over sizing of the system in terms of collector area as well as storage tank volume. It is a general problem when designing an active solar heating system for a passive house – the heating season is shortened to few months, during which the available solar radiation is low. One possible option is to place larger number of collectors, preferably in vertical position to avoid summer problems; another is to install a storage tank for seasonal accumulation. In case of the Koberovy project, it was decided to optimize the solar thermal system for hot water preparation only.

Next question was if to install the solar systems roof-parallel (45°) or whether to place them in the optimum position, i.e. 35° for PV and 50° for solar thermal , respectively. It can be seen from the solar analysis (see Figure 2) that the area close to the optimum position is rather flat meaning a certain deviation from the optimum is possible without much loss in solar energy gain. In the Koberovy project the solar systems were installed roof-parallel. In general, if the overall concept is strictly solar oriented, the building form should be adjusted accordingly. However, in many cases this is not possible due to lot orientation, local regulative, etc.

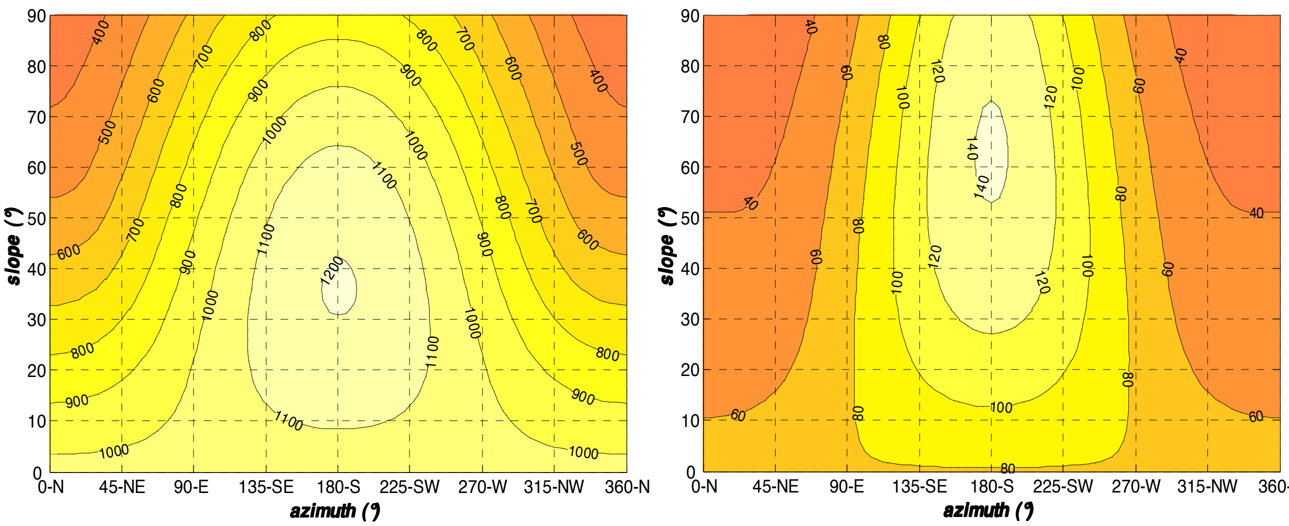

Figure 2 Yearly (left) and winter (right) sum of global irradiation on surfaces of various slopes and orientations in kWh/m^2 for the location of interest (Koberovy, Czech Republic) – based on Meteonorm data.

2. Energy problem consideration

2.1 Background

In generally, the overall energy problem of a house or other unit can be described in an *energy matrix*, bringing relations between all types of *energy demands* (typically: space heating, hot water, electricity for household technologies, electricity for appliances) and *energy carriers*. One of possible forms of such matrix is that the energy savings due to better building design compared to standard solution are classified as a special sort of energy carrier with zero negative impact on environment – see Table 1. As a standard solution one can understand the business-as-usual design, corresponding exactly to the current standard for particular case. Such a simplifying approach can help to set priorities concerning operation energy in the preliminary design stage.

The data in energy matrix can be expressed in the form of final energy (at the system boundary of the building) or – in more instructive way – in the form of primary energy (see Gemis, 2008).

Table 1 Operation energy matrix with examples of energy carriers

Energy service ↓		Energy carrier								
			Conventional			Renewable				Savings due to better building energy design
		Identification number	1.1	1.2	1.x	2.1	2.2	2.3	2.y	3
		Type	Gas	Electricity	….	wood	solar thermal	PV	….

A	Space heating									
B	Space cooling									---
C	Hot water									---
D	Electricity for technology									---
E	Electricity for appliances									---
F	Other									
	Total									

2.2 Studies on solar system integrations

From this perspective, the optimal use of solar energy is a logical further step in the development of passive houses - see Feist at al. (2007). The substantially reduced space heat demand to the today level of best-available technology (BAT) here represents about 1/3 of total energy need of the whole household unit only.

The sizing of solar thermal system for hot water preparation is limited usually by 60-70% covering of the yearly energy demand. Larger solar thermal installations can be effectively used for supporting of space heating also in the climatic condition of the Czech Republic, but only to limited extend. The corresponding heating system (low-temperature heating) has to be designed in parallel.

Therefore an integrated design approach is strongly needed here, starting at the first design study. Solar collector areas have to be placed close to vertical position on relatively large areas (façade installation, at balconies etc.), which could be very challenging for visual concept, too.

Another approach can be using building integrated photovoltaics (PV): Larger systems are usually connected to public grid, smaller PV-installations can serve as supporting systems for the particular house. In any case, an extra attention should be given to attractive visual form of installation, together with correct solution from building physics point of view.

From the point of view of architecture and building science, the term *solar system integration* is a real keyword that can be understood in different ways:

- Integration of a solar energy unit into the energy balance of the building
- Integration as an architectural design (visual) and structural problem
- Integration from a building-physics point of view
- Integration into building construction costs and operation costs schemes (project cash-flow), etc.

3. Residential area in Koberovy

3.1 Overall design approach

The concept of sustainable building was consequently followed by designing a new residential area in Koberovy (a village in the northern part of the Czech Republic, in a protected landscape area called Bohemian Paradise – see Tywoniak and Moravek (2006). Strong limits concerning the form of buildings are given here in order to reflect local tradition. Together 12 single family houses + one house of the same size and structure serving as an information and education centre for energy saving technologies are in operation since September 2007.

The design priorities were formulated by the developer at the beginning:

- urban concept allowing passive solar use together with privacy of clients
- passive house standard level or closed to should be reached
- maximum use of renewable construction material
- maximum use of renewable energy for operation of each house
- comparable investment costs with other developments in the region combined with very high indoor quality
- use of advantage the construction of all houses at the same time

Figure 3 Part of new residential area in Koberovy

3.2 Form and load bearing structure

The houses have timber framed load bearing structures completed by extensively insulated envelope. The slope of pitched roof was set by authorities at 45°, which is close to, but not an optimum either for solar thermal or photovoltaic systems. The houses have unified structure and form. They differ slightly in lengths and in the form of open car ports and garden service rooms only. The size and place of openings and the different surface layers of the walls (plaster on external thermal insulating system or wooden covering) were designed according to wishes of clients individually.

The structural solution consists of wooden skeleton in the first floor and nailed roof truss in the attic. Its bottom part creates the ceiling joist directly. The amount of structural timber is significantly reduced here compared to usual two-by-four system.

Note: In generally, the number of houses with timber structures is very low in the Czech Republic. Among low-energy and passive houses is their relative amount much higher, with increasing tendency. Two reasons are often discussed in this respect: The advantage of placing of higher thickness of thermal insulation without exceeding acceptable overall thickness of the building envelope and the minimizing of ecological footprint by using renewable materials.

3.3 Building envelope and details

Thermal transmittances of the building components were calculated carefully considering even small thermal bridging elements – see Table 2. All areas with significant multi dimensional heat transfer were quantified and included in U-values or added to the heat transmission, respectively.

Table 2 Thermal transmittance (U-Value) and heat transmission

Thermal transmittance	U [W/(m²K)]	
	Design values	Required values according (Czech standard)
Slab on grade	0,17	0,45
External wall	0,11	0,3
Pitched roof	0,09	0,24
Roof in attic space	0,09	0,24
Entrance door	1,14	1,70
Windows	0,84	1,70
Heat transmission (according to EN ISO 13790)		
Heat transfer coefficient	67,2 W/K	100 %
Ventilation heat transfer coefficient	6,4 W/K	↕ 6,4 %
Transmission heat transfer coefficient	60,8 W/K	93,6 %
Thermal bridges – total effect	1,4 W/K	(2,2 %)
Thermal bridges – positive	↕ +4,8 W/K	
Thermal bridges – negative	-3,4 W/K	

Table 3 Expected energy balance of a house with a large building integrated PV system

Energy service ↓	Energy carrier [MWh]						
	Type	Conventional	Renewable				Saving due to better building energy level[2)]
		Electricity	Wood	Solar thermal	PV		
	Primary energy conversion factor →	3,0	0,05	0,05	0,2	Total	0,0
Space heating		1,5	1,5	0,1		3,1	12,5
Hot water		0,4	0,3	2,1		2,8	---

Electricity for appliances		2,4				2,4	---
Total		5,2	1,8	2,2	*(7,7[1)])*	9,2	
Note: Division by energy carrier as a design assumption only. Thermal energy is collected in central accumulator regardless to its origin.							

[1)] *PV-generated electricity is not connected to the energy systems of the house.*

[2)] *Calculated for the parameters of the house's envelope according to Czech standards (2007)*

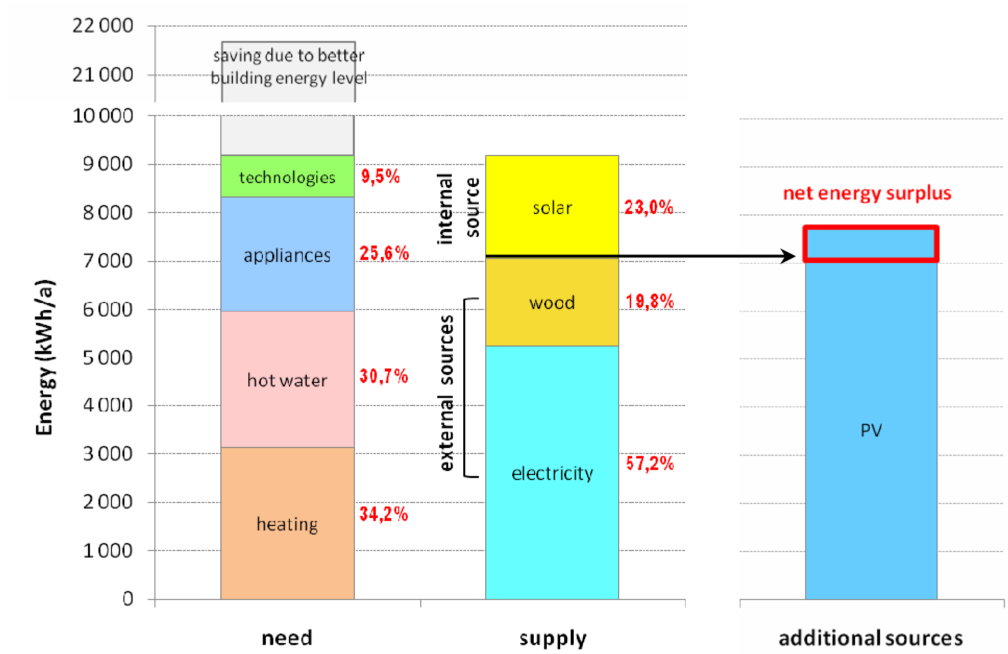

Figure 4 Breakdown of energy needs and supplies of a typical passive house in the Koberovy project (left). When an additional source (large building integrated PV system) is used, its production can be included in the overall energy balance resulting in a zero energy or even energy plus house (right).

The energy balance described above still does not provide sufficient information on overall sustainability of the performance of the house during its operation. For this reason, the energy balance was transferred into primary energy balance using different conversion factors for the respective energy carriers used to cover energy needs of the house (see Table 3). Values of the conversion factors were calculated using specialized tool GEMIS.

The impact of a large building integrated PV system on the primary energy balance of the house was calculated under the following assumption: The PV system produces green electricity having the conversion factor as low as 0,2. On the other hand, the PV-generated electricity is not connected to the energy systems of the house but is fed into the local grid (on-grid PV system), while the house uses standard electricity mix from the very same grid having conversion factor of 3. However, it can be assumed that the grid serves as an infinite accumulator and that the house can virtually take all the green electricity back. Such reasoning allows using the conversion factor of 0,2 for the electricity mix taken from the grid, of course, to an amount not exceeding the PV-production.

The following figure shows the primary energy balance for a passive house without and with a large building integrated PV system.

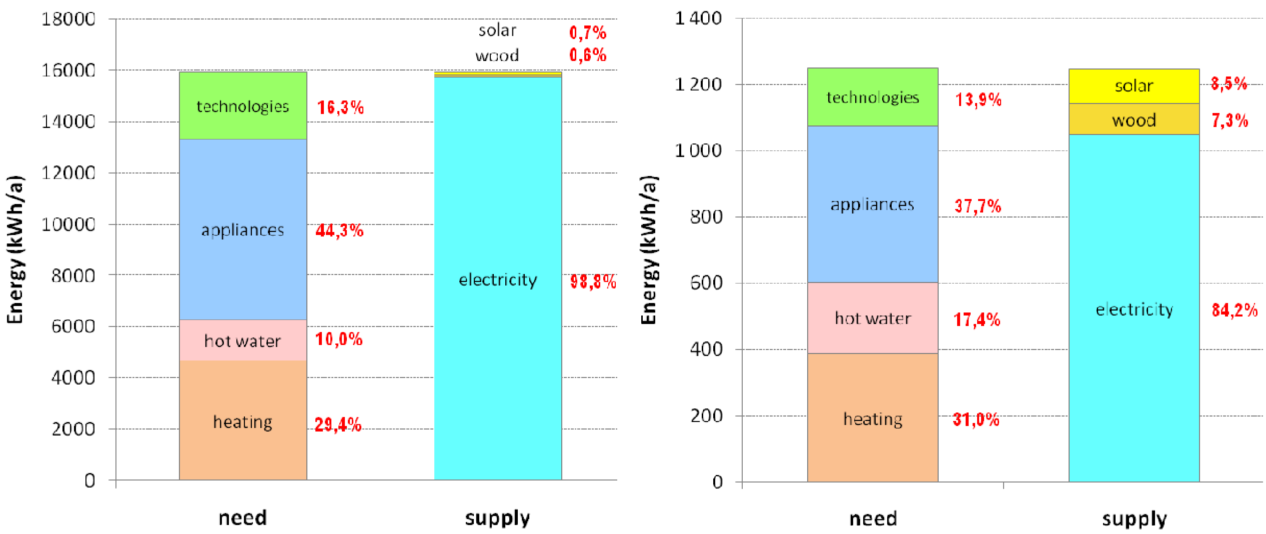

Figure 5 Breakdown of primary energy consumption of a typical passive house in the Koberovy project (left). When a large building integrated PV system is used, its production significantly lowers the overall primary energy consumption of the house (right).

It can be seen that integration of a large scale on-grid PV system (8,45 kW_p in this case) lowered the primary energy consumption of the house 12,5 times resulting in the specific primary energy need of 8,5 $kWh_p/(m^2.a)$, while the passive house concept requires 120 kWhp/(m2.a) - see Feist at al. (2007). For the design without a large scale PV system the specific primary energy need is 107,9 $kWh_p/(m^2.a)$, which is still well below the requirement. In general, use of a PV system can be a favourable option to decrease primary energy consumption of a building when other measures are not possible or suitable.

3.4 Heating and ventilation concept

The energy system of each house consists of a central thermal accumulator (0,615 m^3) with an integrated hot water preparation system and connection to a mechanical ventilation unit with a highly efficient heat recovery – see Tywoniak (2007). Energy from several inputs is used in the thermal accumulator - solar thermal circuit, wooden stove circuit and electrical heating rods, if needed. The doubled earth heat exchanger with a closed loop was developed to have higher efficiency in summer to avoid possible overheating, as described in Kopecky (2007).

3.5 Optimized solar use

Hot water is prepared from approx. 70 % by solar-thermal collectors installed on each house. Every individual unit consists of 3 solar thermal collectors having total area of 6 m2 in vertical oriented strip. The collectors are roof-integrated with smart design in detailing (see Figure 4). The hot water is stored in the central thermal accumulator.

3.6 PV roof

The house for information and education is equipped by large photovoltaic system (PV), total area of 62.9 m^2 with 8,45 kW_p, fully integrated in pitched roof 45° (Figure 4). The annual energy production of the PV system should be approximately equivalent to the amount of energy supplied to the house from external sources. This would lead to a zero-energy house over the year. The produced electricity will be sold to the local distributor to avoid losses resulting from the inequality between the production and consumption curves. However, it also means that the PV system is not connected to the energy systems of the house and has to be treated independently when calculating energy balance. According to the data in Table 3 the energy to be delivered from external sources is approx. 7 MWh/a. Expected yearly PV-production is about 7,7 MWh/a (AC).

In principle, integration of a large on-roof PV system has unquestioned impact on the overall appearance of the house. Therefore, full structural integration of the PV modules into the roof was one of the important requirements. Properly chosen supporting structure made it possible to replace traditional roof tiling by PV modules. The fact that the crystalline silicon PV modules operate best when their temperature is kept low has led to the design of a 100 mm high ventilated air gap at the back of the modules.

Figure 4 House for information and education with large PV-roof (zero-energy house) in Koberovy (50°37'29" N, 15°13'42" E)

3.7 PV for higher independency

Passive houses have generally low energy demands, however it does not prevent them form impacts of black-outs. On the other hand, when a certain minimum of electricity is delivered from a back-up system, the passive houses are able to withstand the back-out with less harm than usual buildings. To explore the potential of solar driven electricity back-up, one another house in the Koberovy project was equipped by a smaller PV system (1,1 kW_p only) extended by batteries and electronic control unit to guarantee grid-independence for basic operation in the house in case of black-out. The PV system operates in two basic modes. The first mode applies when the electricity supply from the grid is undisturbed: a grid-tied DC/AC inverter is in operation, PV-produced electricity id fed into the grid and the batteries are kept charged. The second mode applies when the grid is not detected: an island DC/AC inverter is in operation using electricity from the batteries and feeding AC power into the selected circuits in the house. All technological equipment, like fans of mechanical ventilation, circulating pumps together with selected lighting can be in use at least for 24 hours of energy delivery break.

4. Conclusions

Koberovy – houses reached the level of passive house standard at acceptable costs, which are fully comparable with other new developments in the region. The Koberovy project was a big challenge for the general contractor, who was for the first time faced to a) passive house approach, b) use of wooden structure. Very intensive and consequent supervision on construction site and technical support was therefore needed, together with repeated checking the quality during finishing works (air-tightness by blower door – see Novak (2008)), to avoid problems and un-acceptable "improvisations" on site. At the urban level, this new residential area is already quite well integrated in the structure of the existing village and accepted by local people. The long-time monitoring of the energy flows, indoor quality and effects of solar use has started at four selected houses here. The general solution is repeatable, regardless to the form of particular building, the building envelope can be further simplified and the air tightness concept improved. The high quality detailing is necessary to attract the people to follow the passive house strategies and to use solar energy at all.

Basically, solar systems have a real chance to be a part of buildings on a larger scale only if the stakeholders (developers, building owners, architects and building designers, facility managers, etc.) are familiar with these technologies. The solar system should be designed very consequently considering the energy targets and the overall sustainability parameters, like primary energy, embodied carbon dioxide values, etc.

It was clearly shown that the only effective way to zero-energy house (possible future target?) starts at well adopted passive house principles. The search for overall attractive solutions can be understood as an opportunity for "inventory" of our design habits. Especially at housing projects the basic structures should be highly effective not only to save materials (and embodied energies) but also to help to create a "financial space" for use of advanced technologies for saving of operation energy and to minimize the ecological footprint in general.

Acknowledgements

The building of information centre was partially financial supported by Czech Energy Agency. Long time monitoring is supported by MSMT Project 1M0579 within the CIDEAS research centre. Theoretical studies are supported by MSMT Project 6840770005.The installation of energy back-up system combined with PV is a part of research project co-supported by Ministry of Industry and Trade, Czech Republic, 1TP1/129. All support is gratefully acknowledged.

Summary

An energy efficient design is an important component for a sustainable and LEED certifiable building. Moreover, innovative technologies such as daylight control systems have led to the improvements in electrical energy reduction. However, while previous researches have pointed out the problems of daylight control systems they have focused almost exclusively on the electrical savings to be gained by such systems. There is a lack of comparative study on the different fenestration systems and a need to evaluate the total energy performance with a daylight control system. The aim of this paper is to investigate, by using an eQUEST energy simulation program, how the energy demands in an office building change with daylight control and a variety of fenestration systems. Specifically, the impacts on energy performance with daylight control are analyzed for building size, window area, glazing type and properties such as U-factor and SHGC for two geographical locations in the U.S. The results are compared with a reference model that uses the ASHRAE standard and the methodology of the LEED 2.2 green building rating system. The results demonstrate the potential of energy savings by integrating a daylighting control system with design decisions to optimize the fenestration. In addition, this paper provides fenestration guideline that can be used to assist in the window design, selection and placement of windows with daylight control systems.

1. Introduction

1.1 Building Energy Use

Buildings are responsible for an increasing share of the total energy consumption in the U.S., consuming 40% of the nation's primary energy. During the last two decades (1990–2005), the primary energy consumption of U.S. buildings has grown by 31% and CO_2 emissions have increased by 39%, making them responsible for 22% of the world's carbon dioxide emissions. Building emissions in the U.S. are equal to the combined emissions of Japan, France, and the U.K. The energy usage is especially high for electrical consumption, with commercial and residential buildings in the U.S. consuming 72% of the nation's electrical energy. It will have grown to 80% by 2030. A comparison of building types shows that commercial buildings use 18% and office buildings represent the largest portion of the energy use in this sector. Mercantile, education and health-care follow. Moreover, even though it is predicted that residential energy consumption will decrease, commercial consumption is predicted to increase by 20%. Among the energy usage, artificial lighting is one of the major energy consuming items in commercial energy end-use (around 26%) and this growing trend will continue (U.S Department of Energy 2007).

1.2 Background Study

In order to reduce energy consumption in commercial buildings, there has been great demand to design energy efficient buildings. Based on the above reference data on building energy use, this paper will focus on the energy consumption of a typical office building in different U.S climate zones. There are numerous energy saving strategies that consider architectural design, engineering, HVAC systems, renewable energy, weather, climate zones, environmental factors and so on. However, in this paper, energy simulation was conducted to evaluate the energy conservation impact of daylight control and window type. In other words, the main objective is the analysis of energy performance using different window designs including factors such as area and other properties (U-factor and SHGC) with a daylight control system. A variety of studies dealing with the two parameters of daylight control and fenestration can be found in the cited reference. The sections below will discuss two types of studies; electrical energy saving with daylight control and energy performance with different window designs.

1.2.1 Electrical energy saving with daylight control

Energy is not saved by daylighting. Energy is saved by dimming down or switching off electric lights (Leslie 2003). Lighting control integrated with daylighting is recognized as an important strategy in energy-efficient building designs and operations (Li and Tsang 2005). The purpose of daylight control systems is to maintain target illuminance levels regardless of the amount of available daylight. To satisfy such a purpose, the electric light output is continuously adjusted based on the changes in the available daylight, as measured by photosensors (Choi et al 2005). These systems consist of three basic components; a photosensor, lighting controller and dimming unit. A photosensor detects luminous flux and converts this into a signal this is sent to the controller, which in turn processes the signal and defines the desired dimming level. (Choi and Sung 2000) By using simulations and actual measurement, previous researches have shown that daylight control systems can reduce the electrical energy consumption in office buildings by as much as 30–70% (Li et al 2006, Doulos et al 2008). Moreover, in the New York Times Headquarters daylighting mockup test, the daylighting control systems demonstrated very reliable performance after they were commissioned properly. The average lighting savings were 20–23% and 52–59% for two target areas of the mockup (Lee and Selkowitz 2006).

Although researchers agree on the benefits of daylight control systems, there is a difference about their real savings and actual energy consumption (Roisin et al 2008). Moreover, research has also shown that daylight control systems do not show the guaranteed energy reductions after construction (Floyd and Parker 1995, Atif and Galasiu 2003). Therefore, based on previous researches, a consideration of total energy performance is needed when the daylight control system is installed because previous researches focused solely on the electrical savings from artificial lighting reductions, and did not address the effects on total energy performance with daylight control. In an effort to overcome these problems, this paper includes an analysis of total energy consumption with daylight control and various combinations of fenestration parameters.

1.2.2. Total energy performance related to window with daylight control

Building façades can make a major contribution to the overall energy savings (Saridar and Elkadi 2002). Moreover, windows are responsible for 22% of the heating loads and 32% of the cooling loads in commercial building component loads (LBNL 1998). Windows plays a major role in determining the thermal performance of a building and represents a major opportunity to conserve energy (Sekhar and Toon 1998). Nonetheless, fenestration type and design have often not been considered in the early design stage even though they can play a large role in determining total building energy usage. For example, Aboulnaga (2006) examined the status of buildings in Dubai to investigate the problems associated with misuse of glass. The results revealed that window were misused in 70% of the buildings. Therefore, in order to save energy, more consideration about windows is essential to create low-energy building.

Summing up the background study, there are problems with a daylight control system when it is used without considering all of the fenestration parameters. This means that there is a limited understanding of the links between daylight control systems and fenestration including design and type. Although almost all researches guarantee the electric energy savings, the total energy consumption should be verified. In order to effectively increase energy saving, the window systems associated with the daylight dimming control systems should be addressed. Therefore, to take full advantage of their savings potential, this paper presents a methodology to analyze the potential for energy savings with a daylight control system and different window systems including a consideration of window area and properties.

2. Main Research Objective

The main purpose of this study was to establish guidelines to improve energy conservation in an office building with daylight control used in conjunction with different window systems. The study presented here is based on simulation results. This study is divided into two parts. The first determines the energy conservation for different combinations of window properties in terms of global energy consumption. To increase achievable LEED credits for the optimization of energy performance, energy savings were determined by comparisons with the ASHRAE Standard. In the second part of the study, the impact of different parameters including floor area, window size and properties is analyzed. Then, selected results from a series of parametric analyses are discussed.

This section is meant to provide guidance in the process of choosing windows by evaluating the influence of the window area and type on the energy use. These results provide the minimum fenestration criteria for architects with regard to the selection of the U-factor, SHGC, and window sizes.

3. Methodology

3.1 Model Description and Assumptions

Since the LEED green building rating system was designed to guide high-performance commercial projects, with a focus on office buildings, this research considered the energy usage in three typical office buildings (USGBC 2005). Simulations were run for the open plan office buildings. Obstructions due to interior and exterior features and surrounding buildings were not considered. Three building models were selected for the analysis. Typical seven-story office buildings were considered. Approximately calculations were made for these based on Huang and Franconi (1999) and each simulation model had square geometries because Cho (2007) showed that more than 30% of high-rise office buildings have a square shape. Two statistical references show that the range of average floor area for an office building was 1,022-2,183 m^2 (11,000-23,500 sq.ft) before 1980 and 1,486-2,416 m^2 (16,000-26,000 sq.ft) after 1980 (LBNL 1998) and that from 1959 to 2003, the average office building floor area has been 1,319 m^2 (14,200 sq.ft) (EIA 2006). For these reasons, three different office building sizes were selected for this paper to represent typical small (Office 1), medium (Office 2) and large (Office 3) typical office buildings. Therefore, we decided to focus our study on the seven storey office buildings with square geometries. Fig. 1 provides a representation of the building models and the data and assumptions are presented in Table 1 and 2.

Figure 1 Perspective of simulated model

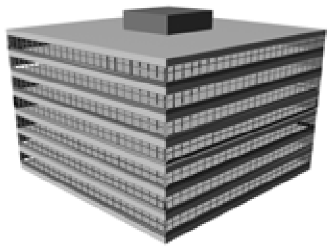

Table 1 Description of three office types

	Office 1	Office 2	Office 3
Dimension	24.5 X 24.5m (80 X 80 ft)	36.5 X 36.5m (120 X 120 ft)	49 X 49 m (160 X 160 ft)
Floor Area	595 m^2 (6,400 sq.ft)	1,338 m^2 (14,400 sq.ft)	1,821 m^2 (25,600 sq.ft)
Perimeter Zone		4.6m (15 ft)	
Floor to Floor Height		4m (13 ft)	
Floor to Ceil Height		2.7m (9 ft)	
Number of Floor		7	

The floor space was divided into a core zone and open office area, regular occupancy area. The four zones, the open-plan office area, are oriented to the north, south, east, and west, respectively. The perimeter zone was 4.6m wide around the floor and the floor-to-floor height was 4m (13 ft) with a 2.7m (9 ft)-high ceiling. Lighting density was 11.84w/m^2 (1.1w/sq.ft) based on the ASHRAE/IES standard office value. As shown in Table 3, the occupancy and operation schedules, heating, ventilating, and air-conditioning system, and envelope construction including insulation values were set in accordance with the ASHRAE Standard 90.1–2004, IESNA and the default values for a high-rise office building in the eQUEST energy simulation program.

Table 2 Summary of Details on Simulated Models

Parameters		Value / Descriptions
Building Type		Office, High-rise
Insulation	Roof / Wall / Floor	R-19 / R-13 / R-19
HVAC System	System Type	Variable Air Volume
	Cooling type	Chilled Water
	Heating type	Hot Water Fossil Fuel Boiler
	Design Temperature	Summer : 23.9 C° (75 F°), Winter : 22.2 C° (72 F°)
Schedules	Occupancy	Weekday (8:00-17:00)
	Operation	Weekday (7:00-18:00)

3.2 Daylight control system

Using daylighting controls, the electric lights were dimmed continuously by photosensors in each perimeter spaces. The dimming range was from 100% to 10% of the lighting output. A daylight control sensor was placed in the center of the each perimeter zone at 2.3m (7.5 ft) from the exterior wall. The required design illuminance level was 500 lux (50 foot candles) at workplane height during office hours (IESNA 2000).

3.3 Weather and climate zone

In order to verify the influence of the climatic and geographical location, the methodology was demonstrated in a typical open plan office in a cooling-dominated location (Houston) and a heating-dominated location (Chicago) in the U.S. (Lee and Tavil 2006). Due to the new weather classification, Houston and Chicago represent the hot and cool climate types, respectively. Specific climate data is shown in Table 3 (ASHRAE 2004, Briggs et al 2002).

Table 3 Weather data

	Houston	Chicago
Latitude / Longitude	N 29.95 W 95.35	N 41.98 W 87.90
Climate Type by ASHRAE Standard	2A	5A
Climate zone name	Hot	Cool

3.4 Fenestration Systems

As mentioned earlier, the main objective of this study was to verify the impact of the fenestration system used with a daylight control system. Therefore the study considered two main parameters; window size (WWR) and window properties (U-factor and SHGC).

The first, window area is represented by the window-to-wall ratio (WWR). The window positions and sizes are shown in Figure 2. Simulations have been performed with incremental glazed façade areas ranging from 15% to 50% at increments of 5%. These are presented in Ghisi and Tinker (2005) and in the author's previous research (Ko et al 2007). Due to the prescriptive limit of the WWR in the ASHRAE standards, a vertical fenestration of less than 50% was considered. Moreover, in previous researches on window size, Keighley (1973) showed the results that visual satisfaction is achieved when window area is 30% and, in relation to window shape, Dogrusoy and Tureyen (2007) found in a survey that horizontally continuous windows were the most preferred window types. Moreover, Cuttle (1983) showed that 25% or more large horizontal windows were the most appreciated. These findings and the standard were used in the selection of the fenestration shapes and sizes used for 3D models simulated in this paper.

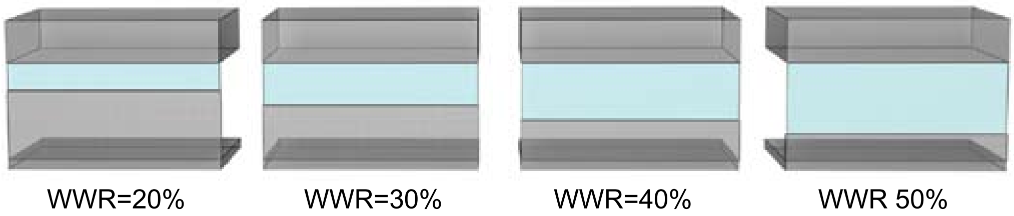

Figure 2 Proposed Façade Compositon and WWR

In relation to the second parameter, the current ASHRAE Standard for non-residential buildings is based on two window properties; the U-factor and solar heat gain coefficient (SHGC). Therefore, five different types of glazings with various U-factors and SHGCs were considered, as described in Table 4. Each glazing's type was selected by typical thermal performance of the window type (ACEEE 1996, NFRC 1999). Glazing 1 (G1) is the required window property of the ASHRAE standard in each climate zone. In order to determine the fenestration guideline, simulations were performed with five different kinds of glazings by decreasing the U-factor and SHGC.

Table 4 Analysis of five glazing properties

Type	Houston			Chicago			
	U	SHGC	Type	U	SHGC	Type	
G 1	1.22	0.25	Single-Pane	0.57	0.39	Double-pane	ASHRAE Standard
G 2	0.98	0.20	Single-Pane, Tinted	0.46	0.34	Double-Pane, Low-e, Gas-fill	20% reduction of ASHRAE Standard
G 3	0.73	0.15	Double-Pane	0.34	0.23	Triple Pane	40% reduction of ASHRAE Standard
G 4	0.49	0.10	Double-Pane, Tinted	0.23	0.16	Triple-Pane, Low-e, Gas-fill	60% reduction of ASHRAE Standard
G 5	0.24	0.05	Triple-Pane, Low-e, Gas-fill	0.11	0.08		80% reduction of ASHRAE Standard

3.5 Simulation Program: eQUEST

To investigate the impact of fenestration properties with a daylight control system, energy simulations were carried out for the above described typical office floor and two cities in the U.S. A parametric simulation is presented using eQUEST. It is the most updated to date building energy use simulation tool. Moreover, it is free and contains a complete version of DOE-2.2 and its documentation. eQUEST and PowerDOE feature the identical DOE-2.2 simulation engine. It is the newest DOE-2 building energy simulation and cost calculation engine (Hirsch 2003 and 2006). DOE has been used extensively for more than twenty-five years for both building design studies, the analysis of retrofit opportunities, and for developing and testing building energy standards in the U.S. and around the world (Crawley et al 2008). In this study, eQUEST was used to calculate energy consumption with a given fenestration system when a daylight control system was installed.

3.6 LEED 2.2: Optimize Energy Performance

To evaluate and calculate the energy conservation, LEED 2.2 criteria were considered in this research and the expected results can be applied to the LEED green building rating system in order to increase the achievable LEED points. There are six categories; sustainable site (SS), water efficiency (WE), energy and atmosphere (EA), material and resources (MR), indoor environmental quality (EQ) and innovation design (ID). Among these categories, energy saving is dealt with "EA credit 1. Optimizing Energy Performance" and it offers up to 10 points. These 10 credits contribute to 39% of the credits required to be certified by the LEED Green Building Rating System. In this credit, LEED 2.2 required at least two points after June, 2007.

The aim of optimizing energy performance can be achieved by increasing energy savings to above the baseline. There are four compliance path options as described in Table 5.

Table 5 Four compliance path options in 'optimize energy performance'

Type	Path Options	Detailed requirement	Points
1	Whole Building Energy Simulation	- Energy analysis for the Building Performance Rating - Must comply with ASHRAE Standard and include all the energy costs and compared against a baseline building.	1-10
2	ASHRAE Advanced Energy Design Guide for Small Office Buildings 2004	- Buildings must be under 20,000 sq.ft and office occupancy and comply with all applicable criteria for the climate zone in which the building is located.	4
3	Advanced Buildings™ Core Performance™ Guide	- Buildings must be under 100,000 sq.ft and may NOT be health care, warehouse or laboratory projects.	2-5
4	Advanced Buildings Benchmark™	- Projects registered after June 26, 2007 may not use this option	1

In this research, to increase points and evaluate the entire building performance, option 1 was selected. This requirement pertaining to the goal of optimizing the energy performance is the attainment of a percentage of energy savings, which is determined by the difference in the proposed or designed model and the baseline building model. The ASHRAE Standard 90.1-2004 was used as the baseline model. The equation for the energy saving calculation is described below in Eq (1). Table 6 shows the minimum energy cost savings percentage for each point threshold. The percentage of saved energy compared to the baseline model determines the achievable points (USGBC 2005).

$$\text{Energy Saving (\%)} = \frac{(B - P)}{B} \times 100 \qquad (1)$$

where B is the base model (ASHRAE standard model); P, the proposed model (designed model)

Table 6 Possible points by Energy saving (%)

New Buildings	Existing Building Renovations	Points	New Buildings	Existing Building Renovations	Points
10.5%	3.5%	1	28.0%	21.0%	6
14.0%	7.0%	2	31.5%	24.5%	7
17.5%	10.5%	3	35.0%	28.0%	8
21.0%	14.0%	4	38.5%	31.5%	9
24.5%	17.5%	5	42.0%	35.0%	10

4. RESULTS

This paper compares the energy consumptions by using different window systems, for two locations in the U.S. with energy simulations have been carried out using the computer program eQUEST. The objectives were to (i) to evaluate the impact of façade design alternatives – glazing area and other properties with daylight and control (ii) to provide fenestration guidelines on selecting glazing area and other properties for use with daylight control at the early design stage in order to increase energy conservation.

The simulated results, energy usage differences between G1*(ASHRAE Standard without daylight control) and Glazings 1, 2, 3, 4, and 5 for Houston and Chicago, are displayed in Tables 7 and 8, respectively. Table 7 and 8 show the energy consumption (btu/sq.ft) and saving when Glazings 1-5 are used with daylight control system. Even though hundreds of parametric simulations were done in the original study, here the most representative data of Office 2 are shown.

Table 7 Energy Consumption and Savings, Houston

	WWR	15%	20%	25%	30%	35%	40%	45%	50%
G1*	Btu/SF	5095.5	5201.7	5313.1	5441.0	5592.0	5745.5	5895.0	6044.9

	Saving	11.8	14.2	16.8	19.1	21.5	23.7	25.7	27.5

(G1*: meet ASHRAE requirement without daylight control, G1-5 : with daylight control)

As expected, more energy is saved by using advanced windows. The results of the simulation show that, if windows with lower U-factors and SHGCs are installed, this results in a higher savings in total energy use. The achievable energy savings range from 5.2% to 35.7% (office 1), 4.5% to 26.8% (office 2), 3.8% to 21.2% (office 3) in Houston, and 3.4% to 34.4% (office 1), 3.2% to 27.5% (office 2), 2.9% to 22.2% (office 3) in Chicago. Comparing the office areas, greater energy saving can be achieved in office type 1, and maximum reduction was 35.7% and 34.4% (G5 window with a WWR of 50% and daylighting control), in Houston and Chicago, respectively.

However, as shown in Tables 7 and 8 and in Figure 3, Glazing 1 and 2 provide another perspective on the energy impact of windows with daylight control. It was found that the total energy savings with daylight control could be reduced with Glazings 1 and 2 (Houston) and Glazing 1 (Chicago). This means that when the building was equipped with a window of type G1 or G2, it had lower total energy savings, even though the window area was increased and larger windows and daylight control are widely known to increase electric energy savings. Although they had lower window properties (G2) and ASHRAE window (G1), the energy saving with lighting control did not follow this trend in the case of G3, G4 and G5.

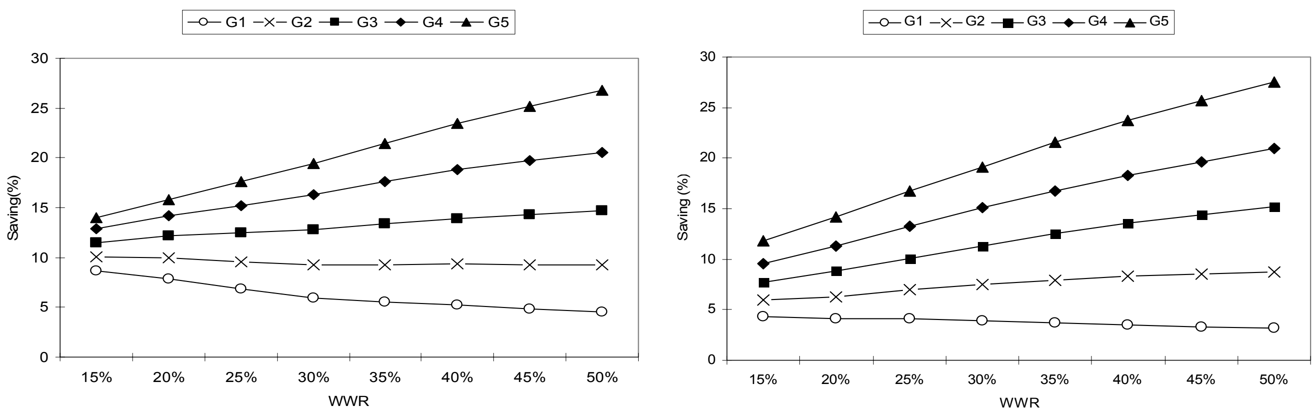

Figure 3 Energy Saving with Daylight Control as a function of Window Type (Houston and Chicago)

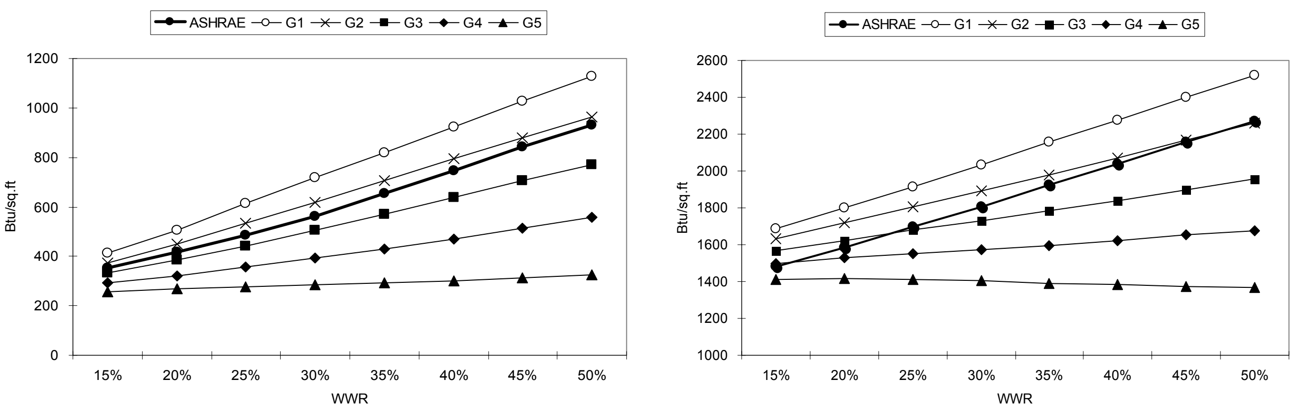

Figure 4 Annual Heating Energy Consumption as a function of Window Type (Houston and Chicago)

In order to verify the reason for this more analytically, Figure 4 shows the annual heating energy (space heating and hot water). Although it is not shown in this paper, electrical consumption was reduced 10-20% in all the glazing cases just as mentioned above based on previous researches. However when the annual cooling energy consumption was compared to G1*(ASHRAE), G1 and G2 consumed more energy than G1*(without daylight control) when daylight control was installed. We can notice that when increasing the percentage of glazed surface was increased, the annual heating energy was increased in associated with the window systems. The explanation is that the larger window area and properties could have caused the increased of heat losses in the winter because of the windows and dimmed artificial lighting.

Therefore, with regard to the weather data in Houston and Chicago, the use of a higher performance window (U-factor<0.73, SHGC<0.15 in Houston and U-factor<0.34, SHGC<0.23 in Chicago) is recommended in order to increase the energy savings and achievable LEED credits. The results of the simulation show that, if the glass type is very well chosen with daylight control, the building can perform better than the used and designed building. Furthermore, in order to obtain more LEED credits, glass characteristics and the type and size of the windows should also be considered by architects and engineers in the schematic design process.

5. Conclusion

The objective and methodology of integrating daylighting control and the fenestration system was developed and presented. In order to overcome the limitations of the previous studies, the detailed building energy simulations were carried out using eQUEST and simulation procedures were conducted using different combinations of the U-factor, SHGC and WWR when a daylight control system was used. The final step was a comparison of the energy consumption of the reference building (no daylight control with ASHRAE standard) to the simulated model with daylight control when different kinds of glass were installed (G1–G5). The significant findings are listed below.

• The energy saving was increased by using the high performance windows with daylight control because the total energy consumption was significantly reduced by the low U-factor and SHGC of the windows.

• With lighting control, although energy saving also can be increased using more advanced window and larger windows (G 3,4 and 5), it can be reduced when the U-factor and SHGC exceed the minimum criteria specified in this study, as in the case of Glazing 1 and 2 (Houston) and Glazing 1 (Chicago).

• Increasing window size does not necessarily result in more energy savings because of the complex relationship of heating, cooling and lighting energy requirements. Generally, utilizing a glazing with good thermal properties, energy savings will increase with increasing window size but this is also dependent on climate. As shown in Figure 3, G1 and G2 in Houston that increasing window size increases energy required whereas for G3, G4 and G5 increasing window size actually decreases energy required (increases energy savings).

• In relation to the annual heating energy, G1 and G2 consumed more than G1*(without daylight control) when daylight control was installed due to the increased loads associated with the heat losses in the winter from the windows and dimmed artificial lighting.

• Therefore, for a fenestration property guideline, the recommendation is to increase energy conservation with a daylight control system as follows; U-factor<0.73, SHGC<0.15 in Houston and U-factor<0.34, SHGC<0.23 in Chicago.

This paper provides a fenestration guideline to increase energy saving and obtain more LEED credits based on the LEED 2.2 green building rating systems. Moreover the fenestration problems can be found or fixed to determine energy savings resulting from building and building envelope installation retrofits because 44% of the glass used in nonresidential window stock in 2005 was clear, insulated glass, even though the usage of clear glass was decreased from 2001 (EIA 2003, AAMA/WDMA 2006). It is hoped that these criteria will enable architects and engineers to achieve better fenestration performance through a consideration of window properties, daylight control systems, and local climate types.

Keywords: climate, robustness, simulation, survey

Summary

Nine energy-efficient office buildings in Norway were studied in order to get an overview of the state-of-the-art of low energy office buildings in Norway. This paper includes a description and classification of the energy concepts and the corresponding technologies for reducing energy consumption in the buildings. Then, the implications of these technologies are studied with the help of a simulation model and the key issues that influence the energy performance of these buildings with special emphasis on envelope performance are reported. The results show that a careful design of climate adapted and super-efficient envelope systems with very good air tightness, moderate window sizes as well as ventilation systems with excellent heat recovery system can further enhance energy-efficiency. The local climate (and change) has a significant influence on the energy performance and should therefore be taken into consideration. Expected climate change over the next 50 years will influence the energy consumption and can cause great uncertainty in future energy consumption of office buildings.

1. Introduction

More efficient use of energy in the built environment is essential to reach political goals within Norway and the European Union on reliable energy supply and reductions of emissions of greenhouse gases. The built environment affects nature through energy use, emissions and use of raw materials. The total energy use in buildings accounts for about 40% of the total energy use in the country, excluding the energy sectors (Statistics Norway 2006). The construction industry may thus make significant contributions to environmental improvement through energy efficiency and utilization of renewable energy.

In order to realize energy performance requirements of a higher standard in the new Technical Regulations, it is necessary to develop new design strategies to meet these requirements - without sacrifices in other performance codes, standards or guidelines. Prior experience related to the introduction of new energy performance requirements has shown that the design energy performance levels are either not met, or they are fulfilled at the expense of indoor climate, technical quality (e.g. moisture related problems), or architectural quality. Facing the future risks of climate change, Norway also provides a unique “laboratory” for testing of the robustness of new building envelope solutions (Lisø 2005).

Therefore it seems appropriate to determine the parameters of building design that have the biggest influence on energy consumption of buildings. This work is a part of the Norwegian project entitled Climate Adapted Buildings (CAB) that runs from 2007-2009 and is financed by the Norwegian Research Council. Special focus has been put on the building envelope and some parameters that have an influence on the building load (Andresen et al. 2005). The starting point was to focus on office buildings but other building types will be studied in the near future.

2. Objectives

The project’s principal objectives are to develop more energy-efficient building envelope assemblies and new methods for the design of building envelopes in harsh climates, resulting in more accurate and geographically dependent design guidelines. The project includes analyses of building envelopes applied in different kinds of climates, different uses, and different construction methods.

Energy-efficient office buildings in Norway were studied in order to get an overview of the state-of-the-art of low energy office buildings in Norway. This paper includes a description and classification of the energy concepts and the corresponding technologies for reducing energy consumption in the buildings. Then, the implications of these technologies are studied with the help of a simulation model and the key issues that influence the energy performance of these buildings with special emphasis on envelope performance are reported.

3. Methodology

First, a survey of energy efficient office building projects in Norway has been conducted. Nine projects have been identified that met the following requirements:

- Energy consumption data (designed/measured) available
- Reduced energy consumption (compared with Norwegian average)
- Construction details available

The findings of the survey included the following issues:

- Context: climate, surroundings, building use
- Energy concept
- Envelope construction
- Energy performance – calculated/measured (have been reported in (Haase and Andresen 2008))

Then, a reference building was chosen because for this case monthly measured energy consumption data was available. The 3-storey building is 116m long and 18.1m wide and comprises 6 300m^2 heated floor area as illustrated in Figure 1. The construction of internal structure consists of medium weight furniture, medium weight partition construction with a thermal capacity of 12 Wh/m^2/K. For full hourly simulation the software SCIAQ Pro was used and then input parameter were changed one at a time. Detailed input data and validation with measured data have been reported (Dokka and Dokka 2004; Haase and Andresen 2008). The parameters listed in Table 1 have been studied with input and output variations as summarized in the same Table. Robustness estimation has been applied using the following equations (Lam and Hui 1996; Lomas and Eppel 1992).

$$SC1 = \left\{ \frac{d(OP)}{d(IP)} \right\} \tag{1}$$

with

d(IP) = overall change in input

d(OP) = overall change in output

$$SC2 = \left\{ \frac{d(devOP)}{d(devIP)} \right\} \tag{2}$$

with

d(devIP) = overall change in input deviation

d(devOP) = overall change in output deviation

SC1 and SC2 are sensitivity coefficients that give an indication of each parameter of the sensitivity of the output towards changes in the input. SC1 is often used in comparative energy studies because the coefficients so calculated can be used directly for error assessment. SC2 have the advantage that the sensitivity coefficients are dimensionless values expressed in percentage.

With the help of equation 1 it is possible to determine the robustness RI of the parameter by calculating the amount of change in input parameter (in its specific unit) that will result in a 10% change in output.

$$RI = 10\% \times OP_{BC} \times \left\{ \frac{1}{SC1} \right\} \tag{3}$$

with

RI = robustness indicator of parameter

OP_{BC} = output basecase (= 102kWh/m^2/a)

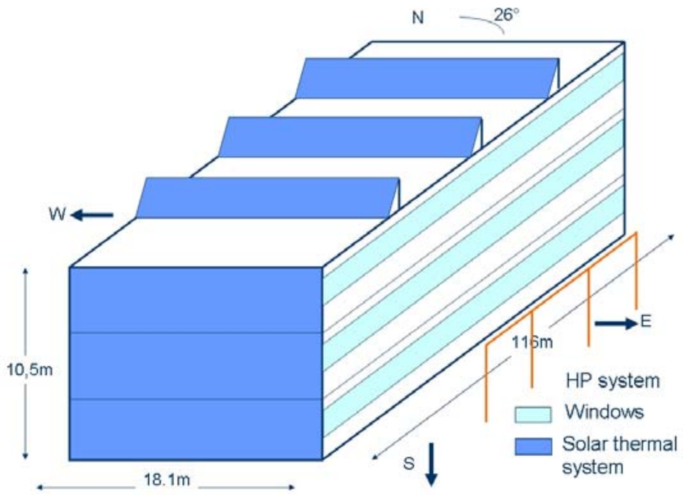

Figure 1 Model set-up

Table 1 Parameter for robustness analysis

Parameter	description	unit	Input min	Input max	IP range	Output min [kWh/m²/a]	Output max [kWh/m²/a]	OP range [kWh/m²/a]
Climate	annual average temperature	[°C]	4,70	7,80	3,10	86,56	151,30	64,74

Heating set point temperature	set point temperature	[°C]	18,00	24,00	6,00	91,00	129,42	38,41

4. Results

4.1 Survey

The key parameters of the buildings construction are described and performance data is summarized and results are shown in Table 2 and 3. The energy concepts have been categorized according to Dokka and Hemsted (1996). For projects that have been completed the surrounding context and building use is described in the following sections. The climatic context for each location is given in Table 2 as annual mean temperature (Tmean).

Table 2 Results energy concept

			Category											
Name	**Location**	**T(mean)**	**1**		**2**								**3**	**4**
			double-facade	superwindow	double-facade	earth coupling	heat pump	hybrid ventilation	passive cooling	PV-roof	biomass	thermal collector	demand control	district heat
Bravida	Fredrikstad	6.7°C		X			X				X	X	X	
Hamar Rådhus	Hamar	4.1°C	X		X									
Miljøsenter Bli.	Oslo-Blindern	5.9°C		X			X			X	X		X	X
MMS Horten	Horten	6.5°C					X							
Nydalspynten	Oslo	5.9°C		X					X		X	X	X	
Røstad	Levanger	5.0°C				X		X						
Sig. Halvorsen	Sandnes	7.4°C					X							
Telenor Kokstad	Bergen	7.8°C	X		X		X							X
Vestveien	Ski	5.5°C		X		X		X	X					

4.1.1 Bravida

Situated shortly above the Swedish border, Fredrikstad is a city and municipality with 71 000 inhabitants and covers a area of 290 km^2 at the mouth of the river Glomma about 100 km south of Oslo on the east coast of the county of Østfold.

The building is situated next to a 4 lane road (110) and its main axis is in North-South direction reducing south facing façade. The site of the building is embedded between a large 4 lane road in the west and mostly residential buildings on the east. The building was completed in 2002. It comprises of 6 300m^2 mixed offices and commercial space. The 3 storey complex (2 100m^2 per floor) consists of two buildings that are linked with an atrium that also hosts the staircase and lift. On the flat roof there are three shed roofs containing solar thermal energy systems, one system is integrated into the roof of the atrium, thus reducing solar heat gain into the atrium, and one system is integrated into the south facing facade.

The south facing façade does not provide windows. Instead, solar thermal panels are vertically installed. East and west facing façade comprises strip windows of the entire length of the building. The windows are equipped with 2 layered 12mm glass with argon filling with a U-value of 1.3 $W/m^2/K$).

4.1.2 Hamar rådhus

Hamar is a town and municipality in the county of Hedmark, Norway. The city is located on the shores of lake Mjøsa, Norway's largest lake, and is the principal city of the Hedmark County. Hamar is situated in the heart of the country and covers a area of 351km^2 and approximately 27 500 inhabitants.

The Hamar Town hall was completed in 2001. Snøhetta Architect AS was commissioned by the Municipality of Hamar to design the new town hall. The centre of Hamar is the pedestrian walkway in the middle of town, with the library, cinema and farmer's market on Stortorget (the big square) on the western side, and Østre Torg (the eastern square), which sits on top of an underground multi-story carpark, on the eastern side.

Table 3 Results of survey

Surveyed building	Year of constr.	Location	heated area [m^2]	Building	Geometry and orientation
1 Bravida	2003	Fredrikstad	6 300		
2 Hamar Rådhus	2001	Hamar	10 500		
3 Miljøsenter Blindern	2006	Oslo-Blindern	15 000		
4 MMS Horten	1996	Horten	3 700		
5 Nydal-spynten	appr. 2008	Oslo	2 700		6 Røstad	2002	Levanger	792		
7 Sig. Halvorsen	2006	Sandnes	?		
8 Telenor Kokstad	2000	Bergen	26 800		

9	Vestveien	appr. 2008	Ski	3 200	
The building is 5 stories tall and has a gross floor area of 10 500 m^2 and used as an office building. The depth of the plan is approximately 17m and the floor to ceiling height is 3m. The town hall has two double facades; the south façade and the north façade. The main reason for choosing a double façade in the north façade was to screen the interior from the traffic right outside this façade (Kleiven and Aschehoug 2005).

The outer layer is 8 mm glass while the inner is 2 layered 'energy glass' from Saint Gobain of type Planitherm Futur 1.1. The north facing facade is next to Hamars main traffic road, so the main reason for using it was it noise reducing function. The noise reduction was calculated during the early design stage to be 30 dBA. The south façade is used in combination with an automatic controlled solar shading system placed in the cavity for preheating ventilation air during the winter.

4.1.3 Miljøsenter Blindern

The new built office building **Miljøsenter Blindern** is located in Oslo. The capitol of Norway, and has in excess of approximately 530 000 inhabitants and covers an area of 453 km^2.

The building is situated in Blindern, where the many University buildings are located. It consists of an existing building complex and a new built extension. The extension complex is in completion phase (expected date end of 2007). The new extension complex is being built on the south facing orientation and attached through an atrium. It comprises 15 000m^2 offices and laboratory space in a 4 storey high building (3 storeys above ground).

4.1.4 MMS Horten

The 3 storey high building is situated near the water front next to the harbour in Horten, Norway. Horten muncipality has approximately 24 800 inhabitants and covers a area of 69 km^2 in Vestfold.

The long axis of the building is orientated in east – west exposing the long façade to the sun. The brick building comprises an atrium with metal sheet block that is placed in the centre. It is mainly used as office building, now occupied by the kusteverk.

4.1.5 Røstad

The new built office building of the Nord-Trøndelag College (HiNT) in Levanger is located 80 km north of Trondheim, Norway. The region has 17 000 inhabitants, of those approximately 7 000 in the village of Levanger which is known as the "green town" on account of its avenues and green areas. It is also a "school town" with a steadily growing college community.

The site is located near the city center on a slope overlooking the fjord. The building has two storeys, no basement, but instead a culvert for supply of ventilation is embedded in the ground along the central axis of the wing. The HiNT-wing has a net area of 478 m^2, of which 269.5 m^2 are used as office cells. Each cell is about 9 m^2. The gross area of the wing is 835 m^2, of which 112 m^2 is used for culvert, air intake tower and exhaust tower (Mathisen et al. 2005). Venetian blinds on west facing and roller blinds on east facing façade are automatically and simultaneously controlled for each façade, with a possibility for individual control.

4.1.6 Sig. Halvorsen

The new built office building **Sig. Halvorsen,** located in Sandnes, Norway (south of Stavanger). Sandnes has a population of 57 000 inhabitants and is located on the south-western coast of Norway. The coast is very flat, while the inland area is more dominated by mountains and fjords. The building is situated in an industrial area with low rise buildings surrounded.

4.1.7 Telenor Kokstad

The new built office building **Telenor Kokstad,** located in Bergen, Norway. Bergen municipality has approximately 239 300 inhabitants and covers a area of 465 km^2. The city is clambering up the mountainsides, looking over the sea, forming a spectacular amphitheatre.

The building complex is located central in Kokstad, one of Bergen most attractive new outskirts. The area is facing in south direction towards the Flesland airport. Prevailing winds are in the summer periods cooling from nordwest and in the winter periods wet temperate winds from south-southeast. The building was completed in 2000 and consists of a straight protecting complex in the north with four wings facing south, creating three protected gardens. It comprises 26 800m^2 office space for 1 100 office workers in 5 storeys with a large parking area underneath (10 000m^2). The technical installations were designed for a flexible use of the building offices.

4.2 Robustness study

The results are shown in Table 4. Results for SC1, SC2, and RI are given in the last three columns together with the deviation ranges of the input (IP) and output (OP). It can be seen from Table 4 that SC1 gives a good indication of the sensitivity of each parameter. The larger the number for SC1 the larger the sensitivity of this parameter to changes in the output. SC2 gives a percentage of this sensitivity but is related to the varying changes in input. RI gives comparable numbers that are related to the input units. The greater RI the better is the robustness of its parameter.

Results for SC1 give a clear indication of the sensitivity of each parameter. Large numbers indicate a strong sensitivity while small numbers indicate a weak sensitivity. It can be seen that e.g. the window size (WFR), the occupancy, and the U-values of roof and wall have the largest numbers, indicating the strongest sensitivity. On the other hand, e.g. heating capacity and U-value of floor have the smallest numbers, indicating a weak sensitivity. Results for SC2 relate to the deviation in input (and output) and are given in percentage. The highest percentages can be found for the cooling set point temperature, followed by the heating set-back temperature and the climate. This has to be used with care since the deviation in input is the basis for the percentage.

The last column with results for RI gives a clear picture of the robustness of each input parameter. It shows that e.g. a change of 10% change in annual energy consumption is caused by an annual mean temperature change of 1.62 °C, 1.48 ach (at 50Pa), etc.

Table 4 Results robustness study

Parameter	description	deviation range IP [%]	deviation range OP [%]	SC1 = d(OP) / d(IP)	SC2 = d(devOP) / d(devIP) [%]	RI = (IP value that changes OP 10%)	
Climate	annual average temperature	160.9	63.5	6.29	39.4 %	1.62	[°C]
Air tightness of envelope	air leakage	250.0	35.8	6.88	14.3 %	1.48	[ach at 50 Pa]
U-value	floor	50.0	0.0	0.24	0.0 %	42.3	[W/m^2/K]
	roof	50.0	3.5	36.28	7.0 %	0.28	[W/m^2/K]
	wall	75.0	4.5	30.92	6.0 %	0.33	[W/m^2/K]
Windows/glazing type and size	U-value	85.7	13.4	11.40	15.7 %	0.89	[W/m^2/K]
	WFR	233.3	26.3	87.94	11.3 %	0.12	[-]
Shading and daylighting systems	Fs	120.0	3.7	6.24	3.1 %	1.63	[-]
Efficiency of heat recovery system	μ	58.3	29.3	86.16	50.2 %	0.12	[-]
heating capacity	Ch	160.0	3.8	0.05	2.4 %	212	[W/m^2]
Occupancy	persons/m^2	150.0	5.7	38.45	3.8 %	0.27	[pers./m^2]
cooling set point temperature	set point temperature	15.4	30.0	7.64	194.8 %	1.34	[°C]
Heating set-back temperature	set-back temperature	35.0	16.2	2.37	46.2 %	4.31	[°C]
lighting load	Inst. load	175.0	28.8	1.68	16.5 %	6.07	[W/m^2]
Equipment load	Inst. load	175.0	30.1	1.73	17.2 %	5.91	[W/m^2]

5. Conclusions

5.1 Energy efficient office buildings in Norway

The results show that a very airtight envelope is an important step towards low-energy buildings. The climate has a large influence on the energy performance and should therefore be taken into consideration. Expected climate change over the next 50 years will influence the energy consumption and can cause great uncertainty in future energy consumption of office buildings.

It could be demonstrated that a careful design of climate adapted and super-efficient envelope systems with very good air tightness, moderate WFR as well as ventilation systems with excellent heat recovery system can further enhance energy-efficiency. In a well designed energy efficient office building further increase of thermal insulation does not reduce annual energy consumption significantly.

5.2 Robustness of parameter

This work tried to focus on parameter related to building envelope construction. Other parameters have been included in order to find out the relative significance of the parameter. Some parameters are difficult to measure and it is very important to see the robustness of each parameter. Results for RI for each parameter give a good indication of its robustness and the possibility to compare the parameters. A change in annual mean temperature of 1.62 °C for example results in the same change in output as a change of U-value of the walls of 0.33 $W/m^2/K$, a change in efficiency of the heat recovery system of 0.12, or a change of the internal load of app. 6 W/m^2. Further reduction of U-values for the floor or of the capacity of the heating system for example does only marginally effect the annual energy consumption.

5.3 Limitations and further work

Local sensitivity analysis gives only results for changing one parameter at the time. Synergy or other effects of changing more than one parameter could not be analyzed in this work. Future work will focus on this aspect and apply a global sensitivity analysis to the problem. It is hoped that these findings will assist in setting up future analysis work. More work is needed in order to accurately quantify the consequences and to develop envelopes that are capable of adapting to the changing climate. The supporting effect towards other energy concepts as heat pumps, natural/hybrid ventilation should be fully explored in order to realize sustainable energy-efficient buildings in Norway. A sensitivity analysis should be applied in order to evaluate the parameter with the biggest influence on building lifetime energy consumption.

Summary

The effects on both the indoor and ambient thermal environments of a rooftop garden on a large-scale commercial building were studied from three standpoints. Firstly, the thermal insulation effect of the rooftop vegetation was estimated. Measurements of heat transmission through the ceiling slabs both with and without vegetation showed an approximately 4.5% reduction in the annual cooling load due to the vegetation. Secondly, mitigating effects of the vegetation on urban warming were evaluated from surface temperature measurements by an infrared camera on fine days in summer. The vegetation was expected to reduce the sensible heat emitted into the atmosphere to 37.2% less than that with the whole rooftop garden covered with colored concrete. Thirdly, since the rooftop garden is mainly planned for visitors, the thermal environment of resting places and foot paths, and the behavior of visitors in summer were observed. The SET* evaluation results show that people do not feel “hot” in the tree shade or the shade of the tower building on sunny days. The mean residence time of the visitors tended to be longer in the tree-shade than in the sun under strong solar radiation, while on cloudy days or in the evening places without tree shade tended to be preferable and had longer mean residence time.

1. Introduction

Greening of cities is an urgent requirement in Japan. The main objectives are mitigation of urban warming (so-called a heat island phenomenon) and improvement of the landscape. For urban warming, improvement of roofs and rooftops are the first priority because they are the hottest places in a city during daytime in summer. Thus, many local governments have already started subsidizing green roofs.

Mitigation of urban warming by rooftop vegetation has been discussed in many studies and its validity has been established (e.g. Takakura et al., 2000, Wong et al., 2003). Reduction of cooling and heating load is said to be relatively small because its influences is limited to the top floor. However, large rooftop gardens have become popular in recent years. They not only conserve energy for a large top floor but also produce a large cool area in the city.

Little is known about the thermal environment of a rooftop garden with many tall trees where people can enjoy staying. It is thus important to understand the relationship between the thermal environment and human aspects such as a thermal sensation and people’s behavior. Thorsson (2003) investigated human behavior in a park, a plaza and an open café which was partially shaded. She showed that the ratio of people in the shade increased as the mean radiant temperature increased in all places, particularly in the café. She also suggested that human behavior was influenced not only by the thermal environment but also by psychological aspects.

This study focuses on the three aspects of thermal environment in a rooftop garden of a large-scale commercial building: energy conservation, mitigation of urban warming and human comfort.

2. Summary of object building

The building investigated comprised nine stories above ground and four under ground, and was located in the center of Osaka, Japan’s second largest city. Its gross floor area was 167,200 m^2 and its rooftop area was approximately 8,000 m^2 including approximately 3,300 m^2 of vegetation at the time of this research, which was from 2003 to 2005. (After its grand opening in 2007 it had a gross floor area of 243,800 m^2 and its rooftop was approximately 11,500 m^2 including approximately 5,300 m^2 of vegetation.) Photo 1 shows an overall view of the building, taken during this research in 2004. The garden was distributed on a terraced rooftop from the 2nd to the 8th floor, which faced north and sloped an average of 16.3%. A 150 m tower building was located to the west of the rooftop garden and cast its shadow on the garden in the afternoon. Footpaths passed through the site from top to bottom and several rest areas were arranged along the paths.

Photo 1 Overall view of building (left). Enlarged image of rooftop garden (right).

3. Reduction of Heat transmission into building due to vegetation

3.1 Measurements

The temperature on the underside of rooftop slab was measured at both vegetation and non-vegetation points. Fig.1 shows a floor plan of the rooftop garden and the measuring positions including those mentioned in chapter 5 (see legends). Points G and N indicate measuring points with and without vegetation, respectively. Fig.2 shows cross-sectional views of the ceiling slabs and the measuring positions. Measurements were carried out from August 2003 to March 2005.

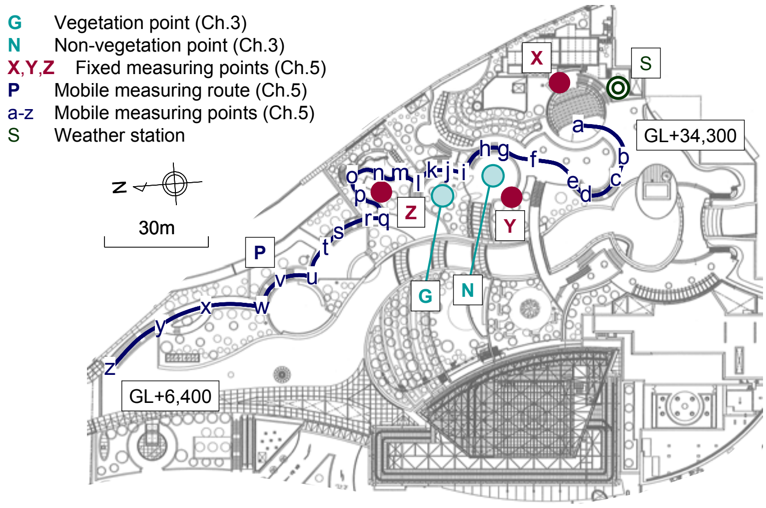

Figure 1 Floor plan of rooftop garden and measuring positions including those mentioned in chapter 5.

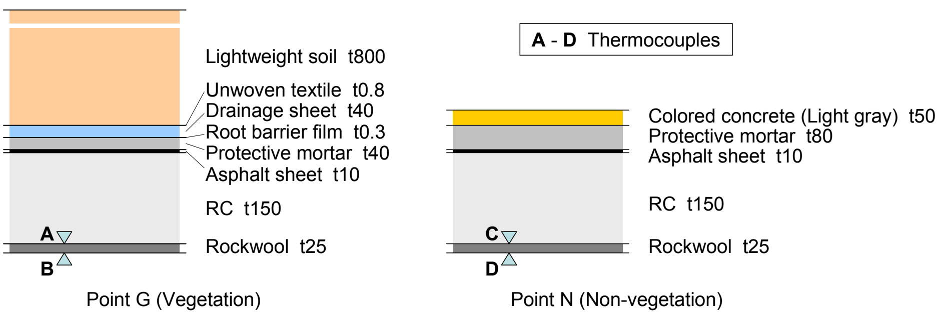

Figure 2 Cross-sectional views of ceiling slabs.

3.2 Results

Fig. 3 shows annual variations of surface temperature on the underside of the rooftop slab (points B, D in Fig.2) and the outdoor air temperature from April 2004 to March 2005. The temperature at point D (non-vegetation) changed and fluctuated following the air temperature, while that at point B (vegetation) changed gradually within a narrow range between 22 and 29 deg. C throughout the year. This indicated that the vegetation and earth of 80 cm thickness improved the top floor's insulation.

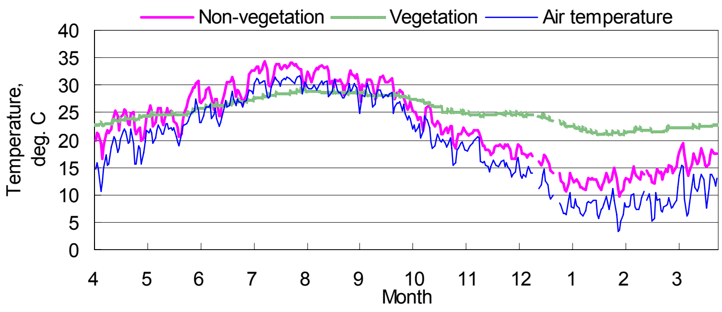

Figure 3 Annual variations of daily mean temperature on underside of rooftop slab from April 2004 to March 2005.

Fig.4 shows diurnal variations of heat transmission into the room through the ceiling slab measured on 9 July 2004. Those at the non-vegetated point varied between 2.6 W/m^2 and 7.6 W/m^2, while those at the vegetated point varied between -0.7 W/m^2 and 0.3 W/m^2. The maximum difference in heat transmission between two points was 7.6 W/m^2 at 20:00 h. That is to say, vegetation with adequate earth has the potential to remove most of heat transmission into a room even during the hottest season.

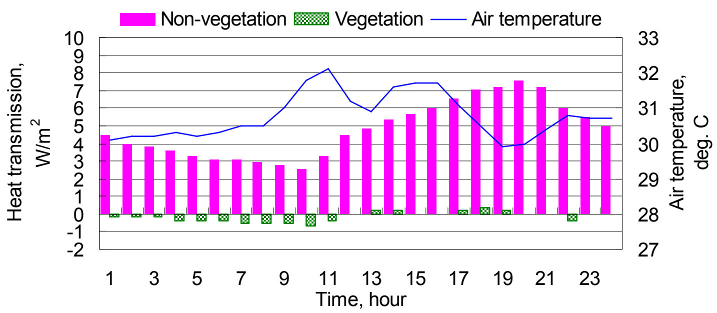

Figure 4 Diurnal variations of heat transmission into room through ceiling slab measured on 9 July 2004.

Accumulated heat transmission at the non-vegetated point during the cooling period (May – Sept.) was -3.7 MJ/m^2, while that at the vegetated point was 19.0 MJ/m^2, making a total reduction of 22.7 MJ/m^2. Total cooling load on the top floor during the cooling period was assumed to be 50,242 MJ when the object area was 100 m^2, the cooling period was 1,000 hours, and the cooling load was 34.9 W/m^2 from building fabrics, 20 W/m^2 from people and 70 W/m^2 from lighting. Since the reduction in cooling load by the rooftop vegetation was 2,274 MJ per 100 m^2, the reduction ratio was estimated to be approximately 4.5 %.

4. Reduction of sensible heat emitted into atmosphere by vegetation

4.1 Measurements

Thermal images of the targeted building and its surroundings were captured by an infrared camera (TH9100MV, NEC San-ei Instruments, Ltd.) from the top of an adjacent high-rise building. Images were taken at intervals of 5 minutes for one day from 00:00 h on 29 July 2005.

4.2 Results

4.2.1 Diurnal variations of surface temperature of various materials

Fig.5 shows diurnal variations of mean surface temperature of vegetation (trees), colored concrete (Light brown), asphalt paving, train tracks, a water cascade and building wall facing east. The average temperature was calculated from the numerical data of target areas in thermal images. The asphalt paving rose to approximately 51 deg. C, while vegetation rose to around 35 deg. C at maximum, which was nearly equivalent to that of the water flow. The colored concrete, which is a typical paving material for foot paths, rose to 43 deg. C, which was approximately 10 degrees higher than that of the adjacent vegetation. During night, the temperature of the artificial materials remained a few degrees higher than that of the vegetation and water due to their higher heat retention.

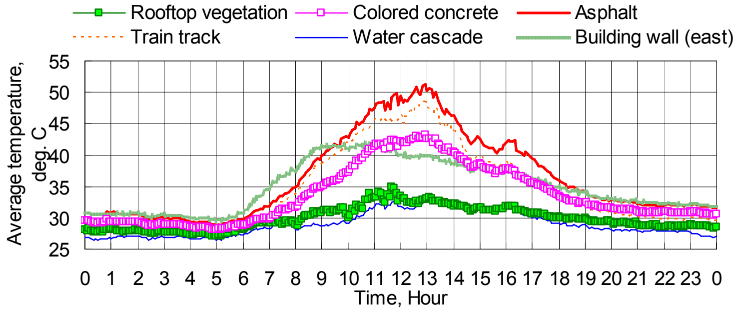

Figure 5 Diurnal variations of mean surface temperature of various surfaces on 29 July 2005. Note that the colored concrete was light brown, which was different from the place measured in Ch.3

4.2.2 Estimation of accumulated sensible heat from various materials

Fig.6 shows accumulated sensible heats Q_s [MJ/m^{2}day] on 29 July 2005 estimated as follows. Data were accumulated for 24 hours.

$$Q_s = \sum_{t=0}^{23} HS = \sum_{t=0}^{23} \left[\alpha_c (T_s - T_a)\right] \quad (1)$$

$$\alpha_c = (5.3 + 3.6U)/0.86 \qquad U \leq 5.0 \quad (2)$$

where HS [W/m^2] is the sensible heat flux from the surface, T_s [K] is the surface temperature obtained in the previous subsection, T_a [K] is the air temperature, α_c [W/m^{2}K] is the heat-transfer coefficient, and U [m/s] is the wind speed. The maximum wind speed was approximately 3.3 m/s on the test day. Eq. 2 is usually applicable to a plane surface. The sensible heat flux emitted from the vegetation is generally difficult to evaluate because of its form, so it was estimated by assuming that it was a plane surface.

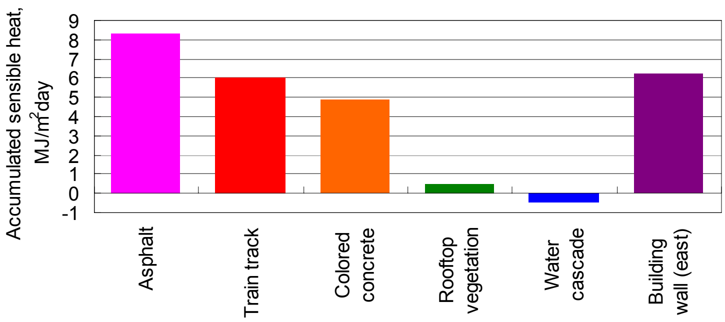

Figure 6 Accumulated sensible heats from various surface materials on 29 July 2005.

The figures show how much each material heated the atmosphere during the 24 hours of the test day. The total sensible heat per day from the vegetation was slight: approximately one seventeenth of that from the asphalt paving or approximately one tenth of that from the adjacent colored concrete. This suggests that the vegetation on this building reduced the sensible heat emitted into the atmosphere to 37.2 % less than that with whole rooftop garden covered with the colored concrete. The building wall facing east also had a large impact on the urban warming. (Unfortunately the southern and western walls of the tower building were out of sight in the thermal images. In general, a western wall emits the largest amount of sensible heat of walls facing the four cardinal points, particularly in summer.)

5. Thermal environment in rooftop garden

The rooftop garden was open to the public, and was mostly used by customers visiting shops in the commercial complex. Due to its terraced form, people who intended to take a rest outside or to stroll through the rooftop garden usually went up to the top floor first and then down the paths.

5.1 Thermal environment at rest areas

Measurements were carried out on 28 - 30 July 2005. The points X, Y and Z in Fig.1 indicate the rest areas and also the fixed measuring positions, in which several benches were installed. Fig.7 shows hemispherical photographs taken using a fish-eye lens at those points. Table 1 shows measuring factors and measuring instruments.

Point X Point Y Point Z

Figs.8 (a) - (f) show the total vertically emitted solar radiation, wind velocity, air temperature, wet-bulb temperature, MRT (Mean radiant temperature) and SET* (Standard new effective temperature, Gagge, 1986) measured on 28 July 2005. SET* is a thermal index defined as the equivalent dry bulb temperature of an isothermal environment at 50% relative humidity in which a subject, while wearing clothing standardized for the activity concerned, has the same heat stress (skin temperature) and thermoregulatory strain (skin wettedness) as in the actual environment (ASHRAE, 2001). It is usually used to indicate indoor thermal comfort. However, in recent years it has often also been used as a most suitable index for evaluating outdoor thermal comfort. SET* was calculated using MRT (Mean radiant temperature) [K] estimated from observation data such that:

$$MRT = T_g + 2.37\sqrt{U}\left(T_g - T_a\right) \tag{3}$$

where T_g [K] is the globe temperature measured using a globe thermometer.

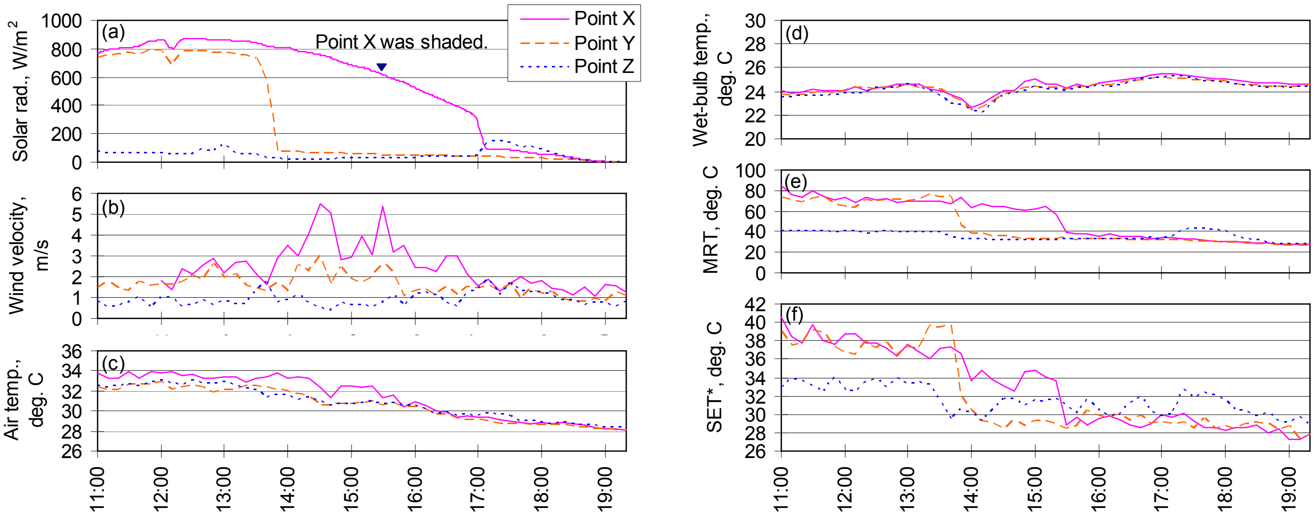

Figure 8 Vertical quantity of total solar radiation (a), wind velocity (b), air temperature (c), wet-bulb temperature (d), MRT (e) and SET (f) measured at the points X, Y and Z on 28 July 2005. Note that the total solar radiation measured at the point S was used instead of that of the point X.*

On the test day, point X, located at the top of the rooftop garden, was in a sunny location. Point Y was in the shade of the tower building after 13:30 h and point Z was in the shade of trees all day. The wind velocity at the top of the garden (point X) was 3 - 5 m/s in the afternoon, and this was the highest of the three points because it was in a relatively open location. The wind at point Y was lower than that at point X because the rooftop garden had a terraced form and the intermediate floors were partly surrounded by walls. Point Z had the weakest wind of around 1 m/s because it was sheltered by trees. The air temperature at point X was higher than that at the other points by 1-2 degrees in the afternoon, which was probably due to the colored concrete surround. At points Y and Z, it shifted at a similar level, that is, the air temperature in and out of the tree shade was of almost the same scale. The humidity was almost the same at the three points, that is, the quantity of water vapor in the tree shade was not exceptionally high.

It is suggested that the differences between the SET* values of the points were mainly affected by air temperature, wind velocity and MRT. The SET* values at points X and Y were extremely high before they were shaded by the tower building, after which they became lower than that at point Z. The weaker wind at point Z seemed to make the SET* value higher than at points X and Y. Yamashita et al. (1991) examined the relationship between the SET* values and the thermal comfort outside in summer. It is suggested that 33 deg. C of SET* indicated the boundary between hot and warm in the seven classes from hot to cold. Consequently, it can be said that people on the rooftop garden feel “hot” if they are in the sun, while in the tree shade or the shade of the tower building they do not feel “hot” and outside tree shade is preferable.

5.2 Thermal environment along footpath

The points on Line P in Fig.1 indicate the measuring points where the instruments were successively moved. The data were collected within a few minutes at each point and the total time per run was around 1.5 hours. Five runs (RUN 1 - 5) were carried out per day at roughly two-hour intervals. Figs.9 (a) and (b) show the height above the ground and the view factors of each material surrounding the measuring points. The view factors were calculated using hemispherical photographs assuming that a man was a rectangular parallelepiped. The number on the abscissa indicates the distance along the path. Note that the right end of abscissa is the start position corresponding to the top of the rooftop garden. From the distributions of view factors it was found that people on the path were surrounded by vegetation at a high ratio particularly at around the middle and end of the path.

Fig.9 (c) shows the time variations of SET* values on the path. The SET* values at most parts of the path are lower than 33 deg. C for all RUNs except RUN 1. This means that the footpaths offered “non-hot” conditions during most of the afternoon when the number of customers visiting the shopping complex gradually increased.

5.3 Thermal environment and residence characteristics

The relationship between thermal environment and residence characteristics were investigated from 2 - 4 August 2004 and from 28 - 30 July 2005. The numbers of visitors entering and leaving points X and Z were counted every ten minutes by video images.

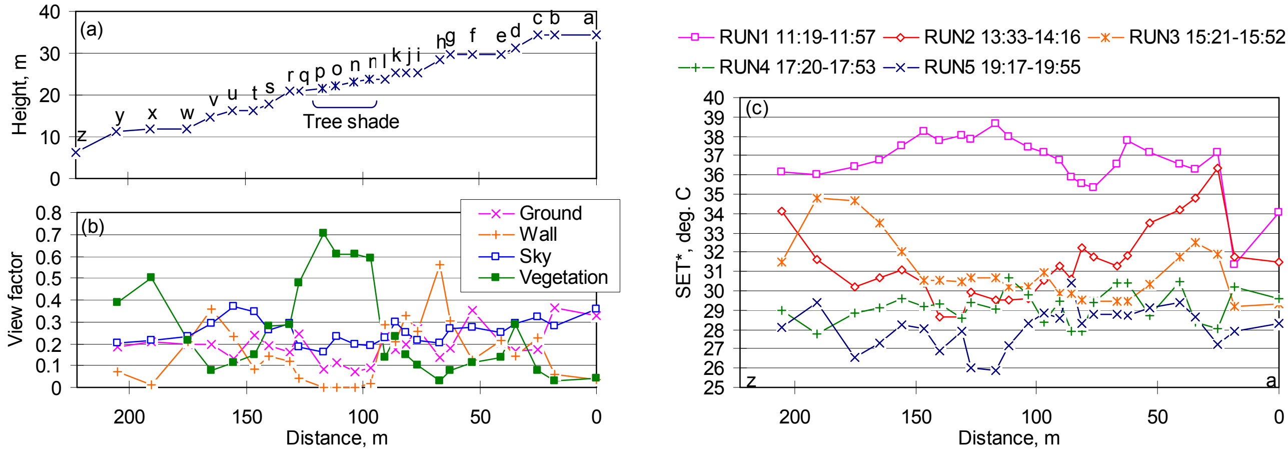

Figure 9 Height above ground (a),view factors of each material (b) and time variations of SET on path P (c) at RUN 1 - 5 on 28 July 2005.*

Fig.10 shows the relationship between the total numbers of visitors at points X and Z from 11:00 h to 15:30 h. Accumulated solar radiations are also indicated as proportionally sized circles. The cumulative number of visitors tended to be relatively small on the day with abundant solar radiation at both points. Furthermore, point Z, in the tree shade, seemed to be preferable as a place to visit. In contrast, the cumulative number of visitors tended to be large on the day with little solar radiation at both points. Furthermore, point X, which had no tree shade, seemed to be preferable as a place to visit.

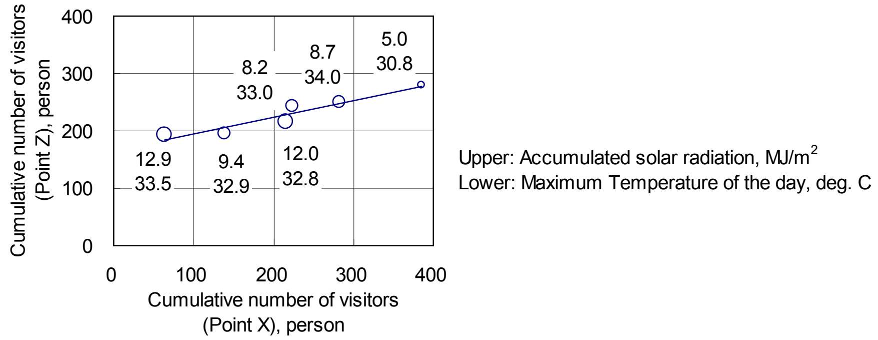

Figure 10 Relationship between cumulative number of visitors at points X and Z from 11:00 h to 15:30 h.

The mean residence number L [person] was calculated such that:

$$L = \lambda W \quad (3)$$

where λ [person/min] is the arrival rate and W [min] is the mean residence time.

Fig.11 shows the relationship between the solar radiation and the mean residence number (a), the solar radiation and the mean residence time (b) at the points X and Y on the sunny days (02/08/04, 28/07/05 and 29/07/05). No apparent relation was found among the figures.

Fig.12 shows the results when the solar radiation in Fig.11 was substituted for SET*. This clearly shows that both the mean residence number and the mean residence time had a negative correlation to the SET* value. Consequently, it can be said that outdoor human behavior is affected not only by solar radiation but also by air temperature, wind velocity, humidity and radiation from the surroundings. In other words, SET* seems to be an appropriate index for evaluating the outdoor thermal environment, particularly where people enjoy staying or strolling in summer.

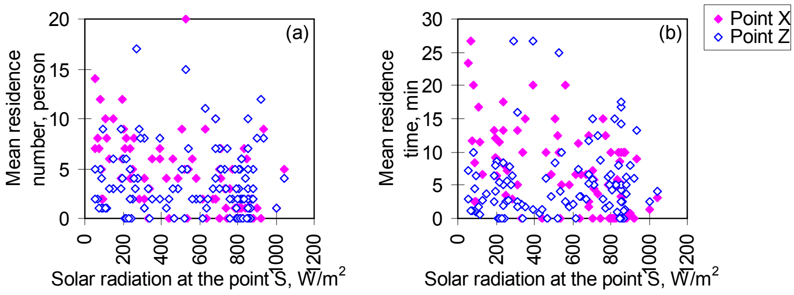

Figure 11 Relationship between solar radiation and mean residence number (a), solar radiation and mean residence time (b) at points X and Y on the sunny days (02/08/04, 28/07/05 and 29/07/05).

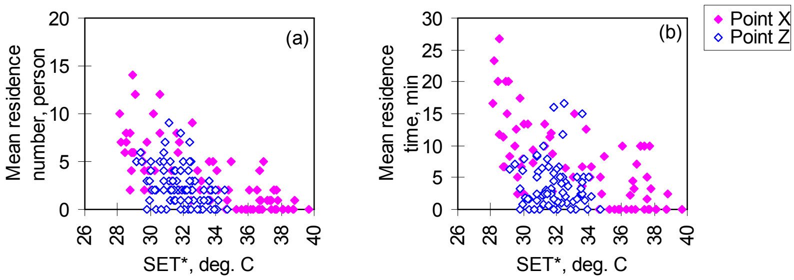

Figure 12 Relationship between SET and mean residence number (a), SET* and mean residence time (b) at points X and Y on the sunny days (02/08/04, 28/07/05 and 29/07/05).*

6. Conclusions

Reduction in a building's heat load, reduction in sensible heat emitted into the atmosphere and the thermal environment in pedestrian spaces in summer were investigated for a large rooftop garden on a commercial complex. Results are summarized as follows.

Reduction in annual cooling load due to vegetation on the rooftop was estimated to be approximately 4.5% compared with colored concrete.

Reduction in sensible heat emitted into the atmosphere by vegetation was estimated to be 37.2 % compared with that when the whole rooftop garden was covered with colored concrete.

The SET* evaluation results show that people do not feel "hot" in the tree shade or the shade of the tower building on sunny days.

Both the mean residence number and the mean residence time had a negative correlation to the SET* value. The mean residence time tended to be longer in the tree shade than in the sun under strong solar radiation, while on cloudy days or in the evening, places without tree shade tended to have a longer mean residence time.

UNDERSTANDING CITIES AS SOCIAL-ECOLOGICAL SYSTEMS

Chrisna du Plessis[1]

[1]CSIR Built Environment, Pretoria, South Africa, cdupless@csir.co.za

Keywords: social-ecological, system, complexity, cities, ecosystem, resilience

Summary

This paper builds on earlier ecological approaches to urban development, as well as more recent thinking in the fields of sustainability science, resilience thinking and complexity theory, to propose a conceptual framework for understanding cities as social-ecological systems (SESs) as a point of departure for further dialogue in the study of urban sustainability. It proposes that cities should be understood as (1) complex, adaptive systems that are (2) integrated across spheres of matter, life and human social and cultural phenomena (or mind), (3) are structured as nested systems that allows interaction across scales and levels of organisation, and (4) that what differentiates cities (and SESs) from other types of ecosystems is the introduction of abstract thought and symbolic construction that allows for considered novelty, communication of ideas across time and space, and therefore learning, and reflexive thinking.

1. Introduction

As we are improving our understanding of the intricate relationship between human well-being and ecosystem integrity, it is becoming clear that the great global challenge of urban development in the 21st century lies in finding ways in which city planning and management address not only the needs of urban dwellers in large, rapidly growing and mainly poor cities, but address these needs in a way that acknowledge the interdependent relationship of cities and the ecosystems of which they are part. There is growing consensus that a reductionist command and control approach is perhaps not the most appropriate way of interacting with what is in essence a dynamic complex adaptive living system; and that resilience and adaptation are factors of urban sustainability as important as (if not more than) conservation, efficiency and equity. This necessitates a quite dramatic mind shift in how cities are viewed. The notion of cities as ecosystems can be traced back at least to the 1960's and the thinking of Howard Odum and Ian McHarg. More recent thinking attempts to describe the interface space between humans and nature (of which cities are one example) as social-ecological systems. However, while there is general consensus that social-ecological systems refers to the human-nature relationship, exactly how this relationship is to be comprehended and structured as an integrated system is not clear. This paper builds on earlier ecological approaches, as well as more recent thinking in the fields of sustainability science, resilience thinking and complexity theory, to propose a conceptual framework for understanding cities as social-ecological systems as a point of departure for further dialogue in the study of urban sustainability.

2. An Ecological Approach to Cities

Applying ecological thinking to cities is not a new idea and has led to several different approaches, some from the perspective of the science of ecology (such as urban ecology), some using ecological concepts as metaphors or guidelines for human activities (e.g. urban metabolism, ecological footprinting and carrying capacity), and some using nature itself as the metaphor to guide the physical development of cities (e.g. ecological design and engineering, biomimicry).

There are, however, major differences between what Tansey (2006) refers to as old ecological thinking and new ecological thinking. Within old ecological thinking, ecosystems are described as though they follow a linear evolutionary process towards a steady-state climax community; and as closed, localised systems with circular metabolisms that self-regulate into an equilibrium state which results in no waste and maximum resource efficiency (Alberti *et al.*., 2003; Tansey, 2006). New ecological thinking, in turn, shifts from an equilibrium to a non-equilibrium model that sees ecosystems as open, dynamic and highly unpredictable, driven by processes and often regulated by external forces, not necessarily internal mechanisms (Alberti *et al.*., 2003). Some of the foundational concepts of new ecological thinking include complexity, resilience, non-linear system dynamics, adaptive management, and emergence. This expands the ecological metaphor to acknowledge not just the flows of matter, energy and information within the system (the 'economy of nature'), but also the importance of context and relationship, as well as the fundamental role of change and adaptability in an essentially unknowable and unpredictable larger system. New ecological thinking also includes humans as components of ecosystems (McDonnel and Pickett, 1993; Alberti *et a.l*, 2003).

Urban ecology initially concerned itself with ecological studies in urban environments, seeing the city as a particular form of landscape (Weddle, 1986). Cicero (1989) identified four types of such studies: 1) comparing different land-use types within an urban setting; 2) comparing an urban area with a nearby 'natural' area; 3) gradient analysis that assess the ecological effect of urbanization along a gradient such as from inner city to periphery; and 4) urban succession or development dynamics of ecosystems where urbanization is seen as a 'disturbance' similar to fire or flood. However, recent thinkers (e.g. Rees, 1997; Grimm *et al.*, 2000; McIntyre *et al.*, 2000; Alberti *et al.*, 2003) have argued for a new theoretical framework that would include humans into ecosystem studies, and especially the study of human-dominated ecosystems such as cities, and have themselves proposed such frameworks.

A number of these frameworks are based on the concept of resource flows, as explained by Grimm *et al.* (2000:574): "The concept of ecology of cities has to do with how their aggregated parts sum, that is, how cities process energy or matter relative to their surroundings." Amongst the routes proposed that could be used to understand the ecology of cities are: material and energy flow accounting (e.g. Odum, 1967 & 2002; Odum, 1997; Haberl *et al.*, 2004), whole-system metabolism (Girardet, 1996) and the estimation of the ecological footprint of the city (Rees and Wackernagel, 1994; Rees, 1997). These routes take existing ecological methodologies and apply them to the dynamics of resource use in cities.

A second approach to applying ecological thinking to cities is through ecological design and engineering. The argument is that if cities are seen as another of nature's biological systems then they should follow the 'rules of nature'. These rules have been defined as the four laws of ecology by Barry Commoner: "Everything is connected to everything else; everything has to go somewhere; there is no such thing as a free lunch; and Nature knows best" (cited in Ross, 1991:194). Karl-Henrik Robèrt's *Natural Step* (Robert, 1995) describes these rules as four system conditions: we should not take more from the Earth's crust than is slowly redeposited; nature cannot sustain a systematic increase of chemical compounds - we cannot emit more waste products than nature can process; the physical basis for the earth's productive natural cycles and biological diversity must not be systematically deteriorated; and there must be fair use of resources in order to meet human needs on Earth. Frijtof Capra (1996) and Janine Benyus (2002) also identified additional rule sets that make similar statements.

The logical progression from this was that the infrastructure of cities (as ecosystems) should be designed to follow these laws. This approach was introduced into modern 'sustainability' thinking by theorists such as Howard Odum (1967), Ian McHarg(1969), who built on the thinking of Frederick Law Olmsted, Ebenezer Howard and Patrick Geddes to suggest city planning, management and design that learn from and co-operate with nature. From this starting point a number of contemporary scholars and practitioners (e.g. Todd and Todd, 1993; Lyle, 1994; Girardet, 1996; Van Der Ryn and Cowan, 1996; McDonough and Braungart, 2002; Eisenberg and Reed, 2003) developed the basis of what is now referred to as ecological design. Kibert (2006) describes three versions of ecological design: strong ecological design based on principles of biomimicry and cradle-to-cradle design; weak ecological design based on minimizing lifecycle impacts; and intermediate ecological design based on the synergistic integration of built environment systems with ecosystems.

However, the metaphors of ecology cannot be applied to the city without taking into account the human component. Arida, (2002:xix) recounts that Saint Isidore of Seville (c. AD 560-636) traced in his Etymologies the origins of the word city to different sources: "the *urbs* (or stones) of the city, laid for practical reasons, and *civitas*, the emotions, rituals and convictions that take form in a city". Saint Isidore would point out that the approaches described above focus on the *urbs* – on the physical aspect of human activities within an "ecosystem created by humans specifically for dwelling" (as cities are described by Stearns and Montag, 1974). Yet, apart from regulatory suggestions, the *civitas* is not addressed. While attempts have been made by ecologists and sociologists to understand how the social aspect of humans can be included in the study of city as ecosystem, Alberti *et al.* (2003) pointed out that neither of these sciences can explain how integrated human and ecological systems emerge and evolve, because human and ecological factors work simultaneously at different levels. Calls for a "new integrative ecology that explicitly incorporates human decisions, culture, institutions and economic systems" (Grimm *et al.*, 2000:575) has led to a new field of research that focus specifically on coupled human-nature systems, now referred to as social-ecological systems, which will be explored in the next section.

3. Understanding Social-Ecological Systems

Cities are arguably the most closely coupled human-nature system and therefore presents a particular challenge to research on social-ecological systems. The exact nature of social-ecological systems (SESs), or what it is that differentiate SESs from other types of ecological systems, is still open to debate. The Resilience Alliance (2006) describes SESs as "complex, integrated systems in which humans are part of nature." However, while there are numerous methodologies and conceptual frameworks for studying aspects of social-ecological systems, the understanding of how the social and ecological components are to be integrated into one system is still evolving. Grimm *et al.* (2000) suggested a modelling framework that would include variables in social patterns and processes and human perceptions as drivers of change together with ecological drivers. Alberti *et al.* (2003) proposed a similar conceptual model that links human and biophysical drivers, patterns, processes and effects. However, both these models are limited to a view of humans as another species of mammal with no attempt to address those aspects that differentiate social-ecological systems from other types of ecological systems. Haberl *et al.* (2004) moves some way towards addressing this gap by suggesting that social-ecological systems should be seen as a 'biophysical' sphere of causation governed by natural laws, and a 'cultural' or 'symbolic' sphere of causation reproduced by symbolic communication.

An analysis of papers published over the past ten years in the main journal of social-ecological system research, Ecology and Society, suggested the following four propositions as a point of departure for formulating a conceptual framework for understanding the nature of SESs:

- *Proposition 1*: A social-ecological system is one integrated system that spans across matter, life and human social and cultural phenomena (or mind).
- *Proposition 2*: A social-ecological system consists of relationships between elements at a number of scales and within nested systems.
- *Proposition 3*: SESs are systems that are complex and adaptive, with properties of self-organization and emergence.
- *Proposition 4*: What differentiates SESs from other systems is the introduction of abstract thought and symbolic construction.

3.1 SESs as integrated systems of matter, life and mind

Four frameworks that aim to unite matter, life and mind through an evolutionary hierarchy were explored: the 'Spheres of evolution' of Vladimir Vernadsky, Pierre Teilhard de Chardin and others that describes what Barrett (1985) describes as a 'noosystem', Kenneth Boulding's 'Hierarchy of Systems Complexity', Herman Dooyeweerd's 'Cosmonomic Idea of Reality', and Ken Wilber's 'All-Quadrants All Levels (AQAL)' framework. A synthesis of these frameworks suggests that SESs are made up of three distinct, but nested and interpenetrating, spheres or domains of existence: the geosphere (matter), the biosphere (life), and the noosphere (mind). These spheres represent a continuum of increasing complexity and consciousness, with matter as the first (lowest) level, life as the next level emerging from (and thus including) matter, and mind as the last (highest) level emerging from life. Thus, life requires matter in order to exist, and mind requires life and, therefore, matter for its own existence.

Within these spheres there are certain modalities, or irreducible areas of functioning, each with its own set of 'laws' that governs existence within that particular level of functioning, and supports the emergence of the next level. These 'laws' are deterministic at the lowest levels and become increasingly normative in the higher levels. SESs span across all three spheres and the modalities within each of the spheres, although elements within SESs can exist at different levels. As elements of the system become more complex and conscious they inhabit higher levels of development, but at the same time contain all the properties of the lower levels.

Apart from the 'vertical' dimension provided by the holarchy of development, each level of development also spans horizontally across four quadrants of interior, exterior, collective and individual. SESs thus represent the combination of the 'exterior', as created by biogeochemical processes (in which humans have come to play a disproportionate part), and the 'interior', as created by, and experienced through, the human psyche and processes of thought, including the "shared cultural worldspace" (Wilber, 2000). It is proposed that SESs are not seen as made up of humans, their social structures, and the technological and cultural artefacts that support these structures (the social system) on the one hand, and everything else that constitutes life and the universe (the ecological system) on the other. Instead, humans are placed within nature as an integral part of the processes of change and co-evolution. Thus at the exterior level, humans and their artefacts are an indivisible part of the biosphere and they, like any other organism, participate in and co-create the metabolic and change processes that shape the biosphere. Humans are bound by the same laws that apply to other organisms when operating at the lower modalities, but their interior processes allow humans to apply these laws to create and adopt technologies that introduce novel components to the system at scales both above and below that of the individual human. However, this is only one part of the picture. SESs consist of many types of hierarchies with elements interacting across the various levels and types of hierarchy. The next step is to understand the holarchic and cross-scale nature of this structure, and the interrelationships between elements operating at the various levels.

3.2 Nested Across Multiple Scales

Hierarchies of scale are just one aspect of the multilayered structure of SESs to understand. Also important are hierchies of level, and in particular the concept of holarchy, which can be seen as the nested hierarchy of whole/parts or holons. Another multi-level conceptual framework that is prominent in the literature on the study of SESs is that of panarchy.

Hierarchies of scale have to do with the quantifiable and measurable aspects of a system (Gibson *et al.*., 2000). The most commonly used hierarchies of scale fall into three categories: temporal, numerical and spatial. In hierarchies of scale the next hierarchical level is the sum of the previous levels (e.g. one kilometre equals the sum of a thousand metres or of a million millimetres) and the difference between levels is merely a quantitative one. Hierarchies of level, on the other hand, are concerned with organization and structure and, as described by Simon, this category of hierarchy is the ordering structure of complex systems (Simon, 1962). In essence, hierarchies of level refer to a structural organization whereby a system (mechanical or natural) is constructed by first constructing simple sub-assemblies, which in turn are connected into a subsystem of a higher order. These sub-systems are in turn connected to create the final system. The system is therefore constructed from the bottom up in increasing levels of internal complexity.

The difference between hierarchies of level and those of scale is that the difference between the hierarchical levels in the system is also qualitative and functional. The entities at level three have properties and functions substantially different from those at levels two or one. This is also where the major difference between mechanical systems and natural systems enters. With mechanical systems, the properties of levels two and three can be predicted with a certain amount of certainty from the properties and interactions of the elements at the levels below. However, in natural systems the properties of each level that emerges from the interactions at lower levels cannot be “strictly and totally deduced from their components” (Wilber, 2000:54) and are qualitatively different. The most important aspect of this category of hierarchy is that each element is simultaneously a whole (as an individual entity) and, as an element in the system at that level, a part of a larger whole. The whole can thus be seen as an emergent property of the structural relationships and interactions of the parts. This type of hierarchy is referred to as a holarchy (Koestler, 1975:103).

Furthermore, each holarchic level operates according to its own set of rules or patterns that determine behaviour at that level. However, lower levels can influence higher levels through upward causation and higher levels can control or influence what happens at lower levels through downward causation (Roger Sperry cited in Wilber, 2000:28). This notion of interaction and influence across different hierarchical levels is the central tenet of the next major concept to be discussed, namely panarchy.

As part of their quest to develop an integrative theory for understanding processes of change happening globally, Holling, *et al.*. (2002) coined the term ‘panarchy’ to provide an organizing framework for theory dealing with cross-scale dynamics in natural and social systems. The term is a complex wordplay on the idea of hierarchy (of level and scale) combined with the prefix ‘Pan’ to indicate change across the whole. The panarchy framework is based on two premises. The first is the idea of the adaptive cycle and that the levels of the panarchy can be drawn as a set of nested adaptive cycles arranged as a dynamic hierarchy in space and time (Holling, *et al.*., 2002:101). The second is that the adaptive cycle phases at different levels interact or connect with one another. The panarchy is constructed gradually as potential accumulates at one level, until a threshold is passed that allows the establishment of a slower and larger level. Conversely, the panarchy collapses or enters state breakdown when there are simultaneous crises at different levels (e.g. all levels of the system enters the breakdown phase of their individual adaptive cycles at more or less the same time) or a crisis cascades across all levels. From this point of view, the objective of sustainability initiatives is not to resist or reverse change, but to accept that change is inevitable and manage the phase changes within systems in such a way that the system does not lose its fundamental identity and tip into another stability domain, or that such collapses do not cascade upwards into the larger system. This means managing the capacity of the system to experience shocks while retaining essentially the same function and structure, and therefore identity, a concept known as resilience. A resilient social-ecological system has a greater capacity to avoid unwelcome surprises (regime shifts) in the face of external disturbances and so has a greater capacity to continue to provide us with the goods and services that support our quality of life

(Walker and Salt, 2006:37). In order to understand how resilience can be managed, it is necessary to understand the characteristics of SESs as complex, adaptive systems.

3.3 Complex and Adaptive

SESs are complex, in that they are diverse and made up of multiple interconnected elements, and adaptive, in that they have the capacity to change and learn from experience. Lucas (2004) explains that the essence of complex adaptive systems is that they self-organize to optimize the function of the system, creating new niches as necessary, and changing their composition to fit the changing patterns they encounter. Unlike mechanical systems, where systems and parts have fixed functions that either work or do not, adaptive systems have flexible functions that adjust to the context of their environment. A key aspect of these types of systems is that their constituent agents are constantly making predictions based on its various internal models of the world (its implicit or explicit assumptions about the way things are out there), and adapting to each other and to the external environment. These adaptive responses and interactions allow the system as a whole to undergo spontaneous self-organization into collective structures with properties that cannot be predicted from the properties of the parts, and which the agents may not have possessed individually (Waldrop, 1992) - a concept referred to as emergence. Furthermore, the connections or interactions between the elements of the system are non-linear and contain feedback loops, which implies that small causes can have large results. Understanding SESs as complex, adaptive systems therefore means that the important properties to consider are those related to change and the system's ability to deal with change – for example, resilience, adaptability, transformability, connectivity and diversity.

One of the hallmarks of complex systems is the aggregation of local actions into well-defined global patterns such as cities and neighbourhoods (self-organized criticality) (Miller and Page, 2007). Within these systems, microlevel agents interact to create the global properties of the system. These global properties then feed back into the microlevel interactions. This happens in both physical and social systems. What differentiates physical systems from social systems is that the agents in social systems often alter their behaviour in response to anticipated outcomes. This brings us to what it is that differentiates SESs from other ecological systems – their capacity for abstract thought and symbolic construction.

3.4 A Capacity for Abstract Thought and Symbolic Construction

As Westley, *et al.*. (2002:108) describes, the ability of humans to make sense of their world through abstract thought and symbolic construction allows "the formation of social systems and a 'virtual reality' through which options and scenarios can be explored and new possibilities can be imagined". They suggest four elements of the dimension of symbolic construction: the creation of a hierarchy of abstraction (which allows the agent to separate him/herself mentally from the realm of time and space); the capacity for reflexivity; the ability to remember the past and learn from it (hindsight) and imagine the future and plan for it (foresight); and the ability to externalize symbolic constructions in technology. Furthermore, the ability to use symbols and with symbols, language, allowed humans to develop sophisticated means of communication that allow abstract ideas to be communicated not just across vast distances, but also across time. This ability to communicate across space and time allowed for the creation of the three dimensions of social systems identified by Giddens (1979), that is the structures of signification (the social rules that govern meaning), domination, and legitimisation (the rules that actors draw upon to sanction their own behaviour as well as that of others, according to Abou Zeid, 2007).

It is this sophisticated interior aspect and the opportunity it creates for novelty, foresight, reflection and learning, as well as the beliefs, norms and values that are formed at this intangible level, that differentiate SESs from other ecological systems. It not only allows the development of novel social and technological systems that determine the nature of interactions between humans and other aspects of the biosphere, but also allows humans to engage in reflection regarding the meaning and consequences of these interactions.

4. Discussion

The easiest way to illustrate how the above framework applies to cities is to use a narrative example of how a system perturbation such as crime at the level of the individual agent cascades through the different levels and spheres of the city system. In the imaginary city of Ezulweni a burglar breaks into the house of a middle-class couple, stealing their electronic goods and second car. According to his value system (a noosphere concept) he is perfectly justified in doing this as a form of wealth redistribution after his ancestors have endured years of oppression under the wealthy elite. Outraged and fearful, the couple install burglar bars in front of their windows and security gates at the doors (a noosphere response to a biophysical threat resulting in a change of their biophysical environment). A couple of weeks later, the burglar breaks into another house down the road, and then another. He is bold because the social structures that are supposed to protect the community from crime are hampered by a lack of biophysical resources (e.g. patrol vehicles) and normative dysfunction (a demotivated police force) and he no longer has any fear of being caught. Fearful of becoming the next victims, all the houses in the neighbourhood install bars (adaptive behaviour). However, this does not stop the burglar as he merely uses a crowbar to break through the security bars (adaptive behaviour). His success further emboldens his friends, who also try their hand at a little burglary, which escalates the perceived threat and with it fear. The neighbourhood install alarm systems and start building walls around their properties. At this point, while each agent is still acting in response to an external driver (the burglar) and the response of his neighbours, their combined efforts are already having an effect on the function and identity of the neighbourhood (a scale up), and on the local economy as businesses opened up to exploit the new niche presented by a need for security (abstract thinking allowing them to predict a market opportunity). The walls mean that neighbours no longer have social contact (which has implications for social cohesion) and people no longer walk down to the corner store (which adds to local traffic and carbon emissions). The criminals, finding that all these new security measures cannot be overcome by a mere crowbar, up their game and introduce firearms, turning the crime of burglary into robbery and vehicle hijacking (thus upping their effects on the hierarchy of significance). This increases the levels of fear within the neighbourhood, where people respond by either moving (leading to a drop in property values), or increasing their security by purchasing firearms themselves (thus escalating the levels of violence and altering value systems). However, firearms costs money and the thieves find they need higher levels of sophistication to achieve their aims. This leads to criminal specialization and organised crime syndicates with accompanying changes in the value systems of the communities from which the criminals hail. Powerless to stop the criminals on an individual level, the householders now organise themselves and close off their neighbourhood with fences, gates across formerly public streets, and armed security guards. With this action they cause a number of changes to the larger urban system. Firstly, the structure of the city is changed, disrupting traffic patterns and increasing the burden on roads outside the enclosed neighbourhood, which increases congestion and with it, air pollution. Increased levels of air pollution have a detrimental effect on human health within the city and add to global carbon emissions and therefore climate change. In addition, the property values of those houses outside the walls plummet and some houses are simply abandoned, leading to a deteriorating urban environment. Frustrated, the criminals also move their efforts to other, more vulnerable neighbourhoods where householders go through the same cycle until eventually the city becomes fragmented into security enclaves and a new phenomenon – the gated community – emerges in new development, forever altering the character of the city. To this, the city authorities finally respond by introducing legislation that bans enclosed neighbourhoods, but this cannot be enforced as the situation has already escalated out of hand and the city does not have the funds to take all these communities to court to enforce the legislation. In the meanwhile a large economic sector has developed around crime and security and this sector contributes significantly to both the national GDP and the tax base, while providing many low-skilled jobs.

One can continue to unpack this story in many different directions, but the point is that small individual actions have come together to influence the system at much larger scales. These actions were driven by a combination of social and individual value systems across a range of ethical norms, and were enabled by social structures to effect a lasting change on the biophysical system of the city, as well as the national economy and aspects of the global biophysical system. As the story unfolded there were key points at which there was an opportunity to change the trajectory of the story. However, as the changes cascaded up levels, the interventions that would have been required increased in scale and cost. Unfortunately, because many of the changes were initiated at an individual level, they were not picked up by the social structures that should have responded before these changes have already cascaded up a level. If city authorities had understood cities as social-ecological systems where individual actions, driven by value systems shaped by a changing environment, can have far-reaching effects on the identity of the city, they would perhaps have tried to intervene earlier, rather than when it was too late to do anything but adapt to the changes.

5. Conclusion

Understanding cities as social-ecological systems with complex, adaptive behaviour requires the urban sustainability debate to shift from a quest for the ultimate rules for city planning and design, to finding ways that accept and embrace change and novelty while building the capacity for resilience in the interaction between noosphere and biosphere. This would require a rethink of indicator systems to monitor changes not only in the biosphere, but also in the noosphere, (e.g. changes in norms and values) and track the systemic influences and the complex, adaptive processes found in cities. It would further require that planning and regulatory processes are guided by an understanding of systemic interactions; take into account issues of behaviour, relationship, resource flows and resilience across the social-ecological system; and acknowledge that uncertainty and unpredictability is a characteristic of cities that requires adaptive management and flexibility in implementation. Lastly, it requires that the conceptual and other models used to inform systemic planning processes account for the flows between interior aspects (e.g. value systems or structures of legitimisation such as regulations) and both interior changes (e.g. a shift towards a specific value system such as environmentalism) and exterior change (e.g. changing value systems driving the development of new technologies). It must further be able to close the loop by accounting for changes in the exterior related to manifestation of interior events (e.g. the use of a new technology increasing pollution levels).

The ideas outlined in this paper only begin to scratch the surface of a very complex, yet compelling, way of looking at cities. It is hoped that the pebbles it has dropped in the pond will spread beyond this conference to further enrich and stimulate the debate and contribute to a better understanding of how best to achieve sustainability in cities.

THE CONCPET OF PROGRESS AND PROCESS IN A SUSTAINABLE SOCIETY

Yuefeng Guo[1]

Keywords: progress, process, sustainable society, organic world view, sustainable architecture.

Summary

In common parlance, the word “progress” has come to be synonymous with such words as advancement, growth, development or improvement. This usage of the term has caused confusion and even harm, particularly in terms of sustainable development. This paper clarifies the meaning of the term by placing it in three categories: the idea of process, the idea of evaluation, and the idea of control. The paper then suggests a new understanding of the term with reference to a sustainable society. Progress is in one sense essentially a process, not an achievement or an end. Progress signifies evaluation and betterment with regard to basic and intermediate needs, morality and spirituality. Progress implies the idea of controlling or overriding the natural world which is an obstacle for sustainability. With these principles progress of architecture is explored. In addition, this paper discusses the importance of the ideas of process for a sustainable society by maintaining that the absence of these ideas has led to many problems in education, technology, economy and architecture in modern society. A sustainable society is an inevitable and progressive step towards the common future. Sustainable architecture as a reflection of such a society is also a step forward in the history of architecture.

Introduction

Problems of the industrial-affluent consumer society are ubiquitous. Environmental crises, overpopulation, shortage of food and resources, poverty, unemployment, falling quality of life, family breakdown, inequality in the distribution of wealth and in gender, just to list a few, are the predicaments that modern society experiences (Carson, 1962; Black, 1970; Ehrlich, 1970; Goldsmith et al, 1972; Meadows et al, 1972; Schumacher, 1974; Shiva, 1989; Ponting, 1991;). Aurelio Peccei (1976) called the predicament “the world problematique.” Other commentators have suggested current society has entered a “terminal phase” (Trainer, 1995), “the end of the era” (Schumacher, 1997) and the emergence of a quite different society--- a sustainable society (Pirages, 1977; Bookchin, 1980, 1982; Milbrath, 1984, 1989; Trainer, 1985, 1995; Tokar, 1987; Dobson, 1991; Garbarino, 1992; Robinson, 1994). The challenge which all people are now confronting is difficult because to sustain life requires paradigm shifts in almost every sphere of life: education, technology, science, economy, politics, and especially in world view, values and ethics. One of the obstacles is the problem of the concept of progress in existing society, particularly in architecture. People often think that a sustainable society is a regressive step as it appears to restrict human activity, and that sustainable architecture moves architecture backwards as it often looks like vernacular architecture with simple technologies. This paper sets out to examine the problem of progress in modern society and architecture, clarify it in terms of a sustainable society, and demonstrate that a sustainable society is an inevitable step to move human civilization forward, and that sustainable architecture progresses architectural history.

Definitions of Progress

Progress is one of the most abused words in the contemporary vocabulary. Etymologically, progress is of Latin origin, and combines two elements, pro and gradus, meaning to walk forward. In general usage, the term has come to be synonymous with such words as advancement, growth, development and improvement (Bossard, 1931). Historically, the earliest connotations of the term have been rather general and simple, involving essentially a philosophy of life or of history, and constituting a speculation on the nature and direction of the changing life stream. J.B.Bury (1920) who wrote so illuminatingly about the idea of progress, considered it to mean that “civilisation has moved, is moving and will move on a desirable direction towards general happiness enjoyed by all the members of society…The idea of human progress is a theory which involves a synthesis of the past and a prophecy of the future” (1920:2-5). Nicholas Rescher (1997) also defines progress in this manner as a matter of change in a direction of betterment, and believes that progress has two dimensions: retrospective (how far humans have come) and prospective (where they have yet to go). For him, a crucial measurement of progress is to see whether the human condition of children’s children--- and their children’s children will be better. Aldous Huxley (1938) maintained that “real progress is progress in charity, all other advances being secondary thereto.” For him, progress can be achieved by the most nearly free, ideal man, (the non-attached man in his terms), who always combines virtue with insight. The man of non-attachment means non-attached to the self and to what are called ‘the things of this world’ (1938:3-4). This has been associated with the teachings of traditional philosophers and the founders of religions with attachment to an ultimate reality greater and more significant than the self. This doctrine can be found at the very heart of the teachings of Buddha, of Lao Tsu and the Gospel of Jesus. The practice of non-attachment entails the practice of all the virtues and of charity (Huxley, 1938). As people become non-attached, progress in charity will be ensured and thus human society progresses. James H. S. Bossard (1931) has provided a more comprehensive framework to understand the nature of progress, which involves three ideas: the idea of process, the idea of evaluation and the idea of control. Using this framework, this paper will carry out an analysis of progress.

Progress as the Idea of Process

Virtually all usage of the word progress harks back to the idea of a reaching out or movement towards a given end or ends. Nowhere is there any conception of stability, but everywhere an acceptance of the idea of movement or change. Progress, in other words, is in one sense essentially a process, not an achievement (Bossard, 1931).However, progress as the idea of process is largely neglected in modern society (Bossard, 1931; Wright, 1997). The ignorance of this idea lies in the fact that the process of fulfilling an end with a means is omitted because the means becomes the end. The neglect of the concept of process is visible in almost every aspect of affluent-industrial consumer society.

Modern education has become an end, not a means. In terms of vernacular wisdom, education is not an end, but a means to an end, that is, schools do not educate children only for the purpose of educating them, but to fit them for life. The goal of education is to discipline individuals to be the whole person of spirit, mind and body. Schumacher (1974) claimed that the primary aim of education is to teach values and wisdom, and that the teaching of specialised knowledge is secondary. The holistic development of the whole person may help create what Huxley called the man of non-attachment. Therefore, progress in charity is assured, and in turn society moves forward. On the contrary, current education institutions prepare and select specialised workers, experts and professionals for jobs in the industrialised production system as “they are predominantly geared to the reproduction of industrial-affluent consumer society” (Trainer, 1995:166). Specialisation is the product of industrialisation, owing to the division of labour (Smith, 1937), along with the modern concept of progress. This is guided by the mechanistic world view derived from the scientific revolution which was mainly formed at the time of the Enlightenment. The drawback of specialisation is that it puts sole focus on objects rather than relationships (Capra, 1982a), and that it blinds people to see only one aspect or one dimension of reality and think of this as the total reality (Kumar, 1982). In addition, the focus on the significance of success in present education results in education as a means becoming an end. This emphasis reinforces the obsession with being seen to be successful in life, with being promoted, rising in power, wealth and prestige, and therefore being richer and consuming more (Trainer, 1995). It produces men of attachment. Therefore, current society is regressive as it cannot progress in charity with regard to Huxley’s theory and it omits the idea of process.

The lack of process can be also found in modern technology. Obviously, it is wise to regard technology as a means to achieve a better life. Unfortunately, it is not the case in existing society. Once technology ceases to be a means, but becomes an end in itself like a stimulant, it will unavoidably develop by its own law and principles, and then become inhuman. The appearance of inhuman technology is virtually everywhere in the present. Faster travel has increased the risk of accident and environmental pollution, creating diseases unheard of in the past; modern medicine rapidly cures the malady but generates side-effects requiring further treatment; and more significantly, industrialisation on the basis of the division of labour, with its advanced technology has created mindless, repetitive and soul-destroying work. This has destroyed initiative and rotted brains and soul of a vast number of workers, lessening their dexterity, lowering their social status and reducing the chance for them to work, thus worsening the problem of unemployment. Thomas Aquinas defined each person as a being with brains and hands, who enjoys nothing more than to be creative, usefully and productively engaged with both (Capra, 1982a). However, the so-called ‘labour-saving’ technology is most successful in reducing or even eliminating the skilful and productive capacity of human hands, which had previously been in touch with real materials of one kind of another (Schumacher, 1974). When industrial society does not provide an opportunity for its members to be the whole person, it is hard to say that society still progresses. It is no wonder that Huxley (1938) stated that all today’s technological progress is regressing in charity and that technology developed for its own sake may have a hidden cause—attachment to wealth. Since the desire for wealth is not limited by the final gaol to acquire “something better than money” (Ruskin, 1909), and modern people are educated to be passive consumers and attached to materialistic affluence, prodigious technology, as a means to accumulate wealth, inevitably becomes an end in itself. This leads to discussion of another ignored facet of progress, the idea of process in the economy.

The absence of the idea of process in the modern economy lies in the fact that it operates free of morality, ethics and spirituality. Morality, it could be argued, represents the way that people would like the world to work—whereas economics represents how it actually works (Levitt & Dubner, 2005). When the world driven by its economic system does not run in the way morality expects, the economic system is an end in itself due to the fact that it is no longer limited by morality, ethics and spirituality. Schumacher (1997), however, believed that economics without spirituality can provide temporary and physical gratification, but that it cannot offer internal fulfilment. By contrast, spiritual economics brings service, compassion and relationships into equal play with profit and efficiency. Both economics and spirituality are needed together. But today there exists the erroneous belief that being rich is being happy (Schumacher, 1997), and that "I produce and I consume, therefore I am" (Smith, 1993:183). The truth is that when life seems better and much more comfortable, people feel worse and less happy (Batra, 1991; Easterbrook, 2003). Human thirst for happiness is unquenchable. It means that human beings have a spiritual nature. They have needs that cannot possibly satisfied by material objects. The human desire for happiness is infinite, but material things are finite; hence things can never quench the desire. The limited cannot yield the unlimited. Only an infinite entity can satisfy the infinite human hunger for happiness. Spiritual activity is simply a pursuit of the infinite entity (Batra, 1991). The modern economic system is not subject to morality or spirituality, but rather based on the philosophical foundation that the greater the production and consumption, the happier the person. However, since consumption is merely a means to human well-being, the aim should be to gain maximum well-being with minimum consumption. The optimal pattern of consumption, producing a high degree of human satisfaction by means of a relatively low rate of consumption, allows people to live without great pressure and strain and to fulfil the final goal of life: well-being, happiness and spirituality.

The absence of the idea of process in the modern economic system may also result from the loss of traditional wisdom, in that the focus of modern education is laid on specialised knowledge rather than wisdom. In the Western epistemological tradition the most important key to wisdom, the understanding of reality, has been the concept of causation (Smith, 1993). As Aristotle put it, "Men do not think that they know a thing till they have grasped the 'why' of it." Aristotle pursued this investigation by showing that there are four conceptually distinct and essential causes for every rational human activity utilising material resources: the *causa materialis*, the *causa efficiens*, the *causa formalis* and the *causa finalis*. An example is the building of a house, wherein the wood and other materials are the *causa materialis*, the carpenter's labour and the tools are the *causa efficiens*, the blueprint or plan in the carpenter's mind is the *causa formalis*, and the need to have a home for shelter and comfort is the *causa finalis*. To fully understand this act of building a home, it would be necessary to investigate all four of these causes. The same methodological approach needs to be used to examine the modern economic system with the intention of fully comprehending it. In current analysis, however, in economics as well as in other theoretical sciences, two of the types of causes advanced by Aristotle have been largely omitted: the *causa materialis* and the *cause finalis* (Georgescu-Roegen, 1971). In its search for understanding and its quest for reform, modern economics has tended to utilise only the *causa efficiens* and the *causa formalis*, and of these two it has emphasised the *causa efficiens* much more than the *causa formalis*. More accurately, the *causa formalis* is often submerged by the *causa efficiens*. The omission of the *cause finalis* exactly signifies the absence of the idea of process in the modern economic system as it is not a means to an end, but an end in itself free of moral and spiritual constraints.

The loss of progress as the idea of process seems also true of architecture. Architectural design has become a means and simultaneously an end owing to the specialisation of industrial society. As a consequence, the process of building and interactions with the consumers of buildings are neglected. However, in the days of vernacular architecture, the users of buildings understood the process of construction, even if they were not themselves builders (Vale and Vale, 1991). The Eskimos, for instance, built igloos by a natural unselfconscious action-based approach rather than the highly self-conscious and introspective mode of thinking which the modern architect has come to manipulate (Figure 1). For the former, there was no design problem but rather a traditional form of solution with variations to suit different circumstances which were selected and constructed without a thought to the principles involved (Lawson, 1990). Currently, the consumer is supposed to be moved by the architecture, and if not moved, then usually this is because the consumer has failed to understand the purpose of the architect rather than the architect understanding and responding to what the consumer wants. Moreover, in the vernacular process, designing is also very closely associated with making. The Eskimos did not require an architect to design the igloo in which they sheltered while hunting. In most vernacular societies the craftsman offered a complete design-and-build service to customers (Lawson, 1990). In the modern world, things are different. An average modern house and its content represent the products of industrial specialisation and ignorance of the idea of process. The house itself was probably designed by an architect and sited in an area designated as residential by a town planner. Inside, the furnishing and fabrics, the furniture, the machinery and gadgets have all been created by specialised designers who may have never even once dirtied their hands with manufacture of these artefacts. The architect has perhaps muddied his boots on the site when talking to the builder once in a while, but that is about as far as it goes. Architectural design spontaneously as a means and an end has separated the architect from the process of building and the occupant. Nevertheless, this separation does not necessarily promote better design, as Brenda and Robert Vale (1991) have claimed," a green dimension to such issues recognises that a common base must exist between all concerned, whether artist or layperson. Since the journey into space, the fragility of the world has both shocked and challenged. It has become apparent how dependent each person is on the next, for all belong to the same whole (1991: 7).

The importance of progress as process is that the course of the solution to social problems is itself a social process, and that the solution is crucial for progress in society. In other words, progress may mean the process of solving problems. It ought to be kept in mind that education, architecture, technology or economy are a means to well-being, happiness and spirituality, but only when each is a means to an end, not an end in itself.

Progress as the Idea of Evaluation

The term progress not only indicates the process of change but also it signifies its evaluation. It is at once a phrase, not only of description, but of appreciation as well (Bossard, 1931). Progress, along with freedom and democracy, is the manifesto of modernism (MacIntosh, 2007). However, progress stamped in particular by the Enlightenment, expresses more explicitly the self-image of the modern age, and is predicated on the proposition that development of science and technology, and economic growth more or less automatically lead to an increasingly humane society (Burgen et.al, 1997). In reality, the outcome, an increasingly inhuman society, is the opposite to the promise of modern progress. It results from the fact that science, technology or economy are all means, but are utilised to evaluate progress. This also explains the absence of the idea of process in modern progress as discussed above. To assess progress with means makes science, technology, economy and in turn the whole modern social system free of morality and spirituality. Scientific and technological advancement and economic growth as the judgment of progress are problematic.

The Age of Enlightenment, and the theory of progress to which it gave rise, were centred on the sacredness of two categories: modern scientific knowledge and economic growth. It was believed that with the guidance of science and economic growth, society could progress. However, Vandana Shiva (1989) maintains that the unbridled pursuit of progress started to destroy the life-support systems of forests, water and land. The act of living and of celebrating and conserving life in people and in nature seems to have been sacrificed to progress, and the sanctity of life has been substituted by the sanctity of science and growth. If progress based on the advancement of science and technology and economic growth threatens survival itself, there must be something seriously wrong with the evaluation. What none of the thinkers of the Enlightenment envisaged, and their followers today have failed to perceive, is that human life can become more savage, irrational and self-destructive even as scientific advance accelerates (Gray, 2004). The modern stereotype that progress of society merely relies on improvement in scientific and technological knowledge, and economic growth has been cultivated since the Enlightenment when the striking disparity between the development of intellectual power, scientific knowledge and technological skills, on the one hand, and of wisdom, spirituality and ethics on the other was triggered. From that time onwards, scientific and technological knowledge have grown exponentially, while there has been hardly any progress in the conduct of social affairs (Capra, 1982b). Ravi Batra (1991) has stated that spirituality is the foundation of human progress, and that progress in an intellectual and physical sense is impossible unless there is a spiritual betterment at the same time. The reason why progress cannot occur in the physical arena through economic growth and the intellectual through the development of science and technology lies in the very nature of the universe which exists in a vibrational flow balanced by positive and negative forces. The Chinese have named them the yang and the yin. The earth and the atmosphere surrounding it are finite. Any positive waves in this finite realm will have to be counterbalanced by a negative wave (the balance between the yin and yang). Therefore, any invention, creating a positive wave of physical comfort is matched by a corresponding negative wave leading to discomfort (Batra, 1991). For example, air conditioners create physical comfort of some sort, but use CFCs which are closely linked with the greenhouse effect and the ozone hole. In view of the interdependent nature of the natural world, it is not surprising that the result of new scientific inventions will be exactly counterbalanced by their side-effects. Consequently, if life becomes easier in some respects, it will become harder in others.

Economic growth as a means, and as used to evaluate progress, also reflects the obsession with the yang side of progress in modern society. Using the wisdom proposed by Aristotle, the problem with economic growth as an evaluation can be explored. The absence of the *causa finalis* leading to ignorance of the yin of progress, morality and spirituality, has been examined above. Here, the focus is laid on the neglect of the *causa materialis* in the 'growth' economy. Modern economics has been overwhelming devoted to economic growth. The term economic growth has in practice and in theory meant growth in Gross National Product (GNP) (Ekins, 1986). An economy that is growing at 3 per cent per annum is thought to be performing adequately. More growth is splendid, less growth is worrying, and no growth or negative growth indicates widespread economic failure. The assumption is that all problems are to be solved, or at least ameliorated, by an ever growing GNP (Daly, 1996), and that more is better, and big is good (Ekins, 1986). Nevertheless, the problem with GNP is that it counts consumption of natural capital as current income, and does not distinguish between renewable and non-renewable materials (the ignorance of the *causa materialis*) (Schumacher, 1974). For instance, people devote more effort and resources to mining poorer mineral deposits and to cleaning up increased pollution, and they then count many of these extra expenses as an increase in GNP and congratulate themselves on the extra growth. Some resources, such as air, seem to have no price and ownership in a modern economic sense. As a result, people make a profit, not by the efficient use of resources, but shifting the capital cost, which they should pay, to others including their future generations. Taking alternative fuels such as coal, oil, wood and water power as an example, the only difference recognised by modern economy is relative cost per equivalent unit. The cheapest is automatically the one to be preferred, as to do otherwise would be irrational and 'uneconomic'.

According to Mihajlo Mesarovic and Eduard Pestel (1975), Growth can be roughly divided into two types: undifferentiated growth and organic growth. The former refers to mere growth in quantity. The later, in contrast, involves a process of differentiation. The support for the idea of undifferentiated growth being uniform growth and organic growth being growth with differentiation is visible in Herbert Spencer's theory of progress. He (1907) identified progress with evolution. Organic evolution is organic progress and the law of organic progress is the law of all progress. This law, as basically conceived, is the same whether one considers the development of the earth, or of life on its surface, or of a variety of achievements of its people. It consists of the transformation of the homogenous into the heterogeneous (undifferentiated growth into organic growth). Economic growth in modern society is obviously undifferentiated growth as its sole focus is on quantity without concerning its function and the needs of 'the whole organism'. It is rational to think that the goal of economic growth is to meet the physical, intellectual and spiritual needs of all people. However, when modern economy with its productive capacity and an ever increasing rate of growth could easily provide all that people require, it fails to meet the needs of huge numbers of people, or does so in an extremely wasteful way (Trainer, 1996). Len Doyal and Ian Gough (1991) believe that basic needs, survival and autonomy, and intermediate needs like food, water, a non-hazardous environment and significant primary relationships are the fundamental indicator of social progress. Apparently, economic growth has failed to satisfy these needs. It threatens survival and makes people depend on each other in a commercialised way. Pure interpersonal relationships have to be secondary to economic growth. Millions of people cannot access food and clean water. It all implies progress based on economic growth and advancement of science and technology is regressive indeed, and that the evaluation of progress in modern society is problematic.

Modern architecture suffers the same problem. Technological advancement has been an underlying feature of modern buildings (Guo, 2006: 38). Modern pioneer architects were often proud of using advanced technology in their designs as a reflection of the modern concept of progress. However, it is simple technologies that free people from exploitation and which are in the control of the users as found in the autonomous house (Vale and Vale, 2000) (Figure 2), that ensure well-being, In contrast, some so-called 'landmark' sustainable buildings follow the modernist route so as to look 'progressive', and thus be accepted by mainstream society. For instance, Millennium Tower by Norman Foster in Tokyo (Figure 3), has been cited as a good example of sustainable building (Edwards, 2001: 32), although it does not do much in terms of sustainability. Green architecture might look more like vernacular buildings than modern high-tech ones (Vale and Vale, 1991: 181), and have more in common with the vernacular (Guo, 2006:109-121). In terms of the new concept of progress, vernacular architecture appears to be more progressive as it meets people's basic needs, creates a sense of belonging, and provides a built environment for their well-being (Figure 4). Furthermore, the construction industry is dedicated to the capitalist economy (Brolin, 1976:16). Modern architecture has become a big 'consumption box' in which people live. Urbanisation prepares the consumer and the labourer for the growth economy. When considering the nature of a sustainable society, it is no wonder that the ideals of green visionaries were often rural. This is what Nancy John Todd (1977) has called "a revitalisation of the countryside," a changed direction away from urbanisation.

Progress as the Idea of Control

The idea of control over nature is the very core of the modern concept of progress and of universal faith in its promotion (Bossard, 1931; Rescher, 1997). However, the controlling attitude to nature has led to the absence of the *causa materialis* and human inability to recognise that the modern industrial system, with all its intellectual sophistication, consumes the very basis on which it has been erected. It lives on irreplaceable capital, fossil fuels, which it cheerfully regards as income. The idea of domination and mastery over nature is clearly reflected in modern ideologies. Jonathon Porritt (1984) maintains that not only socialism but also capitalism are dedicated to industrial growth, to the expansion of the means of production, to a materialist ethic as the best means of meeting people's needs, and to unimpeded technological development. Both rely on increasing centralization and large-scale bureaucratic control and coordination. From a view point of narrow scientific rationalism, both insist that the planet is there to be conquered, that big is self-evidently beautiful, and that what cannot be measured is of no importance. He then further suggests that to move human society forward there is need to replace the super-ideology with a different world view—a 'systems' view. A 'systems' view, in the sense of general systems theory (Bertalanffy, 1968), is also known as the organic, holistic and ecological world view shared by mainstream societies in the West before the sixteenth century, and in the East before westernisation took effect. According to this world view, the universe is made up of a multitude of objects, but has to be pictured as one indivisible, dynamic whole whose parts are essentially interrelated and can be understood only as patterns of a cosmic process.

Before 1500 the dominant world view in Europe, as well as in most other civilisations, was organic. People lived in small, cohesive communities and experienced nature in terms of an organic relationship, characterised by the interdependence of spiritual and material phenomena and the subordination of individual needs to those of the community. In the Age of the Scientific Revolution (the sixteenth and seventeenth centuries), this ecological attitude changed into its polar opposite; from yin to yang, from integration to self-assertion. From that time onwards, the goal of science has been knowledge that can be used to dominate and control nature, and today both science and technology are used predominantly for purposes that are profoundly anti-ecological (Capra. 1982a). The universe has been treated as a machine, and the world-machine has become the dominant metaphor of the modern age.

The world view proposed by mechanistic science has exerted negative influences on modern society. These can be seen in the shift from wisdom to knowledge, specialisation, and universal faith in progress based on the development of science and economic growth, as discussed above. Vandana Shiva (1989) has woven together a critique of mechanistic science and the Enlightenment's theory of progress, showing how they simultaneously lead to the despoliation of nature, the oppression of women, and the practice of inappropriate and destructive development projects in the Third world. Unlike the claim of the Enlightenment that science and economic growth are universal categories of progress, she believes that the modes of thinking and action that pass for science and growth respectively are not as universal and humanly inclusive as they are made out to be. Modern science and development are projects of male, western origin, both historically and ideologically. They are the latest and most brutal expression of a patriarchal ideology which is threatening to annihilate nature and the entire human species. The rise of a patriarchal science of nature occurred in Europe during the Age of Scientific Revolution. During the same period, the closely-related industrial revolution laid the foundations of a patriarchal mode of economic development in industrial capitalism. Contemporary science and development conserve the ideological root and biases of the scientific and industrial revolutions even as they unfold into new areas of activity and new domains of subjugation.

The scientific revolution in Europe transformed nature from sustaining matter into a machine and a source of raw material (Capra, 1982a). With this transformation all ethical and cognitive constraints against its violation and exploitation were removed. The industrial revolution converted economics from the prudent management of resources for substance and satisfaction of basic needs into a process of commodity production for profit maximization. Industrialism created a limitless desire for resource exploitation, and the mechanistic world view proposed by mechanistic science, and provided the ethical and cognitive licence to make such exploitation possible, acceptable and desirable (Shiva 1989). The new relationship of man's domination and mastery over nature was thus also associated with new patterns of domination and mastery over women (Shiva, 1989; Plant, 1991), others (Bookchin, 1980), and the underdevelopment of the Third World (Trainer, 1985). As mentioned above, because of the loss of the *causa finalis*, there is an unsatisfied craving in modern man. Since he has lost control of his direction, he attempts to regain what he has lost by an inordinate and frantic search for those commodities that will stimulate his sense and thus temporarily quiet his sense of lost direction, or by seeking power that allows him to control the lives of others. This control over, nature, other things and other people, becomes a surrogate for having control over his own life. Lacking the power, ability and will to submit the direction of his own life to an appropriate final gaol, he seeks the false remedy of gaining power over nature, things and persons (Smith, 1993). Progress on the basis of scientific development and economic growth through controlling nature and others is guided by the mechanistic world view and has caused the ignorance of the *causa materialis* and then the environmental crisis, and exploitation. With universal faith in science and economic growth and without the *causa finalis*, modern society actually has lost its direction and become increasingly patriarchal and exploitative.

Modern buildings echo this attitude of overriding nature in order to 'progress'. Guided by the mechanistic world view, modernist architects cheerfully regard architecture as machinery. 'Machine beauty' is an important indicator to judge aesthetics of modern buildings. Modern architecture, based on a confrontation with nature, has lost the craft of materials, the understanding of climate and adaptation to site, the sense of place and locality, the spiritual links of home, family and community, all of which can be found in cultural traditions (Pearson, 1989:21). It is an architecture that has to rely on fossil fuel energy sources to make it work, leading to 50 per cent of world fossil fuel consumption being used for serving buildings (Vale and Vale, 1991: 23).

Conclusion: Sustainable Concept of Progress

When modern education prefers specialised knowledge to wisdom and cultivates people to have attachment to 'the things of this world'; when modern architectural design ignores the process of building and the users of buildings; when super technology turns out to be so inhuman that it destroys initiative; when modern economy, free of morality and spirituality, promotes the cult of materialistic affluence; when the economy grows, but people are less happy; when the focus of scientific development and economic growth is laid only on the yang side of progress; when GNP increases at the cost of natural capital and does not distinguish between renewable and non-renewable materials; when growth in the modern economy is undifferentiated growth, devoted to quantity rather than quality, and bigness rather than smallness; when there lacks the wisdom of the *causa materialis* and the *causa finalis* in the economic system; when economic growth does not meet the needs of a majority of people; when progress of modern society is based on the exploitation of nature, women and developing countries; when the modern concept of progress neglects the idea of process and is evaluated by advancement in science and technology, and growth in economy; when progress promised by modern society has sold out future generations and leads mankind in the direction of self-destruction, it is really hard to say that modern society still progresses. A better interpretation is that it has entered a terminal phase and that the modern concept of progress is severely problematic.

If the general analysis of the problem with the modern concept of progress is basically correct then there is no escaping the conclusion that human beings need a different kind of society; a sustainable society and a new concept of progress. Sustainable progress is necessary to move human civilisation forward. In a sustainable society, progress as the idea of process is emphasised. It is a process, not an achievement or an end. In fact, sustainability could be defined as the process of solving problems caused by affluent-industrial consumer society. It should be realised that the process of tackling problems is itself progress. Education will then be a means to cultivate the whole person of spirit, mind and body. Architecture will recognise the significant role of the process of buildings and the users. Technology and economy will increase the welfare of all people. Technology ought to be technology with a human face such as intermediate technology, radical technology, alternative technology, and appropriate technology. Economics ought to include morality and spirituality like Buddhist economics. Sustainable progress, guided by the holistic and organic world view, would be measured by the satisfaction of the basic and intermediate needs of every person, the balance of physical, intellectual and spiritual development, the harmony of the yin and the yang, rather than advancement of science and economic growth. It includes the idea of control not over nature, women and the Third world, but over the self, over attachment to material affluence, and over behaviour that impacts on the earth and others. A sustainable society is an inevitable step towards the common future as it provides the clear direction to sustain life and achieve something better than money in life. Sustainable architecture as a reflection of such society is also a progressive step in the history of architecture.

Keywords: assessment, optimization, sustainable building design

Summary

Computer tools available nowadays are used in assessing the environmental impacts of buildings and aid in making design decisions especially when examining different options, as defined by the designers. The number of decision variables in building assessment tasks is bigger than in traditional optimization problems. Some communications e.g. Grosso (2002) and Sowa (2007) showed that the overall assessment is not sensible on changes of important decision variables. Other studies in optimization techniques are defining the number of decision variables that can effectively be used in optimizing complex problems with the number of variables being between 8 to 12 Paczkowski et al.(2004). To overcome the problem some special techniques can be applied. One is: evolutionary optimization technique where the problem of finding the set of decision variables that are giving the best assessment rate is decomposed into subset of optimization problems. Finally, the possibility of automatic optimization within given restrictions can be performed as it is presented on the example of designing the new building.

1 Assessment methods

During the last 18 years considerable research has been focused on the development of systems to assess the environmental performance of buildings, based on different initial assumptions and prepared for different purposes. The best-known existing system is the Building Research Establishment Environmental Assessment Method (BREEAM), developed by BRE and private-sector researchers in the U.K. This system provides performance labels suitable for marketing purposes, and has captured increasing interest in the new office building market in the U.K. Many national systems have been developed by different countries world wide as HQE in France, Eco-profile in Norway, Ecoeffect in Sweden, LEED in US, CASBEE in Japan. Every country in Europe has attempted to develop an adaptation of an existing system or an altogether entirely new system. Several other systems (largely inspired by BREEAM and Green Building Challenge initiative) are in various stages of development in Europe and the World. There are also more specialized systems of interest that are more closely tied to Life Cycle Assessment (LCA), including ECO QUANTUM (Netherlands), ECO-PRO (Germany), EQUER (France) and ATHENA (Canada). Several of these systems have taken the next step; a labeling system that clearly indicates the building's approximate performance to end users.

Recent development of the assessment method has been to use the LCA methodology in order to create uniform, properly structured method which takes into account the environmental impact of materials and used fuels, does not cover important issues as indoor environment, quality of management, functionality, and adaptability.

In many methods, the environmental performance assessment framework is structured hierarchically in levels, with the higher levels logically derived from the weighted aggregation of the lower ones, these levels in many cases are defined as following: performance issues, performance categories, performance criteria, performance sub-criteria. The nesting principle is used to describe buildings at necessary detailed levels.

The performance scales which are described quantitatively can generate assessment in one of three ways:

- by the distance between a “best” performance target and the benchmark divided by agreed number of maximum score (e.g.
- by the declaration of a fixed interval and assignment of scores
- by percentage of fulfilling the criteria.

The qualitative criteria should be translated to the taken scale that finally is the same as the quantitative one. An example of qualitative criteria is the conclusion of existence or non existence of specific features. The assignment of score in this case depends on assessor’s choice.

Finally, the assessment is assembled from over 100 features that are integrated using weights in one or few scores, in CASBEE case integration means use of eco-efficiency principle. The weights used for this purpose are defined separately and have been the subject and result of advanced analysis, as some of features are cross cutting and/or could be contradictory.

All the assessment methods can be applied as decision supporting tools, where the user can examine influences of the decision on the final score. Thus, the natural extension of such supporting tools is the possibility of applying optimization techniques that can find a set of decisions leading to the best solution. The best solution is defined by the best integrated overall score or profile. Grosso on Sustainable Building 2002 in Oslo reported the results of sensitivity analysis of GBTool 2002 that indicated limited possibility of optimization techniques application.

Table 1 Variation of GBTool score on changing chosen parameters

Benchmark		**Relative Score Variation**				
Type	*Relative Variation*	*Category*		*Issue*		***Total***
		Type	*Variation*	*Type*	*Variation*	
Daylight Factor B13	25%	Illumination	100%	IAQ	20 %	10 %
Embodied Energy B37	25%	Energy	81,3 %	Resource Consumption	50 %	10 %
Embodied Energy B37	25%	GHG	41,6 %	Loadings	14,3 % %	10 %
End - use Energy B91	26%	Energy	27,3 %	Resource Consumption	33,3 %	22,2 %
End – use Energy B91	26%	GHG	54,5 %	Loadings	50 %	22,2 %
Water Consumption B109	37,5 %	Water	142 %	Resource Consumption	100%	11 %

Sowa reported similar results at the Conference on Indoor Air Quality held in Warsaw 2007, when examining the CASBEE tool. In this case, the sensitivity analysis on overall BEE score has been presented on significant changes of parameters of indoor environment by +/-2 points, while the adequate loading remain unchanged. The overall score remain within the same class.

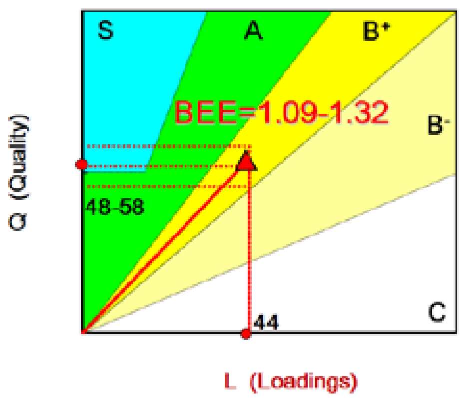

Figure 2 Variation of CASBEE score on changing chosen parameters.

The conclusion that can be drawn from the above examples is a potential difficulty in constructing optimization procedure for hierarchical assessment problems due to the number of parameters, levels of branches and crosscutting issues.

Further, the considerations will be restricted to design stages and the use of assessment methods as a design decision making tool. It would be ideal if the automatic supporting design decision process can be proposed. In optimization literature e.g. Jedrzejuk (2006), Paczkowski et al. (2004), Marks (1997) the complex problems are solved by different approaches: multi criteria optimization (where all the criteria are taken into analysis with adequately chosen data); evolutionary optimization (where the complex optimization problem is decomposed to consecutive sequences of simple problems) or by finding sets of independent decision variables.

2 Definition of optimization problem

One of the possible optimization techniques is the reformulation of the assessment problem as a multi criteria task. Can the criteria used in assessment methods be qualified as criteria in optimization problem? Assessment of existing buildings is not related to decision making process as it is a case of optimization in designed buildings. In case of existing buildings it is enough to have criteria and knowledge of the state of the art of the object. In optimization problems it is necessary to define set optimization criteria, decision variables and restricting conditions. Also, the object of optimization should be very precisely defined e.g. building volume, desired indoor environment etc. If the land is under the considerations of optimization it is necessary to define requirements related to the site.

Most assessment tools follow the building LC stages as construction phase, operation, adaptation to changing requirements and demolition. Some of these requirements can be taken as optimization criteria (energy use) some have restricting character (adaptation, or access to installations). Examining structures of assessment tools for the purpose of optimization seems to justify the decomposition of the assessment to four tasks: optimization of building structure, optimization of site, optimization of construction process, optimization of building operation. Every one of these decomposed elements can be solved separately as the separate criteria of optimization depend on separate decision variables.

2.1 Optimization of building structure

Three groups of criteria can be identified for the building structure construction stage: minimum of energy or energy cost used during the life cycle with exemption to operational energy (cost), minimum operational energy, minimum of environmental impact.

Following criteria from assessment categories can be taken as optimization criteria:

- Resource consumption – minimum cumulative and operational energy, minimum use of products and materials,
- Environmental loadings - minimal green house gases emissions, minimal ozone depletion gases, minimal acidifying gases, minimal sewage, minimal water use.
- Indoor Environment – is considered a restriction.

Further, the listed criteria are accompanied by following restrictions:

- Resource consumption – restrictions on building footprint, requirements related to the reuse of onsite elements,
- Environmental loadings - local noise distribution, shading on neighboring buildings, thermal impact on a ground.
- Indoor Environment – moisture accumulation in building structure, materials with low VOC, low fiber emission materials, transfer of pollutants among building zones, localization of air inlets and outlets, regulation of ventilation air volume, provision of efficient ventilation system, provision of adequate filtration, control of internal temperature, provision of adequate air humidity in winter and summer, avoiding air drafts, provision of day lighting, adequate access to external space, adequate distance to neighboring buildings, access to sun rays, provision of adequate noise insulation, limitation of noise distribution within the building and noise generated from installations.

2.2 Application optimization technique

The example of optimization can be given as an achievement of predefined target expressed as a desired energy standard of designed building. This is a common situation where the investor sets requirements in performance term by e.g. defining maximum desired energy consumption or building energy class. This is a problem that has the horizon defined in energy terms but the same technique can be applied to open problems where there is no demand for energy standards. The goal of optimization is to find a choice of appropriate building materials that will minimize the normalized sum of following elements: cumulated energy (E), emission of carbon dioxide (C) and construction costs (K) achieving a predefined target of operational energy (choice of elements in the criteria can be different than the referred e.g instead of CO2 emission we can have any other environmental impact that can be valuated). These coefficient depend on actual configuration of a building represented by a vector of decision variables x. Formally such a problem belongs to a category of multi criteria optimization which after introducing weighted goal function F(x) can be described as: find optimal configuration x ensuring minimal total cost of a building:

$$\min F(x) = w_E E(x) + w_C C(x) + w_K K(x) \qquad (1)$$

taking into account constraints resulting from available construction technologies.

Weights in this formula are positive scaling coefficients. Moreover w_E and w_C also include appropriate units recalculating energy and carbon dioxide emission to subsidiary costs. Functions E, C and K are sums of unit costs of individual components. Choice of decision vectors which characterize actual configuration of the building unequivocally can be troublesome. The natural solution to this problem is binary variables x_i=0 or 1, which means the presence or absence of a particular component. Taking this into account function K can be written as a sum of unitary costs:

$$K(x) = \sum_{i=1}^{N} k_i x_i \tag{2}$$

In the same way we define functions of energy and carbon dioxide emission. Restrictive conditions take in this case the following form:

$$\sum_{i \in D} x_i = 1 \tag{3}$$

This is equivalent to the choice of exactly one alternative of a class of components (for example wooden or aluminum window). Finally, mathematical model of decision problem leads to binary programming Gajewski et al. (2007). The major difficulty in such approach is large number of decision variables. Genetic programming which enable effective search of the set of acceptable solutions can be an alternative for direct methods of binary programming.

3 Example of calculations

The example of the optimization method is presented on a base of design of single family house. The house is one floor with usable attics, floor on ground with footprint 70 m^2 and 406 m^3 of volume.

Information taken from design documentation as well as from database containing values of cumulative energy (E_i), cumulative emission (C_i) of CO_2 and cost of construction (K_i)of building element or installation were used for preparation of data for poly-optimal procedure and presented in Table 1. Column Opty represents values of criterion function calculated from the formula:

$$\text{Opty} = w_1 E_i + w_2 C_i + w_3 K_i \tag{4}$$

where :

w_1 – average cost of production of 1 MJ of primary energy in Poland 0,03 PLN/MJ (1euro=3,5 PLNł)

w_2 – average cost of short term emission of 1 kgCO2 permit in Poland = 0,076 PLN/kgCO2

w_3 – weight for construction cost =1

Table 1. Data for optimization procedure

Element of construction	Description	E_i MJ/m^2	C_i kgCO_2/m^2	K_i PLN/m^2	Opty PLN
External walls

	ceramic tile 0,015 + roofing paper 0,004 + pine boards 0,025 + vapor insulation foil + gypsum plaster board 0,0125	4321	375	311	469
	cement tile, + roofing paper 0,004 + pine boards 0,025 + insulation + vapor insulation foil + gypsum plaster board 0,0125	4106	379	290	442
	roofing paper 0,004 + pine boards 0,025 + insulation + hard board 0,02	3838	550	226	383
Floor on ground					
	pine boards 0,015 + joint less floor 0,015 + insulation + water insulation + layer of concrete 0,1 + sand 0,015	4045	391	271	422
	Pine boards 0,015 + concrete layer 0,04 + insulation + water insulation + concrete layer 0,15 + sand 0,3	3692	355	334	472

Calculation performed using data from table 1 allowed to indicate the elements of building for which the criterion Opt reached its minimum. Results of the optimization procedure are collected in table 2.

Table 2. Results of optimization procedure

Element of construction	**Description**	**E_i**	**C_i**	**K_i**	**Opty**
External walls	two layer wall: 24 cm of aero concrete 500, 18 cm of insulation+ plaster	3301	274	254	374
Internal walls	24 cm aero concrete 600 + plaster	1141	69	112	151
Division walls	10 cm płyta gypsum – plaster board kartonowa	290	70	44	58
Ceilings	roofing paper + cement layer + insulation + reinforced concrete plane + cement - lime plaster	429	7	235	249
Roofs	roofing paper 0,004 + pine boards 0,025 + insulation + hard board 0,02	3507	512	221	365
Floor on ground	pine boards 0,015 + joint less floor 0,015 + insulation + water insulation + layer of concrete 0,1 + sand 0,015	4045	391	271	422

The calculation is showing the best solution in terms of minimalization of value of criterion F(x), where the decision variables were technological solutions for walls, roof and floor. These solutions can afterwards be used in assessment method to be assessed in the overall framework of assessment procedure. Such approach is not proven to be globally optimal, but is helpful guide in a search for optimal solution.

4 Conclusions

Assessment, by its virtue, is a different process than the designing but the assessment structure can be used to formulate the optimization problem. The general optimization problem has to be decomposed to basic problems that afterwards can be solved by using one of optimization techniques. Genetic and evolution algorithms have become the universal and widely used tool in the global optimization of functions. Usage of the methods that are based on natural selection, cross-breeding and mutation enables an effective search in the domain of the admissible solutions. A feature that distinguishes the genetic and evolution algorithms among other methods of optimization is looking for the best solution starting from some population of points in the solution space not from the single point. This particular feature induces the high efficiency of these methods, which has also been proven in the presented work. In the calculations, the database (developed within the research grant 4 T07E 028 28- Poly-optimal design method of environmentally friendly buildings) that contains the values of CO2 emission coefficients for the main processes and structural materials most popular in Poland has been used. The work was performed within the adaptation of environmental assessment method E-Audyt, Panek (2002) to public buildings and forms a part of works executed within a scientific project STEP undertaken by Warsaw University of Technology and Norwegian Technical University Trondheim.

eea grants	The work has been supported and performed within a framework of the project PL0077 entitled *Thermomodernisation of public buildings conducted in accordance with the conditions of sustainable development* – STEP, financed by EEA Financial Mechanism. The support is gratefully appreciated

BIOINSPIRED ARCHITECTURAL DESIGN TO ADAPT TO CLIMATE CHANGE

Maibritt PEDERSEN ZARI[1]

[1] School of Architecture, Victoria University, Wellington, New Zealand, maibritt.pedersen@vuw.ac.nz

Keywords: biomimicry, climate change, mitigation, adaptation, sustainable, regenerative

Summary

International research suggests that the built environment may be responsible for at least a third of global green house gas (GHG) emissions and that measures should be implemented to mitigate these. It is also the built environment, as the principle habitat of humans that will need to adapt to climate change impacts to keep people comfortable and safe. Architects and designers may need to explore new ideas that are reflective of a shift in both climate and in expectations of the built environment. This paper explores the potential of biomimicry, where organisms or ecosystems are mimicked in human design. The question is posed: in what way is mimicking the living world useful in the design of buildings that are able to either mitigate green house gas emissions or adapt to climate change impacts?

This paper investigates two possible options for an architectural biomimetic response to climate change. The first is integrating biomimetic technologies able to mitigate green house gas emissions into buildings. The second approach is use biomimicry to adapt to the direct impacts of climate change on the built environment. Documented successes and potential benefits and difficulties inherent in such approaches are discussed.

As well as a reduced or potentially negative carbon footprint for the built environment, this paper analyses further significant benefits that such an approach may offer. It is posited that the incorporation of an understanding of the living world into architectural design could be a significant step towards the creation of a built environment that is more sustainable and one where the potential for positive integration with and restoration of natural carbon cycles is increased.

1. Introduction

As the impacts of climate change increase, policies and actions to mitigate green house gas emissions must expand rapidly. This will be particularly crucial in the built environment. Not only is the built environment responsible for at least a third, and potentially more of global green house gas (GHG) emissions, leading to climate change, it also will have to adapt to climate change impacts, as the principle habitat of humans (Hunt 2004; Lend Lease Corporation, et al, 2007). O'Connell (2003) points out that *'investigation into the… effects of climate change, the synergy between adaptation and mitigation strategies, and understanding the importance of adaptation… is seen as critical...'*

Parallel to this, the definition of cutting edge sustainable architecture is changing rapidly. Aiming for 'neutral' or 'zero' environmental impact buildings in terms of energy, carbon, waste or water are worthwhile and difficult targets. It is becoming clear however, that buildings will need to go beyond having little negative environmental impact in the future, to having net positive environmental benefits (Rees 1999). Reed (2007) describes the transition from conventional practice (negative environmental impact), to sustainable architecture (zero impact), through to design with positive environmental impact, termed by him restorative, or regenerative design. By looking to the living world, there may be models that can be mimicked to create and maintain a resilient and adaptable built environment, and possibly improve its capacity for contribution to restoring or regenerating the health of ecosystems (Pedersen Zari and Storey 2007).

2. Biomimetic Architecture

Biomimicry is the emulation of strategies seen in the living world as a basis for design. It is the mimicry of an organism, an organism behaviour, or an entire ecosystem, in terms of its forms, materials, construction methods, processes, or functions, (Pedersen Zari and Storey 2007). It is a source of innovation, particularly in the creation of more sustainable and potentially regenerative architecture (Reap, Baumeister, and Bras 2005). In a similar way to the functioning of an ecosystem for example, a building could be designed to: produce energy and nutrients (materials); clean air and water; use and transform waste; and store carbon in a complex, adaptive and cyclic system (McDonough and Braungart 2002).

Looking to plants or animals that are highly adaptable or ones that survive in extreme climates or through climatic changes may provide insights into how buildings can or should function. Examining the qualities of ecosystems that enable them to be resilient may also offer potential avenues to follow. Although no comprehensive body of research has applied biomimicry to the impacts of climate change in the built environment, several noteworthy examples of biomimetic architecture, or technologies able to be applied to the built environment exist that will be examined in the following sections of the paper.

3. Climate Change and the Built Environment

Changes in climate that will affect the built environment are numerous and have been explored by several researchers. Impacts also will vary greatly depending on the local quality and density of the existing built environment and which specific local climate changes occur. The impacts that climate change will have on the built environment are both direct and indirect. Direct impacts will affect the actual physical fabric of the built environment. Indirect impacts will affect the economic, social and environmental context that the built environment operates in and will therefore also have implications for the built environment (O'Connell and Hargreaves 2004).

Providing detailed explanations of each impact is beyond the scope of this paper; however some of the main direct impacts that appear in a survey of international research[1] have been summarised in Table 1. Such changes to the climate are expected to increase in intensity in the future (IPCC 2001). These factors suggest a re-evaluation of the existing built environment, and that preparations for adaptations or additions may be necessary.

Table 1 Direct Climate Change Impacts on the Built Environment

Potential Direct Climate Change Impacts:	Consequences for the built environment:
Changes in temperatures (Likely to increase in most areas)	Increased overheating and air conditioning load Decreased winter space heating Decreased water heating energy
Increased intense weather events.	Damage to buildings and infrastructure
Changes in precipitation patterns	Damage to foundations Increased inland flooding Damage to facades and internal structure due to rain penetration Increased subsidence Increased erosion, landslips, rock falls Changes in aquifers and urban water supply and quality. Increase pressure on storm drainage Increased storm water run off and leaching of pollutants into water ways or aquifers
Thermal expansion of oceans and changes in the cryosphere (ice systems) such as retreating snow lines, ice packs and melting glaciers	Increased coastal flooding Increased erosion Changes in sedimentation patterns Changes in water tables and possible infiltration of aquifers. Relocation from coastal areas Loss of inter tidal areas acting as buffer zones
Changes in wind patterns and intensities	Changes in wind loading on buildings
Increased air pollution	Increased ventilation needed and provisions for clean air

4. Responses to Climate Change in the Built Environment

As acknowledged by several sources, even if all GHG emissions were immediately halted, the climatic impacts of past emissions would still be experienced. O'Connell and Hargreaves (2004) also point out that despite international treaties such as the Kyoto Protocol, global GHG emissions are increasing. It is important therefore that professionals of the built environment are not only able to mitigate the causes of climate change, but are also able to adapt to the impacts.

The responses to climate change in the built environment broadly fall into two categories:

1: Mitigating the cause of climate change by reducing GHG emissions.

2: Adapting the existing and future built environment to predicted climate change impacts.

Many technologies and established design techniques already exist that are able to mitigate the causes of climate change, adapt to the impacts or climate change and work towards restoring the healthy functioning of ecosystems and global biogeochemical cycles (including the carbon cycle). Lowe (2000) estimates for example, that reductions of 80% in carbon emissions associated with the built environment are possible using current technologies. The potential of well known design techniques to reduce dependence on fossil fuel derived energy, such as passive solar architecture for example are also well understood and documented. However, new techniques, or technologies that are able to mitigate and adapt to climate change with significant other benefits may be revealed by careful study of how organisms and the ecosystems they create are already able to do this. *'Climate change* [is] *now widely viewed as the main challenge facing humankind for this century. We believe that Biomimicry has a huge potential to tackle some of major issues raised by this global change'* (Biomimicry Europa 2006).

5. Biomimicry to mitigate green house gas emissions

Several examples of new technologies illustrate biomimicry that is focused on mitigating GHG emissions, and can be divided into three categories. The first approach is mimicking the effectiveness of living

[1] See reference section for papers referred to in summarising main direct impacts.

organisms and systems in transforming materials and energy in a way that is less resource intensive that what humans typically do. The impetus is that by being more energy efficient, less fossil fuel is burnt and therefore less GHGs are emitted onto the atmosphere.

The second approach is to devise new ways of producing energy to shift human dependence on fossil fuels, and therefore prevent additional GHGs from being emitted.

The third is looking to the living world for examples of how organisms or processes within them are able to sequester and store carbon. Mimicking this comes with the intention of preventing GHGs that are emitted through human activities from reaching the atmosphere and causing additional climate change.

5.1 Biomimicry for energy effectiveness and energy efficiency

Various biomimetic technologies and products have been developed for the purposes of improving energy efficiency. There are numerous examples of living organisms and systems that are highly energy effective and that could yield an understanding of how humans could build and carry out their activities without a dependence on fossil fuels (McDonough and Braungart 2002).

An example of such an approach is DaimlerChrysler's prototype *Bionic Car*. In looking to create a fuel efficient, large volume, small wheel base car, the design was based on the aerodynamic boxfish (*ostracion meleagris*). The chassis and structure of the car are also biomimetic, having been designed using a computer modelling method based upon how trees are able to grow in a way that minimises stress concentrations. The resulting structure appears almost skeletal, as material is allocated only to the places where it is most needed (Vincent et al. 2006).

Mick Pearce's Eastgate Building in Harare, Zimbabwe and the CH2 Building in Melbourne, Australia are examples of architectural biomimicry using this approach to address the causes of climate change. Both buildings are based in part on techniques of passive ventilation and temperature regulation observed in termite mounds, in order to create a thermally stable interior environment that uses much less mechanical cooling (and therefore produces less GHG emissions). Water which is mined (and cleaned) from the sewers beneath the CH2 Building is used in a similar manner to how certain termite species will use the proximity of aquifer water as an evaporative cooling mechanism.

Improving energy efficiency in general is an important part of addressing climate change, but is however an intermediate step. As McDonough and Braungart (2002) point out, improving efficiencies, or 'being less bad' helps to reduce the intensity of GHG emissions but does not challenge basic assumptions about how we make and operate our technologies and does not address the underlying causes of climate change such as dependence on fossil fuels.

The *Bionic Car* illustrates the point. It is more efficient in terms of fuel use because the body is more aerodynamic. It is also more materials efficient due to the mimicking of tree growth patterns to identify the minimum amount of material need in the structure of the car. The car itself is however not a new approach to transport. Instead, small improvements have been made to existing technology without a re-examination of the idea of the car itself as an answer to personal transport.

Improving energy efficiencies does however allow positive changes to be made to existing technologies and buildings rather than make a complete rebuild necessary and is therefore an important step in the transition of the built environment in positively addressing climate change.

5.2 Biomimetic energy generation for mitigating climate change

Several biomimetic technologies or systems aim to replace the use of fossil fuels as the primary energy source that humans use in an attempt to mitigate GHG emissions in the long term. Looking to the living world for inspiration is appropriate because almost all other organisms source energy from renewable sources, predominantly contemporary sunlight (Kibert, Sendzimir, and Guy 2002). An example of research in this direction is the development of artificial photosynthesis, that may eventually be applied to solar cell technology, such as the work done at Arizona State University (Benyus 1997; Moore et al. 2004) and by scientists in Australia (Davidson 2003).

Sea and wave energy technologies are also in development that mimic how sea kelp or tuna tails work in water. Australian company BioPower, is testing prototypes in Tasmania, Australia in 2008. According to company literature, the power generators oscillate in ocean waves and currents rather than rotate like a turbine. Through the use of permanent magnet motors, the low-speed high-torque oscillation is converted into high-speed low-torque rotation. It is anchored to the ocean floor by the use of a series of small root-like devices to avoid large and complicated drilling and installation. The generators rotate freely to orient themselves towards currents and in the same way can lie flat in storm events to avoid damage (BioPower Systems 2007).

Finding methods to replace the use of fossil fuels with contemporary sunlight and other renewable energy sources, is an approach to mitigating the causes of climate change conducive to a long tem solution. Significant time and resource needs to be applied to develop such technology however. While replacing the use of fossil fuels will prevent some additional GHG emissions from being created, biomimicry may also offer ways to address excess carbon dioxide already in the atmosphere.

5.3 Biomimetic Sequestering and storing carbon

There are several organisms and processes in nature that are able to store, sequester or recycle carbon, that are being investigated in the development of technologies that can be applied to industrial processes and the built environment.

In Quebec for example, C02 Solutions is developing carbon sequestration technology based on certain chemical processes that occur in the human body. The technology mimics the enzyme carbonic anhydrase which is able to convert carbon dioxide into bicarbonates (C02 Solution 2007; Geers and Gros 2000). In keeping with Benyus's (1997) observation that processes in the living world tend not to need huge amounts of energy to work, the C02 Solution process works at atmospheric pressure and ambient temperatures, thus it is highly energy efficient (Fradette 2007).

According to the company's literature, the process generates environmentally benign bicarbonate, which can be stored or reused in industrial process in cement works or paper mills. The aqueous solution where the conversion of carbon dioxide to bicarbonate occurs is reused in a closed loop. The technology is intended to be able to be retrofitted onto existing facilities such as power plants, cement works and oil sands operations, or integrated into new ones (C02 Solution 2007; Atkinson 2007).

Another example of the potential of biomimicry is illustrated by research conducted at the Rocky Mountain Institute in the United States, investigating an alternative material to concrete. Cement production accounts for approximately 5% of the world's anthropogenic carbon dioxide emissions (Vanderley 2003). This new material mimics the abalone, which is able to grow a crack resistant shell harder than any ceramics humans are able to create, using only seawater and a series of proteins (Benyus 1997). This process of bio-mineralisation stores carbon much like the growing of forests, locks carbon into the structure of the trees and soil for some time. The concept was that the new material would be able to grow over a structure, with the simple additive of seawater, using proteins imitated from the abalone (Koelman 2004).

As several authors point out, there is no waste in non-human living systems (Kibert, Sendzimir, and Guy 2002; McDonough and Braungart 2002). Detritus is an important part of continuing the process of cycling nutrients and is a fundamental part of the health of an ecosystem (Odum 1969). In using biomimiry to address excess carbon in the atmosphere, researchers such as Benyus have advocated using it as a resource rather than considering it a source of pollution (Benyus 2007). In response, some biomimetic systems look at how biomimicry may be used to replace fossil fuels and store carbon at the same time. An example is a proposal for biofuel crop plantings to be based on how naturally occurring prairies grow, resulting in a controversial net reduction of atmospheric carbon, while improving the fertility of the land (Russelle et al. 2007; Tilman, Hill, and Lehman 2006).

A company formed out of recent research done at Cornell University called Novomer, are examining mimicking carbon sequestration in living organisms, particularly plants, by turning carbon dioxide into carbon-based polymers, or biodegradable plastics. The zinc-based catalyst that is needed for the process works at ambient pressure and temperature. The use of carbon dioxide and monoxide as feedstocks, rather than corn or starch as is used in other biodegradable plastics, means that the plastic does not compete with food production, and may help in sequestering and storing carbon. More research is yet to be done into the characteristics of its carbon release properties on decomposition (Patel-Predd 2007).

A challenge with this approach to addressing climate change impacts is that sequestering carbon by itself does not deal with the problem of excessive burning of fossil fuels, causing climate change, but rather is an anther interim step in becoming more sustainable (Fradette 2007). The issue of depletion of fossil fuels themselves is also not addressed, and there are several logistical, economic, technological and environmental problems with current attempts at carbon sequestration (Schiermeier 2006). Its benefit however is that such technologies may help to retrofit and adapt existing building infrastructure, while addressing GHG emissions in the short to medium term (Herzog 2001).

Several of the examples of a biomimetic approach to carbon sequestration or storage discussed reveal that secondary and useful products are made, such as plastics and potential new building materials, without toxic by-products and the use of high amounts of energy. There may also be important restorative capacity in lowering the amount of atmospheric carbon by using carbon dioxide as a feedstock for new materials. More research needs to be done to investigate the feasibility of this. The built environment uses at least 40% of the materials consumed by the global economy (Rees 1999), so building materials that store carbon long term, or that are made from carbon dioxide itself, if appropriate, durable and safe, have potential to have significant positive benefit in mitigating the causes of climate change.

6. Adaptation to Climate Change

Biomimicry offers several avenues in addressing the issue of adaptation to climate change. The first is responding to anticipated direct impacts of climate change on the built environment (see Table 1). The second is a more comprehensive approach to altering the built environment to be more adaptable as a whole system.

6.1 Responding to Direct Impacts of Climate Change

Several architectural examples of biomimicry exist that look to respond to direct impacts of climate change. Two proposed architectural projects discussed here might be suitable responses to changes in precipitation patterns and a projected water shortage for example.

Grimshaw Architects have used biomimicry to design a building that can desalinate seawater with minimal energy input. They propose that the desalination plant will form a large outdoor theatre called *Teatro del*

Agua in the Canary Islands. The Namibian desert beetle, and the hydrological cycle itself, have been used as inspirations for the design. The stenocara beetle lives in a desert with little rainfall but is able to capture moisture from the swift moving fog that passes over it by tilting its body into the wind. Water condenses on the surface of the beetle's back because its shell is cooler than the surrounding air. Droplets form on the alternating hydrophilic – hydrophobic rough surface of the beetle's back and wings and roll down into its mouth (Parker and Lawrence 2001). The hydrological cycle is based of course on evaporation and precipitation.

The Grimshaw design team in collaboration with Seawater Greenhouse have taken an understanding of these examples from the living world and in 2005 proposed the unique desalinisation process. Seawater will be passed over a series of evaporative grills and, as the sea breeze moves through them, some of the water will evaporate, leaving salt behind. The moist air then continues until it hits pipes holding cool seawater, pumped up from the deep ocean. As the warm moist air touches the cool pipes, condensation forms and clean fresh water trickles down to be collected for use. The seawater pumps are powered by wind turbines using the same sea breeze and any excess water and the resulting cooling can be transferred to neighbouring buildings. This kind of biomimetic system may be useful in areas that are coastal and have difficulties sourcing fresh water, exacerbated by climate change.

Matthew Parkes of KSS Architects demonstrates biomimicry also inspired by the Namibian desert beetle's unique features, with his proposed fog-catcher design for the Hydrological Center for the University of Namibia (Killeen 2002). In a low rainfall environment part of the building is carefully designed and orientated to capture the water from the fog without the use of pumps and large amounts of energy.

This approach has a number of benefits and difficulties associated with it. It requires people to accurately know what the impacts of climate change will be, and to allow enough time to research and implement possible responses to it. A benefit of such an approach however, is that technologies and architectural responses to direct impacts may be transferable to other places that have similar issues. This process of developing technological solutions for individual buildings fits into the current method of extending and renewing the built environment, which is typically a building by building or addition by addition process (Brand 1984). This approach is helpful for a gradual response to the impacts of climate change, particularly if the ability to research, develop and test technologies continues. The living world offers numerous examples of organisms that effectively solve the same problems the built environment will face. Organisms and ecosystems exist that effectively manage overheating, high winds, and erosion for example.

Developing individual technologies or buildings to deal with the myriad of direct climate change impacts on the built environment does not however ready the built environment for unpredicted changes, or address multiple impacts concurrently. Understanding local built environments as whole systems in terms of their strengths and weaknesses may be effective way to plan for future unpredictable climatic changes.

6.2 Improving the built environment as a system

Although ecosystems are typically resilient and many are able to move though massive changes while still supporting organisms to survive, the ability of ecosystems to adapt to the rapid changes that may become apparent through climate change is largely unknown. Mimicking ecosystems may however offer insights into how the built environment could function more like a system than as a set of individual objects (Pedersen Zari and Storey 2007). Ecosystems are readily available models for designers to examine in creating robust, resilient and adaptable systems. Several authors advocate methods for incorporating an understanding of ecosystems into architectural design (Graham 2003; Kibert, Sendzimir, and Guy 2002; Van der Ryn and Pena 2002; McHarg 1992; Reap, Baumeister, and Bras 2005).

As described by Pedersen Zari and Storey (2007), a comparative analysis was conducted of related knowledge of ecosystem principles in the disciplines of ecology, biology, industrial ecology, ecological design and biomimicry and was used to formulate a group of ecosystem principles aiming to capture cross disciplinary understandings of ecosystem functioning. Features of ecosystems that make them resilient were identified in subsequent research as: capacity for self healing; capacity for decentralised organisation; complex feedback loops; interdependence of organisms; diversity in types of organisms and relationships; a responsiveness and dependence on local conditions; and optimisation of the whole system rather than single parts. How such principles may meaningfully be applied to the existing built environment requires more investigation. There are however two notable examples of mimicking ecosystems for greater adaptability that may offer insights.

In designing the Lloyd Crossing Project proposed for Portland, Oregon in 2004, the design team including Mithūn Architects and GreenWorks Landscape Architecture Consultants used estimations of how the ecosystem that existed on the site before development functioned. The stated goals of the project included: reducing environmental impact to pre-development levels; achieving carbon balance; and living within the site's rainfall and solar budget. By understanding the system that had worked previously on the same site, the design team were able to determine appropriate goals for the ecological performance of the project over a fifty year time period (Portland Development Commission 2004).

Examples of successful industrial ecology such as the Kalunborg Project, in Denmark also demonstrate the advantages of a systems approach in creating a resilient and robust environment where energy and materials are circulated and shared, eliminating waste and duplication of effort or energy use in some areas (Jacobsen 2006).

A benefit of such an approach is that through careful urban planning and an integrated and multidisciplinary design method, buildings as part of a larger system, able to mimic natural processes and functions in their creation, use and eventual end of life, have the potential to adapt more readily to climate change. That a greater understanding of ecology and systems design is required on the part of design teams is implicit with such an approach. Increased collaboration between fields that traditionally seldom work together such as architecture, urban design, and ecology would also be required. Systems based climate change adaptation challenges conventional architectural design thinking, particularly the typical boundaries of a building site and time scales a design may be initially designed for.

Barriers include the current competitive economic context of the built environment in many places in the world. Encouraging greater interdependence and the sharing or exchange of resources between buildings requires a different economic and legal frame work to operate than that which is currently in place. The final drawback to this approach is that because it requires communities to become linked, interdependent systems, it requires a coordinated and cooperative approach from land owners and authorities to make it happen at a large scale, which may prove difficult in some areas. The built environment obviously varies greatly between different areas and climates and economic contexts, and systemic approaches that are appropriate to specific places will also vary greatly (Reed 2007). Because there may therefore be limited transfer of knowledge between differing geographic regions, the adoption of such an approach may be slow. Although there are some draw backs to a whole systems based adaptation of the built environment, it may be a suitable solution for a longer term response to addressing climate change impacts.

7. Benefits of a Biomimetic Approach to Architecture

This paper demonstrates that various biomimetic ideas can be applied to a short, medium and long term response to climate change. Biomimetic approaches to climate change mitigation and adaptation in the built environment are diverse and are not preventative of other non-biomimetic approaches being employed. While existing technologies will be crucial in the short and medium term, biomimetic approaches may form an important part of long term solutions to climate change, particularly in the replacement of the use of fossil fuels, development of technologies to address direct impacts on the built environment, and importantly in systemic improvement of the built environment based on ecosystem based biomimicry (Fig 1).

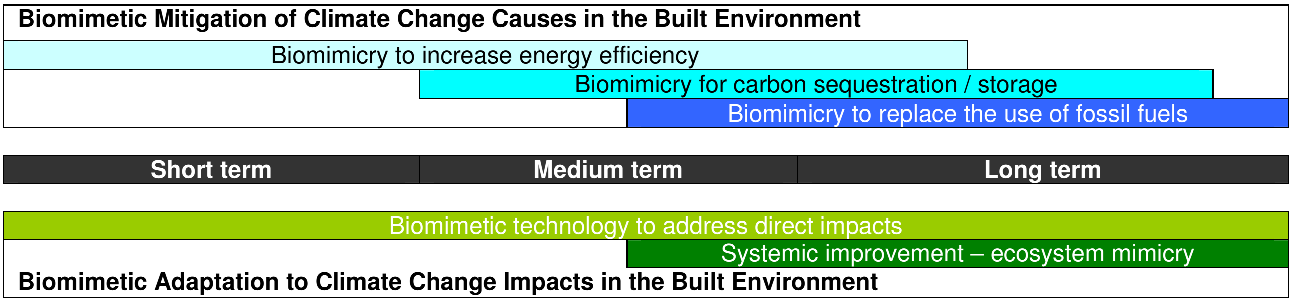

Figure 1 Time line of biomimicry approaches to address climate change

As well as a reduced or potentially negative carbon footprint for the built environment, other significant social and economic benefits of biomimicry in the built environment may exist. Several authors investigate the relationship between bio-inspired design and improved psychological and physical health (Pedersen Zari 2008; Kellert 2005). It is possible, that with a greater understanding of the living world, and its relevance not only to increasing sustainability, but also its possible contribution to psychological wellbeing, architectural design will change accordingly. Links with increased human productivity in commercial buildings that demonstrate aspects of bio-inspired design have been demonstrated (Heerwagen et al. 1998).

As GHG emissions are increasingly regulated, buildings that do not met legal or performance expectations may be more difficult to sell, lease or insure and may have higher financial life cycle costs. There is also growing evidence of 'sustainable' buildings demanding premiums over conventional ones. (Fullbrook, Jackson, and Finlay 2006).

It is posited that the incorporation of an understanding of the living world into architectural design could be a significant step towards the creation of a built environment that allows for positive integration with and restoration of natural carbon cycles. Increased positive integration with ecosystems and a restorative rather than damaging effect on ecosystems may have significant benefits on maintaining biodiversity and the ecosystem 'goods and services' that humans are dependant on for survival (Daily et al. 2000). If the built environment is to become truly regenerative it will increase human and community wellbeing as well as that of ecosystems.

8. Conclusion

The built environment is increasing held accountable for global environmental and social problems with vast proportions of waste, material and energy use and green house gas emissions attributed to the habitats humans have created for themselves (Doughty and Hammond 2004). It is becoming increasingly clear that a shift must be made in how the built environment is created and maintained (Reed 2007). Mimicking life, including the complex interactions between living organisms that make up ecosystems, is both a readily available example for humans to learn from and an exciting prospect for future built environments that may be able to be entwined with the habitats of other species in a mutually beneficial way while addressing climate change causes and impacts.

New approaches will be useful to professionals and governing bodies as they address climate change impacts in the built environment. By looking to the living world, there may be models that can be mimicked to create and maintain a robust built environment, and possibly improve its capacity for contribution to restoring or regenerating capacity in ecosystems. Several case studies have been used to exemplify this.

This paper has considered the different ways that biomimicry may be applied to both climate change mitigation and adaptation to direct climate change impacts. This has illustrated the ways in which mimicking the living world is useful in the design of buildings that address climate change. Distinctions between the different kinds of biomimicry and their short, medium or long term potential in addressing climate change in the built environment has also been examined.

Technologies that increase energy efficiencies and are able to sequester or store carbon may form part of an important short to medium term approach, but should be seen as intermediate steps. As well as a reduced or potentially negative carbon footprint for the built environment, examples of developing biomimetic technologies reveal approaches that use current excess carbon dioxide as a resource for new materials. Design that mimics how ecosystems are able to function in a resilient way, has the potential to form part of a long term response to climate change in relation to the built environment. Along with this, biomimetic technologies that address direct climate change impacts, and biomimetic technologies or systems that prevent further GHG emissions could be implemented alongside systemic change in the built environment.

It is posited that the incorporation of an understanding of the living world into architectural design could be a significant step towards the creation of a built environment that is more sustainable and resilient and is able to adapt to climate change.

Keywords: standardization, assessment, building performance, sustainable building

Summary

The significance of the construction and real estate sector for sustainable development is broadly recognized in Europe. Reflecting this recognition, systems for description, quantification, assessment and certification of sustainable buildings have been development in many countries. A current task is to develop these systems to enable a better inclusion of life cycle analysis methodologies, regarding environmental, social and economic assessment. Consequently, these assessments will, among other information sources, need to apply data comprising environmental as well as health information related to construction products. This provision and communication of information relies on the format of environmental product declarations (EPDs). For both, the assessment of sustainability aspects of buildings and for the description of construction products, the goal is to develop a European wide, unique set of rules, in line with the requirements of relevant ISO standards. The task to establish this European set of rules is handled as a standardization task in CEN, under CEN TC350 "Sustainability of Construction Works". To reach market acceptance, and to fulfil the ISO 15392 general principle "holistic approach", aspects of sustainability are to be considered in its context, not as separate items. Thus, sustainability assessment of a building constitutes a part of an assessment of integrated building performance. The consideration of sustainability aspects is supposed to also have a positive impact on the quality of products and processes. The intention is to also investigate how the quality of building design, technology and functionality has an influence on the economic, environmental and social performance of buildings.

1 CEN TC 350 – goals and content

1.1 Scope and structure

The standards developed under the framework of CEN/TC350 provide a harmonized European system for the assessment of environmental, social and economic performance of buildings based on a life cycle approach as a contribution to implementing sustainable construction. The standardised application of life cycle approach means that the assessment of environmental performance is based on the Life Cycle Assessment methodology [ISO 14040, ISO 14044] and the assessment of economic performance is based on the Life Cycle Costing [ISO 15686-5] methodology and the rules for the service life issues are based on the guidance of Service Life Planning standard series [ISO 15686]. The goal is to develop and implement a system of sustainability assessment of buildings that, at the same time and on same equal footing, allows for the assessment of the environmental, social and economic performance of a building taking into account its technical quality and functionality / serviceability.

The results of assessment help users to understand the impact that a building has from one hand on the environment and from the other hand on the occupant and other users. Social performance includes amongst others the building related considerations of users' health, comfort and safety aspects. The aim of the results of assessment is to allow the client, occupant, owner, investor, designer and others involved in construction and operation to make rational decisions and choices regarding the building.

Figure 1 presents the structure of CEN/TC350. The "general framework standard" establishes the concept of "sustainability assessment of buildings" and describes the context of the environmental, economic and social performance on one hand, and technical characteristics and functionality on the other hand.

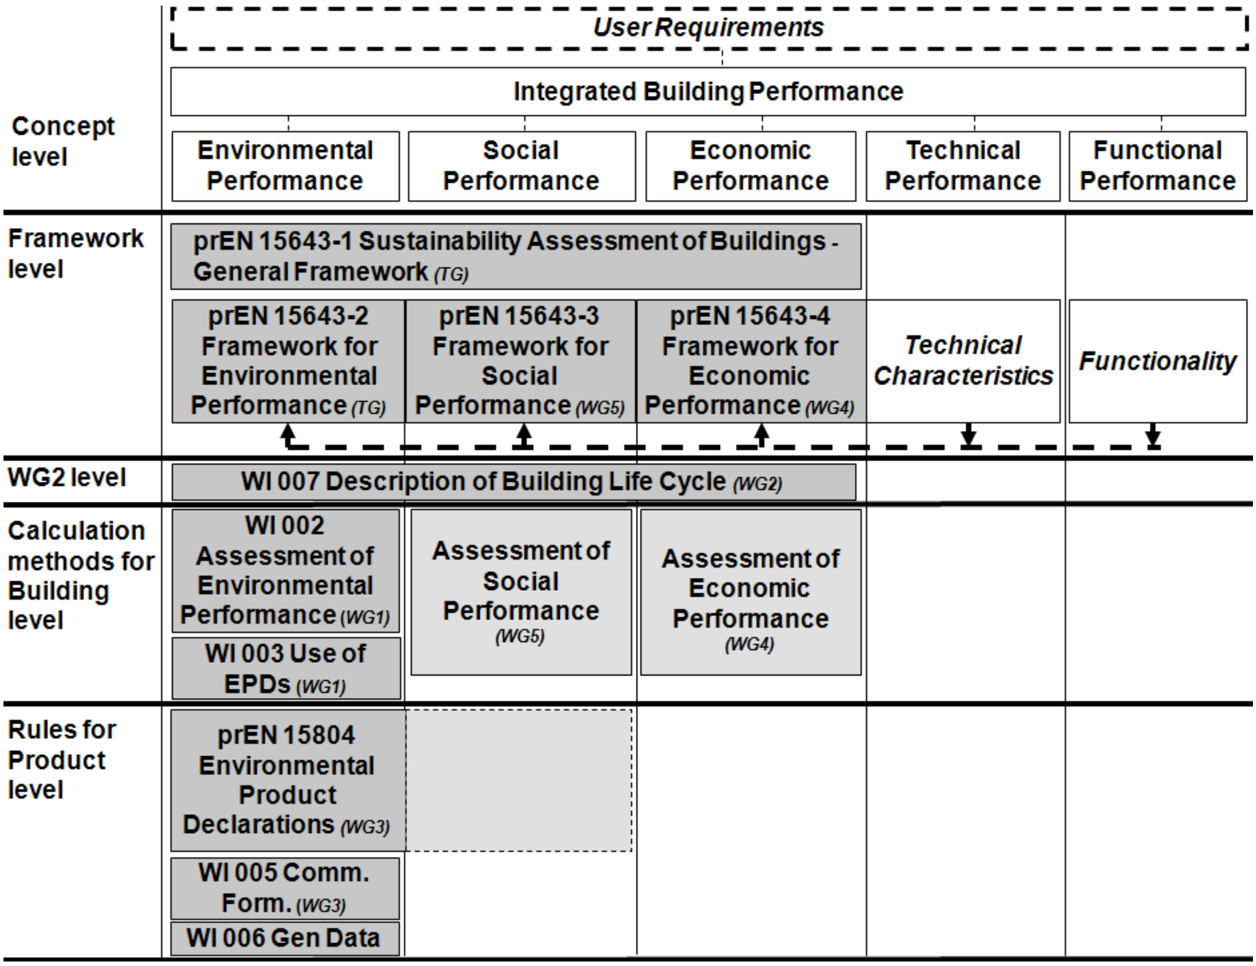

Figure 1: The suite of standards of CEN/TC350.

The suite of standards of CEN/TC350 for the sustainability assessment of buildings has been structured into three horizontal levels (framework, building and product) and into three vertical columns (environmental, social and economic) while always taking into account technical and functional performance characteristics.

1.2 Object of assessment and system boundaries

In this European standardised system of CEN / TC 350 the building, including its foundations and external works within the area of the building site, is the object of assessments and the source of impacts over its life cycle. This clarification means that in order to assess environmental, social and economic performance of the building the physical system boundary for the assessment excludes impacts of non-building related appliances, because the object of assessment is really the building and not the processes carried out in the building. Non-building related appliances are domestic, commercial and industrial appliances and other non-building related goods e.g. entertainment electronics, washing machines, refrigerators, cooking appliances, office electronics and appliances of industrial processes. The impacts of building related appliances are included in the assessment, because they are part of the technical building system, covering the systems for heating, cooling, domestic hot water, ventilation, lighting and integrated building automation and controls.

The suite of standards within CEN / TC 350 is only dealing with the analytical part of the building assessment system, and not with the valuation part. For this reason, these standards do not provide valuation methods and do not set levels, classes or benchmarks for any measure of performance. It is clear that the valuation methods for interpretation of the results are also needed, but because of their nature being always subjective value choices and "political" decisions, they have not been seen as a workable subject for the European standardisation at the moment. Consequently, CEN/TC 350 regards the establishment of assessment and weighting factors to be the task of other bodies, or to be handled as part of national assessment systems.

However, initiatives like LEnSE (http://www.lensebuildings.com) and UNEP-SBCI (www.unepsbci.org) discuss the international approaches to weighting and benchmarking, both internationally and on a European scale.

1.3 The importance of functional equivalent

In communication of the results of the assessment and comparisons of those results between alternative design options in the design stage or between finished buildings a "fair basis" must be always secured. For this purpose, the concept of "functional equivalent" was established. The functional equivalent allows the results of assessments to be provided in a systematic and comparable way. Communication of the assessment results for the environmental performance, social performance and economic performance of a building follows same the requirements.

The functional equivalent should be derived from the requirements for technical performance and functional performance of buildings to form the basis for comparison. The technical and functional requirements can include for example requirements for structural safety, fire safety, indoor air quality, security, adaptability, energy efficiency, accessibility, de-constructability, recyclability, maintainability, durability and service life of a building. These requirements become fixed when they are prescribed in the client's brief or in the project specification. It is clear that these performance requirements influence the results of the assessment and therefore they need to be taken into account in the assessment. Therefore, the requirements for technical and functional performance of the building must be taken into account in the establishment of the functional equivalent through technical and functional requirements defined for the project specific building.

Because of its importance, the functional equivalent must be always communicated together with the results of the assessment. In order to give a short overview also about how a building fulfils its user requirements, the deviating technical and functional performance with the respect to the required technical and functional performance and the possible demands for the environmental, social and economic performance defined in the client’s brief or in the regulations are also communicated together with the functional equivalent and the assessment results. .

1.4 Interrelationship between building level and construction product level

In order to have a transparent and truly performance based European system for the assessments the CEN/TC350 standards only take into account performance aspects and impacts that can be expressed with the quantitative indicators. These quantitative indicators are defined in the framework level standards that set the requirements for the building level and product level to use, in principal, the same set of indicators. In carrying out assessments it is possible only at the building level to provide necessary scenarios and a functional equivalent for the building. Consequently, assessment at the building level means that the descriptive model of the building with the major requirements for technical and functional performance of the building has been defined.

2 Sustainability assessment of buildings

2.1 The multi-step procedure

Developing European standards for sustainability assessment of buildings as a contribution to implementing sustainability of construction works is a multi-step procedure in CEN/TC350. The concept, see Figure 2, combines approaches established in the context of "sustainability in building construction" [ISO 15392: 2008], "service life planning" [ISO 15686] and also "performance based building" [CIB 1982], [Huovila 2005], [Lützkendorf 2005a], [Preiser 2005].

According to priorities set by the European authorities, the suite of standards for the assessment of environmental performance is going to be finished first. The assessment result according to this first step suite of standards to be developed by CEN/TC350 doesn’t yet allow a full sustainability assessment of the building. A precondition for the complete assessment of sustainability aspects of a building is the development and application of the assessment methodologies for social and economic performance. The framework standards for assessment of social performance and for assessment of economic performance of buildings are also under development in CEN/TC350.

The environmental indicators are stated in the framework standard for the assessment of environmental performance. In order to prevent formation of potential trade barriers in the global perspective, the defined environmental indicators are in line with the defined indicators of ISO 21930 (Sustainability in Building Construction - Environmental Declarations of Building Products).

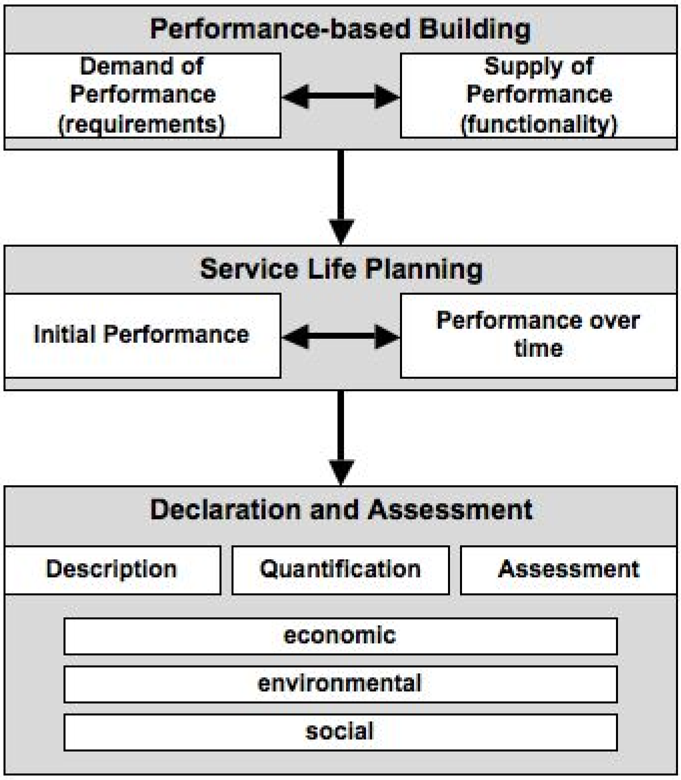

Figure 2: Performance-Based Building (requirements and performance), Service Life Planning (initial performance and performance over time) and Sustainability Assessment (description, quantification and assessment) in context. [Trinius 2007]

2.2 Communication format

Within the suite of CEN/TC350 standards there are also requirements for communication of the results of the assessment in order to ensure that the results can be understood and interpreted in a transparent and systematic way. According to the general framework standard the results of the assessments must be organised and made available for communication as shown in figure 3 below and expressed with the indicators given in the framework standards for the assessment of environmental, social and economic performance of a building without any further aggregation of the defined indicators.

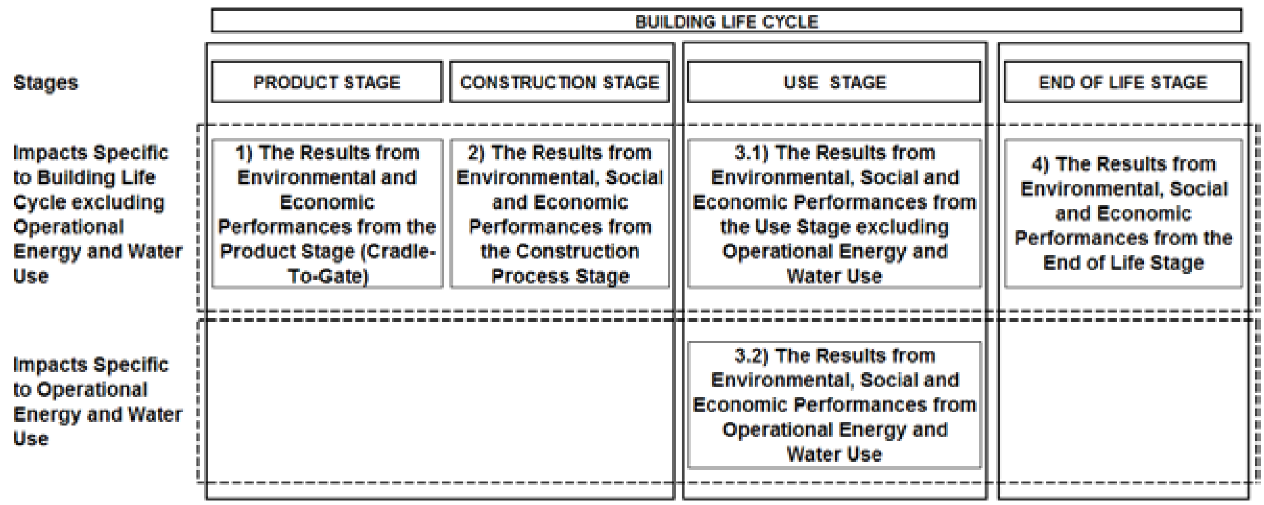

Figure 3: The organisation of the result of the assessment.

The organisation of the result of the assessment of environmental, social and economic performance is to be made available for communication in accordance with the life cycle stages and the normative groups of information.

If necessary for the national, regional or local preferences, it is permissible to communicate the results of the assessments with more aggregated groups of information and/or with more aggregated indicators after valuation, but the possible aggregated results must be clearly separated from the standardised assessment results as additional information.

The Strategic Advisory Body on Environment [SABE 2007] describes a standardised "building pass" – the potential to include sustainability assessments in such a building pass needs to be considered and further discussed.

2.3 Convergence with the performance based building concept

Performance based building is a well established concept dealing with the total quality of buildings, mainly in terms of functionality and technical performance, see [Foliente 2006] and the documents of the Performance-Based Building thematic network PeBBu (www.pebbu.nl). Meanwhile, the approach based on a rather technical description and assessment of performance and functionality is moving towards the inclusion of a consideration of economic, environmental and social aspects [Lützkendorf 2005b]. The description and assessment of sustainability aspects considers economic, environmental and social performance. This performance relates to the technical performance and functionality requirements. In other words, a bridge between performance based building and sustainability in building construction is emerging, the two concepts are coming together.

Summary and outlook

The inclusion of economic and social performance enables us to make the move from an assessment of environmental impacts to a broader assessment of sustainability aspects. With the clear reference to the performance and functionality of the building, the established concepts of performance-based building and service life planning of buildings can be included, resulting in a clear move towards an integrated assessment of sustainability. This assessment is a necessary and significant element in the discussion of the total quality of buildings and the built environment.

The standardization work in CEN/TC350 is still ongoing. European stakeholders still hold the possibility to get involved in the process and to contribute to the standard development through their national standardisation bodies. The standardisation work in international bodies (ISO) is largely concluded – however, the authors are open to communicate and discuss the development on a broad international scale.

Acknowledgment

The authors thank experts and convenors of the various CEN/TC350 working groups for their input.

Keywords: sustainable building, retrofit, hotels, serviced apartments, local government, water, waste, energy

Summary

The City of Melbourne's Savings in the City program is an integrated environmental program to help city hotels cut energy, water and waste consumption. The program provides leadership, support, recognition, toolkits and advice on environmental management and demonstrates that an industry-specific approach is beneficial in delivering desired environmental outcomes.

The Savings in the City program has 30 participating hotels and serviced apartments, large and small. The Savings in the City program has resulted in significant savings:

- *waste* figures alone show that hotels are saving on average 4.8 litres per guest per night which equates to 2410 tonnes annually. For the initial two years of the program 628 truckloads of waste have been saved by the 30 hotels.
- over the last two years an average reduction of *water* use of 15.3 litres per guest per night and that's an equivalent saving of 45 megalitres.
- energy figures demonstrate the total *energy* saved by the 30 hotels over the last two years equates to 24,769 tonnes of greenhouse gas or the equivalent amount of energy used by 2890 households.

The program has identified a range of on-going data challenges which need industry-wide resolution, and has demonstrated that motivation for delivering environmental change is complex and seemingly more dependent on advisory support than financial support.

The potential roll-out of the program across the accommodation industry is currently under negotiation with a pilot roll-out currently underway in the Geelong Otway Region. Most of the hotels are part of international chains are expanding their sustainability efforts beyond those of the hotel in the *Savings in the City* program.

Savings in the City Green Hotels have been 2008 finalists in the Banksia Awards and UNAA World Environment Day Awards in the local government category.

1. Introduction

The City of Melbourne has been running an environmental program called *Savings in the City Green Hotels* since 2005 to help hotels cut energy and water consumption, and reduce the amount of waste sent to landfill.

The *Savings in the City* assists hotels to:

- review and benchmark their current level of environmental performance;
- identify priority actions to save water, waste and energy;
- implement actions including behavioural change in a cost effective manner.

Savings in the City aligns with the City of Melbourne's key environmental strategies including the *Zero Net Emissions*, *Total Watermark* and *2020 Vision for Sustainable Waste Management*.

Fifteen hotels initially joined the program in 2005 on the basis they undertake a waste audit and become Waste Wise Certified. From there, a further fifteen properties joined in 2006.

These properties represent a cross section of the Melbourne accommodation industry from 3.5 star to 5 star properties with sizes ranging from 24 rooms to 548 rooms. The thirty selected properties are located within the City of Melbourne and comprise of twenty-one hotels and nine serviced apartments. For the purposes of this report, all properties will be referred to as hotels.

2. Program Partners

It was important in designing *Savings in the City* that it helped the hotels to undertake environmental programs and not just confuse them. Therefore links were made with the existing programs in order to increase their uptake.

The primary connections built into the *Savings in the City* program are:

- the Green Globe international tourism certification program run by EC3 Global;
- the Waste Wise program run by Sustainability Victoria;
- the WaterMAP program run by City West Water;
- the Our Water Our Future program run by the Smart Water Fund; and
- hotel industry groups: Hotels and Motels Association Australia (HMAA) and the Australian Hotels Association (AHA).

3. Data Collection

3.1 Benchmarking Waste, Water and Energy

An integral part of the *Savings in the City* program is the collection of annual water, waste and energy bill data from participating hotels. Annual guest night data is also required for comparative analysis.

Savings in the City encourages all hotels to collect this information as part of regular accounting processes. Hotels can then enter the annual results into the Earthcheck benchmarking tool.

3.2 Earthcheck

Earthcheck is the benchmarking tool used in the Green Globe program that has been made available for the *Savings in the* City participants. It is an internationally-trusted system of indicators that allows individuals, enterprises, and destinations to systematically measure, benchmark, report and manage their performance.

The City of Melbourne has funded participating hotels to use Earthcheck. This has been offered at a reduced rate by EC3 Global as part of our partnership arrangements. Without the *Savings in the City* program each hotel would fund their own use of Earthcheck as part of Green Globe annual membership fees.

Earthcheck has now developed a new introductory package where members such as hotels can get access to the Entry Level software. This software allows members to measure their core areas Energy, Water, and Waste. The software also has an Auto Reporting feature which means members are able to graph their results from within the Earthcheck Benchmarking Software.

To date, the City of Melbourne has had a large role as the intermediary in helping hotels to collect their data to send to Earthcheck. This has been very time-consuming for City of Melbourne (and its consultant), and it was hoped that more of the hotels would have become independent in this data gathering. The City of Melbourne increasingly requires hotels to show commitment and knowledge growth in this area.

3.3 Reliability/Confidence of data

The *Savings in the City* program relies on the assurance that the water, waste and energy bill data supplied by hotels is correct. The City of Melbourne does not have the resources to determine the accuracy of data supplied by hotels.

The City of Melbourne has supplied hotels with a simple Microsoft Excel spreadsheet to help them retain the relevant bill data over the financial year (Hotel Enviro Collator). However, some hotels still require intensive effort and support by the City of Melbourne to assist them with the gathering of this information.

The City of Melbourne continues to hope that hotels will be self sufficient enough to enter their bill data directly into the Earthcheck™ website. Some progress has been made with this, however the most hotels are still very dependent on assistance to do this.

The *Savings in the City* program has collated 3 years of energy, waste and water data. Council feels relatively confident about the data quality as large inconsistencies can easily be identified and discussed with hotels.

Savings in the City feels that trusting the hotels about their data collection is an important approach as it allows the City of Melbourne to spend more time helping the hotels with environmental initiatives rather than chasing up data management issues.

3.4 Laundries

Laundering of hotel linen is a significant contributor to hotels' overall water consumption. Though some hotels wash their linen on the premises, and should be able to directly measure water consumption, most hotels have these items laundered off-site.

Investigations from City of Melbourne have shown:

- It appears that many laundries are undertaking water efficiencies and have developed baseline figures of 11 litres/kg for their own modified water-saving equipment, and 25 litres/kg for laundering performed on-site at hotels using conventional equipment.
- According to City West Water's *Water Efficiency Handbook*, p. 27, a rate of 12-15 litres/kg represents best practice in this area.

One laundry has calculated that an average hotel sends 7.2 kg of linen per day to laundry for each occupied room. Multiplying the number of rooms sold in a given period by this figure will produce a simple estimate of overall laundry water usage for each hotel, if laundry is done off-site.

City of Melbourne used this information to add 10% to the total water use of those hotels that do laundry off-site. Whilst this figure has not rigorously been developed, it is indicative, and it is consistent.

The first year of data collection for *Saving in the City* did not consider off-site water use for laundry, and therefore the water figures are distorted when comparing 04/05 to 05/06 to allow for the addition of 10% of water use. Only two hotels do on-site laundry.

To date *the Savings in the City* program has not taken into consideration the energy consumption associated with laundering off the premises. According to the *Savings in the City Energy Wise Toolkit,* laundries can account for 10% of the total energy consumed in a hotel.

3.5 Privacy

It is important that hotels participating in this program can trust that their information will be used for environmental analysis and improvement, and that it will not be made available to the public.

The City of Melbourne has devised a system that gives the hotels the recognition they deserve without disclosing their operating details. This is reflected in the program's Five Level Recognition System.

4. Commitment of Hotels to *Savings in the City*

4.1 Take-up of hotels

A total of thirty hotels have been selected for the *Savings in the City* pilot program.

Of the 30 Hotels, seventeen hotels have supplied the City of Melbourne with three years of data (04/05, 5/06 & 06/07). This success rate of 57% demonstrates that there is a need for further independent initiative to be shown by many of the hotels, however the data that has been collected by 17 hotels in *Savings in the City* is one of the best data sets in the accommodation industry.

4.2 On-going commitment from hotels

To motivate hotels to make environmental improvements, *Savings in the* City needs to further consider ways of communicating the success of high-achieving hotels. Suggestions include: clearer presentation of performance on website, more case-studies, promotion of active hotels to conference organisers, Lord Mayor letter of achievement etc.

Commitment is also gained from the hotels by applying the following methodology:

- existing resource use is benchmarked whilst training hotel staff on this process;
- behaviour change provisions for staff and guests are incorporated into the program;
- hotels consider a business case and financial model to encourage immediate action;
- case studies are developed to promote good efforts of hotels;
- rewards, promotions and case studies are developed by the hotel industry as motivation; and
- provision for on-going self-management, including data management.

These steps are shown in Figure 1.

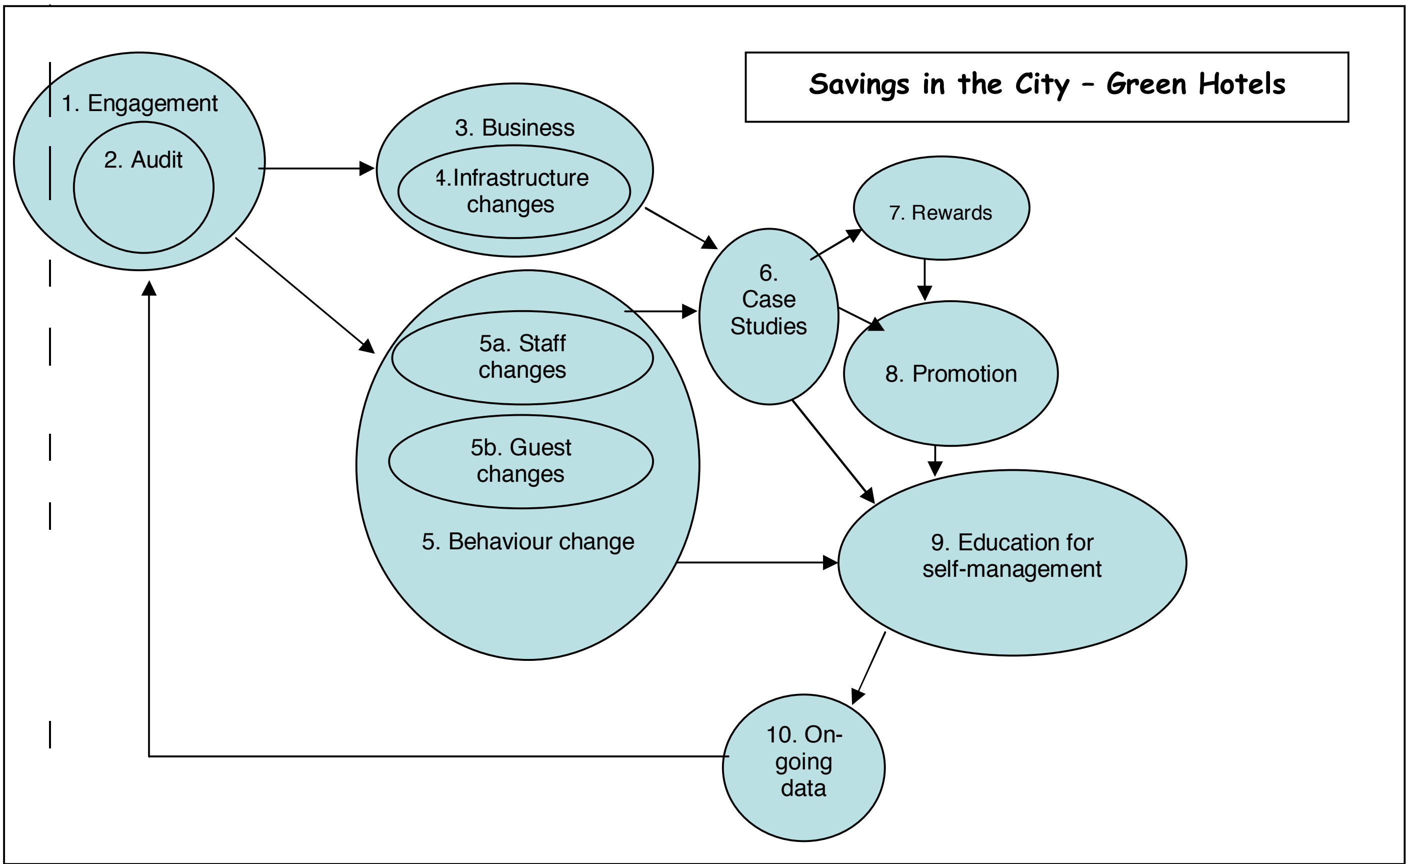

Figure 1: Implementation methodology for hotel environment initiatives

5. How much water, energy and waste should hotels be using?

5.1 Baseline and Best Practice

First year data for 2004/2005 was collected for 22 of the hotels in the *Savings in the City* program. From this Council identified:

1. Baseline – the average of all hotels in the *Savings and the City* program.
2. Best Practice – 30% less than the baseline value.

These values helped hotels to understand how they were performing relative to others, and provided a motivating tool to help hotels reach or better the current baseline and best practice values for each of the water, waste and energy modules.

These figures for waste, water and energy were compared on a per guest per night basis. This is important as it takes into account the occupancy rates of a hotel when calculating their water, waste and energy efficiency.

5.2 Comparing *Savings in the City* Hotel Baselines to National Hotel Baselines

A comparison of *Savings in the City* hotels against national averages provided unanticipated results.

Waste: 'Savings' hotels average 12.7 litres/guest/night well above the national hotel average of 4 l/g/n.

Water: 'Savings' hotels average 257.6 litres/guest/night well below the national average of 700 l/g/n.

Energy: 'Savings' hotels average 189 megajoules/guest/night well below the national hotel average of 300 m/l/n.

Earthcheck is unclear why there is such a discrepancy in our results. The likely reasons are that the national data set is small and predominantly Brisbane based. Earthcheck is due to revise the national data set.

In the meantime, the *Savings in the City* hotels are working off the Melbourne sample set as this is a more accurate and local reflection of resource use.

5.3 Setting the Best Practice Standards

For consistency, *Savings in the City* has applied the Earthcheck methodology for setting best practice standards. This is calculated as 30% less than the average waste/water/energy use. As performance improves, it is necessary to update best practice figures annually.

It is worth noting that City of Melbourne would like to see a more rigorous system for setting best practice targets in the future.

5.3 Current Baseline and Best Practice Standards

Table 1: Melbourne baselines and target figures for hotels and serviced apartments in 2006/2007

Savings in the City	Hotel baseline benchmark (average)	Hotel best practice targets	Serviced Apartments baseline benchmark (average)	Serviced Apartments best practice targets
Waste	11 litres/guest/night	8 litres/guest/night	10 litres/guest/night	7 litres/guest/night
Water	262 litres/guest/night	183 litres/guest/night	197 litres/guest/night	138 litres/guest/night
Energy	188 megajoules/guest/night	132 megajoules/guest/night	93 megajoules/guest/night	65 megajoules/guest/night

5.5 Comparison of properties

The City of Melbourne acknowledges that it is possible to group properties based on additional criteria such as comparing hotels by their star rating, number of rooms, recreational facilites, or number of meals served. This would provide a clearer comparison. Due to resourcing limitations *Savings in the City* has limited its refined grouping to the break up of accommodation services into hotels or serviced apartments.

It is important to note, that the ranking element of the *Savings in the City* program has been designed as a simple tool to motivate hotels to perform better and is not a public ranking for which hotels are accountable.

A NABERS hotel rating tool is currently being designed and it is hoped that it will provide some resolution to these performance data management issues.

6: How to publicly recognise hotel efforts?

6.1 Hotel Recognition System

This City of Melbourne has developed a five level recognition system to show the progress of hotels in making environmental improvements.

The system has been designed to:

- not disclose any private information relating to operating costs and performance of hotels;
- enable hotels that were already relatively efficient to be recognised;
- recognise the efforts made by hotels that may not necessarily show up as resource savings (for example, with some data anomalies it may not be possible to pick up efficiencies even though hotels have been making great efforts); and
- link to the Waste Wise Certification system.

6.2 Certification System

Some hotels have requested that our recognition system be elevated to a certification system.

This is not considered appropriate at this stage as *Savings in the City* is a pilot program that the City of Melbourne is only committed to until the end of 2008. The City of Melbourne is seeking for other organisations to continue the program on an on-going basis; possibly HMAA, AHA or Sustainability Victoria. If this on-going commitment were to be made, a proper certification system would be established.

To keep hotels processes simple, any certification system would need to be consistent with:

- the upcoming ResourceSmart certification being developed by Sustainability Victoria (which extends Waste Wise to cover water and energy); and
- Green Globe certification procedures; and
- recently released NABERS hotel rating tool.

7: Findings

7.1 Waste

The waste module was the first undertaken and linked to the Waste Wise program already in operation by Sustainability Victoria. Sustainability Victoria funded the module and recognised the value of the *Savings in the City* program as a way of encouraging more businesses to become Waste Wise Certified.

As a result from this work with 15 hotels, a Waste Wise Hotels Toolkit was developed and distributed to the wider hotel industry.

Data from the first year of the program has shown a 35.5% reduction in waste to landfill which has been achieved thanks to the waste savings of 36% (17) of participating hotels (Table 2). Some hotels are not yet active in waste management with four recording increases in waste to landfill.

Table 2: Reduction in average amount of waste to landfill

	Average amount of waste sent to landfill
Year 1 (04/05)	12.66 litres/guest night (baseline)
Year 2 (05/06)	11 litres/guest night (12.2% reduction)
Year 3 (06/07)	8.05 litres/guest night (35.5 % reduction from 04/05)

The waste module differs significantly to the energy and water module because savings are reliant a lot more on behaviour change and a lot less on infrastructure requirements.

80% of waste in typical hotel can be recycled or composted. Waste initiatives have included:

a) Staff and contractor training to change disposal habits

b) Placement of bins, systems and signage to facilitate waste reduction, sorting and management

c) Recycling bottles, metals, plastics, paper and corks from kitchens

d) Minimising and recycling paper from offices and receptions

e) Several of the hotels have linked to a local food charity organisation that collects food that cannot be used and turns it into nutritious meals for the homeless. They also take half empty shampoo bottles.

Sustainable purchasing has not yet been strongly progressed by hotels and is perhaps a further initiative. Attempts to arrange organic waste collection have not proved viable because of the expense (primarily due to the lack of demand in the city for an organic collection service). Two hotels have set up on-site composting systems.

Table 3: Figures and commentary on reduction of waste to landfill

Waste		
Savings	**Commitment of Hotels**	**Comment**
Litres of waste saved: • 16 out of 20 hotels have made reductions in waste to landfill; • 4 out of 20 hotels have increased their waste to landfill; • On average, hotels are saving 4.8 litres/guest/night. • Total savings 8034 m3 or 2410 tonnes annually. These savings are equivalent to a reduction of 401 garbage trucks from being dumped at landfill (the year before in 05/06 the hotels saved 227 garbage trucks from being dumped at landfill). Altogether 628 truckloads saved.	• 8 of the 22 hotels were meeting base year Best Practice standards when they joined the program, now 19 are; • 13 of the 22 hotels were meeting base year Baseline standards when they joined the program, now 19 are.	The majority of hotels have seen a reduction in the waste that is disposed to landfill each year, with over 86% of reporting hotels (22) now meeting the base year Best Practice level. This overall performance exceeds the SITC program's target of 56% of hotels that was to be met by December 2008

7.2 Water

Results from the water module are varied and overall comparatively low. The average water use decreased by 4%, due to the efforts of 40% (12%) of the hotels that recorded water savings (Table 4).

Note that the water figures are distorted for 05/06 and 06/07 as it was necessary to increase all water consumption figures for hotels by 10% to account for water used for off-site laundry (this had not been accounted for in 04/05).

Table 4: Reduction in average amount of water consumption

	Average water consumption
Year 1 (04/05)	273 litres/guest night (baseline)
Year 2 (05/06)	256 litres/guest night (6% reduction)
Year 3 (06/07)	262.8 litres/guest night (4% reduction from 04/05)

Water efficiency audits have shown that it is possible to reduce water consumption by an average of 20% without compromising guest comfort. With many hotels spending $200,000 or more on water bills this provides a solid business case for investing in water efficiency. Water initiatives from the hotels in the program have included:

a) Staff training to change water use habits particularly in the kitchen.

b) Some guest education through signage or welcoming guests to use a shower timer provided.

c) Inserting flow reduction valves and low flow showerheads to reduce the flow of water. Only 20% of hotels in the program had acceptable shower flow rates of less than 9 litres per minute.

d) Upgrading toilets to dual flush – well established with 80% of toilets already dual flush.

e) Using more efficient appliances including washing machines, ice makers, steamers, and dishwashers.

f) Water-efficient pools and gardens.

Hotels have not yet progressed greatly on water efficient cooling towers and fire-sprinkler testing systems. Alternative water sourcing has only been pursued by two hotels in the form of rainwater tanks. It is considered that it is more economically feasible for hotels to concentrate on water saving because of the financial benefits as their first response to water management. A Water Wise Hotels Toolkit has been developed as a guide.

The water module has provided disparate results for reasons which are not yet understood. This could reflect problems with data collection, billing methods, leaking pipes or other reasons.

Close analysis of this module has interestingly shown that providing a free audit (as was done for ten hotels) did not result in these hotels making greater water savings than the hotels that did not receive the audit. Only four of the ten audited hotels decreased their water use. The program has instead shown that that the best way to spur action is through 'hand-holding' and being in contact with hotels to encourage and give advice.

Table 5: Figures and commentary on reduction of water consumption

Water		
Savings	**Commitment of Hotels**	**Comment**
Litres of water saved: • 12 out of 19 hotels have made water savings; • 7 out of 19 hotels have increased their water use; • On average, hotels have decreased their water use by 15.3 litres per guest night (which is a saving of 1.5 buckets per guest per night) • Total savings of 25.4 megalitres. • This is equivalent to saving or 25.4 Olympic swimming pools annually. (the year before in 05/06 the hotels saved 20 Olympic swimming pools)	• 7 of the 22 hotels were meeting base year Best Practice standards when they joined the program, now 10 are; • 13 of the 22 hotels were meeting base year Baseline standards when they joined the program, now 15 are.	The water module commenced in Year 2 of the *Savings in the City* program in September 2006. Whilst some hotels have successfully implemented projects that have seen reductions in water use, not all hotels have focussed greatly on this area. 10 of the 22 reporting hotels (45%) now meet the base year Best Practice levels, slightly below the SITC target of 50% for Dec 2008. It is expected that better results will be seen in the 07/08 data once the hotels have implemented water action plans.

7.3 Energy

Energy is the most recent module undertaken in the *Savings in the City* program. As a result the savings are only starting to show with the average energy use decreasing by 3.2%, which has been achieved by the efforts of only 43% (13%) of the hotels (Table 6).

Table 6: Reduction in average amount of energy consumption

	Average energy consumption
Year 1 (04/05)	177.4 MJ/guest night
Year 2 (05/06)	171.8 MJ/guest night (3.2% reduction)
Year 3 (06/07)	137.14 MJ/guest night (23% reduction from 04/05)

Energy management in hotels can reduce energy by approximately 20% per hotel. Initiatives undertaken by hotels include:

a) Lighting efficiencies – less lights, more efficient lighting, and motion sensor controls.

b) Upgrading and/or greater maintenance of heating, ventilation and air-conditioning systems

c) Installing variable speed drives on motors so they aren't needlessly running at full capacity all the time

d) Installing energy management systems to automatically and efficiently control building services.

Table 7: Figures and commentary on reduction of energy consumption

Energy		
Savings	**Commitment of Hotels**	**Comment**
Megajoules of energy saved: • 14 out of 20 hotels have made energy savings; • 6 out of 20 hotels have increased their energy consumption; • An average of 38.5 megajoules /guest night saved (which is a saving of 200 black balloons per guest per night). • Total of 64,170 GJ saved annually This is equivalent to 24,769 tonnes of greenhouse gas, or annually saving the same amount of greenhouse gases as generated by just over 2000 average Victorian houses (up from the equivalent of just over 890 average Victorian houses).	• 10 hotels were meeting Best Practice standards when they joined the program, now 12 are; • 13 hotels were meeting Baseline standards when they joined the program, now 17 are; • 2 hotels have made reductions of more than 40%.	The energy module is commending late in Year 2 of the *Savings in the City* program. At the time of data collection, audits had not been piloted with hotels, and the proposed energy saving kit not published. This module is the scheduled to commence in March 07, and so results will be most clearly seen in the next two financial years. Whilst awaiting the energy module, some hotels have been able to undertake ad-hoc energy efficiency measures. These actions were motivated by the program, and have been undertaken by keen hotels.

10: The Future of *Savings in the City – Green Hotels*

10.1 City of Melbourne's commitment to the *Savings in the City – Green Hotels* program

The City of Melbourne developed *Savings in the City* as a pilot program that would:

a) demonstrate the effectiveness of supporting an industry sector (hotels) to achieve environmental efficiencies;

b) develop the necessary tools to guide that sector (toolkits, spreadsheets and training programs);

c) develop the program design for replication on an on-going basis (recognition system, templates, toolkits and partnerships).

The City of Melbourne feels that it has demonstrated the effectiveness of the *Savings in the City* program through the following indicators of success:

a) significant, and growing savings by hotels in water, energy and waste;

b) growing knowledge and engagement by participating hotels;

c) support from a range of stakeholders, and success in obtaining grant funding for the program;

d) hotels (other than participating hotels) wanting to be involved in the program.

Page 2: [1] Deleted adm-stetan 28/03/2008 11:24 AM

1.1 Resources provided to hotels

The *Savings in the City* program has provided participating hotels with a large amount of informal and formal support and resources to assist them in reducing their water, waste and energy use. Information seminars have been held on water, waste and energy. These seminars have provided opportunities for hotels to gain technical advice on resource efficiency measures as well as providing a forum to discuss obstacles and solutions of emerging technologies.

The *Savings in the City* program as developed three toolkits on water, waste and energy use in hotels. Participating hotels have also been provided with these toolkits so that they can gain an understanding of where water and energy is used in their hotel, where waste can be reduced and what the opportunities are for making savings. The toolkits also have case studies and details about energy, water and waste saving technologies.

The toolkits also to provide a means for hotels to conduct their own audits and as a briefing tool to engage consultants to carry out the audits.

The more years of data that is collected the more we

Page 2: [16] Deleted	katyun	28/03/2008 9:22 AM

can feel confident about data quality as large inconsistencies can be identified and discussed with the hotels.

THE BUILDING SECTOR FACING THE CLIMATE CHANGE CHALLENGE: HOW TO TURN CONSTRAINTS AND WEAKNESSES INTO OPPORTUNITIES, THE CDM EXAMPLE

Stéphane POUFFARY

Head of the International Expertise in Energy Management Unit, French Environment and Energy Management Agency (ADEME), 06560 Valbonne, France & SBCI Climate Change Think Tank Chairman, stephane.pouffary@ademe.fr

Keywords: SBCI, building, climate change, energy efficiency, CDM, Kyoto Protocol, negotiation

Summary

The building and construction sector is accounting for a significant and increasing part of the worldwide energy consumption and is responsible for an important greenhouse gas emissions share. On another hand, this sector has a huge impact on social and economic development for developing, transition as well as industrialised countries. This is why is has to be considered as a key sector regarding sustainable development and climate change issues. Taking advantage of the UNEP (United Nations Environment Programme) SBCI initiative (Sustainable Buildings and Construction Initiative) which gathers private and public buildings and construction stakeholders, the topic of this paper will be, after having presented a general overview of this sector and the challenge of reducing climate change impacts, to evaluate how we can mobilise in an appropriate way Kyoto flexible mechanisms. The paper will use the first SBCI report's results "Buildings and climate change: status, challenges and opportunities" and results of the ongoing work on climate change issue. On this topic, one key element will be to evaluate why, despite eligibility to receive support from the Clean Development Mechanism (CDM) and the Joint Implementation (JI) funding Kyoto Protocol mechanisms, only very few building related projects have been registered or implemented. For that purpose, barriers will be identified and potential measures to overcome them will be highlighted taking into account the need to work on baseline issues. Finally, we will present a set of recommendations in order to ensure that energy efficiency improvements in buildings will be fully supported and eligible both on the current Kyoto Protocol and also in the post 2012-agreement which is under negotiation.

1. Introduction

The building and construction sector is accounting for a significant and increasing part of the worldwide energy consumption and associated greenhouse gas (GHG) emissions share. On another hand, this sector has a huge impact on social and economic development for developing, transition as well as industrialised countries. This is why it has to be considered as a key sector regarding sustainable development and climate change issues.

Taking advantage of the UNEP (United Nations Environment Programme) SBCI (Sustainable Buildings and Construction) Initiative, the topic of this paper will be to evaluate how we can mobilise in an appropriate way the Kyoto Flexible Mechanisms and especially the CDM (Clean Development Mechanism). For that purpose, we will take advantage of SBCI reports "Buildings and climate change: status, challenges and opportunities", “Assessment of Policy Instruments for Reducing Greenhouse Gas Emissions from Buildings” and the results of the ongoing work on climate change issue undertaken by UNEP Risoe Center and the SBCI Climate Change Think Tank.

After having presented the SBCI Initiative and its objectives, we will draw a general overview of the building sector and the challenge of reducing climate change impacts. We will evaluate why, despite the eligibility to receive support from the Kyoto Flexible Mechanisms, only very few building related projects have been registered or implemented. For that purpose, barriers will be identified and potential measures to overcome them will be highlighted. Finally, we will present a set of recommendations which could contribute ensuring Energy Efficiency (EE) improvements in buildings to be fully supported both in the current Kyoto Protocol and in the post 2012-agreement under negotiation.

2. The UNEP Sustainable Buildings and Construction Initiative

The UNEP Sustainable Buildings and Construction Initiative was established in 2006 as an UN-building sector partnership with the objective of promoting sustainable buildings, in particular those that are energy efficient. The specific goals of SBCI are to provide a common platform for all building and construction stakeholders to collectively address sustainability issues of global significance, to establish globally acknowledged baselines for sustainable buildings and construction practices, principally those based on the life cycle approach, to develop tools and strategies for achieving wide acceptance and adoption of sustainable building practices throughout the world and to promote adoption of the above tools and strategies by key stakeholders.

These goals have been translated in to the current SBCI work program to the following focus areas: (1) Influence the Kyoto Protocol to provide, under the international climate change framework, positive and realistic incentives for the building sector to use more energy efficient solutions when constructing and refurbishing buildings, (2) Encourage and support national level policy makers to change market conditions in favor of stakeholders who provide sustainable building solutions, especially stakeholders adopting life cycle approaches, (3) Establish a global "common language" on sustainable buildings by developing global benchmarks keeping in mind that SBCI not intends to develop standards, as they need to be developed and adopted at the national level, (4) Highlight the benefits of adopting sustainable building practices in developing countries.

The SBCI focus areas are closely linked and mutually supportive of each other:

- The work on the Kyoto Protocol serves to establish policies and economic tools that make investment in sustainable and energy efficient buildings attractive.

- The effort on policy tools serves to establish corresponding tools at the national level, and also systems and standards that will encourage sustainable building approaches in other ways as well.

- The benchmarking aims to provide a common language for building sector stakeholders so that they can understand, identify and quantify benefits from sustainable buildings. Again, this can be used to develop national certification systems, reporting standards, sustainable property investment analyses, financial tools, etc… It is important to understand that this work does not aim to replace or compete with existing national systems but to complement them by promoting adoption of similar systems in other countries and by attracting more building projects to be certified under existing systems.

- The work on sustainable buildings in developing countries highlights the contributions sustainable buildings make to other national development priorities, such as poverty reduction and shelter for all. This agenda being most important in markets where the awareness is low.

For more information regarding the Initiative, thank you to visit the www.unepsbci.org website.

3. The building sector's high energy efficiency potential

Buildings are responsible for 30-40% of total worldwide final energy use and associated GHG emissions, both in developed and developing countries and this figure should continue increasing due to the high demand in developing countries. Energy is mainly consumed during the use stage of buildings for heating, cooling, ventilation, lighting, appliances etc… and only a small percentage (10-20%) is used for materials manufacturing, construction and demolition. According to the Intergovernmental Panel on Climate Change Forth Assessment Report, building's sector related GHG emissions could increase by 32% in a low growth scenario, and up to 81% in a high growth scenario in 2030 which main part coming from developing countries.

On another hand, the combined GHG mitigation potential by 2030 in non-OECD and Economy In Transition countries can reach up to 3.15 Gt $CO_{2\text{-eq}}$, which is significantly higher than the OECD countries 1.8 Gt $CO_{2\text{-eq}}$ potential. This being considered and whatever the scenarios, it is clear that the building sector's energy saving potential is very high. The IPCC AR4, based on the results of over 80 worldwide surveys, shows that the global reduction potential can reach 29% in 2020 of the projected baseline emissions and 31% in 2030 for residential and commercial buildings. But, in any case, and unfortunately, the building sector's GHG emissions will remain at 30% of the worldwide GHG emissions.

In addition, it is necessary to underline that the mitigation costs for tapping such high reduction potential are very low from a life-cycle point of view. With proven and commercially available technologies and processes, the energy consumption in both new and old buildings can be cut by 30-50% without significantly increasing the investment costs. The IPCC AR4 report states that the building reduction potential is relatively independent from the cost per ton of $CO_{2\text{-eq}}$. The report estimates that, in 2030, 5.5 billion tons of $CO_{2\text{-eq}}$ could be mitigated for less than 20 US$/ton and 6.1 for100 US$/ton (see Figure 1).

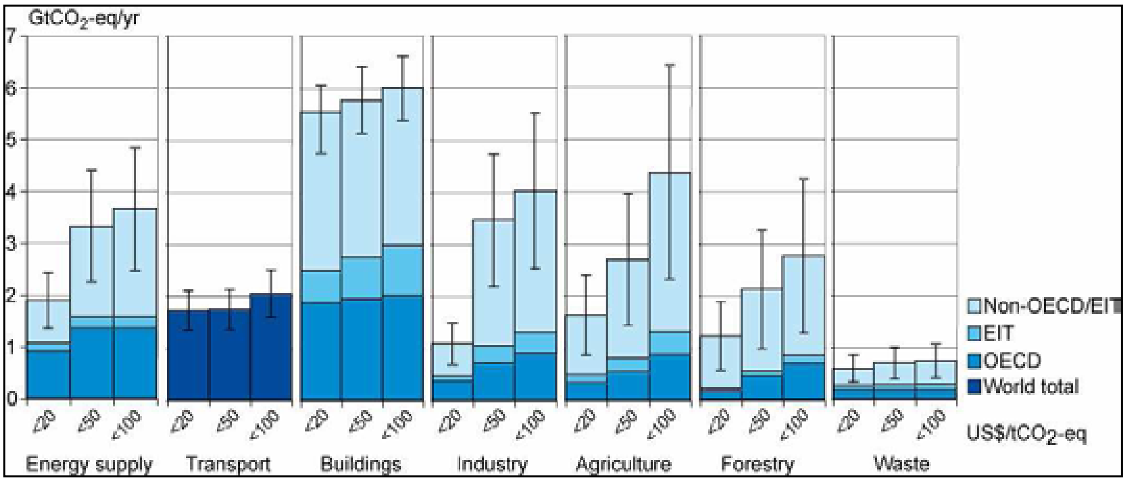

Figure 1 *2030 emission reduction potential in different sectors depending on reduction measure costs (US$/co2 equivalent) - Source: IPCC, 2007*

This potential can be achieved through a range of measures including smart design, improved insulation, low energy appliances, high efficiency ventilation and heating/cooling systems, significant integration of renewable energies, appropriate maintenance schemes and building users' behaviors encouragement to conserve energy. These technologies and concepts have been already widely tested and are fully commercially available.

4. Generic barriers to EE in the building sector

Barriers to building's energy efficiency measures financing. Energy Efficient Buildings (EEB) construction requires additional funds at the initial stage compared with standard ones, because design, construction materials, heating/cooling equipments and appliances are more expensive. However, these additional costs only represent 5% to 10% of the total building cost for new buildings according to the World Business Council on Sustainable Development 2007 report. Furthermore, if we consider a lifecycle analyse, the energy saved would easily cover and even exceed these initial investments. Despite these considerations, investors are still reluctant as short term investments decisions are based on immediate costs rather than long-term investment plans.

Among others, one of the main identified reasons is the high credit risks perception due to the lack of financial history and financial tools for EEB projects investment's evaluation and pay back ability of such projects. Building and construction professionals are facing difficulties to provide relevant data and information for projects risks assessments and to convey projects benefit in terms of investment in the context of a controlled risk-return environnement, which is a prerequisite to any bank decision process. These high perceived risks are resulting from a combination of many criteria, such as multi-ownership of buildings, relatively small size of the investment, construction and building sector's organisation, lack of information, and shortage of expertise to ensure deliverability of energy savings.

Contradictory interests, the landlord/tenant paradox. Buildings normally have a long life cycle with only limited interaction between stakeholders involved in the different phases. The parties typically making decisions about the building design (designers and investors) are seldom the ones who would benefit from energy efficiency improvement and its reduced associated costs (owners and users).

For example, in most cases, in existing buildings, owner and occupant are different. The first one (the landlord) is interested in limiting its investment as he will not be concerned by the energy bill and he will not naturally invest in high efficiency equipment. The tenant will be the one to pay for the energy bill, but he will not be really interested in paying for energy efficient equipments (such as boilers, efficient windows…) that he cannot take with him. Investing in energy efficient equipments and buildings will not be a natural move and this is a critical barrier. This paradox remains a reality for all types of buildings and even if this problem is well identified and the solution well known, coordination of all the concerned stakeholders remains clearly a challenging issue.

A highly fragmented sector. The building sector is a very fragmented one with many stakeholders involved in the various phases of the construction such as developers, capital providers, designers, engineers, contractors, agents, owners, users, and local governments. In addition, the complexity of interaction between them reinforces the difficulties to conduct a project with an EE friendly environment approach. This barrier is well illustrated in the WBCSD's "operational island" graphs (see figure 2). The first pyramid describes the different technical disciplines involved, the second one the building delivery process and the third one emphasizes the ineffective coordination resulting from functional gaps and management discontinuities. The whole process is definitely not optimised and not integrated even if some players try to optimise their own part of the process.

In addition to this complexity and due to the construction history (uncertain business environment, construction bubbles, recession cycles…), this sector is generally conservative and risk-adverse to new approaches. This is all the truest as incentives for energy savings and associated benefits are also split between the different players and with regards to the different phases of the building cycle. Therefore, investment decision process will not go naturally to long term energy prospective. Last but not least, this leads to higher transaction and management associated costs and this is even more significant if we keep in mind that most of the projects are dispersed and small by nature.

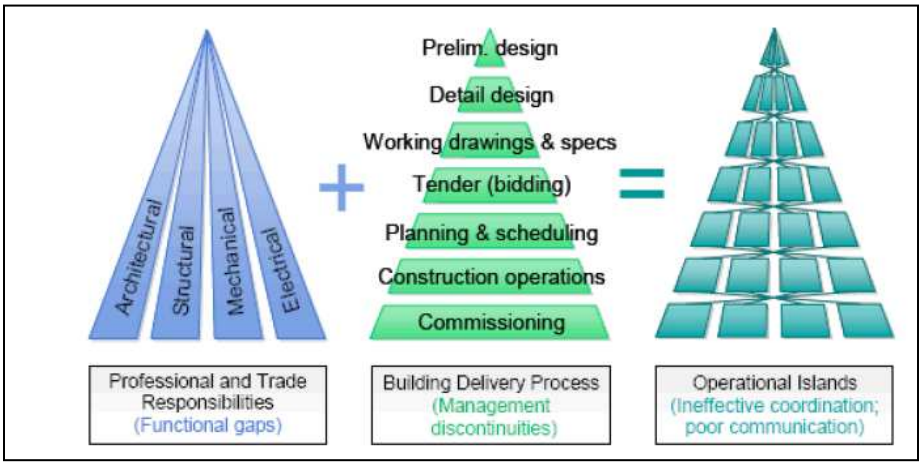

Figure 2 WBCSD's "operational island" graphs or how the construction sector is fragmented and complex – Source: WBCSD, 2007

Insufficient and ineffective governments' policies. This issue is definitely a strategic one and in order to illustrate the need for government support, the UNEP SBCI "Assessment of Policy Instruments for Reducing Greenhouse Gas Emissions from Buildings" report released in September 2007 by CEU (Central European University) has provided very interesting results. A global review of lessons learned from existing policy instruments in more than 50 countries around the world have been realized and the conclusion is that many policy instruments are not only effective in achieving emission reductions, but also result in net savings to society, up to US$ 200 per ton of $CO_{2\text{-eq}}$ avoided.

Having a look to developing countries, standards and regulations for EE in the building sector are generally lacking. In addition to governments' limited capacity and resources to design and implement appropriate policies and programs, the difficulties for their concrete implementation are generally underestimated. For example, in China, officially 70% of the new buildings in big cities reach the requested compliance level, but, in reality, it seems that only 30% fulfil the requested expectations. Considering small cities and rural areas, this is even more difficult, as for less developed countries. Beside the lack of government policies, and even when existing, clear implementation programmes with appropriate monitoring tools are not well defined and, in some cases, requirements are mostly qualitative.

EEB real costs and benefits misperception. Numerous studies have illustrated the misperception of building and construction stakeholders with regards to EE solutions and associated costs and benefits.

A study on additional costs perception has been conducted by WBCSD in 2007. It concluded that estimated over cost for an energy efficient building is considered between 11% and 28% of a "business as usual" one. As mentioned before, real figures are different as for Industrialised Countries 5% to 10% seems more realistic even if it is a little bit more for Economy in Transition ones. In addition, IPCC AR4 also underlines that, when existing, information about energy efficient solutions is not really appropriate to the different stakeholders' expectations (banks, developers, investors, builders, users…).

Another conclusion of the study is that, even if professionals seem to be aware of the importance of EE measures, they underestimate the GHG emissions sector contribution (19% which is quite far from the approximately 40% real contribution). "Lack of personal know-how about how to improve a building's environmental performance" and "lack of knowledge about where to go for good advice" are ranked as major barriers in the decision making process.

5. The Kyoto Protocol and the building and construction sector

A few words about the Kyoto Protocol. The United Nations Framework Convention on Climate Change (UNFCCC) was signed during the Earth Summit in Rio de Janeiro in 1992. UNFCCC Annex I countries are mainly OECD countries (Organisation of Economic Cooperation and Development) and countries undergoing the process of transition to a market economy. Countries have committed themselves to return jointly or individually under their 1990 level of GHG.

The Kyoto Protocol was adopted at the 3rd session of the Conference of the Parties (COP3) to the UNFCCC held in Kyoto, Japan, in December 1997. This Protocol defines quantified greenhouse gas (GHG) emissions reduction targets for UNFCCC Annex I Parties (now called Protocol Annex B countries) in order to reduce collectively their GHG emissions by 5.2% below their 1990 level on a committed 2008-2012 period. Each Annex B Party has different GHG emission ceiling for the first commitment period called "assigned amounts Unit" (AAU) calculated as follows: "the base-year emissions" x "emission reduction target" x "5". The base-year emissions being Party's aggregate 1990 GHG emissions. Non Annex B countries have also agreed to reduce their emissions but without any binding obligation under the "common but differentiated responsibility" principle.

Beside national policies and measures, Annex B Parties can meet their objectives using 3 market mechanisms called the "Kyoto flexible mechanisms": the Joint Implementation (JI), the Clean Development Mechanism (CDM) and the International Emissions Trading (IET).

The first one (Article 6 of the Protocol) allows Annex B countries to implement projects in another Annex B country; the correspondent credit will be issued based on the amount of emissions reductions achieved by the project activities. The credit from the JI is called Emission Reduction Unit (ERU).

The second mechanism, the CDM (Article 12 of the Protocol), allows Annex B countries to assist non Annex B countries in implementing project activities to reduce GHG emissions and corresponding credit (Certified Emission Reduction – CER) will be issued based on associated emission reductions.

The third one, the IET (Article 17 of the Protocol) allows Annex B countries trading AAU, CERs and ERUs with others Annex B countries.

The objectives of these market mechanisms is to decrease total cost of Annex B countries to achieve their collective emission reduction targets and to encourage technologies transfers in "cleaner" projects in non Annex B countries.

A few considerations about CDM projects' eligibility. The purpose of this paper is not to go too much in details in Kyoto Protocol concrete implementation, but in order to clearly illustrate building and GHG mitigation link under this Protocol, it seems important to explain how projects process implementation is arranged and which concepts are required. Having said that, some compulsory criteria are needed to be able to qualify a project as a CDM one. The so called Marrakech Accords specify that emissions reductions have to be real, measurable, benefit to the mitigation of climate change and contribute to the host country national sustainable development goal.

The baseline for a CDM project activity is the scenario that reasonably represents GHG emissions that would occur in the absence of the proposed project activity. To establish scenario and emissions baseline, concerned stakeholders can use approved and new methodologies to demonstrate additionality and to refer to monitoring concerns. The difference between the baseline emissions and GHG emissions after implementing the CDM project activity is emission reductions. A CDM project activity is additional if GHG emissions are reduced below those that would have occurred in the absence of the registered CDM project activity.

Today, the CDM is known as one of the most important international market based mechanisms to reduce GHG emissions. End of 2007, the 2700 CDM including registered projects and the ones waiting for validation were representing more than 600 million tonnes of $CO_{2\text{-eq}}$ abatement per year. As an example, if we consider the price for a ton of CO_2 between 10 and 30 US$, this would mean a market potential value between 6 and 18 billion US$...

The building sector and the Kyoto Protocol flexible mechanisms. Even if buildings are eligible for the Kyoto Protocol flexible mechanisms, only a small number of the projects in the CDM/JI pipeline are related to energy efficiency in building (as of 8th November 2007, 14 out of 2700 projects). In addition, within these 14 projects, no significant Certified Emission Reduction credits (CERs) have been generated.

With regards to the building sector's large emission reduction potential, it is clear that so far, CDM has not been able to attract significant number of projects. This has been underlined in the IPCC's AR4, which indicates that CDM, as designed and implemented today, creates low CO_2 mitigation effectiveness and furthermore is not cost-effective for the building sector. If we go back to the figure 1 data, which means that, in 2030, between 5.5 billion and 6.1 billion tons of $CO_{2\text{-eq}}$ could be mitigated, with a price for a ton of CO2 between 20 and 100 US$, this represents a potential market value between 110 billion and 610 billion US$. This calculation is a little bit simplest regarding the EEB building barriers but the purpose here is just to illustrate that a significant amount of money can be mobilised to support project implementation.

6. The CDM process weaknesses to support EEB projects implementation

As already mentioned and despite a real potential, some limitations in modalities, procedures and methodologies in CDM current arrangements make this market mechanism not effectiveness to support EEB projects implementation. Without being exhaustive, some key issues need to be considered.

Additionality requirements can be considered, in some cases, in opposition with mandatory policy implementation strategies or, at least, can make standards and regulations implementation difficult. This point has to be linked with baseline considerations and, even if it is a clearly identified problem, nothing, for the moment, has been clearly answered in order to overpass this difficulty. A tentative answer is highlighted in the Program of Activities (PoA) and CDM Program Activity (CPA). The first one is a voluntary coordinated action by a private or public entity which coordinates and implements any policy/measure or stated goal which leads to GHG emissions reductions. The second one is a project activity under a program of activities, representing a single or a set of interrelated measures to reduce GHG emissions applied within a designed area defined in the baseline methodology. The objective is to encourage voluntary actions keeping access to CDM potential additional revenue having in mind policies implementation according to a pre-define action plan. It can be also underlined that current PoA guidance states that only one single approved baseline and monitoring methodology can be applied under a program which means that even if a project intends to mix different methodologies for different efficiency measures, they can not be eligible in the same CPA under one PoA. To illustrate this purpose, it means that project which includes envelop improvement, energy efficiency measures, solar water heater and electricity generation can not be applied under the same PoA because they refer to four different approved methodologies. This conducts to unnecessary complexity associated to highest transaction and management costs and even disadvantages putting forward “best building practices” to be eligible (and so visible) under the CDM.

The above concern can be called the “baseline” one. Another key issue is linked with the existing methodologies and associated monitoring requirements. First of all, existing methodologies are technologies oriented and do not answer overall building performances (but building’s answer to climate impacts is not only related to addition of efficient technologies but also to a lot of different items such as design, users’ behaviors…). Another related point is the size of individual projects and even if existing methodologies such as AMS-IIC (demand-side energy efficiency activities for specific technologies such as lamps, refrigerators, appliances…) or AMS-IIE (energy efficiency and fuel switching measures) are applicable to buildings and also concern small scale projects, they are still technologies oriented and require difficult and complicated real measurements and audits on all installed technologies to demonstrate emissions reduction reality. In addition, the associated amount of CERs is not generally significant enough to encourage projects developers entering into the process and to cover management associated high costs.

The lack of existing baseline for new buildings due to the complex nature of an EEB project by definition and the difficulty to have a comparative base for the evaluation of the project emissions reductions is also another important point. Moreover, each project being unique because of using different approaches to reduce GHG emissions makes the problem even more difficult. For what concerns refurbishment of existing buildings, this can be over passed if accurate existing data are available, which is not the general situation. For those who decide to still go into the process, this conducts to very conservative baseline scenario and for what concerns monitoring and auditing processes to difficulties to demonstrate reality of emissions reductions. This point is of the utmost importance and explains why so far no new building has been approved in the CDM process. In addition, the existing arrangements answer neither to the evaluation of thermal performance buildings improvements nor to energy end-use patterns for heating and cooling. Once again, this comes from the existing technologies oriented methodologies which do not reflect small projects with many end-users having different behaviors (comfort, culture and consumption habits).

The above points lead us to another difficulty as soft measures are not taken into account in the current arrangements. We all know, how from a life cycle perspective, it is crucial to encourage energy consumption reduction during the building operation. This can be done through appropriate procedures but also by motivating and associating end-users to the process. The AR4 report shows that energy savings can reach up to 38% in cooling and 62% for heating.

Last but not least, the ownership and the benefit of the potential CERs issued will not easily answer the numerous stakeholders concerns in a project implementation.

The above list is not exhaustive but already reflects a lot of complexity and limitations to support EEB projects implementation. This is even more true for low income residential buildings where sustainability criteria is the first concern as the point is to improve poverty reduction but where the availability of funds is not so evident and where CDM revenue can not fill the gap.

How CDM process can contribute to EEB projects implementation. As described in the EEB barriers presentation, the building sector is a very fragmented one with numerous and sometimes contradictory interests if we consider a life cycle approach. For what concerns the CDM process, it is clear that the management issue is of the utmost importance. Reaching the real, measurable and verifiable emissions reductions objective means that all the building and construction process needs to be properly arranged. Without going to much in details in the monitoring process, it has to be done by a third party auditor authorized by the national designated operational entity which is an independent legal entity accredited by CDM executive board that can validate proposed CDM projects, verify and certify GHG emissions reductions. To summarize, CDM requirements can be compared in a way to a quality insurance approach. Having that in mind, it can be easily imagine how this process can encourage investors and decision makers to clearly support EEB projects with real GHG mitigation.

Another very interesting item is linked to requirements for validated methodologies which allow replicability from a project to another one. What we try to say here is not to minimize what was stated in the previous chapter but just to say that as soon as a methodology has been approved it can be easily re-used for numerous projects. The issue will be then to have a clear picture of the concerned perimeter.

As far as user's behavior change is concerned, monitoring requirements, which conduct to have a clear picture of emissions reductions reality, can clearly encourage end-users in the global energy saving effort by raising their interest to be associated to the global performance of the building and even to obtain parts of the benefit. This can be called a "virtuous quality performance circle approach".

For what concerns implementation of government policies (standards and regulations) which are by nature top-down approaches, CDM can support market transformation through the above quality approach process and through the scale-up effect by encouraging more voluntary projects because of the additional revenue when trading CERs. In that way, CDM can contribute to fill in the gap between policy enforcement and policy compliance.

Going back to the financing question, CDM can support EEB projects implementation by reducing investments and financial risks perception, by demonstrating opportunities to support life cycle based investments and to have additional funds to cover transaction and higher management associated costs. For the first point, it will encourage numerous small projects to be implemented in a coordinated manner using the same process. The quality insurance control mechanisms minimize the risk of payment default. In addition, all the above comments can be also a good communication tool to be compared to all voluntary initiatives such as LEED, HQE, BREEAM… in order to raise interest of potential stakeholders. This can be a real interesting point as far as we deal with sustainability criteria in the host countries and that, in many cases, international funds will be mobilized.

7. The way forward… How to transform and adapt CDM constraints into opportunities to improve building sector GHG emissions reductions

What has been presented so far may look like quite a not so optimistic picture. This is not really true if we consider that all concerned stakeholders have now a very clear picture of the situation and that the concern about climate change mitigation is agreed by everybody. Considering the high building contribution to climate change, everybody is now aware and we collectively need to work on this issue as urgently as possible. We need to work on best ways to over pass barriers, to take advantage of the already successful arrangements and even to go through new options. Besides the need to develop national regulations and standards for energy efficient buildings and/or sustainable ones, key topics to work on can be summarized as below (definitively a non definitive list):

* Allow energy performance based methodologies instead of technology ones as described in the current Kyoto Protocol arrangements. As explained before, the technology based does not reflect EEB projects reality. In addition, such approach is in line with thermal regulations implemented or in development and per square meter energy performance is also a common used indicator for a global approach of energy concerns in buildings. Such approach can support removing several of the economical, technological and associated barriers. For example, it can over pass restrictions of bundling different measures in the same project and also it would avoid uncertainties regarding eligible measures. This would allow flexibility for taking into account factors such as design, use of building materials and user's behavior improvement. Last but not least, such performance approach would also encourage a building's lifecycle energy efficiency approach and would also reinforce interest for future improvements. This topic has to be linked with the next point.

* Need to develop common baselines. As already explained, having such information for each country is of the utmost importance to facilitate project implementation process. This work has to be prepared by hosted Designated National Authorities (DNA). If each country defines and agrees on an average ratio per type of building and per type of use according to climate conditions and to EEB rules, it can significantly attract project developers in the CDM market. This point is very important for new buildings but also concerns refurbishment needs. Large-scale surveys and building benchmarking efforts need to be undertaken in order to be able to propose to CDM Executive Board realistic figures.

* Mobilize all public and private building and construction sector stakeholders by developing appropriate tools such as financial ones, evaluation and monitoring of EEB projects. CDM, as described, can make coherence by the associated requirements. Coming back to support the implementation of national

standards for energy efficiency in buildings, allowing CDM and associated CERs could provide incentive to EEB projects in countries where the enforcement capacity of standards is low.

* Reinforce capacity building through guiding materials and standardization of activities and documentations for EEB projects and related CDM activities. Even if some examples exist and if quite a significant literature on the overall process is available, only a few of it has been designed to answer building and construction sector's needs. Such tools need to cover all project phases from design, commissioning, monitoring to the financial one. On this subject, good case studies and demonstration projects can be push forward. The first one being to make easy duplication and the second one to develop innovative approaches.

8. An urgent need for advocacy

The first crediting period has started less than one year ago and we already know that reaching objectives will not be as easy as expected. Negotiation process for next period has also started and the challenge is much more difficult as it is commonly agreed that reduction objectives will be much higher for Annex B countries and that the involvement of developing countries will be also a determinant aspect.

Going back to the building and construction sector, and if we consider the high GHG contribution and the even higher mitigation potential, would working on an international agreement without incorporating the buildings and construction sector have sense?

Regarding Kyoto flexible mechanisms and even if we surely need to work on an adaptation, we can take advantage of the existing experience to propose, as soon as possible, a new and adapted approach. The above recommendations have not to be considered as a conclusion. They are just recommendations and in-depth actions need to be implemented as urgently as possible. SBCI will definitely contribute working on this challenging issue by pushing forward the buildings and construction at the top priority of the political agenda in the framework of the UNFCCC ongoing activities.

Before concluding this paper, it is important here to highlight that the above contribution is based on a collaborative work including UNEP SBCI Secretariat and Members, UNEP RISOE Center, SBCI Climate Change Think Tank Members and all SBCI associated partners and initiatives. Thanks to all of them.

Keywords: urban sprawl, sustainable land use, internal development, driving forces, approaches

Summary

Our built environments drive human, organisational and regional productivity and contribute to the national economy. During the last decades the development of our surroundings has led to a worldwide phenomenon that has often been associated with prosperity and quality of life: urban sprawl. But what is the price we have to pay for it? The impacts of urban sprawl to our Natural Capital and to the dimensions of sustainability (integrative perspective, intragenerational and intergenerational equity) are significant.

There is growing recognition that internal prior to external development[a] of our built environments is an appropriate strategy to encounter a further increase of land use. In this regard, important questions emerge in three main fields. *Land use:* How did the landscape as well as its use evolve? How will it develop in future? *Driving forces:* What are the driving forces of urban development? Which stakeholders are involved? *Approaches:* What kind of planning and regulation approaches are adequate to slow up or even stop the trend of land use? How well are these instruments known by the planning authorities?

For the case of Switzerland, the paper will analyse and discuss today's situations for these three fields. It will demonstrate that efforts on several levels are needed in order to reach a sustainable land use and that there *are* ways to face the continuous settlement expansion. However, a Swiss-wide survey amongst selected municipal and cantonal planners revealed that there is an insufficient awareness and implementation of both already existing and innovative instruments.

1. Introduction

1.1 Urban Sprawl

According to Jaeger et al. (2007) urban sprawl can be paraphrased as follows: Urban sprawl is a phenomenon optically perceivable in the landscape. The more a landscape is interspersed with buildings the more it is sprawled. The degree of sprawl is the extent of the landscape's building development and its dispersion. The more an area is built up and the more dispersed the buildings are, the higher urban sprawl therefore is. The socio-economic driving forces of urban sprawl characterise the development of built environments in most of the countries worldwide. The European Environment Agency states in its report, that Europe-wide urban sprawl is increasing in a mechanistic way in areas where unplanned, decentralised development dominates (European Environment Agency EEA 2006). The report also describes, why urban sprawl matters: "Sprawl threatens the very culture of Europe, as it creates environmental, social and economic impacts for both the cities and countryside of Europe. Moreover, it seriously undermines efforts to meet the global challenge of climate change. Urban sprawl is synonymous with unplanned incremental urban development, characterised by a low density mix of land uses on the urban fringe. Classically, urban sprawl is a US phenomenon associated with the rapid low-density outward expansion of US cities, stemming back to the early part of the 20th century. It was fuelled by the rapid growth of private car ownership and the preference for detached houses with gardens. In Europe, cities have traditionally been much more compact, with a dense historical core shaped before the emergence of modern transport systems. Compared to most American cities, their European counterparts still remain in many cases compact. However, European cities were more compact and less sprawled up until the mid 1950s than they are today, and urban sprawl is now a common phenomenon throughout all Europe. Moreover, there is no obvious slowdown of these trends." The report therefore suggests to develop European guidelines in order to coordinate and monitor urban planning in Europe.

[a] The term "internal development" is also known as "in-fill development" or "inward development".

1.2 Sustainable Development

The Swiss understanding of sustainable development is described by the federal council of Switzerland in their strategy-report from 2002 (Schweizerischer Bundesrat 2002). For them the most adequate definition of sustainable development is still the definition from the conference of the World Commission on Environment and Development in Rio de Janeiro in 1987, which the chairmen called the “Brundtland-Definition”. Accordingly, a development is sustainable as long as it can assure that the needs of the today’s generation can be satisfied without affecting the possibilities of future generations to satisfy their own needs.

Hence, the Swiss developed an enhanced three-dimensional model, which adds a spatial dimension for the global long-range effects and a time dimension for the intergenerational equity to the three common dimensions of environment, economy and society. The sustainability-model of the Swiss federal council therefore includes three main principals: integral, well-balanced consideration of the environment, economy and society; consideration of the interests of future generations (intergenerational equity); consideration of the interests of all residents worldwide (intragenerational equity) (Wachter 2006). The strategy Sustainable Development 2002 includes ten spheres of activity with 22 tasks altogether; the sphere of activity no. 7 is dedicated to the spatial development and the development of settlements. The strategy also demanded a monitoring for sustainable development. Therefore an indicator system for the evaluation of sustainable development called “MONET” was created and applied. Three of the nearly 120 MONET-indicators are directly linked to the topic of urban sprawl: “settlement area”, “average settlement area per capita” and “land usable for agriculture”. While the settlement areas in total and per capita still grow, the areas potentially suitable for agricultural use decrease.

1.3 Urban Sprawl versus Sustainable Development

There is no doubt that positive effects come along with urban sprawl. Our built environments drive human, organisational and regional productivity and contribute to the national economy. Low-cost land at peripheral locations is made accessible by high-capacity highways which makes detached housing affordable to almost everyone. In addition, the development of settlements on greenfield areas rather than brownfield sites (previously developed land) may contribute to the conservation of precious and intact heritage sites in historical town centres.

On the other hand, there are many aspects of urban sprawl which are not considered to be sustainable. First of all there are *practical concerns.* For many residents in suburban areas, urban sprawl is associated with over-average expenditure of time for commuting. Apart from that the growth of urban sprawl generally involves the loss of high-quality agricultural area. Furthermore, the building zones are too large and are sometimes situated in strategically unsuitable areas (ARE Bundesamt für Raumentwicklung et al. 2005). The 2005 report on spatial development also accentuates, that the population and workplaces are excessively concentrated in the Swiss metropolises. Therewith, the “city system Switzerland” threatens to loose its balance.

Ecological concerns: Urban sprawl is also associated with an increase in traffic as well as in the consumption of energy and space (e.g. Binswanger et al. 2004). The ongoing urbanisation (sealing and fragmentation of the landscape), the increasingly intensive agriculture, the standardisation of the characteristic landscape as well as the development of tourism and traffic infrastructures put the biodiversity at risk. Many species which used to be widespread are nowadays endangered (BFS Bundesamt für Statistik 2008).

There are also *economical concerns.* According to the Federal Office for Spatial Development, the competitiveness of metropolitan areas as well as touristy destinations suffers (ARE Bundesamt für Raumentwicklung et al. 2005). They are not protected long term. In some rural areas the economical substance is decreasing. Thereby, the ability of those areas to develop autonomously lessens. Urban sprawl often also aggravates a cost-efficient public service. Thus, the development of infrastructures for sewage, water supply, traffic and electric power in a spatially dispersed settlement can lead to up to three times higher costs per capita than for an inwardly dense settlement development. As the beneficiaries of the infrastructures are often not compensating for the entire financing, these higher costs do not only strain private households but also the public authorities (ECOPLAN 2000, Schultz et al. 2006).

Furthermore, there are *societal concerns:* Urban sprawl can encourage social exclusion and contribute to the atomisation of family life. Moreover, it complicates the preservation and development of urban quality (Wachter 2006). In agglomerations there is a tendency towards social and functional segregation (ARE Bundesamt für Raumentwicklung et al. 2005).

One can express *aesthetical concerns* as well. Urban sprawl affects the characteristic landscape and is complicit in the sterile and uniform character of so many dispersed, peri-urban developments. Precisely the “spoiling” of the characteristic landscape could have a negative impact on tourism, which is so essential for many Swiss regions.

Last but not least, a non-sustainable today’s land use is likely to delicately narrow the potential possibilities of development for future generations (ARE Bundesamt für Raumentwicklung 2006).

Despite the fact that urban sprawl can show positive effects, the negative impacts in terms of sustainability prevail (figure 1). As the impacts of urban sprawl on sustainability are mainly negative, it is only logical that 2002 the federal council of Switzerland for the first time not only complained about urban sprawl, but has since aspired to stabilise the indicator “average settlement area per capita” at around 400 m^2 (Schweizerischer Bundesrat 2002).

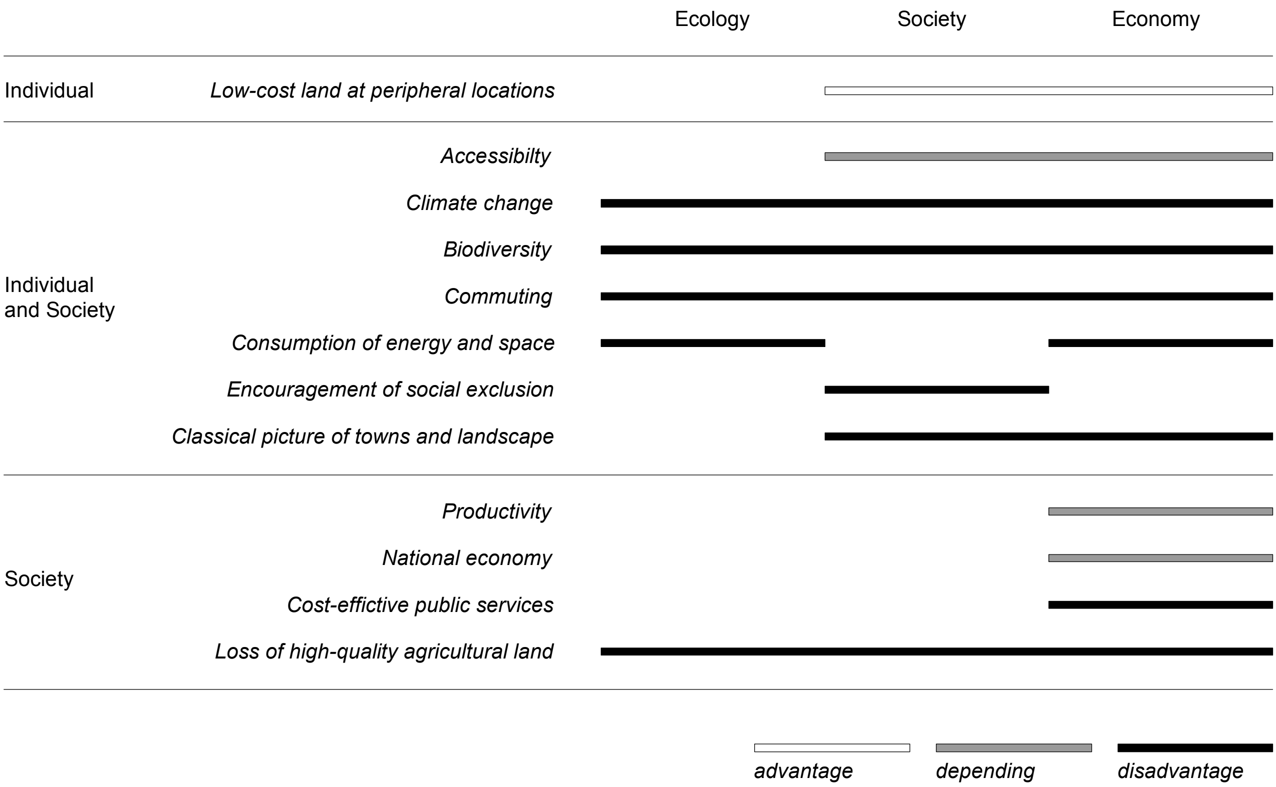

Figure 1 Main advantages and disadvantages of urban sprawl.

1.4 Urban and Regional Planning in Switzerland

Urban sprawl is not a topic discovered nowadays. Already in the first article of the Swiss spatial planning law from 1979 they say: "The federation, the cantons and the municipalities take care that the land is used thriftily" (Bundesversammlung der Schweizerischen Eidgenossenschaft 1979). In the 1980s there were several studies on the use of land, and from 1985 to 1991 proposals for a thrifty land use were developed in line with the national research programme 22 called "Land Use in Switzerland". In his 1996 report on the main features of the Swiss spatial development, the federal council records that "the existing capacious reserves of building zones within already built-up areas could theoretically meet all building demands" (BRP Bundesamt für Raumplanung et al. 1996).

Within the 2005 report on spatial development (ARE Bundesamt für Raumentwicklung et al. 2005), not only the situation of the Swiss spatial development was analysed, but also a main urban and regional planning strategy was developed. A first strategic approach consists in striving increasingly for internal instead of external settlement development. The second approach aims at preserving and enhancing the "city system Switzerland" – a network of towns which characterises the spatial structure of Switzerland.

Basically, the Swiss spatial planning disposes of good planning instruments which impact surely must not be underestimated. Since tasks of internal development are usually more complex than those of external development (higher number of stakeholders, more conflicts of interests, uncertainties, risks and surprises), the usual formal instruments normally are not sufficient to clarify the emerging questions. They have to be complemented by innovative informal procedures and instruments (ARE Bundesamt für Raumentwicklung et al. 2005; Scholl 2007). Thereby, the existing legal instruments provide enough tolerance for an optimisation of the existing mechanisms, also allowing unconventional and innovative solutions (Näf-Clasen 2006). However, as long as the stakeholders do not have any economical and actual incentives for a reduction and qualification of land use, and as long as the possibilities of regulation by the spatial and urban planning authorities remain restricted, the success of any land use policy will remain limited (Schultz et al. 2005).

2. Land Use

Switzerland is situated in the centre of Western Europe. With its total land area of 41'284 km^2 it belongs to the smaller states of Europe. The north-south-dimensions amount to 220 km, from west to east there are up to 350 km. The natural and cultural area is strongly affected by the Alps which cross Switzerland from west to east. The Alps form a distinctive both climatic and hydrological parting line. The major part of the federal territory is situated to the north of the Alps and is characterised by a moderately humid climate. To the south of the Alps, Mediterranean influences affect the climate and vegetation (BFS Bundesamt für Statistik 2008).

In 1997, a good 25% of the total 4.13 million hectares (ha) were non-productive areas and around 30% were forest areas. 1.57 m ha or approximately 37% were agricultural areas and 0.28 m ha or just under 7% of the territory were built-up areas (BFS Bundesamt für Statistik 1997). With a population of over 7 million people, land is a very restricted resource in Switzerland and is threatened by the increased standards regarding dwelling and transportation.

In Switzerland, the lifestyles and hence the forms of housing schemes have changed vitally during the last decades. The 2005 report on spatial development depicts the current trends of spatial development in Switzerland (ARE Bundesamt für Raumentwicklung et al. 2005). Due to the shift towards a service economy (tertiarisation), modern media and the enormous mobility, a clear rapprochement between the urban population in the centres and agglomerations and the rural population has occurred. The classical picture of settlements with a clear borderline between towns and countryside is becoming more and more a phenomenon of the past. The functional areas interwoven with the town are no longer limited to clearly bordered areas, but can stretch over dozens of kilometres across wide surrounding areas. The areas within the original city boundaries together with their first agglomeration belts still feature high densities regarding to the building development, residents, jobs as well as cultural, economic and social activities. They are surrounded by sparsely populated areas, where agricultural zones with expanded single family house settlements, unstructured industrial and commercial areas, shopping centres and theme parks with huge parkings alternate. This settlement formation is hardly structured by intentionally designed public space anymore. Instead, the spatial structures are determined by the improved accessibility.

2.1 Previous Evolution of Landscape and Land Use

Between the first survey of the Swiss area statistics 1979/85 and the update 1992/97, land use changed as follows. Increase: forest areas +1.4%, built-up areas +13.3%. Decrease: agricultural areas -3.1%, non-productive areas -0.1% (BFS Bundesamt für Statistik 1997). The absolute changes are shown in figure 2.

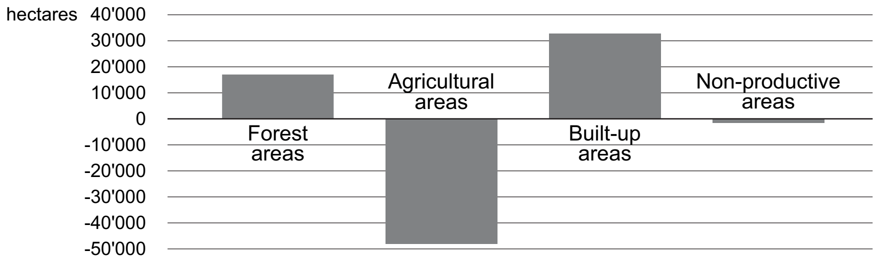

Figure 2 Evolution of land use between 1979/85 and 1992/97. Source: ARE Bundesamt für Raumentwicklung et al. 2005; BFS Bundesamt für Statistik 1997

Thus, the built-up areas grew by 0.86m^2 per second on average between 1985 and 1997, namely at the cost of agricultural land. This growth however has to be differentiated spatially. Within 12 years, the built-up area of the midland increased twice as much as the average and amounted to 14% of the total area by the end of the 1990s. Accordingly, the population density in this area adds up to approximately 450 persons per km^2 (Swiss average: 173 Personen/km^2). The rural built-up areas of the midland are growing faster in percentage than the urban agglomerations (Haag 2007).

2.2 Future Evolution of Landscape and Land Use

Current values of land use change are surveyed in line with the ongoing Swiss areal statistics 2004/09. First results from 623 municipalities of western Switzerland show a slowed evolution of the landscape: From 1981 to 1993 the built-up area in this part grew by 15%, whereas from 1993 to 2005 the area grew by 9%. In the same periods, the loss of agricultural areas was reduced from 3.1% to 2.1%. A comparatively weak business activity and therefore limited economic development during the nineties could have been the reason for this deceleration (BFS Bundesamt für Statistik 2008).

3. Driving Forces and Stakeholders

There are manifold reasons that lead to an undamped growth of settlements. Alongside with population growth (natural population development plus migration), urban sprawl is an expression of a change in life style with higher claims regarding dwelling and transportation.

According to Haag (2007) the socio-economic developments in Switzerland are reflected by the way people dwell. The financial autonomy of the younger and the older generations, the high percentage of employed persons as well as the well developed welfare all support the trend towards small independent households. Thus, the number of single-person households increased above average from 1970 to 2000. A further expression of the societal prosperity can be seen in the increase of size of newly constructed flats. Thereby, the flats' floor area increased without necessarily adding to the number of rooms, which means that there was a rise in comfort and quality. The average dwelling area per capita increased from approximately 24m^2 (1950), to 34m^2 (1980) and then up to 44m^2 (2000). Furthermore, the desire of a lot of Swiss to own a detached house in the countryside is unbroken. That way, 75% of all newly erected buildings for dwelling in 2004 were detached houses. Finally, the number of second homes has increased, both in touristy villages and – job-related – larger towns.

Haag (2007) detects land prices and today's transportation as further driving forces of urban sprawl. Low-cost land at peripheral locations is made more and more accessible by high-capacity highways. And as transportation is still rather cheap in Switzerland, purchasing a plot of land in the countryside and commuting long distances by car often pays off financially. Moreover, dispersed settlements of detached houses can hardly be made efficiently accessible by public transport.

During the twelve years between the first and the second Swiss area statistics, not only the dwelling areas increased, but also the industrial and commercial areas namely by a good 24% (BFS Bundesamt für Statistik 1997). The positive economic development was doubtlessly one reason for this growth during that period.

The municipalities' planning sovereignty and the tax competitiveness respectively certainly also contribute to the continuous expansion of the settlement areas. Assuming that wealthy habitants prefer living in detached houses and aspiring to attract appealing taxpayers, a lot of municipalities have provided building zones of unreasonable sizes for detached housing. Many municipalities still follow this formula today although the correlation "more detached houses, higher tax revenue" may not always be true (anymore) (Schultz et al. 2006). Once building zones are provided though, only few incentives remain to conserve undeveloped land.

As abovementioned driving forces of urban sprawl display, various stakeholders with different motivations are involved in the processes of settlement area expansion. According to Maurer (2007), stakeholders are the most important source to uncover exposed and hidden intents and solve problems. Therefore, the causes and effects of urban sprawl have to be pointed out increasingly to the involved stakeholders and the public – this primarily applies for investment costs and ongoing "shadow costs" from external development for municipalities, private households and companies respectively (Reiss-Schmidt 2007).

4. Approaches

4.1 General Approaches

As mentioned earlier, a main urban and regional planning strategy was developed in line with the 2005 report on spatial development (ARE Bundesamt für Raumentwicklung et al. 2005). A first strategic approach consists in striving increasingly for internal instead of external development. The second approach aims at preserving and enhancing the network of towns.

4.2 Planning and Regulation Approaches

It was also outlined that in Switzerland municipalities are very autonomous and dispose of a great freedom of action regarding urban and regional planning. In terms of internal settlement development, the municipalities therefore play a key role. The growth of settlements however has to be spatially differentiated. In towns different driving forces are active than in agglomerations or mountainous areas. Varied approaches are therefore needed for the different municipalities.

The complexity of the challenge reveals that only a combined bundle of actions could possibly be successful, whereupon the tax, zoning and urban and regional planning laws, dwelling and town planning promotions as well as transport policy would have to be involved. The combination of instruments as well as their intervention intensity would have to be chosen in a way that assures an altogether equitable distribution of benefits and charges and that preferably avoids negative economic and social impacts (Jörissen et al. 2007).

A compilation of *existing* Swiss strategies and instruments are classified into the following categories (Stauffiger 2006):

- urban compaction,
- restriction of the settlement area,
- careful handling regarding development outside the zoning-plan,
- constrict traffic volume and infrastructure,
- improvement of settlement quality,
- regional planning,
- strengthening of nature and landscape conservation,
- raise awareness for land waste problem,
- constrict construction of second homes.

The following *innovative* strategies and instruments were designated:

- formulation of regional land saving mission statements,
- compaction model,
- promotion of alternative forms of housing schemes,
- compilation of municipal or regional area pools,
- sealing regulation,
- handout for property owners and house builders.

Jörissen et al. (2007) split the bundle of instruments for Germany into the following main categories:

- planning law instruments,
- potential of regional cooperation,
- informational instruments,
- fiscal instruments,
- economic incentives and
- financial promotion instruments.

Based on computer simulations, they discovered that it is a matter of actions with relatively moderate and justifiable intervention intensities that would lead to the achievement of the sustainable land use goals. As the simulations show, the impact on economic indicators like gross domestic production, employment and rental costs are likely to be marginal.

4.3 Self-assessment of Planning Authorities

In the preceding paragraph it was mentioned that only a combined bundle of actions could possibly be successful regarding the achievement of the sustainable land use goals and that in terms of internal settlement development, the municipalities would play a key role. Repeatedly appearing in the literature is also the strategy called "regional cooperation" that involves regional planning associations and the cantons in Switzerland. In this context, an important question is not only how far the addressed instruments are discussed in the literature, but how well they are known and applied by the executive public planning authorities. Therefore, in line with a master thesis at our chair of sustainable construction, we carried through a Swiss-wide survey amongst selected planners (Albisser 2007). Our master student conducted 33 interviews in total, the coverage of Switzerland is displayed in figure 3.

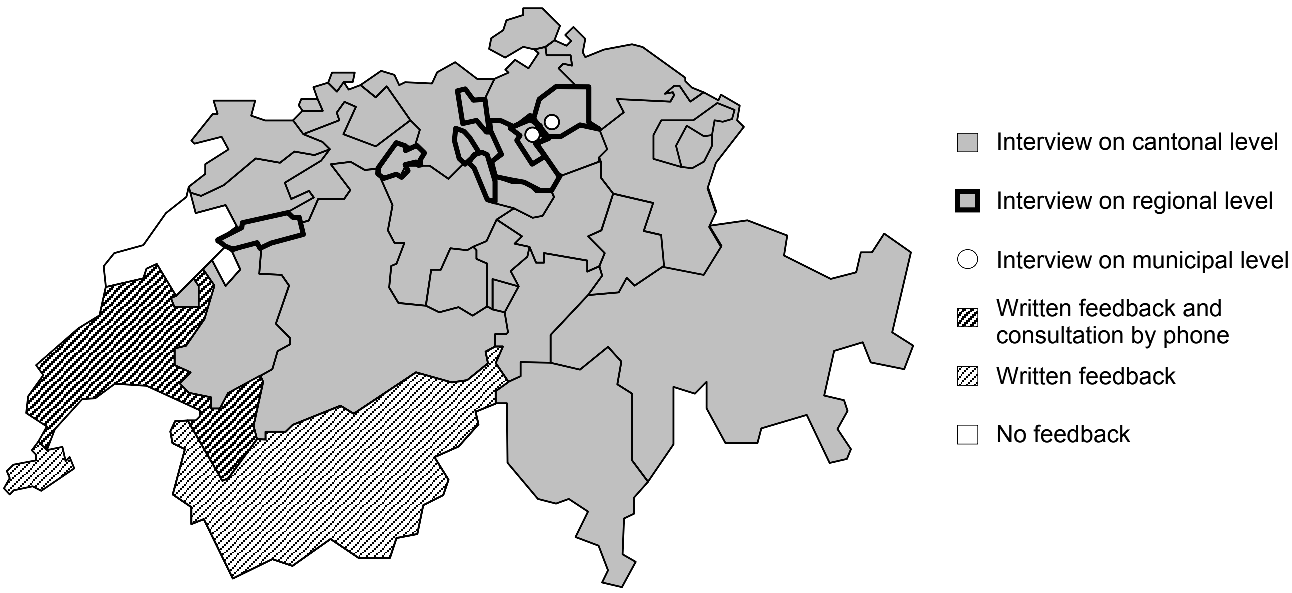

Figure 3 Coverage of the survey.

In order to find out how the planning authorities would self-assess their work towards an internal settlement development and their knowledge about instruments and tools to control it, they were interviewed about topics like internal development in general, the reception of the federation's goals, the application of formal and informal instruments, etc. The survey lead to interesting results which are summarised in the following.

According to the planners, the autonomy of the Swiss municipalities slows coordinated action. Rural municipalities in particular continue to prioritise economic interests over the goals of sustainable land use. Furthermore the up-to-dateness and acuteness of the land use topic is Swiss-wide insufficiently known. Thus according to the interviews the awareness within the authorities, politics and the population is only around 36%, within the economic field even only around 20%. Besides that, the awareness alone does not automatically ensure that the general principles concerning traffic and economic and municipal development are concretised. Moreover, the efforts and projects of the Federal Office for Spatial Development are not always known well by the cantons. This suggests a certain shortcoming of cooperation. In terms of innovative instruments, cantons initially respond to such rather tentatively. According to statements from cantonal planners, especially the mechanisms and effectiveness of new instruments are often said to be vague. Last but not least, an insufficient awareness of already existing instruments can be detected. Thus, it can be explained why the planners mainly refer to the formal, well-established planning tools when being asked what instruments they would apply regarding internal settlement development (table 1).

Table 1 Applied instruments by cantonal planning authorities according to interviews

It would not be adequate to question the Swiss subsidiarity principle or the guarantee of ownership by means of constitutional amendment. This would not be successful on a political level anyway, given that in most cantons not even the surplus absorption can be implemented. In urban areas the federal instrument "agglomeration programme" is at least encountering wide acceptance and has – even though it also addresses further aims – advanced internal development because of a close linkage of traffic and settlement development topics.

5. Conclusions

It was demonstrated that urban sprawl can not be encountered effectively by traditional means. Instead, efforts on several levels are needed in order to head for a sustainable land use.

In Switzerland however, the political goal to stabilise the average settlement area per capita at around 400 m^2 lacks a subsequent determination of serious actions. As abovementioned examples from abroad show, there *are* ways to face the continuous settlement expansion – provided that the issue does not remain a mere lip service.

Swiss urban and regional planning experts are currently discussing various instruments to control urban sprawl. It is crucial though, that approved instruments further establish among spatial planners throughout the country. Besides that, there is need of continued research in two ways. On the one hand, the different instruments' impacts on sustainability have to be analysed more precisely. On the other hand, it is important to detect what mix of instruments will be appropriate to encounter urban sprawl best possible in the various spatial settings and on the different planning and political levels (municipality, canton, federation).

Unfortunately, it seems this goal has not been recognised on all levels so far. And due to the federal structure of Switzerland, presumably there won't be an earnest agreement in near future. Today, energy and climate change are en vogue, if ecological topics have any priority at all. At least, the "Swiss spatial development concept" currently being compiled, may soon provide detailed information about the intended future development of Switzerland. These results will hopefully have a certain impact on the spatial development goals on both cantonal and municipal levels.

BARRIERS TO DECONSTRUCTION AND MATERIALS REUSE

Abdol R. CHINI, PhD, PE [1]

[1] Rinker School of Building Construction, University of Florida, Gainesville, FL, USA, chini@ufl.edu

Keywords: deconstruction, reuse, recycling, construction and demolition waste, standards, sustainable

Summary

Deconstruction may be defined as the disassembly of structures for the purpose of reusing components and building materials. The primary intent is to divert the maximum amount of building materials from the waste stream. Top priority is placed on the direct reuse of materials in new or existing structures. Immediate reuse allows the materials to retain their current economic value. Though definitely on the rise, deconstruction and reuse of building materials is faced with several challenges such as, consumer tastes and perceptions concerning used and recycled building materials, additional time required to dismantle buildings, lack of markets for used components, and the fact that building codes and materials standards often do not address the reuse of building components. In the end, the increased use of reused and recycled building materials is in the hands of the architects, builders, and consumers that use them. Slowly but surely, perceptions have become increasingly positive over the last few years. The natural trend towards increased social and environmental responsibility, along with the maturation of the deconstruction industry, will aid in the effort to improve perception of reused and recycled building materials. This will increase the profitability of the building materials salvage market, making deconstruction a more desirable business alternative. This paper discusses these challenges and suggests ways to make deconstruction and reuse of building materials an alternative to demolition and landfill.

1. Introduction

In the United States every year construction industry contributes to a large amount of waste to municipal solid waste stream. The US Environmental Protection Agency (EPA) has estimated that total waste generated from construction, renovation and demolition of buildings, roads, bridges, and dams was 295 million metric tones (MMT) in 2003 (RCRA, 2004). Building related C&D waste was estimated to be 143 million metric tons in 2000 (Chini and Bruening, 2005). It is estimated that 70 MMT of this was the product of demolition. Table 1 summarizes estimated waste due to building and infrastructure related construction and demolition as well as municipal solid waste (Chini, 2007). The table also shows estimated weight of recovered materials. As Table 1 shows only concrete and steel have a recovery rate of 50 per cent or above. The recovery rate for other materials is not significant, but it is increasing due to rising cost of landfilling waste, stringent new government regulations, and a steady growing concern for the environment.

Figure 1 shows that over 27% of the waste that is generated from construction and demolition of buildings is wood waste. If a portion of this can be reused back in the construction industry in place of virgin lumber, this would mean a great reduction in harvesting, transporting, processing, and other energy intensive steps that are used to produce virgin lumber (Chini and Acquaye, 2001). The United States is fortunate to have a vast supply of trees that are harvested each year. In fact, about one-third of the US land mass is currently forested; from this over 255 MMT of wood are produced each year (Falk 1997). In the past century over 4 billion metric tons of lumber have been produced, and much of it still exists in buildings around the country. According to Horne-

Brine and Falk, if only 2% of these buildings were deconstructed each year, with only 25% of the lumber being reclaimed, it would supply up to one quarter of the overall lumber market in the United States for over 50 years (Horne-Brine, Falk 1999).

Table 1 C&D waste generation and recovery (MMT)

Material	Building C&D Waste	Infrastructure C& D Waste	Steel Products	Municipal Solid Waste	Re-covered
Concrete	55	127	-	-	91
Wood	36	-	-	27	10
Drywall	13	-	-	-	2
Roofing	10	-	-	-	NA
Steel	9	12	59	13	70
Bricks	4	-	-	-	NA
Plastics	4	-	-	24	1

NA: the recovered weight is Not Available

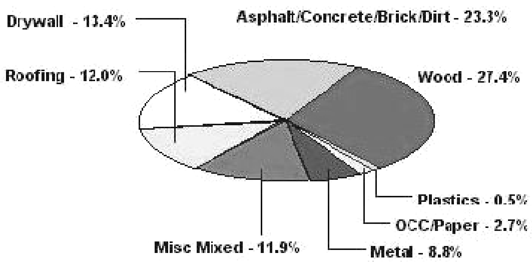

Figure 1 Waste Generated by Construction and Demolition (MSW Factbook 1997)

Deconstruction may be defined as the disassembly of structures for the purpose of reusing components and building materials. The primary intent is to divert the maximum amount of building materials from the waste stream. Top priority is placed on the direct reuse of materials in new or existing structures. Immediate reuse allows the materials to retain their current economic value.

Deconstruction of buildings has several advantages over conventional demolition and is also faced with several challenges. The advantages are an increased diversion rate of demolition debris from landfills, "sustainable" economic development through reuse and recycling, potential reuse of building components, increased ease of materials recycling, and enhanced environmental protection. Deconstruction preserves the invested embodied energy of materials, thus substituting recovered existing materials for the input of embodied energy in the harvesting and manufacturing of new materials.

The challenges include: consumer tastes and perceptions concerning used and recycled building materials, existing buildings have not been designed for dismantling, dismantling of buildings requires additional time, lack of markets for used components, building codes and materials standards often do not address the reuse of building components, and the fact that buildings built before the mid-1970's contain lead-based paint and asbestos containing materials.

Though definitely on the rise, perceptions of reused and recycled building materials must be improved in order for the long term profitability of deconstruction to increase. This paper discusses ways to rectify the many doubts consumers have concerning recycled and reused building materials.

2. Consumers Tastes

The successful implementation of deconstruction relies on successful resale of recovered building components. If materials cannot consistently be marketed and sold in a timely manner, it is virtually impossible for deconstruction to be profitable. For this reason, consumer tastes and perceptions concerning used and recycled building materials is often a barrier to the successful implementation of deconstruction. The most influential persons regarding the purchase of used and recycled building materials are the architects, the builders, and the consumers.

2.1 Planners

Architects and landscape architects have the potential for impacting the use of used building materials in new construction. Although architects tend to be more open to the use of used and recycled materials than builders, their perception overall appears to remain negative. Brand or manufacturer loyalty poses one barrier to expanding the use of used and recycled building materials. Currently, architects are more likely to specify a particular product from a product line or manufacturer they trust than to establish a non-brand specification which allows used materials to fill that specification.

2.2 Builders

Builders and their subcontractors play an important role in the selection of construction materials. In an industry that is conservative the movement towards new products is slow. This attitude reflects real worries in construction, where products that are not up to high standards of quality and safety can cause disastrous accidents. For this reason, builders are the market segment that is slowest to accept used and recycled building materials. Contractors view the use of reused and recycled building materials negatively because they perceive them to have the following characteristics (Grothe and Neun, 2002):

- Dimensional Problems: Contractor's view finding used materials that fit into a pre-dimensioned space as more difficult than purchasing a new product.
- Inconsistency in Supply: Contractor's perceive the inconsistent availability of the right quantity and size of used materials as inconvenient.
- High Risk: Due to the high personal risk involved when something goes awry in the construction process, builders are reluctant to trust used and recycled products.
- Poor Quality: It all boils down to the overall perception that used and recycled materials are of lesser quality than virgin materials.

2.3 Consumers

Those people purchasing commercial and residential construction, as well as those renovating buildings, are extremely important in driving the environmentally sound construction movement, including the use of recycled and reused building materials. The prevailing attitude remains that reused and recycled building materials are "substandard but environmentally friendly." Many architects and builders have admitted that they would use more used and recycled products if their clients directed them to do so.

3. Lack of Design for Deconstruction Strategies

The aim of design for deconstruction is for the next generation of buildings to be more efficiently disassembled at the end of their useful lives. More efficient disassembly implies a process that is quicker, causes less damage to recovered building components, and is safer for the workers involved. The problem facing the industry today is that the benefits of design for deconstruction will not be realized until many years from now. Currently, the lack of design for deconstruction in the buildings that are coming to the end of their useful lives is a major barrier to efficient and profitable deconstruction (Chini and Balachandran, 2002).

Buildings that are approaching the end of their useful lives today were not built with deconstruction in mind. Deconstruction is a fledgling industry, much younger than the houses being deconstructed. There are several aspects of design for deconstruction that are currently hindering the materials recovery process. These are lack of kept construction records, abundance of hazardous materials, use of adhesives to hold fasten building components, and lack of labeling of building components.

3.1 Construction Records

Today, buildings to be deconstructed do not contain of the original construction information. This lack of information drastically decreases the speed and efficiency of the deconstruction process. The presence of blueprints, materials lists, location of wiring systems, and photographs of connections used in the construction of the building would aid in the planning and implementation of its dismantling (Guy, 2001).

3.2 Abundance of Hazardous Materials

Government policies concerning hazardous materials abatement are higher for deconstruction than they are for demolition. This is due to the higher exposure levels for deconstruction workers. These stringent policies increase the cost and time necessary to complete a deconstruction project. Additionally, hazardous materials drastically increase the salvageability of building components. Wastes are defined as hazardous by EPA if they are specifically named on one of four lists of hazardous wastes or if they exhibit one of four characteristics: ignitability, corrosivity, reactivity, or toxicity. Typical examples of C&D wastes that are considered hazardous according to EPA's definition are:

- C&D debris containing mercury: fluorescent lamps, thermostat probes, old paint
- Lead-based paint debris: woodwork, siding, window and doors painted before 1978
- Asbestos debris: Insulation, resilient floor covering, siding shingles, roofing products, and cement products made with asbestos before 1977

3.3 Use of Adhesive

The use of various glues and adhesives in the installation of building materials may increase the stability of those building systems but it serves to decrease the efficiency of the deconstruction process and increase the likelihood of damage during extraction. This is particularly true with glue use on wood products and the grouts used in masonry construction. The glues previously used in wood construction tend to cause splitting and cracking of the wood during extraction. Certain mortars used to bond bricks are not conducive to later separation and cleaning of the bricks. It is only possible to clean bricks that are bonded with soft lime mortar. Those bricks that are bonded with Portland cement based mortar cannot be effectively separated and cleaned.

Currently, it is not standard practice for building components to be labeled before installation. The recovery process is slowed by the necessity to identify the components makeup, how it was fastened, what kind of chemicals may or may not be present, etc…

Design for deconstruction will identify issues involving labeling of building components to speed up the deconstruction process.

4. Additional Time

The successful large scale implementation of deconstruction in the United States is contingent upon increasing the efficiency of the deconstruction process. Currently, time constraints pose a legitimate threat to the growth of the deconstruction industry. In the construction industry, where time is of the essence, the extra time involved to remove a building via deconstruction, as opposed to removal through demolition, may be a deterrent. The level of efficiency on any project is directly proportional to its profitability. Deconstruction must become a more profitable industry if it is to be implemented on any substantial level.

Several factors are limiting the efficiency of the deconstruction process. As discussed earlier, the lack of design for deconstruction has a negative effect on its efficiency. However, the benefits of designing buildings for disassembly will not be felt until the useful lives of the next generation of buildings have expired. There are other factors affecting the efficiency of deconstruction that can be and are being improved right now. One of the major factors affecting the efficiency of the deconstruction process is the current lack of tools available that stimulate the speed of deconstruction while minimizing the damage incurred by recovered materials.

To date, the tools used during the deconstruction process have generally been the same hand tools used in the construction process. These tools were not designed with the efficient, safe disassembly of buildings in mind. For example, crow bars are frequently used tools on deconstruction sites for prying apart building components such as wooden planks. However, a crow bar was not designed to pry apart wooden planks without damaging them. Consequently, the planks are often split during extraction. This damages the wood, reducing its reusability and thus its resale value. Tools must be developed that facilitate the speed and safety of materials recovery during deconstruction while at the same time minimizing the damage incurred by those materials.

The lack of deconstruction training available is also a barrier to its growth as an industry. Development of programs that promote deconstruction of buildings as an alternative to traditional demolition by training contractors how to effectively dismantle structures with the purpose of reclaiming materials will facilitate the full-scale implementation of the deconstruction industry.

5. Lack of Markets for Used Components

The economic structure of the deconstruction industry requires that the recovered materials be sold in order to achieve any level of profitability. Thus, access to salvaged materials markets is a critical element to the successful implementation of deconstruction. At this juncture, a lack of markets for used building materials is a barrier to deconstruction. The strength of the used building materials market in a given area is directly related to the area's local attitude toward used building materials and the population and location of the area.

As discussed earlier in this chapter, perception of low value of salvaged building materials remains a problem in the construction industry today. This perception of low value has a direct influence on the demand for salvage materials. Thus, the presence of negative perception has an adverse affect on the market for used components. As time passes, the continued effort of the deconstruction industry to educate the public on the benefits of using salvaged building components will serve to alleviate this issue.

Large metropolitan areas tend to support the strongest used building materials markets. There is obviously a positive correlation between the size of a city and its demand for consumer goods. Additionally, the available building stock for deconstruction will tend to be greater in highly developed areas such as large cities. Export Markets in border and port cities create an additional market for used building materials. These markets have the capability to increase the consumer base for deconstructed materials exponentially. Export of used building materials is a strong market in the Miami area, and exporters were identified as a major customer group for recovered materials. Several used building materials markets in the Miami area sell approximately half of their material to exporters from Central American and Caribbean countries.

The problem facing the deconstruction industry at this point is that the majority of towns in the United States are not large, port cities with high public perception of used building materials. A major focus of the construction industry must be to network together those areas that may not be able to establish strong reuse markets with those that can. The use of the internet creates an additional medium to obtain and sell used building materials. "Internet sales have the potential to change existing market relationships by allowing end users to purchase materials at reduced prices from sources other than their traditional supplier" *(Grothe and Neun, 2002).* Currently, Internet sales are more conducive to the sell of high-end salvaged building materials because of the intensely high demand for these goods, particularly high-quality structural timbers. Low-end materials do not benefit as well from the internet because added shipping and processing fees tend to negate the money saving benefits of these materials.

6. Lack of Standards for Reuse of C&D Materials

The success of any recycling effort is tied to the marketability of the products that are recycled. The National Demolition Association (NDA) suggests that the U.S. EPA develops a program that analyzes the marketability of the components of the various elements of the demolition waste stream and promotes the reuse of these materials. NDA believes that the EPA could produce a substantial increase in the recycling and reuse of C&D materials by establishing purchasing guidelines and specifications for these materials. The guidelines could contain quality assurance components that would allow specifying agencies to feel comfortable with the use of these materials (NDA Report, 2004).

Total building related and infrastructural concrete waste generated annually in US is estimated to be about 200 million tons (Sandler, 2003). It is estimated that about 100 million tons of concrete is recycled annually into usable aggregates. This is roughly 5 percent of 2 billion tons total aggregates market. The rest is supplied by virgin aggregates from natural sources. If the EPA, working with the Federal Highway Administration and the state transportation agencies, would develop model specifications for the quality of recycled material, this total recycling number would increase dramatically. Standardization of the specifications for the reuse, on a national level, could produce a boom comparable to President Clinton's paper recycling directive.

Similarly, establishing criteria for the reuse of wood products generated on deconstruction sites could significantly increase their reuse. Lumber re-grading for structural use, has become a hot topic in the deconstruction industry. The grade stamp on lumber verifies the quality of each piece of lumber. Currently, existing grading rules can be used to grade salvaged lumber. However, these rules do not specifically address salvaged lumber. Current grading procedures are time consuming and expensive. Grading of salvaged lumber, other than in very large quantities, is not cost-effective. Because the extent to which salvaged lumber defects and their affect on its strength are somewhat uncertain, grading agencies are hesitant to give it their stamp of approval. When they do, they minimize risk by downgrading the lumber or restricting it from particular applications. These issues create a barrier to the implementation of deconstruction by raising costs and reducing the possible applications of salvaged wood. In addition, structural salvaged lumber would draw a much higher price on the market than non-structural wood. Currently, steps are being taken to develop a nationally recognized salvaged lumber re-grading system.

Other materials produced through deconstruction including roof shingles, carpet, drywall, glass, ceiling tiles, plastics, and other construction products are being studied to see if they too can be recycled or reused in an economically viable manner.

7. Setting Goals

Although the federal government has largely avoided any effort to set C&D recycling rate targets, many states and smaller jurisdictions have active programs that encourage C&D waste recycling.

California adopted a legislation in 1989 that requires counties to recycle 50 percent of their waste streams. With C&D material making up such a large percentage of those streams, it did not take long for county and city officials to begin devising C&D recycling initiatives. City of Oakland requires contractors to submit a job-site recycling and waste reduction plan along with their initial bids to the city. The contractor that wins the bid must also submit required reports prior to receiving the final payment. In San Jose, contractors have the option of bringing material to one of more than 20 city-certified facilities (www.sjrecycles.org) that are expected to meet pre-determined recycling rates. The City Council in Irvine requires builders of large projects (more than one residential unit; nonresidential structures measuring 5,000 square feet or more and nonresidential properties that are 10,000 square feet or more) to submit recycling plans. Companies will have to pay a material diversion deposit to the city that will be refunded after the project is complete. At least 75 percent of concrete and asphalt and 50 percent of other C&D debris must be taken to material recovery facilities for a company to get its deposit back. In Sonoma County, California C&D waste loads that have not been sorted for recyclables must pay a 25 percent surcharge for the county to handle resorting (Taylor, 2007).

The commonwealth of Massachusetts bans certain materials from its landfills to obtain an 88 percent statewide recycling rate by 2010. In mid 2006 a ban on the disposal, or transfer for disposal, of asphalt pavement, brick, concrete, wood, metals and old corrugated containers became the rule in Massachusetts. The state's Department of Environmental Protection singled out those materials based on a belief that healthy recycling markets existed for all of them. The goal is to add additional C&D materials such as gypsum wallboard, asphalt shingles, carpet and ceiling tiles in the future (Taylor, 2007).

The regional government for the Portland, Oregon has approved construction and demolition recycling legislation that will go into effect in 2009. The policy requires mixed loads of C&D debris to be sorted for recyclables prior to dumping, leaving no more than 15 percent recyclables in the remaining material. The regulation is part of the agency's overall plan to increase recycling rates in the Portland area by 64 percent by the end of 2009. It is anticipated that this policy will keep an approximate 33,000 tons of C&D material out of landfills, enough to boost the overall recycling rate by 1.25 percent (Taylor, 2007).

Chicago recently adopted an ordinance requiring a certain percentage of construction and demolition waste to be recycled — 25 percent for projects that had a permit issued in 2007, and 50 percent if the permit is issued in 2008 (Martin, 2007).

8. Deconstruction is Cost Effective

In almost all cases, the cost of deconstruction is higher than that of demolition. This is due to the labor intensive nature of deconstruction. However, the salvage value regained in deconstruction often makes it more cost effective than demolition. Because the labor intensive factor of deconstruction is somewhat unavoidable, it is important to focus on minimizing other factors in the cost to make it more competitive. Minimizing costs and maximizing salvage value of building materials is essential to maximizing the potential of deconstruction. Having well trained workers can have a major impact on overall cost. A high level of safety reduces overall costs of deconstruction projects.

According to a survey conducted by the New Jersey Department of Environmental Protection, recycling C&D materials is usually the most cost-effective and environmentally friendly method of disposal. Builders and contractors can save money recycling their construction and demolition materials. The average cost to recycle concrete rubble is $4.85 per ton vs. an average of $75 per ton to haul and dispose of the material in a New Jersey landfill. Similar cost savings came from recycling asphalt ($5.70 per ton) and bricks and blocks ($5.49). Even recycling wood at $45.63 per ton and trees and stumps at $37.69 per ton is economical compared to the $75 average transportation and disposal cost, according to the survey.
(www.state.nj.us/ep/dshw/recycle/builderinfo.htm).

9. Recommendations

In the end, the increased use of reused and recycled building materials is in the hands of the architects, builders, and consumers that use them. Slowly but surely, perceptions have become increasingly positive over the last few years. The natural trend towards increased social and environmental responsibility, along with the maturation of the deconstruction industry, will aid in the effort to improve perception of reused and recycled building materials. This will increase the profitability of the building materials salvage market, making deconstruction a more desirable business alternative.

The following aspects of the industry and consumer perceptions must be addressed in order to rectify the many doubts consumers have concerning recycled and reused building materials.

9.1 Information Availability

Aided by the numerous industry associations and increased publicity, information accurately explaining the benefits of recycled and reused building materials has become much more accessible over the last few years. However, as a whole, public knowledge concerning these products is too low. The natural increase in available information and networking that will occur naturally as the industry grows should help to rectify this problem.

9.2 Overcoming the Perception of Risk

Because of the perception of risk, products must show they perform as well or better than virgin products. Component recertification processes must be refined and standardized before this can occur. Additionally, recycled products should be tested and certified in order to offset the high-risk aversion of the industry.

9.3 Economic Incentives

In a market economy, decisions involving which resources are used are primarily driven by economic forces. Therefore, the most effective ways to promote deconstruction industry are to use economic incentives to promote efficient recourse use and minimize waste generation. These include waste generation fees and credits to reward purchase of products that rely on recycled materials. Developing more efficient recycling technologies and developing markets for recycled materials or products are essential for recycling industry to flourish. Government should also play a role through government purchasing programs that increase demand for products with recycled contents.

9.4 Guidelines and Specifications

As the National Demolition Association suggests the federal government should establish specifications and purchasing guidelines for each recovered material; take a leading role in promoting the development of new technologies and processes that will produce durable, economical, high quality recycled products; and develop national inspection standards for recycling facilities.

Keywords: C&D wastes, resources, life-cycle, assessment method for Buildings

Summary

Actions for reduction of C&D wastes and setting forward recycling become more important in late years, because of an enormous the amount of resources consumption and C&D wastes are made in building construction and demolition works, the shortage of final disposal sites in Japan. In this study, the assessment method for the amount of resource consumption and C&D wastes that are generated in the future were developed. By use of detail cost estimate method, variety and quantity of resources from buildings were calculated in detail with this method. To develop the method, following things were done. List up general specification of building components and materials made up for each component. With each component, data of weight, resource category and way of waste treatment etc. are collected. For the effective maintenance and improvement, the rule for the estimation of C&D wastes from maintenance and improvement process are established. For the effective planning with C&D wastes treatment, the rule for the separation of C&D wastes are established from the investigation of actual C&D wastes treatment and recycling arts in Japan. And some building models are calculated by the method and the result of the assessment method are surveyed.

1. Introduction

The construction industry is required to reduce and recycle construction waste because of the shortage of remaining landfill capacity and issues related to limiting resource consumption and waste generation. For this reason, the separation of demolition and recycling of construction materials is enforced by *The Construction Materials Recycling Act* was enforced in 2000, and a variety of measures have been implemented. While these instruments have proved to be moderately successful from the viewpoint of achieving target values such as defined recycling ratios for C&D waste, the establishment of evaluation methods and measures for reducing resource consumption in individual buildings is not yet considered to be satisfactory.

We therefore developed a standardized method for assessment “life cycle C&D wastes” (hereinafter referred to as LCW) based on estimating standards. Such a method would facilitate the estimation and determination of the category and the amount of resources of the building required by upstream levels of the construction workflow, such as at the projecting, planning, designing and estimating phases, and could be used to precisely calculate the amount of waste generated by the building activities in the future. Using this method, the “lifecycle” of a building is defined as the period from the beginning of construction activities at a site to the termination of reform, renewal and demolition activities of the building.

While LCW assessment methods have been employed in previous studies, these authors restricted their attention to the most frequently used of the resources in their LCW assessments and other materials were not considered. The contribution of these minor materials is difficult to consider because they require considerable labor to evaluate. However, since the LCW assessment method proposed in this study makes it possible to determine the amount of resources required and estimate costs at the same time, it does not require the separate assessment of the materials necessary for conducting assessments and can thus more accurately determine the variety and the amount of materials.

Using this method, it is possible to determine the variety and the amount of resource consumption of a building, and to classify these into categories according to available or future recycling techniques can be applied. This method can determine the category, category and the amount of resources of the building, and it is considered effective for managing resources and C&D wastes, as well as the renovation history of buildings in the future.

2. Summary of LCW assessment method

The applicable range of this method is as follows:

- Object for evaluation: individual buildings

- Values to be calculated: the amount of resources and the amount of C&D wastes

In terms of the amount of waste, this method calculates construction waste (limited to solids) likely to arise from a construction (or demolition) site. This method is presented as a prototype and was developed by limiting its application range to the following applications:

- Housing complexes and offices

- Construction materials used in construction work (excluding materials related to equipment or packing materials).

Figure 1 shows the assessment flow of LCW.

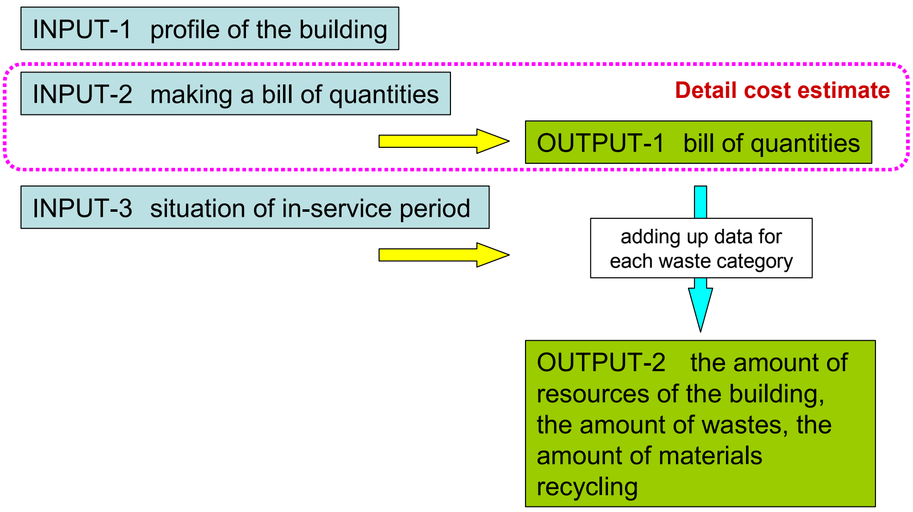

Figure 1 the Assessment Flow of LCW

3. Outline of the development of the LCW assessment method

This method aims to calculate the amount of materials and C&D wastes generated at each stage of the building life cycle while estimating costs at the same time. We therefore conducted a thorough review of price information for construction work and related materials (e.g. "Japan Building Cost Information" and "Construction & Material Costs in Japan", both published by the Construction Research Institute). However, since more than ten thousand items are described in these periodicals, we prepared a list of approximately 1,000 items having different sizes, shapes and elements. In considering these items, we added any relevant information regarding their specifications and units, which would normally accompany the process of obtaining quotes. We added these metadata to the items being considered, as well as the construction methods and specifications used in a case study of two actual building examples.

We broke down the selected and extracted specifications into each composite material, and collected and organized data such as the mass-based quantities used per unit and categories of materials to be discharged as C&D wastes.

The composite materials and the quantities used per unit were collected with relative ease from the construction coefficient information. However, since usage was primarily measured in "m^2", etc., not by the unit of mass, the mass of the materials used was determined based on product catalogs and the physical properties of each material.

Waste categories were prepared based on the categories provided under *The Waste Disposal and Public Cleaning Law* while considering the current situation of waste disposal. For recycling, it is important to collect the waste after separating the materials and building materials. As a result of classifying materials as those that can be recycled using current technologies, and those for which it seems feasible that recycling technologies will be available in the near future and that are listed in the Waste Disposal and Public Cleaning

Law, the number of categories under consideration increased to over fifty. Table 1 shows the waste categories.

Table 1 Waste Categories

category				content
industrial waste of stabilized type	wreckage 1	A		concrete waste
	wreckage 2	B-0		wreckage 2
			B-1	brick, stone, roof tile waste
			B-2	roof tile
	wreckage 3	C		concrete waste with asphalt, asphalt waste
	ceramic waste	D-0		ceramic waste
			D-1	glass waste
			D-2	ALC, tile, ceramic waste
			D-3	glass wool
			D-4	silicate calcium
			D-5	tile, brick, ceramic
			D-6	rock wool
			D-7	ALC
			D-8	ceramic board
	plastic waste 1	E-0		plastic waste
			E-1	PVC pipe waste
			E-2	polyolefin floor tile
			E-3	PVC tile carpet waste
			E-4	FRP product waste
			E-5	thermoplastic resin product waste
			E-6	heat-hardening resin product waste
			E-7	expanded polystyrene product waste
	metal waste 1	F-0		metal waste 1
			F-1	reinforcing steel 1
			F-2	reinforcing steel 2
			F-3	product waste using metal
	metal waste 2	G–0		metal waste 2
			G-1	aluminum product waste
			G-2	electric cable waste
			G-3	stain less waste
	rubber waste	H		natural rubber waste
	other 1	I		board with metal and plastic
	mixed waste 1	J		mixed waste of A to I
industrial waste of controlled	polluted mud	K		polluted mud
	ceramic waste and wreckage 1	L-1		plaster board
		L-2		wood wool cement board
	ceramic waste and wreckage 2	M		ceramic waste and wreckage with organic waste
	plastic waste 2	N-1		wall paper waste
		N-2		plastic products with wood powder
	metal waste 3	O		metal waste with organic waste
	wood waste	P-0		wood waste
			P-1	wood waste from lumber
			P-2	wood waste from wooden board
			P-3	particle board
	paper waste	Q		wall paper waste
	waste textile	R-1		tatami
		R-2		tatami made by plastic
		R-3		other waste textile
	oil waste	S		oil waste
	other 2	T-1		fluorescent lamp
		T-2		air-conditioning equipment
		T-3		kitchen unit, bath unit

(shaded) materials which is assigned by *the Waste Disposal and Public Cleaning Law*

We set four levels of separation and established recycling scenarios with different degrees of separation and disposal in order to consider the countermeasures required for separation and disposal.

The establishment of the policy required for each scenario is shown below:

Scenario I: Separation to the level required by *The Construction Materials Recycling Act*

Scenario II: Scenario I plus separation into valuable resources and normal-level separation

Scenario Ⅲ: Scenario Ⅱ plus separation of materials which is assigned by *The Waste Disposal and Public Cleaning Law* or materials with well developed disposal systems that are currently available

Scenario Ⅳ: Full separation (assuming that a disposal facility using a as-yet-unavailable technology is constructed)

Each scenario assumes a well-established recycling method. Since pre-consumer wastes are processed separately from post-consumer wastes that have been earmarked for different levels of disposal or recycling, the scenarios were developed separately, an example of which is shown in Table 2. Each waste is separated and collected based on the selected scenario. For example, consider “E1 PVC pipe”; pre-consumer wastes from construction are separated and collected as “E-0 waste plastic type 1” in Scenario Ⅱ and as “E-1 PVC pipe” in Scenario Ⅳ. Conversely, the materials arising from demolition materials are separated and collected as mixed waste in Scenario Ⅱ and as “E1 PVC pipe” in Scenario Ⅳ.

Table 2 Example of Separation and Established Recycling Scenarios

category			separation and established recycling scenarios							
			Ⅰ		Ⅱ		Ⅲ		Ⅳ	
			pre-consumer	post-consumer	pre-consumer	post-consumer	pre-consumer	post-consumer	pre-consumer	post-consumer
plastic waste 1	E-0	plastic waste	—	—	—	—	—	—	—	—
	E-1	PVC pipe waste	J	J	E-0	J	E-1	E-1	E-1	E-1
	E-2	polyolefin floor tile	J	J	E-0	J	E-2	E-5	E-2	E-5
	E-3	PVC tile carpet waste	J	J	E-0	J	E-3	E-3	E-3	E-3
	E-4	FRP product waste	J	J	E-0	J	E-0	E-4	E-0	E-4
	E-5	thermoplastic resin product waste	J	J	E-0	J	E-0	J	E-0	E-5
	E-6	heat-hardening resin product waste	J	J	E-0	J	E-0	J	E-0	E-6
	E-7	expanded polystyrene product waste	J	J	E-0	J	E-7	E-5	E-7	E-5

4. Examples and LCW considerations for the results obtained using this method

A summary of the buildings used for the assessment of LCW is shown in Table 3.

Figure 2 shows a breakdown of materials considered for the assessment of materials resource of the building.

Table 3 Summary of the Building Model Used for the Assessment of LCW

building use	office
structure	SRC
floor number (above ground)	8
floor number (under ground)	0
building area	350㎡
total site area	2,400㎡

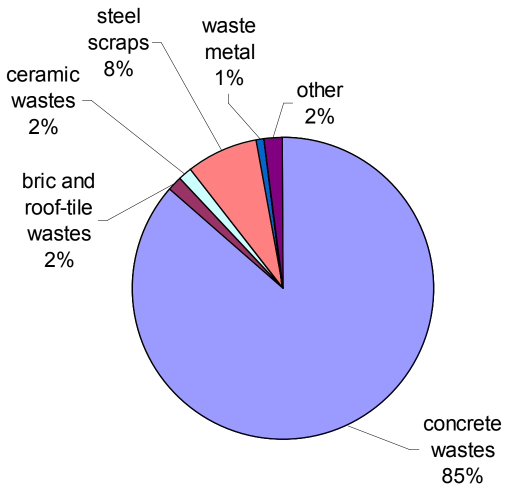

Figure 2 Break Down of the Amount of Resources of the Building Model

Concrete wastes accounted for 85% of the entire resources. *The Construction Waste Recycling Law* prescribes that concrete wastes and wood waste be separated and recycled, which translates into a marked reduction in the mass volume of construction waste and promotes recycling.

Figure 3 shows the amount of materials for recycling and final disposal for each separation and recycling scenario. The amount of waste recycled in Scenario I (at a level required by the Construction Waste Recycling Law), Scenario II (normal-level separation at present), and Scenario III (at an advanced level in the present situation) were all similar. The amount for final disposal in Scenarios II and III were slightly less than that obtained for Scenario I. While the amount recycled in Scenario IV (full separation) was less than other scenarios, the final disposal amount for this scenario was considerably larger than the others. In developing this method, it was anticipated that the higher the scenario (the separation level) was, the greater the amount of material would be sent for recycling and the lower the amount for final disposal would be. However, since the higher the level of separation involved more advanced recycling technology, the results differed from what was expected (Fig. 3). Especially, the low rate of recycling of concrete wastes, which constituted 85% of the amount of resources of the building, had a marked effect on the results, since only aggregates are removed and used as resources in Scenario IV.

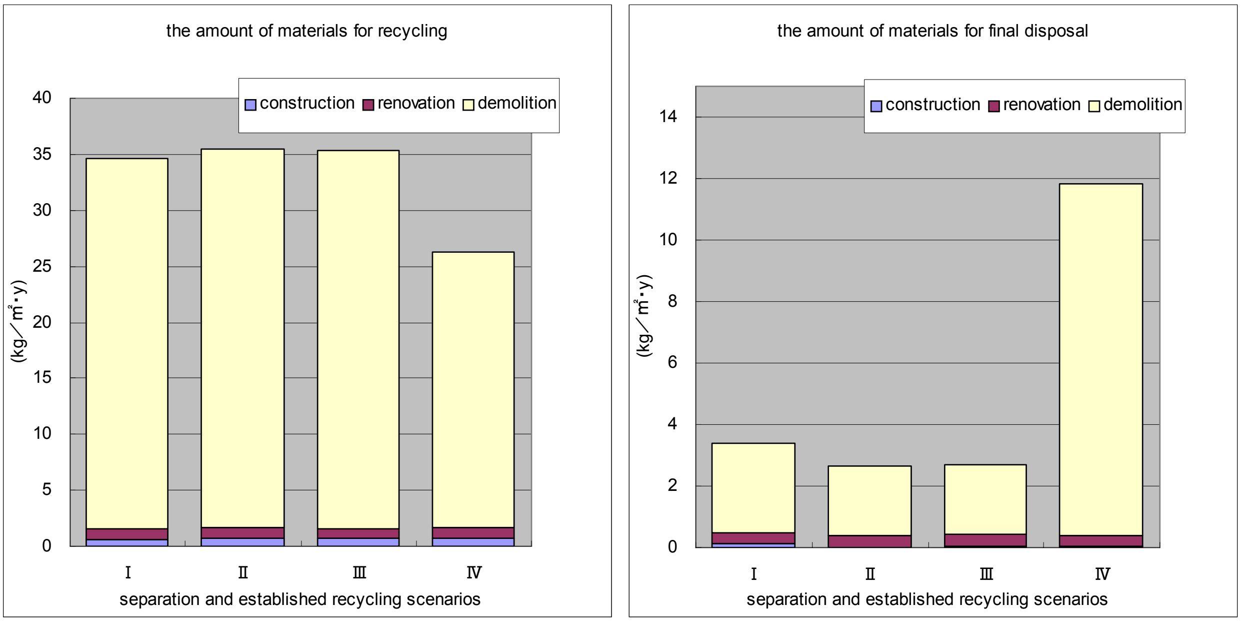

Figure 3 the Amount of Materials for Recycling and Final Disposal for Each Separation and Recycling Scenario

However, the assessment results do reflect the present situation of C&D waste disposal in the area of construction. From the viewpoint of the amount of materials for recycling, the current levels of recycling has reached a certain level, and even in the event that higher levels of separation and more advanced recycling methodologies are employed, the effect on the amount of C&D wastes generated from one building and, by extension, by the entire nation, would be minimal.

From the viewpoint of effective resource utilization, it is necessary to evaluate not only the amount of materials for recycling, but also the change in obtained for each scenario. Figure 4 shows the kind and the amount of materials for recycling of calcium silicate boards for each separation and recycling scenario.

When Scenario IV is excluded and only the amount is considered, Scenario I (at a level required by *The Construction Materials Recycling Act*) is more advantageous than Scenario II (current normal-level) and Scenario III (current advanced-level). Taken together, these findings may indicate that separation for recycling is at a level that is currently adequate for the requirements of the Law. However, the calcium silicate boards can be used as fuel, even though recycling is not effective if the fuel efficiency is poor. Conversely, under Scenario IV, they are recycled as raw materials for calcium silicate boards and circulated as building materials; therefore, the latter process is a more effective way of recycling. These findings indicate that a single quality index is not sufficient for evaluating recycling efficiency.

While the method described here does not include a method for quality evaluation, we believe that qualitative evaluations can be undertaken by considering the amount of energy consumed by each recycling method and by estimating demand. The development of a quality evaluation method will remain an issue for future research.

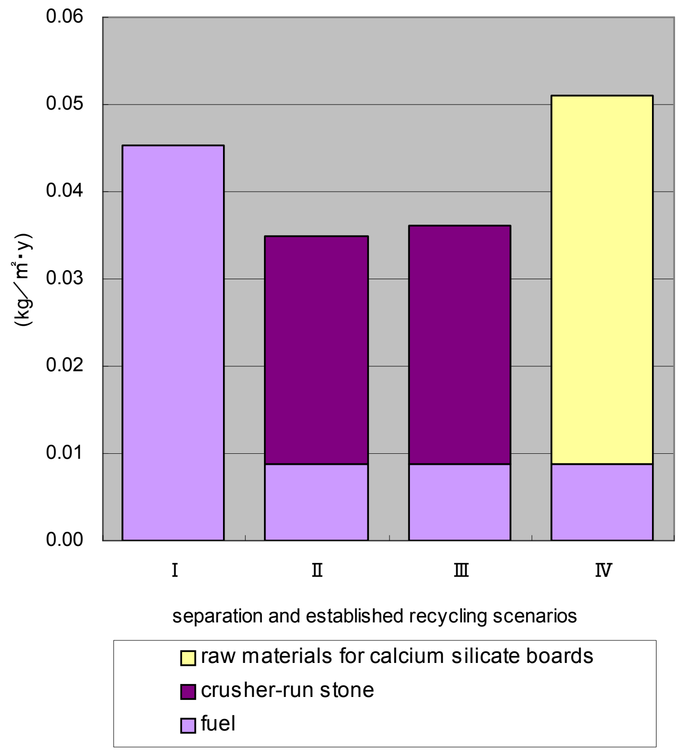

Figure 4 shows the kind and the amount of materials for recycling of calcium silicate boards for each separation and recycling scenario

5. Perspectives

Use of this method made it possible to obtain details of the amount of resources of the building, using categories that employ current or potentially feasible recycling techniques. We intend to develop the method further in the future in order to apply the technique to the management of historical information as well as for resource management. The development of this method required the collection and organization of data required for assessment the amount of resources and waste for commonly used construction specifications. Since we prioritized the collection of data in order to obtain a rough calculation, this data considered here includes data with low general applicability. We are therefore interested in refining the accuracy and use of data in the future by acquiring new data.

THE WASTE COMPONENT OF "SUSTAINABLE BUILDINGS" – VOLUNTARY OR MANDATORY?

Jenny CAMPBELL[1]

[1] Encycle Consulting Pty Ltd, Perth, Western Australia, jenny@encycle.com.au

Keywords: waste management, buildings, rating tools, Australia

Summary

Several planning and building regulatory bodies throughout Australia, including federal, state, territory and local governments are well on the way to implementing mandatory sustainability requirements for energy and water into their planning and building processes.

However, there are currently no national and few state or territory Government or industry regulations specifically requiring new or existing buildings to comply with any sustainable waste management and recycling requirements. A small number of state and local government authorities require particular sustainability assessments for residential and non-residential planning applications, including the need for a waste management plan for either or both the construction and operational phases of the building.

National voluntary rating tools such as Green Star and the recently released National Australian Building Rating System (NABERS OFFICE Waste) are useful for measuring waste generation and diversion from landfill, and comparing performance against benchmarks for a range of building typologies.

This paper identifies current Australian mandatory and voluntary sustainability assessment tools for buildings that include a waste management component. The waste and recycling requirements of the tools are compared and the need to regulate the building industry to achieve state-based waste minimisation targets is discussed.

1. Introduction

According to the Green Building Council of Australia (GBCA), the impact of buildings on the environment is significant. Reportedly, activities around buildings consume 32% of the world's resources including 12% of its water and up to 40% of its energy. They also produce 40% of waste going to landfill and 40% of air emissions (GBCA, 2003).

These figures are likely to vary from region to region, and in Western Australia for example, the waste to landfill from the construction and demolition of buildings is actually above average. A recent study undertaken for the Commonwealth Department of Environment and Heritage revealed that in Western Australia up to 55% of all waste to landfill (compared to 34% across other states) is derived from the construction and demolition sector (Hyder Consulting, 2006). It should also be noted that waste from buildings during the operational phase (classified as commercial & industrial waste) continues to contribute waste to landfill for the remainder of the life of the building.

The Basel Convention defines wastes as "substances or objects which are disposed of or are intended to be disposed of or are required to be disposed of by the provisions of national law" (Basel Convention, undated). The generation of waste represents poor use of resources which are not just limited to the materials used in the product, but also the energy and water consumed during the process of extracting natural resources and in manufacturing and transportation.

The environmental impacts from landfills are significant and while existing landfills are filling rapidly, new landfill sites are becoming less available. Landfills are also a source of greenhouse gases (mostly methane) that contribute to climate change. By diverting waste away from landfill to recycling there is potential to save significant tonnes of greenhouse gases. The savings would be derived from not only the reduced production of landfill gas, but also the reduction of lost embodied energy in the resources. Embodied energy is defined by the total life cycle energy used in the collection, manufacture, transportation, assembly, recycling and disposal of a given material or product (Greater London Authority, 2008).

Federal and State Governments are working with local governments (who manage municipal waste and own a large number of Australia's landfills), industry and the community on strategies to avoid and reduce the generation of waste, recover the waste that is generated and appropriately manage landfills.

Most of Australia's state and territory government's waste management policies include targets for reducing waste to landfill. In Victoria for instance, Sustainability Victoria through its *Towards Zero Waste Policy* has committed to a target of reducing the amount of waste to landfill from 4.2 million tonnes (2007/08) to 2.44 million tonnes by 2014. It is also aspiring to the recovery of 75% of the total amount of waste generated for reuse, recycling or conversion to energy by 2014 (Sustainability Victoria, 2007).

South Australia in its *Zero Waste Strategic Plan* has set a target of reducing waste to landfill by 25% by 2014 (using 2002/03 data as the baseline) (Zero Waste SA, 2005).

For New South Wales, the Department of Environment and Climate Change in its Waste Strategy 2007 states targets for recycling of commercial and industrial waste from its baseline of 28% to 63% by 2014 and construction and demolition waste from the 65% baseline to 76% by 2014 (DECC NSW, 2007).

Whilst there is a significant amount of waste produced from buildings (both in their construction and operation) producing the associated impacts on climate change and the rapid filling of landfills, there is a disconnect between state and territory governments who are actively seeking waste reduction target achievement and the inclusion of buildings in any waste reduction regulatory requirements. It appears that the few localised mandatory sustainability requirements set by a small number of organisations and the voluntary building rating tools are the main drivers for encouraging a reduction of waste to landfill from buildings.

2. Existing mandatory state and local government and voluntary national waste management and recycling requirements

National mandatory requirements pertaining to recycling from construction sites or from operating buildings currently do not exist. However in some Australian States, such as Victoria and Western Australia several state and local government organisations include mandatory waste management and recycling requirements in their planning and development application process. Listed in table 1 are some of the mandatory sustainability requirements set by five organisations. Table 2 lists the three national voluntary rating tools.

Table 1 List of mandatory sustainability assessment tools and/or guidelines for the built environment and their key waste management and recycling requirements.

Organisation and name of tool or guideline	Key waste management or recycling requirements
VicUrban – *Melbourne Docklands ESD Guide* (2006)	• Provision of recycling facilities in all new developments • No recycling performance targets stipulated
Manningham City Council – *Doncaster Hill Sustainability Guidelines* (2004)	• Waste management and avoidance plans required for construction and operational phases • Waste management design strategy • No recycling performance targets stipulated
Moreland City Council – *Sustainable Design Scorecard* (2005)	• Waste management design strategy • Construction phase waste management plan with a 60% recycling performance target • No operational phase recycling performance targets stipulated
Department of Sustainability and Environment Victoria – *Environmentally Sustainable Design and Construction Principles and Guidelines* for Victorian Government departments (2003)	• Waste management design strategy • Construction phase waste management plan with a 90-95% recycling performance target • Operational waste management plan with a 80% recycling performance target
Armadale Redevelopment Authority, Western Australia – *Sustainable Audit Scorecard* (2003)	• Operational phase recycling strategy with a 50% or 75% recycling performance target • No construction phase recycling targets stipulated

Table 2 List of national voluntary rating tools for the built environment and their key waste management and recycling requirements

Organisation and name of tool or guideline	Key waste management or recycling requirements
Green Building Council of Australia: Green Star – Office Design v3; Green Star - Office As Built v2; Green Star - Healthcare (Pilot)	• Awards innovation • Waste management design strategy • Construction phase waste management plan with a 60% to 80% recycling performance target • No operational phase recycling performance targets stipulated
Green Star – Office interiors v1	• Waste management design strategy • Fit-out phase waste management plan with a 40% to 80% recycling performance targets • No operational phase recycling performance targets stipulated
Green Star – Office Existing (Extended pilot)	• Commitment to waste reduction/recycling monitoring and landfill disposal targets • Demonstrate recycling storage area
Green Star – Education (pilot)	• Waste management design strategy • Construction phase waste management plan with a 60% to 90% recycling performance target
Green Star – Shopping Centre (pilot)	• Waste management design strategy • Construction phase waste management plan with a 60% to 80% recycling performance target • Operational phase waste management plan with annual non-prescribed waste reduction targets.
National Australian Built Environmental Rating System - NABERS OFFICE Waste	• Applies to operational phase of offices only • Very detailed ongoing assessment and analysis, monitoring and performance based.
Urban Design Institute of Australia (UDIA) Qld - EnviroDevelopment (currently under development in WA, SA and Vic)	• Waste management design strategy • Construction phase waste management plan with a 40% minimum recycling performance target • No operational phase performance targets stipulated • Mainly applies to multi-residential developments
Sustainability Community Rating (VicUrban) • Urban Renewal Community v2007 • Master Planned Community v2007 • Provincial Community v2007	• 90% of infrastructure and building construction and demolition waste to be recycled and or reused.

These case studies show that use of waste management plans and target-driven requirements is achievable and can produce positive outcomes. Ultimately, these requirements will only prove effective if there are mechanisms for ensuring that waste management plans are actually adhered to on construction sites and during the building's operations. Sound data collection, recording and reporting systems are crucial elements in the ability to measure performance, and such systems are not always easily implemented. Data collection is discussed further in section 3.

3.1 How do waste management requirements in these tools compare?

Tables 1 and 2 provide a summary of the types of sustainability assessment tools and guidelines that exist today for the built environment. This includes those mandatory, location-specific requirements and the national voluntary programs. It can be seen that mandatory waste management requirements only apply to those few locations in Victoria and Western Australia. The organisations that have developed and/or implemented them should be regarded as leaders in incorporating sustainability requirements, including waste management and recycling, into their planning application processes.

Table 3 sets out the phase of a building's lifecycle each tool applies. As can be seen only 3 tools include waste management requirements for each phase of the building (design, construction and operational).

Table 3 The building phase or phases to which each tool applies

Organisation and name of tool or guideline	Design phase	Construction phase	Operational Phase

3.1.1 Mandatory tools and guidelines

It is important to understand the objectives of each tool and guideline before comparing their functional differences. For instance the guidelines developed for the Melbourne Docklands precinct, Doncaster Hill precinct and Victorian Government Departments all aim to inform stakeholders of the ecological sustainable design principles, frameworks and practices for their respective development areas. Both the Melbourne Docklands and Doncaster Hill frameworks are bound by policy and are incorporated into the planning and development application process.

The Guidelines for Victorian State Government departments are not incorporated into any local or state authority planning process, but rather are designed to be incorporated into the tender process for capital works. There is a high risk that the principles may not be included as there does not appear to be a mechanism that enforces their inclusion throughout the tender process, building design, construction and operation. Further these Guidelines specify that a voluntary rating tool be used to provide an environmental impact rating for the building. This would only apply if the development was an office, healthcare or education facility.

In comparison to the three sets of guidelines the mandatory assessment tools developed by the Armadale Redevelopment Authority (ARA) and the City of Moreland provide a basis for calculating a numeric score against the level of sustainability a building is predicted to achieve. While the tools specify performance requirements to be met, there is no mechanism for checking whether the development actually achieved the predicted performance targets once the building has been constructed. Furthermore, the assessment tools focus on two different phases of the building. The ARA tool focuses on waste from the operational phase, while the City of Moreland tool, the Sustainability Design Scorecard (SDS), only applies to the construction phase of the development.

This demonstrates that the tools used in different parts of Australia are not comparable and the data from the performance targets (if collected from each development and aggregated) are unlikely to be meaningful on a national level. Furthermore, the mandatory assessment tools and guidelines that exist today have been developed for a range of purposes and for a specific group of buildings i.e. Victorian Government, Melbourne Docklands or Doncaster Hill precincts.

3.1.2 Voluntary assessment tools

The national voluntary rating tools are also selective in the types of buildings in which the tools apply. There are Green Star tools that apply to offices, health care facilities, education facilities, shopping centres, multi unit residential and mixed use developments. The National Australian Built Environment Rating System (NABERS) only applies to buildings that are offices while EnviroDevelopment seems to only applies to multi-residential developments in Queensland, although the UDIA in other states such as Western Australia, South Australia and Victoria are looking to adopt similar models.

VicUrban, the Victorian Government agency for sustainable urban development, has initiated in partnership with industry the Sustainable Community Rating. While three tools have been developed (Master Planned Community, Urban Renewal Community and Provincial Community), only the Master Planned Community tool has been road tested (Sustainable Community Rating, 2007).

While there is a small amount of overlap with mandatory tools in terms of the geographic locations in which they apply, the voluntary national tools can generally apply to certain commercial building typologies in any location. This increases the number of buildings within Australia that are able to adopt the rating tool and proactively drive the reduction of waste to landfill. The EnviroDevelopment and Sustainability Community Rating tools can apply to communities located anywhere in Queensland and Victoria, respectively and the tools cover mainly residential developments and in Victoria, mixed use developments. The way Green Star tools are designed to award innovation is a clever way to encourage the building and property industry to think of alternative ways for a building to function so as to minimise its impact on the environment. By awarding points for adequate recycling storage and collection access, it encourages designers to focus on the practical issues of waste management and recycling. Many existing buildings are restricted in their ability to recycle simply because there is not the space to store recycling bins, balers and other waste handling equipment.

The Green Star tools also award points for incorporating building materials with recycled content. This is another very positive aspect to the tool that helps to drive the demand for recycled building products by providing a ‘pull’ along the recycling supply chain. Supporting the end markets and in turn, the whole recycling industry, makes it easier for construction sites overall to recycle.

A downfall of the waste management aspect of the Green Star tools is the component that specifies performance recycling targets at the construction phase. As the tool is a predictive one, there is no mechanism to actually check that the predicted target was actually achieved and it may be questionable as to how appropriate the recycling practices and systems in place actually are once the construction phase is underway.

Another concern with the Green Star tool is the fact that credit points relating to waste management and recycling within the tool are optional. Obviously buildings that wanted to achieve a higher rating would need to comply with the criteria, but it is not essential for every Green Star rated building.

Furthermore, it has been observed that there are problems with recording and reporting data to enable performance to be measured. For instance, in Western Australia anecdotal evidence suggests that some recycling companies do not have the means for recording the weight of materials from individual building sites (in most cases weighbridges are not installed at recycling facilities) and the composition of mixed loads of recyclables would need to be known before the volume can be converted to weight.

In addition, it appears that little effort is put into setting up robust data recording mechanisms for individual construction sites. It is acceptable under the Green Star Office Design & Office As Built v3 tools for those projects who engage a recycling contractor to sort and recycle construction waste on the project’s behalf, and does so on a bulk basis instead of a project basis, to use the recycling facility’s average recycling rate for the total material that comes through the gate. The recycling contractor is required to provide this evidence (GBCA, 2008). Although useful, this information is not accurate for individual construction sites, who may or may not benefit from such a method.

The recycling rate methodology and data collection mechanism is something that should be incorporated into any waste management plan, to ensure that only contractors who are able to provide the necessary data are employed to collect and recycle the material.

3.1.3 Comparison between mandatory and voluntary guidelines and tools

When comparing mandatory tools with voluntary tools, in all cases except for the Moreland City Council SDS tool, there are no specific recycling performance targets for the construction stage in the mandatory tools. In comparison, voluntary tools provide more exacting targets that provide credibility but can be off-putting to developers and planners perhaps due to the difficulties in obtaining accurate data and reporting performance.

While the requirements for each guideline or tool vary there are some similarities. In the design phase many tools require either a waste management plan and/or dedicated storage area to be incorporated into the project. Construction waste management plans are a requirement of all tools and guidelines that do actually include the construction phase in the assessment.

However, very few of the tools actually specified what should be included in a waste management plan. They also fail to provide a methodology for evaluating the recycling performance, including recording and reporting systems. A little more detail of such requirements would allow for a more standardised approach and ensure that the plans were not only meaningful and useful but had the ability to be compared in a consistent manner.

One general observation is that the waste management components of the mandatory tools are usually less onerous and specific than the requirements of voluntary rating tools. For example, the *Doncaster Hill Sustainability Guidelines* (2004) in Victoria require on-site waste management separation and recycling during the construction phase, with no specific targets, while the voluntary Green Star - Office Design v3 tool requires a waste management plan and contract provisions to reuse and /or recycle from 60% to 80% of construction waste by weight.

Overall, there is greater focus on the waste minimisation aspects of the construction stage of buildings than the operational phase. Further, the waste performance measures for the operational phase of buildings are where there is the widest variation in performance across the tools. Except for NABERS Office Waste, the waste requirements range from having a "commitment to recycle", to education programs, to percentage targets, to waste management plans. The NABERS Office Waste tool is clearly the most comprehensive tool in terms of operational performance; however, it is only limited to the Building Code of Australia class 5 office buildings.

It is important to note that the effectiveness of recycling systems during the operational phase relies heavily on the design of the building. However, there should be just as much emphasis placed on the requirements of operating waste management plans, including the need to meet recycling targets.

In saying this, the ARA tool specifies targets such as either a 50% or 75% recycling rate of the total waste stream from the operational phase of buildings but fails to state whether this is by volume or weight, an important factor when it comes to determining whether or not compliance was or was not achieved. It is important to note here that mass is the standard unit of measure for waste and if this is not stipulated in the guidelines, there is potential for waste to be measured by volume. While volume can be converted to mass (if the composition of the waste is known), it is necessary to ensure that data is recorded accurately by using a consistent unit of measure.

Finally, many of the tools could be strengthened by requiring or providing evaluation tools for ongoing reporting of criteria such as recycling rates or achievement of waste minimisation targets, particularly if standardised against other similar buildings to allow owners continued opportunities to show off their environmental credentials.

3.1.4 The need for a national mandatory approach

As waste from the demolition and construction sector contributes approximately 34% of all waste to landfill in Australia (and in some states, significantly more) (Hyder Consulting, 2006), stakeholders within the industry should firstly be required to meet standard proportional recycling targets for all new and existing buildings. Consistency in performance requirements will then help to drive markets for recycling of building materials. By also incorporating standard proportional use of building products containing recycled materials in the construction of new buildings, recycling markets will continue to grow and develop.

An example of where this is already occurring is in the United Kingdom. As from April 2008 it is a legal requirement for construction sites in England to have a formal Site Waste Management Plan (SWMP) for developments over £300,000 and for those over £500,000 a more detail plan is required (Building Research Establishment, 2008). Implementation is enforced by both local authorities and the Environment Agency. The United Kingdom's Building Research Establishment (BRE) has developed a free software tool for preparing, implementing and reviewing a SWMP. This tool is called SmartWaste Plan and helps manage all aspects including the creation of a SWMP to measuring and reporting waste generation.

BRE's *Code for Sustainable Homes* also requires the mandatory use of a SWMP (BRE, 2008). The Code came into effect in May 2008 and to satisfactorily comply with the Code, compliance assessments conducted both at the design phase and at the completion of construction must be successful. A final assessment certificate is issued upon compliance.

The United Kingdom's regulatory model shows that it is possible to prescribe national waste management requirements for building sites and that they can be readily enforced. This type of model should be considered when investigating suitable options for Australia.

It is imperative that any national Australian approach includes, like the United Kingdom model, a mechanism for ensuring compliance as well as verifying performance. The data to prove performance must be collected in such a way that it will enable data to be aggregated on local, state and national levels. This will enable governments to more easily and accurately determine the effectiveness of waste reduction and climate change policies and achievement of targets, particularly for reduction of total waste to landfill, the quantity of construction and demolition waste generated and proportion of construction and demolition waste recycled. It will also help to highlight opportunities for improvement in the future.

The consistency in requirements will help the building and property industry develop standard waste management plans with standard data collection and reporting requirements for individual building sites. This information will enable building owners, developers, construction companies to report aggregated recycling performance rates to interested parties. This data will also be critical for large building companies to comply with greenhouse gas reporting obligations, such as the National Greenhouse Energy Reporting System, who would also be keen to demonstrate and promote the tonnes of CO_2 equivalent they have saved.

4 Conclusion

Current and proposed sustainability legislation for buildings ensures consistent standards are required to be met for energy and water in new homes and some commercial buildings. Holistic sustainability requirements for other building typologies across Australia are *ad hoc*, with some state and local government organisations in Victoria and Western Australia leading the way in requiring new developments to incorporate sustainability into the design at the planning stage of projects.

The waste minimisation requirements in both mandatory and voluntary assessment tools vary across the design, construction and operational phases of buildings. Voluntary tools such as Green Star and NABERS Office Waste require more rigorous performance requirements than mandatory tools. The waste components in the mandatory tools tend to be vague and performance requirements largely non-specific. Furthermore, processes for checking compliance and/or actual performance once the buildings are constructed appear to be lacking in the majority of the tools.

The voluntary tools go some way toward specifying meaningful waste minimisation performances in the design and construction phases of buildings, but the waste management components within tools such as Green Star do not necessarily have to be met in order to become a Green Star rated building. Further, the tools only apply to certain building typologies and no tools address waste minimisation on single residential building sites.

While the waste management and recycling requirements within the few mandatory sustainability rating tools for new and existing buildings are varied, the organisations who prescribe the conditions should be commended for at least incorporating them. The voluntary tools with their more onerous waste management requirements are also a great step in the right direction. However, those buildings located within a geographic region whose local authority does not require waste-related sustainability requirements or whose owner has not prescribed an aspiration for the building to meet any voluntary sustainability status or branding, are unlikely to assist state and territory governments to achieve their demanding waste to landfill reduction targets.

Therefore, the introduction of consistent mandatory requirements for waste minimisation into sustainability tools for buildings, or separate legislation, will be of paramount importance in achieving some of the goals of many state government policies. This would also be instrumental in assisting the development of localised recycling markets, which in turn could result in a greater range of building materials with recycled content for use in new buildings in the future.

ADAPTABILITY POTENTIALS IN HONG KONG PUBLIC HOUSING

Nyun Ling PAN [1]

[1] School of Design, The Hong Kong Polytechnic University, Hong Kong, sdgracep@polyu.edu.hk

Keywords: adaptability, public housing, building stock, environmental impact, sustainable

Summary

How sustainable the public housing is planned, designed and constructed can largely determine our way of life in the future. A favorable public housing built environment must be one that sustains ongoing wellness and integrity of the natural environment as well as the individual and their society. Public Housing in Hong Kong has been undergoing a tremendous change for the pass 50 years. It has progressed from housing policy to housing design development. Over the course of a building's lifetime, change is inevitable, in social, economic and in physical renovation in response to the needs and expectation of occupants. In theory, building that is more adaptable will be utilized more efficiently, and stay in service longer.

As the world faces resource scarcities, ecological problems, and environmental impact, a concern and consideration for the adaptability of building, and designing building with adaptability in mind is becoming a critical consideration. A report study on LCA and LCC models conducted by Housing Authority is used as a tool to explain the feasibility of the concept of adaptability that should be adopted for future. This paper is intended to share some information on issues of building adaptability in existing public housing stocks and examine the concept of adaptability potential towards sustainable public housing design in Hong Kong.

1. Overview of Hong Kong

1.1 High Density Living and Land Shortage

Hong Kong is a classic example of a compact city undergoing phenomenal changes. Given the hilly territory that presents physical and economic constraints, it is known that there is 20% of land that is build-able within an area of 1,100km^2. Apart from land reclamation due to insufficient build-able land area, as asserted by Fung (2001), the government of Hong Kong has opted for a high density approach to accommodate the growing population in order to reduce the demand for extensive land reclamation. Introduction of high-rise building had become the norm in all practice of planning, design and construction - including public housing. Current public housing is approximately 40 stories high with 10 stories added over the past decade.

1.2 Building Stock and Life Span

To cope with the population growth and needs in the past, there were huge amounts of building constructed. Although there are no concrete figures on the building stock currently, there were huge masses of construction material flow estimated in Koenig and Liu's study (2000) in which they found over 40% of the material flow contributed to construction materials.

According to the Citizen Party Hong Kong (1998), the average lifespan of a building is about 30 years, sometimes even less. Many of these structures, especially older buildings, have been built with low standards with insufficient maintenance throughout occupancy. Some current public housing estates are in similar condition. Concerning the global environmental impact, building stock in Hong Kong induces the largest energy and massive flow of materials of all production sectors. It represents the largest financial, physical and cultural capital of industrialized societies. What the building stock can offer at this point remains a challenge for Hong Kong.

1.3 Construction and Demolition Waste

Renovation work carried out by dwellers in Hong Kong is a most wasteful business. MDR (1994) concluded that "fit out" is a waste of public resources as large amounts of "fit out" provided by the developer has been discarded before use. This implied that the public housing design tends not in competency of occupant's needs. In the study of Koenig and Liu (2000), construction & demolition (C&D) waste has also increased 4 times in 26 years. There is similar waste with construction material consumption.

Based on a short mean life span of buildings of 30 years, the percentages of renovation and demolition waste in the total building (C&D) waste are very high. Current statistics from Environmental Protection Department (EPD, 2006) shows that 27% of disposal in the landfill came from (C&D) waste which account for 4,125 tonnes per day. Clearly, early demolition of buildings contributes the largest portion of building (C&D) waste and presents an issue on environmental impact.

2. Overview of Public Housing Development

2.1 Emergence of Public Housing

The development of public housing in Hong Kong can be traced back to 1953 when a large fire broke out in one of the squatter areas, Shek Kip Mei, leading to 50,000 people rendered homeless. The Hong Kong Government carried out a massive *Resettlement Program* to house the homeless within a short period of time. By 1973, nearly 50% of population lived in public housing which accounts for around 1.8 million people. Following the steps of industrialization and improvement of the economy, the Hong Kong Government gradually upgraded the living standard and environment of the public housing.

2.2 Public Housing Design from 50's to Now

There is a significant change in the public housing design approach from 1950s to now as shown in Figure 1. In 1950s, buildings were designed and built to suit the environment within the limitations of the material availability, current technology and land conditions. Public housing structures built later in the 1960s has increased in value by having more features such as individual toilets and vertical transportation systems. Then, the extensive concept of 'efficiency through uniformity'- a standardized housing form - became dominant in the 1980s. As described by Yeung (2003), it has reduced cost and time consumed for design and construction.

At the end of 1980s through 1990s, the Harmony and Concord types were developed as new housing prototypes. The concept of modular planning and standardization was adopted in the Harmony Blocks with the purpose of reducing labor costs, accelerating construction speed, and upgrading construction quality. Without much doubt, Jia (2000) expressed that this approach has made these factory produced components, mechanized construction and prefabricated concrete building elements possible in housing construction.

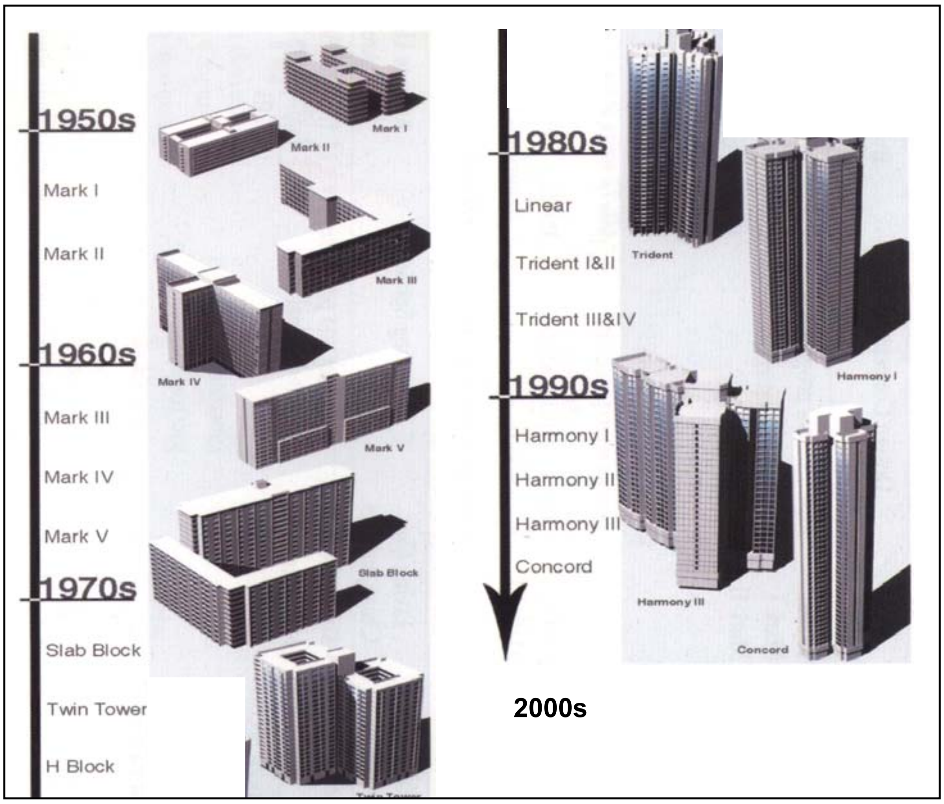

Figure 1 Housing types from 1950s to 1990s.

In 21st century, it is site oriented, environmental consciousness, quality, durability, adaptability and efficiency in the use of resources became the key considerations for the design and construction of public housing. A few effective measures such as segregation of waste material during demolition; and prefabrication of building elements have been employed to enhance environmental protection.

As asserted by Ng (2002), a housing unit must be able to cope with the different spatial needs associated with the growth and aging of occupants, and changes in family structure. Thus, flexibility and adaptability in the design of flat units are important considerations to meet the changing needs of people.

However, to what extent the adaptability qualities and potential in existing and future public housing in order to be sustainable remain a challenge for Hong Kong and the success of the intention depends upon actual performance later.

3. Overview of Building Adaptations

3.1 Role of Building Stocks

Cities and towns account for a huge proportion of the world's consumption of natural resources and world's production of pollution and waste. In the future, the urban building stock will also become the largest raw material resource for new buildings. The existing building stock is a financial and physical assets, a sustainable society is not possible until the resources can be managed sustainably. According to Douglas (2006), maximizing the reuse of old building is a key of sustainability.

As the world faces resource scarcities, ecological problems, and contends with the environmental impact of building and construction, a concern and consideration for the adaptability of building is becoming relevant, especially in Hong Kong. These trends and relevancy has also been asserted by Kohler (1998) in his earlier study.

Current public housing stocks built in 60s and 70s as shown in Figure 2 such as in Shek Kip Mei Estate, So Uk Estate and Ngau Tau Kok Estate are facing demolition due to these buildings becoming obsolete. Lessons are learnt based on what and how they were built and how these building were maintained. There is nothing much we can do to these building stocks now to revitalize them, but the sustainability of future public housing can not be overlooked. After all, the future of public housing is part of the total building stocks.

Figure 2 Illustrations of public housing stock built in 60s and 70s

3.2 Adaptability Implications

3.2.1 Avoidance of Building Obsolete

A combination of interrelated conditions has made many buildings functionally obsolete. Such interrelated conditions are over-building at once; the economic recession and subsequent real estate crash; structural changes in the economy; innovations in communication and information technologies; changing preference on how we work and live and other factors as well. According to Gause (1996), the issue on obsolescence can be avoided if an anticipation of change - socially and economically - is predicted and considered carefully when planning for the adoption of the adaptability concept.

3.2.2 Extension of Building Life Span

The service life of every building is unique and its lifespan is strongly determined and influenced by change in the economy, society and the environment over time. Under a suitable building condition, adoption of adaptability to a building will eventually result in an efficient use of building and extend a building life span.

3.2.3 Reduction of Environmental Impact: Waste, Energy, Gaseous

Buildings should be looked as resources, and building that is unable to adapt will be demolished. Some useful results can be found in Larsson's (1999) research study. Materials that are not recyclable from demolition can consequently induce higher levels of demolition waste.

Apart from that, new build building requires more energy flow (embodied energy including initial energy & transportation energy) and further gain environmental burden since new construction contribute a huge amount of materials in contrast with adapting existing building. Adapting existing building will lead to reduction in green house gas emissions. Therefore, designing building with adaptability potentials will definitely contribute to the reduction in a negative environmental impact.

3.2.4 New Value and Product Generation

Once a building is determined to be in good condition to be adapted for reuse, it is feasible to generate new function and significant value to the building and the community. It is the adoption of this concept that enhances its acceptability and generation of new market for recycling products as well as an educational tool to inform new vision and responsibility to reduce environmental impact.

3.3 Building Adaptability Criteria

Adaptability is the key attribute to building adaptation. According to Douglas (2006), adaptation refers to any work to a building over and above maintenance to change its capacity, function or performance. That is any intervention to adjust, reuse or upgrade a building to suit new conditions or requirements. Adaptability refers to the capacity of buildings to accommodate substantial change as expressed by Grammenos (1997), Russell and Moffatt (2004) and HKBEAM (2005). In theory, building that is more adaptable will be utilized more efficiently, and stay in longer service, because it is responsive to change at a lower cost compared to a newly built project.

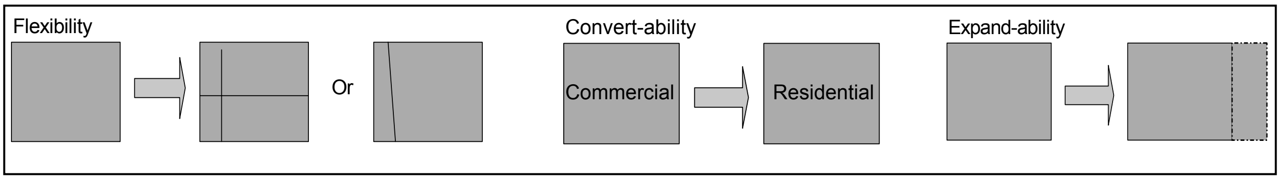

Figure 3 Illustrations of adaptability criteria

Flexibility; Convertibility; Expandability; Dismantle-ability; Disaggregate-ability are the five criteria of adaptability. Among all criteria, flexibility, convert-ability and expandability which are shown in Figure 3 are more common. Flexibility enables minor shift in spatial planning, reconfiguration to the layout is very typical. Convertibility allows for change in use within the building economically, legally, and technically. Expandability makes allowance for increase in volume or capacity, inserting another level to the building vertically or inserting addition horizontally is very common.

3.4 Feasibility of Inherent Adaptations

Criteria such as flexibility, expandability and convertibility are more likely feasible for building stock adaptation. However, careful assessment on the appropriateness on the concept adoption is required. In Hong Kong, the low adaptability of some building design has limited the usage range. These buildings were not plan, design and construct to allow for flexibility to accommodate the continuous changing economy, living standards, control regulations and technology.

Feasibility is a significant critical path in the process of building adaptations in any construction project at any levels. Three primary factors determined the adoption, such as viability (economic feasibility), practicality (physical feasibility) and utility (functional feasibility). Viability is usually the most important and influential of the assessment criteria because ultimately, all development decision is dependant on financial considerations. A good starting point in assessing the significance of the estimated cost of adaptation is to compare them with redevelopment programs whereby it defines the context of existing building and inevitably involves demolition and erection of new building. Life Cycle Assessment (LCA) and Life Cycle Cost (LCA) can definitely be used as part of future planning tool and adoption for building adaptability.

The practicality of undertaking an adaptation scheme is influenced by the extent of access required for the work and the condition that building is capable of adaptation without major or long term disruption to its use and its structure. In congested urban city such as Hong Kong, some of the key barriers public housing stocks offered are little structural change and access room on site for contractors and their storage.

Any successful adaptation project, however, must fulfill the spatial requirement needs of the building's occupant. In the outset, the aim should be to minimize wastage of underused space on one hand. The distribution of building stock by age gives some indication of the adaptability. The larger the coverage areas of building at same age within a context, the better the feasible of its utility for adaptations.

4. Findings of LCA/LCC Model

There are at present no comprehensive data sets of environmental information in relating to product manufacture, use and disposal for the Hong Kong region. The Housing Authority sees the essence to use materials in a productive and efficient way as a common objective of the different players in the Life Cycle of a building in their specific decision making situations they need with different tools and reference values. The best method of establishing such information is through the comprehensive life cycle mapping of construction materials in terms of cost and environmental burdens resultant from the existing building designs. As a consequence, international data has been sourced and analyzed to provide an underlying basis for the Housing Authority LCA/LCC model.

To examine if the concept of adaptability is feasible to widely adopt in Hong Kong public housing, report study of LCA/LCC (Life Cycle Assessment/ Life Cycle Cost) conducted by Housing Authority is observed and investigated. It is used as tool to understand how improvement in the sustainability performance of Hong Kong's buildings through adaptations can be achieved, through the identification of the economic and environmental profiles of the buildings' designs.

Functional units such as piles; RC walls; windows etc. were used in the study and the ranking results obtained from the study are listed below and in Figure 4:

4.1 Initial Cost Ranking and Environmental Impact Result

In terms of the overall expenditure profile, it is relatively unsurprising that the items with largest physical quantity dominate the top level. According to results obtained from Housing Authority (2005), it is clearly demonstrated that approximately 20% of the functioned units have a cost impact in excess of HK$1 million. Equally, these 20% of items also constitute 86% of the total capital cost.

Referring to Figure 4, the top 10 functional units, in terms of capital cost are piles followed by RC walls and RC slabs etc. At the same time, these RC walls, pre-cast facades and RC slabs yet are the dominant functional units in contribution to environmental impact.

	Life Cycle Cost Impact	Life Cycle Environmental Impact
1	RC Slabs – Fairfaced	Precast Facades – Type 1
2	RC Walls – Fairfaced	RC Walls – Fairfaced
3	Wall Finishes – Internal Flat Areas	Precast Facades – Type 2
4	Floor Finishes – Kitchens and Bathrooms	RC Slabs - Fairfaced
5	Piles	RC Water Tanks
6	Small Power Installation – Flats	Aluminium Windows – Bedrooms
7	Panel Walls – Internal	RC Walls – Generally
8	Fresh Water System - Distribution	Aluminium Windows – Living Area
9	Lighting Installation – Flats	Piles
10	Internal Waterproofing	Mains & Distribution

Figure 4 Top 10 LCA and LCC ranking functional units. Source: Final Report of LCA and LCC Study of Buildings Materials and Components

4.2 Initial Quantity (Mass) Ranking Result

As with all other aspects, the large quantity items (RC slabs; RC walls, piles) dominate the results and again the structural items top the results listing. In this case the options available for assessing alternative strategies will be more limited without fundamentally revising the structural design of the building. The above results ultimately are not remarkable and it was within expectation. In the context of the whole life profile these items do not have as large an impact since they are not replaced frequently. However, due to their dominance at the initial stage they remain in the top rankings even on a whole life basis.

4.3 Whole Life Cost and Environmental Profile

From the report of Housing Authority (2005), it is found that over 90% of the total impact is attributable to just 17% if all the functional units. This implied that the environmental impacts are concentrated on a small group of items such as structure and services of building in which these items contribute to a substantial capital cost at the same time. Similar situation will carry through to the whole life profile and rankings.

4.4 Implications of Result

The assessment has been carried out on the basis of functional units, rather than individual. This approach reflects how materials are actually combined into the building. Base on the ranking on Life Cycle Cost impact and Life Cycle Environment Impact indicated in Figure 4, on the whole architectural items, whilst significant, are generally less dominant than the structure and building services items in cost terms. Similarly, structural elements dominate in environmental terms since their impact is driven largely by the substantial mass of the material they contain. Thus, the study method and results does make clear implications on how much wastage and environmental burden if no adaptation is adopted appropriately.

The results did not show whether adaptability is a good thing to be applied, but the studies shown that over 60% of building mass are from the structure and building block. This again implies that if building stock is to be demolished, there will be big portion (or percentage) of cost, energy, and resources became less useful. However, waste, and chances of adding burden to the environment are definite considerations.

As asserted by Yeang (1995), if the building be regarded as a form of energy and material resources that is managed and assembled by the designers into temporary form, the demolition at the end of the period with the materials should be either recycled within the built environment or assimilated into the natural environment.

5. Conclusions

Given the data obtained and implications derived from LCA/LCC study, improvement made to new built, to extend future building life span and reduction in construction and demolition waste by adaptation is rather relevant. In Hong Kong, one of key challenges would be provision on housing needs. Due to the limitation of land for further urbanization, and increasing demand of public housing and increasing demolition waste, it seems adoption in design for adaptability is valid, so that public housing life can be extended and reduce further land reclamation, as well as further demolition waste in future.

Even a new building will become obsolete over time under some conditions such as new technologies required and new functionality. So a building has to respond to the present state and also to the future, even unanticipated, changes in requirements, and this at a minimum transformation cost. The importance of new structure should not be overlooked. After all, today's high technology is tomorrow's low technology. The adaptability of new and modern public housing is just as important as that of old construction. Therefore, it is important that adaptation should be taken into account in either existing public housing stock or new build schemes.

The consequences are clear as shown in Figure 5, that a series of reduction in environmental impact can be achieved. Adaptability prevents, in many cases, the premature demolition of buildings, adding many years to the life span, which is a significant contribution to sustainability. Adaptability has to be incorporate at the early stage of planning and design.

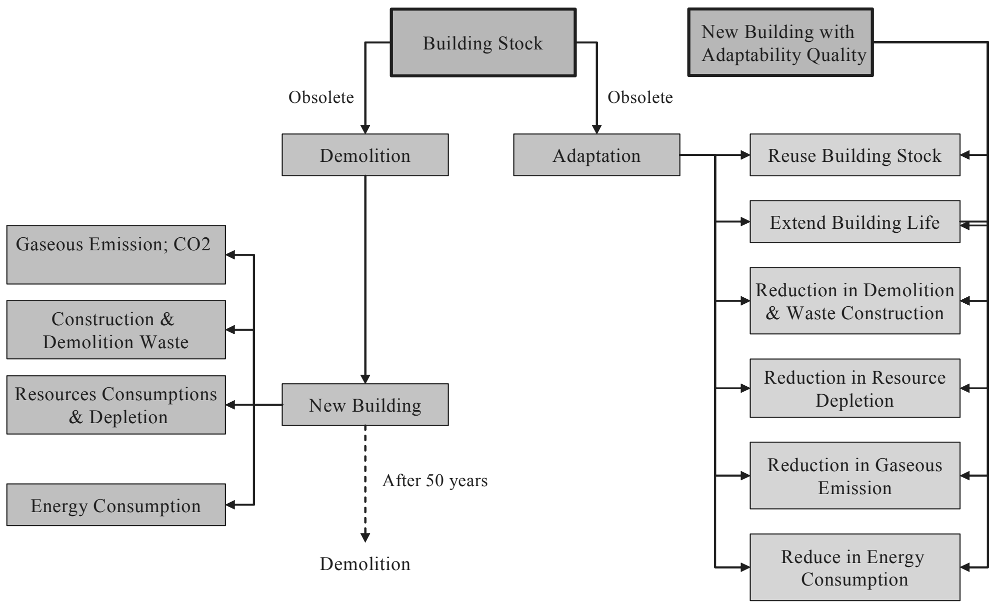

Figure 5 Illustration of consequences of adaptation of building stock & adaptability on new building

5.1 Design Strategies Adoption

Sustainable built environment with adaptability should aim to save resources, reduce waste and become a high quality stock of society and emphasis the well-being of the citizens on the quality of their environment, whether man made or natural, which accommodate human needs and aspiration.

What is needed is a way to protect all natural resources and to live within the carrying capacity limits of our environment, minimizing negative impact and make efficiency use of these resources.

Apart from using strategies such as design for long term needs and climatic responsive approach and using designing product with dismantle-ability as suggested by Kohler and Schwaiger (1998) in new public housing design in Hong Kong, "Open Plan Concept" as suggested by Kendall and Teicher (2000) and Wood (2003) and design building integrity as suggested by Russell and Moffatt (2004) which provide extra load capacity to foundation and superstructure to certain extent will reinforce the feasibility of the adaptation which can all be adopted to a certain extent as pilot study for its actual performance.

How the design strategies can be employed in practice and catering to functional needs and requirement in design can be shared later in oral presentation.

5.2 Way Forward

We know that the situation in Hong Kong is unlikely to remain static – change is inevitable and the pace of change is trending greater due to technology advances. The development of adaptability as a potential market in an adaptable structure, will present both challenges and opportunities to Hong Kong for building sustainable building into the future.

This sustainable housing design requires a holistic approach. Thus, participation and contribution of all construction stakeholders and developer and governmental representatives are essential. Integrating soft system such as highly organized site logistics and management and new procurement methods in tendering and contracting will also be required to try out new adaptability concepts and advanced construction technologies.

It is important to give credit to buildings that are designed in ways that extend their useful lifetime, and use materials and space efficiently. Designing and building with adaptability potentials in Hong Kong public housing to new scheme not only meets basic needs of present but more importantly future generation.

The way forward is to do more valuable relevant studies and hope to generate and produce a set of design guidelines to inform and make policy for all to comply in the future.

ANALYSIS OF THE MICROCLIMATIC IMPACT OF GREENING IN HIGH RISE URBAN BUILT ENVIRONMENT USING SITE MEASUREMENTS AND SKY VIEW IMAGE PROCESSING TECHNIQUES

[1] Department of Architecture, The University of Hong Kong, Hong Kong, China, h0599009@hkusua.hku.hk
[2] Department of Architecture, The University of Hong Kong, Hong Kong, China, ssylau@hku.hk

Keywords: microclimate, urban heat islands, urban greening, urban density, tree canopy density

Summary

Urban greening is believed to be capable of providing passive cooling by its shading and evaportranspiration[1]. High density in high rise milieu could influence greening cooling effects by altering solar and infra-red radiation exchange within so called urban canyons in ways differently with that within low rise settings. One of the most significant differences is that tall buildings can shade the greening at ground level instead of being shaded by them. In this scenario, an increase of built density could dilute cooling effect of greening by both shading and evapotranspiration in daytime, while increase of either building or tree canopy density could hamper irradiative cooling by reducing visible sky area at night. To test this hypothesis, site measurements at typical points in selected high rise residential developments in Shanghai is carried out. Microclimatic data and site-specific parameters are recorded in clear and calm days. A tool to measure built density and tree canopy density is developed using fish eye lens digital sky view imaging and WINSCanopy software. Temporal and spatial variations of microclimatic data are correlated to site parameters to evaluate their significant levels. The findings are useful for landscape and urban planning practice in high rise built environments with an aim to improve their bioclimatic performance and to mitigate urban summer heat islands.

1. Introduction

The economic booming of China is accompanied by the radical developments of many cities. However, the highest priority being given to economic growth in these cities causes various loads on the urban environment, which seriously affect the urban living standards. The urban heat island[2] is a particular phenomenon derived from these cities. It can give rise to many problems, such as the change of ecosystems of wildlife and vegetation, degraded outdoor thermal comfort, increasing number of heart stroke patients, expansion of infectious diseases (e.g. the SARS breakout in Hong Kong), and increasing demand for cooling energy consumption, and thus threaten the living environment and health of urban habitants.

Urban greening is believed to be capable of providing passive cooling by its shading and evaportranspiration (Kozlowski et al. 1997; Oke, 1987). But hitherto most of the relevant studies use built sites featuring low rise and high density, while study on greening cooling effect in high rise high density urban built environments, which are commonly found in modern Asian cities such as Hong Kong and Shanghai, is scarce.

2. Literature review

2.1 Previous research on cooling effect of urban greening

Bonan measured the microclimate of a low-rise residential area in a hot-arid climate, and found that plant species, water availability and housing density all contribute to forming a thermal-pleasing environment (Bonan, 2000). Shashua-Bar studies cooling effect of vegetation in various configurations of streets and small public spaces in cities with a hot-arid summer climate, by empirical modeling (Shashua-Bar et al. 2000). They conclude that site-specific effects (tree characters, site geometric configurations, water regime, etc.) are quite minor. This may be because that variation of site-specific effects among sites is small, and the finding could be different in a high-rise built setting in the subtropical climate of Shanghai.

The present study focuses on urban greening at micro scale. The aim is to assess the micro scale influence by greening as a joint function with other land use and built form variations. Unlike at larger scales, at micro scale, climatic impacts of greening is inevitably altered by urban built properties such as sky view factor,

[1] Evapotranspiration (ET) is the sum of evaporation and plant transpiration.
[2] The urban heat island is the temperature difference between developed areas and its surrounding undeveloped areas.

surface thermal properties, radiant environment, etc. (refer to Oke, 1989, for a detailed explanation of the energy exchange between urban trees and its street canyon environment.) Therefore, for study at this scale it is important to take all the above factors into consideration, for a comprehensive understanding of how greening performs in various urban settings. On the other hand, study of urban greening at this scale is scarce in sub-tropical Asian cities.

2.2 Research objectives

The present study aims to investigate the cooling performance of greening within a high rise residential development, and to understand the contribution of built density, land use and building layout to this cooling performance.

2.3 Brief description of the site under survey

The Brilliant City Project is located in Putuo District, Shanghai. The Suzhou River runs across by its southern side, and Shanghai Metro Line No.3 runs along its northern boundary. The site area is 49.5×10^4 m^2; the total floor area 160×10^4 m^2; Floor area ratio is about 3.2, and green cover ratio is 45%. The majority of the residential towers are at a height of 100m, the height defining high rise and super high rise buildings in China building codes. Because of the vast site area while the limit in man power and instruments, the site is divided into the east part and west part, divided by Zhongtan Road. Each site is to be surveyed on separated days.

Figure 01: Satellite image of the Brilliant City, Shanghai

3. Methodology

3.1 Selection of dependent and independent variables

Table 01: Lists of Dependent and independent variables

Descriptors	Independent Variables
Planning and Building design descriptor	Building View Factor (BVF) Sky View Factor (SVF) Ground Surface Albedo (AL)
Vegetation descriptor	Leaf Area Index (LAI) Tree View Factor (TVF) Green Coverage Ratio (GCR)
Natural descriptor	Wind Velocity (VW) Solar Radiation (SR)

Dependent variable: UHI_{day} and UHI_{night}, but only UHI_{day} is discussed in this paper due to page limit.

3.2 Measurement procedures

The site work can be divided into two parts: climatic measurement to record microclimatic variables such as temperature, wind speed, solar radiation etc. and site survey to measure design variables in planning, building design and land-use descriptors (Table 01) .

3.2.1 Climatic measurement

Measurement was carried out in Brilliant City West (referred to as BCW hereafter) on 26 September 2007 and in Brilliant City East (BCE) on 27 September 2007. In BCW 15 measurement stations were selected, and in BCE 14 stations. The criteria of selection are to maximize the possible variations in planning and design and land use variables. The overall sample size is 29.

The climatic condition of the dates under measurement is summarized in Table 02. Compared with institutional data, the on-site observation found that on 26 September it is quite cloudy, and mean solar radiation intensity measured on site (1pm to 6pm during mobile measurement) is 316.45W/m^2. It is considerably lower than 393.82 W/m^2 of 27 September.

Table 02: Climatic conditions on the survey days (from 0600 hours to 2200 hours)

Date (Sept.)	Air Temp. (^{o}C)			RH (%)	Cloud Cover (0800, 1400 and 2000)			Wind Velocity (m/s)		Solar duration (hr)	MSR (MJ/m^2) (0600 - 1800)
	Max	Min	Ave	Ave	08	14	20	Max	Ave		
26	29.7	21.8	26.6	77.1	7	4	0	2.6	1.48	8.4	1.50
27	32.3	23.7	28.6	72.5	1	3	0	2.9	1.24	8.6	1.50

Note: MSR - Mean hourly solar radiation
Data source: Shanghai Observatory

Among stations in each site, a pair of two stations was selected with similar building but different greening surrounding environments. A pair of Hobo weather stations was installed at these two stations, which records air temperature, relative humidity, wind speed and global solar radiation from 6am to 10pm at the height of 1.5m above ground. Another weather station was placed on rooftop of one of the residential buildings on site at the height of about 100m above ground. As it has the minimum obstruction of view to the sky, it is used as a reference of global radiation received on site. The effect of aerosol on radiation reduction is not considered in the study.

The rest of stations were covered by mobile measurement. Handhold Kestrel Pocket Weather Tracker was used to record air temperature, relative humidity, wind speed and wind direction 1.5m above ground. Mobile measurements covered the period from 1PM to 10PM and were taken every two hours. Totally 5 rounds were made at each station.

All on-site measured temperature readings were calibrated on a pro-rata basis to match the record timing at Nanhui Observatory, which is located to the south-eastern of the site and in rural area. UHI at a station is then calculated using measured temperature minus temperature recorded at the same time at Nanhui Observatory. The average UHI of round 1, 2 and 3 (1pm to 6pm) is taken as the daytime UHI; the average UHI of round 4 and 5 (7pm to 10pm) as the nocturnal UHI.

Table 03: Specification of the instruments in use

Instrument	Model	parameter measured	Accuracy	Operating Range
HOBO weather station kits	Temperature/RH Smart Sensor: S-THB-M002	Ta, RH	± 0.2^{o}C over 0 to 50^{o}C; ± 2.5%RH from 10 to 90% RH	- 40^{o}C to +75^{o}C; below 95% RH
	wind speed smart sensor: S-WCA-M003	WV	± 0.5 m/s ± 3% at 17 to 30 m/s ± 4% at 30 to 44 m/s	0 - 44 m/s
	Global radiation sensor: S-LIB-M003	GR	± 2% at 45^o from vertical	0 - 1280 W/m^2 over a spectral range of 300 -1100 nm
Kestrel Pocket Weather Tracker	Kestrel 4000	Ta	± 1 ^{o}C	- 45.0 to 125.0 ^{o}C
		RH	3.0 %	0.0 to 100.0 %
		WV	Larger of 3% of reading or least significant digit	0.4 to 40.0 m/s

3.2.2 Site survey

Site survey was conducted to measure on-site design variables including Sky View Factor (SVF), Building View Factor (BVF), Surface Albedo (AL), and greening variables including Tree View Factor (TVF), Green Cover Ratio (GCR), and Leaf Area Index (LAI).

To measure SVF, BVF and TVF, Hemispherical sky images were taken at each station using Nikon fish eye lens and digital camera, and then the magnitudes of SVF, BVF and TVF of each station were calculated using the image by WinsCANOPY™ software.

Surface properties of an about 1000m^2 area with a radius of 17-20m centred by each measuring point were elaborately recorded using a site survey form. These properties include percentages of soft and hard paving materials. In soft materials a sub-categorization was done to classify various vegetation (grass, shrub and tree) and water bodies. In hard paving materials, sub-division was done based on colour and paving materials. GCR is directly calculated from the surveyed data. LAI is estimated by surveyed data and other research findings on LAI (Ong, 2003; Scurlock et al. 2001). AL is estimated using surveyed data and other research findings on thermal properties of urban materials (Oke, 1987; Santamouris, 2001; Taha, 1997).

4. Analysis and discussion

4.1 Impacts of tree canopies and building canopies on radiation and temperature

4.1.1 Comparison of two stations

In BCE measurement on September 27, 2007, two stations with similar built canopies but different tree canopies, No.8 and No.9 were installed with weather stations to monitor and compare their micro climatic environments. The profiles of air temperature and global solar radiation were plotted and related to their hemispherical sky images. (Figure 02)

Figure 02: measurement point P8 （Left） and P9 (Right)

Table 04: Comparison of P8 and P9 in surface and geometry properties

Stn No.	Ground Cover proposition (%) (within 17m radius area of stations)						Geometry: View Factor (%)		
	Soft paving					Hard paving	SVF	CVF	
	Green Cover ratio	*Grass*	*Shrub (<1m)*	*tree (>1m)*	*Water*			*TVF*	*BVF*
8	45	*0*	*0*	*45*	5	50	27.79	13.73	70.03
9	55	*5*	*40*	*25*	5	40	15.14	39.03	68.69

Note: CVF: canopy view factor, including TVF and BVF.

4.2.2 Analysis and discussion

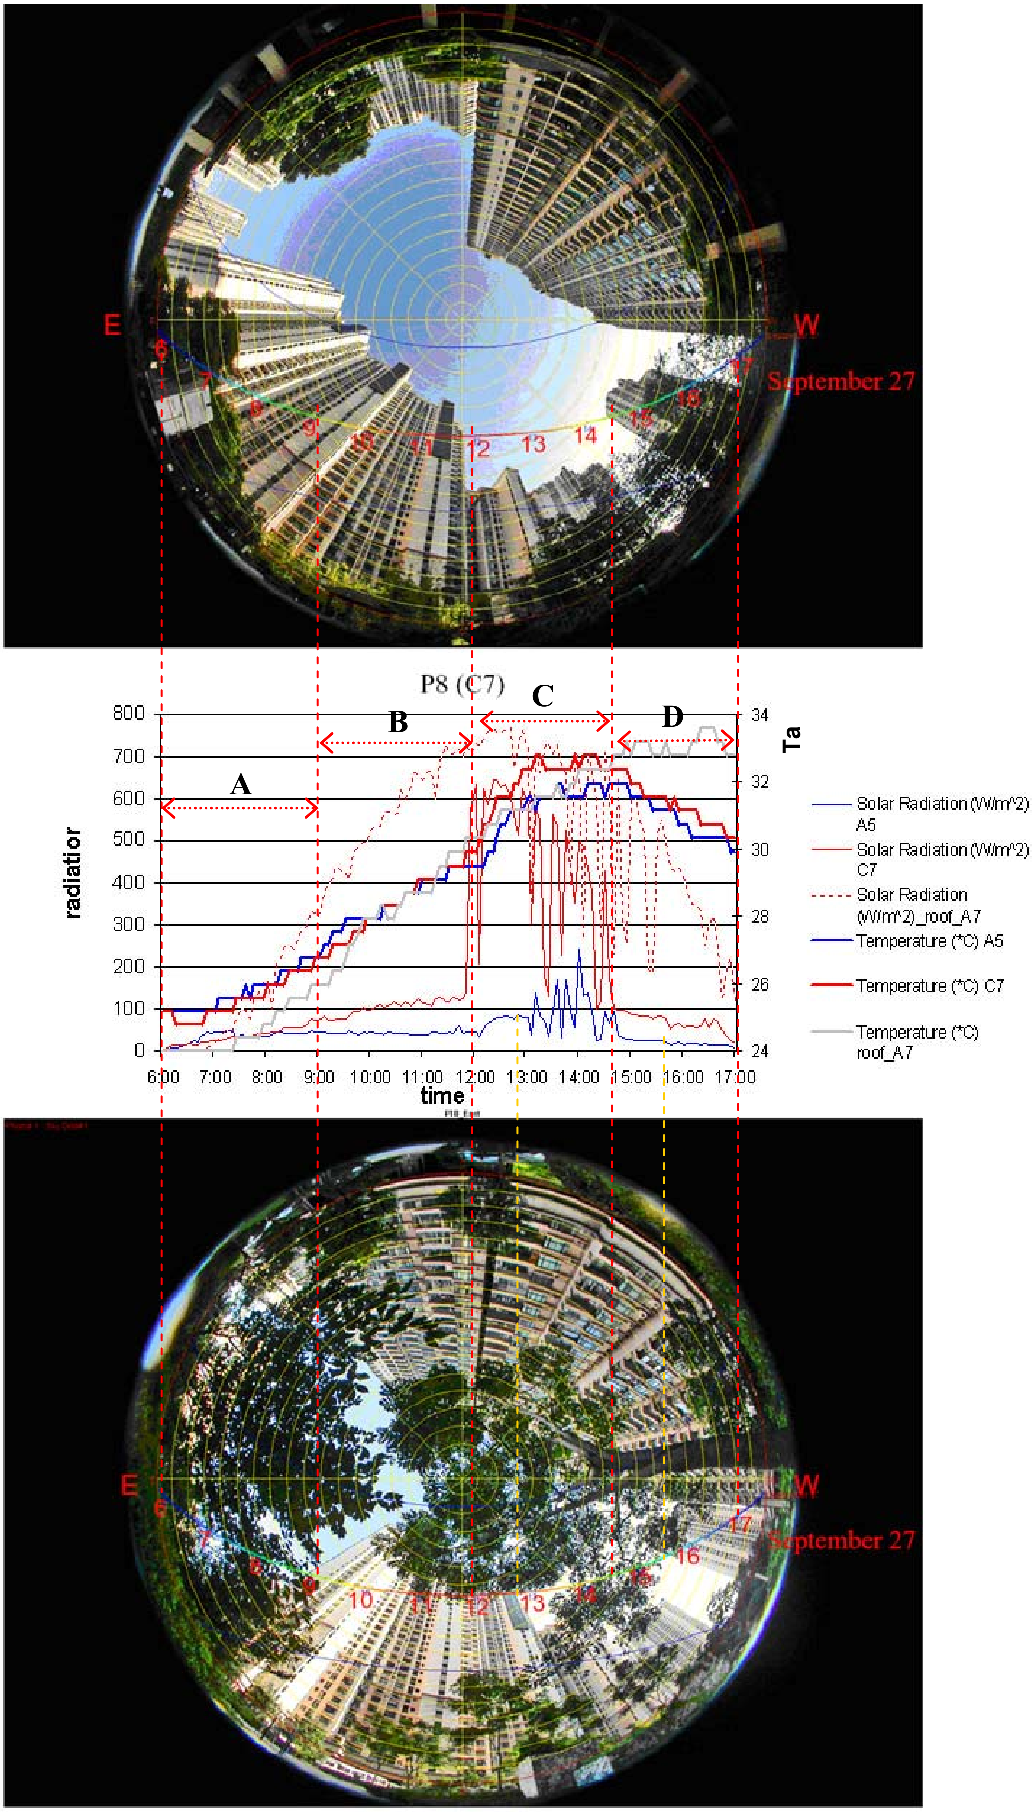
Other surface parameters being similar, the patterns of air temperature and globe radiation show significant variations due to different building and tree canopy densities (Figure 03):

6AM to 9AM (**Period A**): Temperatures show not much difference though T_9 is little higher (Max. 0.4^{o}C) than T_8 possibly because that shading by buildings blocks more solar radiation than tree canopies due to its porous nature.

9AM to 12AM (**Period B**): both points are shaded by buildings. T_8 grows up faster than T_9 and gradually outruns T9. This can be explained by the presence of tree canopies over P9: Although buildings intercept the same amount of direct radiation, tree canopies above P9 intercept a portion of reflected and diffused solar radiation (as can be seen from the Global radiation pattern), thus slowing its temperature increase.

12AM to 2PM (**Period C**): P8 is un-shaded and P9 is shaded by trees. The temperature shows significant differences (Max. 1.2^{o}C), as shaded P9 received much less radiation and thus are cooler than P8.

2AM to 5PM (**Period D**): both points are shaded by buildings. T_9 remains lower than T_8; the reason is the same with period B.



P9 (A5)

Figure 03: diagrammatic analysis combining sky view images and climatic patterns

Another comparison made at BCW yield similar findings. The above observation indicates tree canopy density as an important factor to lower air temperature, for its capability to intercept solar radiation, direct, reflected and diffused. Other greening factors such as grass cover and shrub cover seem not play an active role in environmental cooling. This is further discussed in the following section on regression analysis.

4.2 Multiple regression analysis

4.3.1 Daytime UHI in BCE: impact of greening variables

The first stage analysis focuses on each site, and regression was done using the six on-site design variables, in order to identify most significant combinations of variables. Because the main interest of study is on greening variables, the variable set containing three greening variables is used to build the base case model. (Because the R^2 of BCW model is quite low, only BCE model is presented in Table 05).

Table 05: Results of BCE regression analysis

	Coefficients					
	Model 1 (3 vars)	Model 2 (3 greening vars)	Model 3 (3 vars + SVF)	Model 4 (3 vars + AL)	Model 5 (3 vars + BVF)	Model 6 (all 6 vars)
Constant	*-1.135(.320)*	*2.595 (.000)*	*3.120 (.003)*	*3.564 (.000)*	*1.025 (.233)*	*-.586 (-.853)*
GCR	*.007 (.048)*	*.004 (.394)*	*.005 (.380)*	*.003 (.675)*	*.005 (.247)*	*.003 (.630)*
TVF	--	*-.025 (.101)*	*-.024 (.112)*	*-.028 (.053)*	*-.015 (.274)*	*-.010 (.550)*
LAI	--	*.225 (.264)*	*.151 (.499)*	*.309 (.117)*	*.103 (.567)*	*.196 (.349)*
BVF	*.041 (.006)*	--	--	--	*.023 (.061)*	*.036 (.173)*
SVF	*.023 (.111)*		*-.014 (.440)*	--	--	*.026 (.383)*
AL	--	--	--	*-3.909(.108)*	--	*-1.045(.716)*
R^2	.627	.385	.427	.546	.593	.674
F statistic	5.597	2.090	1.676	2.704	3.275	2.410
Case No.	14	14	14	14	14	14

Independent variable: UHI_{day}

Values in the parentheses are significant levels of variables.

As the first step stepwise regression is applied. The three most significant variables are BVF, SVF and GCR (Model 1). Secondly, regression analysis uses three variables representing variations in greening, i.e. GCR, TVF and LAI. The model generated explains 38.5% of variability in the dependent variable, and the F statistic is only 2.090, the model is not strong (Model 2). This suggests that variations in greening solely are not capable of explaining the majority of temperature variations. Based on this, the other three variables, SVF, AL and BVF were added to the model one at a time. It is found that, compared with Sky View Factor and Surface Albedo, the incorporation of Building View Factor significantly increase the R^2 (.593) and F statistic increases to 3.275. (Model 5) (In fact, in forward regression with sig. level set at 5%, only BVF is included in the model, with R^2=.379; F=7.330.) The model 5 suggests that an increase of 10% in Building View Factor increase UHI by 0.23%. As BVF indicates surrounding built density of the station, the finding shows the significance of including density parameters in study on greening in high rise built environments.

The magnitude of evapotranspiration (ET) of vegetation depends on the species of vegetation, local meteorological factors (solar radiation, temperature, air movement, humidity) and availability of moisture. In complex high rise building environment, ET of greening needs careful consideration. In all the five models in table 03, both coefficients of LAI and GCR show positive signs. This is possibly because that, for the outdoor area in Brilliant City, the ground is generally artificial surfaces with underground car parks. Unless regularly irrigated, the growing substrate for vegetation is usually shallow and unable to hold consistently enough water for one day period. During the survey, the author did not see any irrigating work in progress in the site. So insufficiency in moisture in soil could contribute to reduced ET of greening, and thus the cooling effect.

Further, as albedo tends to decrease with the increase of Green Cover Ratio and Leaf Area Index (Fig.04), so the stations with higher green cover and green biomass have higher net all-wave radiation, and thus more heat to dissipate (Grimmond et al. 1996). Since ET was suppressed as discussed above, the sensible heat fluxes were enhanced and so was higher the increase in air temperature.

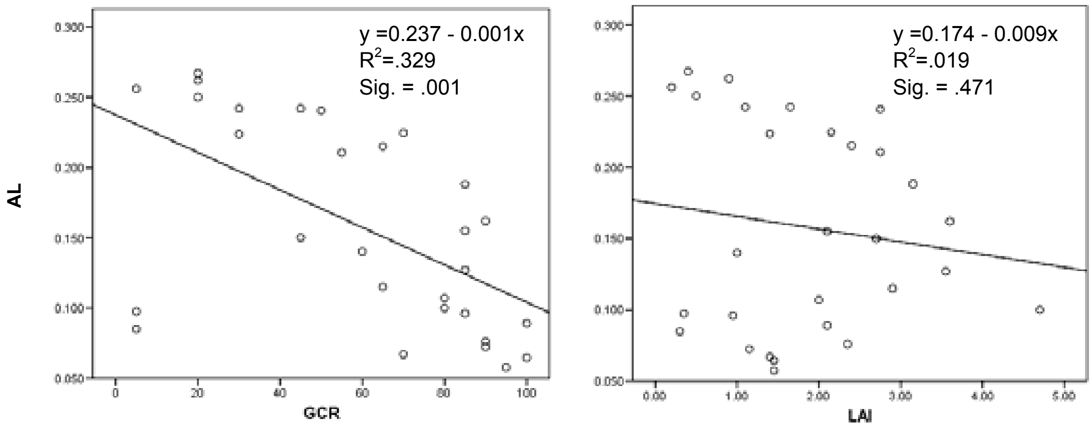


Figure 04: Albedo vs green cover ratio scatter plot (Up) and Albedo vs Leaf area index (down)

4.3.2 Daytime UHI in combined sites: impact of Building View Factor

Based on the findings from 4.3.1, the second phase regression analysis was carried out to test the hypothesis that high built density would dilute cooling performance of urban greening. All cases in two sites are included in the model, and natural variables WVD and SR are included. The results of regression models are presented in Table 06.

Table 06: Results of regression analysis with combined BCE and BCW

	Coefficients			
	Model 1: All cases (8 variables)	Model 2: All cases (4 variables)	Model 3: BVF<60% (4 variables)	Model 4: BVF>=60% (4 variables)
Constant	*-4.377 (.018)*	*-2.581 (.008)*	*-1.823 (.191)*	*-3.514 (.012)*
SR	*.013 (.000)*	*.014 (.000)*	*.013 (.006)*	*.017 (.000)*
TVF	*-.006 (.644)*	*-.018 (.047)*	*-.038 (.015)*	*-.007 (.551)*
LAI	*.110 (.447)*	*.129 (.209)*	*.467 (.025)*	*-.002 (.986)*
AL	*-1.162 (.515)*	*-1.377 (.312)*	*-3.650 (.114)*	*-.884 (.628)*
BVF	*.018 (.179)*	--	--	--
GCR	*.001 (.903)*	--	--	--
SVF	*.021 (.211)*	--	--	--
WVD	--[a]	--	--	--
R^2	0.667	0.631	0.745	0.768
F statistic	6.003	10.243	5.839	9.105
Case No.	29	29	13	16

Independent variable: UHI_{day}
Values in the parentheses are significant levels of variables.
Note: a. WVD is excluded from regression because of multicollinearity.

For linear fit estimation of each independent variable with the dependent variable, it is found the most significant variable is SR (R^2=0.525, F=29.827). The magnitude of SR in each site is the same, using the mean value from 1pm to 6pm. This finding suggests that despite variations in planning, building and greening descriptors, solar intensity still influences temperature pattern to a large extent. Secondly, stepwise regression was used to identify the variable set containing the most significant four variables. The four most significant variables are SR, TVF, LAI and AL (model 2 in Table 06). The model is totally different with model 1 in Table 05. This is because of the influences from the incorporation of SR and combination of cases of BCE and BCW.

As found in the previous sector, tree canopy cover intercepts solar radiation and helps lower air temperature. Therefore higher tree view factor should lead to lower UHI_{day}. In the BVF<60% model, the coefficient of TVF shows the right sign. While in BVF>60% model, although the sign remains negative, the coefficient is much smaller (-0.007 compared with -0.038) and the linear correlation is very weak (sig. = 0.551, compared with 0.015), it is therefore deduced that the higher building density, because of more radiation being blocked, introduces more uncertainty to shading and ET mechanism of vegetation at ground level, and is possible to dilute its cooling performance. Similar changes can be found in the impact of albedo. This is because in denser built surroundings, the cooling performance of high albedo surfaces is negated by enhanced multiple reflections between ground and vertical surfaces (Giridharan et al. 2004). But due to limited sample size in the models, further analysis with larger data sets is needed to confirm this finding.

6. Conclusion

1. Vegetation canopy above pedestrian level provides shade from solar radiation and reduce the increment of air temperature. A variable named Tree View Factor (TVF) used in this study is capable of quantifying vegetation canopies above pedestrian level at a certain point and it shows negative correlations with UHI in multiple regression models.

2. Green mass, quantified by Green Cover Ratio (GCR) and Leaf Area Index (LAI) are suppressed in evapotranspiration because of lack of water in substrate and high albedo in high rise residential developments in Shanghai. So they seem to have shown no cooling effect on outdoor air temperatures. But this still needs further study.

3. The combined impact of greening variables (TVF, GCR and LAI) cannot explain well the variations in UHI. Solar radiation has significant impact on UHI intensity. Building density is also found to have significant impact. In this study a variable named building view factor (BVF) is able to quantify the building density.

4. Higher building density blocks more radiation and introduces more uncertainty to shading and ET mechanism of vegetation at ground level, thus is possible to dilute its cooling performance. But further analysis with larger data sets is needed to confirm this finding.

7. Limitation and future study

Due to the logistic problem, this preliminary study measured only two sites with only one day period for each site. And the dates under measurement are not among the hottest days in Shanghai summer. These limitations could to some extent influence the data obtained and reliability of analysis. Despite all the limitations, the study yields reasonably good results, and testifies the method used in this study is reliable and applicable in larger scale data analysis. For future study, several issues should be addressed:

1. More extensive measurement is needed to be carried out in more sites with more diversified characteristics in building layout, surface material, green cover ratio etc. Each site is to be measured for a period of at least three days with similar weather conditions.

2. All wave radiation should be measured at each station, to calculate mean radiant temperature and other thermal index, in order to understand the impact of greening on human thermal comfort.

Keywords: indoor environmental quality (IEQ), perceived IEQ, environmental comfort, comfort evaluation criteria, comfort indicators, psychological effects, work performance

Summary

This study attempts to examine how indoor environment influences occupant comfort and performance in work environments. As concern about environment and energy has been growing, indoor environmental quality (IEQ) has received considerable attention lately. However, there are gaps between actual measurements and perceived IEQ when evaluating environmental comfort. Understanding indoor environmental influences on occupants in buildings can be a way to achieve healthy environments as well as energy efficiency. Psychological factors such as natural light and personal control enable green or sustainable buildings to improve occupant comfort and performance, decreasing energy use. Human resources are the most expensive and the greatest resources of organisations, therefore, a small increase of employees' performance results in a great deal of benefit to organisations. This paper describes the IEQ factors affecting environmental comfort and work performance and develops a theoretical framework of environmental comfort-performance evaluation model. The comfort criteria is categorised into five areas: Thermal comfort, Indoor Air Quality (IAQ), Acoustic comfort, Visual comfort and Spatial comfort. The environmental comfort indicators for physical, physiological and psychological comfort are respectively proposed and the hypotheses based on the theoretical framework are also proposed in the present paper. A follow-up paper will report on detail studies of office buildings in Seoul, Korea.

1. Introduction

As concern about the environment and energy has been growing, indoor environmental quality (IEQ) has received considerable attention recently. Specific design features and technologies have developed to improve environmental comfort and energy efficiency such as advanced natural ventilation to help avoid air conditioning and glazing systems with better thermal and daylight performance (Cohen et al, 2001). However, research has focused on energy efficient and sustainable buildings rather than on occupant comfort because of the direct benefits to be made out of saving operational expenses in buildings. While the relationship between environmental comfort and employee performance is difficult to measure in comparison with more tangible benefits like energy savings, there is significant and growing evidence to support this link. Improved productivity and reduced absenteeism lead to potentially massive financial benefits when employees are physically and psychologically comfortable. Human resources are the most expensive and the greatest resources of organisations, therefore, a small increase of employees' performance results in a great deal of benefit (Becker, 1990, Becker and Pearce, 2003). Staff costs amount to 10-20 percent of a business total revenue. Given that 1 percent increase in staff performance can offset total energy costs, it is important that environmental conditions are conducive to productivity (Oseland, 1998). Green or sustainable buildings specially have potentials of the indirect benefits to be made out of increasing occupants' health, comfort and productivity because of psychological factors such as natural light and personal control. Therefore, a holistic approach to understanding the issues of environmental comfort and human performance should be required to find out the way how people feel or react in the work environment.

The primary aim of the present paper is to examine how indoor environment influences occupant comfort and performance in work environments based on literature. In order to achieve it, this paper describes the IEQ factors affecting environmental comfort and work performance and develops a theoretical framework of environmental comfort-performance evaluation model. The comfort criteria is categorised into five areas: Thermal comfort, Indoor Air Quality (IAQ), Acoustic comfort, Visual comfort and Spatial comfort. The environmental comfort indicators for physical, physiological and psychological comfort are respectively proposed and the hypotheses based on the theoretical framework are also proposed in the present paper.

2. Indoor Environmental Quality (IEQ)

Indoor Environmental Quality (IEQ) has received attention recently since people have been staying longer indoors. Indoor environment encompasses a range of components including temperature, humidity, IAQ, lighting, ventilation, noise and crowded work space (Clements-Croom and Baizhan, 2000). However, the early research of IEQ is more likely to focus on IAQ problems which come from the airtight buildings which were completed with the 1970's energy crisis. The buildings were designed to be sealed from outside air to save heating and cooling costs brought out the damage of environmental health. Therefore, guidelines and standards for acceptable air quality have set to resolve the IAQ problems. Furthermore, it has been found that the improvement of the indoor environment do not just include IAQ issue, other environmental factors, temperature, humidity, light, acoustic and even ergonomic factors, need to be considered to provide comfortable surroundings. The study of the indoor environment was initially approached from a technical or a medical point of view and the technical measurements in the indoor environment have typically been performed without taking the response of the occupants into account (Engvall et al.,2004). However, the measured and perceived conditions have been found to be different in field research (Leaman and Bordass, 1999) since there are some dominant components contributing to overall environment comfort and some combined effects between components.

The dominant components of IEQ are an important key to satisfy environmental comfort, allowing energy savings in a sustainable way. If an individual is comfortable with some components of their environments, they are more likely to forgive others (Bordass et al., 1995, Leaman and Bordass, 1999, Humphreys, 2005, Vischer, 2005). An attractive view from windows enables occupants not to complain of cool temperature or noise from outside. Clements-Croome (2000) stated that building users report most dissatisfaction with temperature and ventilation, while noise, lighting and smoking feature less strongly. It might be that temperature and ventilation can be affected by changes at all levels in the building hierarchy, and, most fundamentally, by changes to the shell and services. In comparison, noise, lighting and smoking are affected mainly by changes in internal layout and workstation arrangements, which can often be partly controlled by users. Recent studies show that temperature control and the provision of outdoor air are important considerations in energy efficient buildings in tropical climates (Sekhar et al., 2003, Tham, 2004). Thermal comfort and IAQ are two important aspects of IEQ that receive considerable attention by building designers and occupants (Humphreys, 2005, Huizenga et al., 2006). Satisfaction with air quality and thermal comfort is more important than satisfaction with the level of lighting or noise although the relative importance of the various aspects depends on personal preferences, types of tasks and climates (Humphreys, 2005). However, the satisfaction can be achieved by individual control such as personalized ventilation and individually controlled thermal environment, being compatible with energy efficiency and sustainability (Fanger, 2000). In addition, the combined effects of IEQ have been investigated by researchers, mainly focusing on the combined conditions of temperature and noise. Temperature and noise often interact in buildings since heating, ventilation and air-conditioning systems usually increase noise level to maintain thermal comfort requirements. Pellerin and Candas (2003, 2004) found that acoustic perception decreases when thermal environment is far from thermoneutrality. They concluded that interactions between environmental components do exist, right from perceptual level, and might explain some combined effects on cognitive performance in their studies.

Besides these physical components, psychological factors have an influence on the occupant perception in their environment. Occupant perception is the mediator of the relationships between objective measurements of distracting stimuli and subjective appraisals of social environment (Woo, 2008). Research has shown that numerous office workers considered their work environments to be thermally uncomfortable although measured conditions are within thermal comfort requirements. This occupants' evaluation demonstrates that the methodology of environmental comfort research need to include the discipline of environmental psychology in order to fully measure IEQ (de Dear, 2004). People who have greater control over their indoor environment are more tolerant of wider ranges of temperature (Leaman and Bordass, 1999). Therefore, the energy efficient way can be found without sacrificing environmental comfort; however, the combination of physical and psychological factors adds to the complexity of defining IEQ. The perception of different aspects of the indoor environment is of great importance since it influences both the behaviour and the comfort of the occupant. Moreover, perceptions and physiological symptoms are affected by psychological aspects as well as physical environment. Engvall et al. (2004) stress that perceptions and medical symptoms is not only related to the physical indoor environment, but also influenced by social and cultural impacts, organisational aspects, lifestyle, as well as personality aspects and other individual factors.

3. Environmental Comfort

3.1 Concept of environmental comfort

As the drive for energy efficient and sustainable buildings continues, there has been interest in a wider definition of comfort that might allow future energy savings. Comfort has been meaningful beyond physical relaxation across various disciplines. Occupational health studies define comfort as having some control over the psychological and the physical aspects of an environmental situation. Researchers have long argued that a key way to increase workers' psychological comfort is to provide them with some control over the space they occupy (Vischer, 2005). In the built environment context, the ASHRAE definition of comfort is "the condition of mind that expresses satisfaction with the thermal environment; it requires subjective evaluation". This clearly embraces factors beyond the physical and physiological, therefore, the physiological neutrality may be precondition of comfort (Auliciems and Szokolay, 1997). The term of environmental comfort can be defined as a concept experienced by human beings and developed in their daily interaction with the environment, which means a balanced state of physical, physiological and psychological comfort between a human being and the environment.

3.2 Environmental comfort indicators

The environmental comfort incorporates physical, physiological and psychological comfort. The physical comfort is an essential prerequisite of the environmental comfort and brings about physiological and psychological comfort (Vischer, 2005). Physical comfort is typically provided through codes, standards and norms for building safety and health and also includes building convenience such as access, service and maintenance. Traditionally, only few relevant standards of IEQ have been addressed such as ventilation (ASHRAE, 2003) and thermal comfort (ISO, 2003, ASHRAE, 2004). The standards and guidelines are based on average values for a large group occupant; however, field studies demonstrate that there are substantial numbers of dissatisfied people in many buildings, even though existing standards and guidelines meet the requirements. The reason is that the level of requirements specified in these standards are relatively low in comparison with occupant expectation (Fanger, 2000), or there could be individual differences and preferences (Melikov et al., 1994).

Physiological comfort is obtained by the human body's operating controls, however, people often feel unwell for no apparent reason when they are in a building. This symptoms can be explained as the term sick building syndrome (SBS), which is a situation in a building where more people than normal suffer from various symptoms. According to a World Health Organisation working group (WHO, 1983), the SBS is characterised by the following: eye, nose and throat irritation; a sensation of dry mucous membranes and skin; skin redness; mental fatigue; headache; a high frequency of airway infections and cough; hoarseness; wheezing, itching and non-specific symptoms such as: nasal dryness; nasal congestion (stuffy, blocked nose); nasal excretion (runny nose); pharyngeal symptoms; difficulty in concentration; and difficulty in breathing and tight chest (Seppanen et al., 1999). The symptoms tend to increase in severity with the time that people spend in the building and to improve or disappear when people are away from the building. The SBS symptoms are also associated with common illnesses and allergies, usually in a relatively mild form so that many sufferers may not see a doctor and may not take time off from work (Appleby, 1996). Therefore, the SBS symptoms can be the indicators for the measurement of physiological comfort in buildings.

Psychological comfort depends on privacy, control and crowding in the work environment. The definitions of privacy focused on a person's right to individual privacy, to be alone and away from other people in the early literature (Chapin, 1951, Bates, 1964) and then expanded beyond the definition to include a person's environment (Bellingar and Kupritz, 2006). Therefore, privacy can be defined as the regulation of interaction between individuals and/or their environmental stimuli with the ability to control it depending on the situation (Kupritz, 1998, Woo, 2008). Personal control can be one of important factors to achieve productive work environments in terms of energy savings and workers' productivity. It is vital to give occupants power of intervention to control their environment. Workers' control over the physical environment-both actual and perceived-can enhance physical health and offset the stressing effects of heavy workloads and fast work paces (Bellingar and Kupritz, 2006). Crowding is the experiential state, in which the restrictive aspects of limited space are perceived by the individuals exposed to them. Crowding appears to arise through the proximity of density with certain social and personal circumstances which sensitise the individual to the potential constraints of limited space. The particular form of one's response to crowding will be a function of the relative intensity of spatial, social and personal factors, and the degree to which they can be modified (Stokols, 1972).

4. Work Performance

The literature that attempts to link office environments and productivity largely addresses the physical environment. However, there appears to be no universally accepted means of measuring office productivity, it is a key issue how to measure productivity, especially for non-repetitive, knowledge work. As a result of this difficulty, research in office settings often resorts to a self-assessed measure of productivity which is better than no measure of productivity (Heerwagen, 2000, Haynes, 2007). The term "productivity" can be defined as the ratio of effectiveness (output) to the cost of achieving that level of effectiveness (input), on the other hand, performance is defined as behaviour with an evaluative component, thus in this study, the term "performance" is used as a broader meaning, focusing on human behaviour.

4.1 Physical environment and work performance

Research on physical environment with work performance can be categorised into two main topics: environmental comfort and office layout. However, the physical environment literature reviewed appears to lack theoretical framework even though it has shown sufficient empirical evidence. In general, studies of the IEQ in work environments including temperature, lighting, noise and existence of windows suggest that such elements of the physical environment influence employee attitudes, behaviours, satisfaction and performance (Crouch and Nimran, 1989, Veith and Gifford, 1996, Larsen et al., 1998). The improvement of IEQ results in the increase of employees' performance. Indoor environmental conditions may directly influence the performance of physical and mental work. An early study for the Westinghouse Furniture Systems Company in Buffalo, New York (BOSTI, 1982) suggests that the physical environment for office work may account for a 5-15 percent variation in employees' productivity (Clements-Croome, 2000). Recent studies constantly show that improvement of IEQ increases office productivity (Vischer, 1989, Sundstrom et al., 1994, Fisk and Rosenfeld, 1997, Veitch and Newsham, 1998, Heerwagen, 2000, Leaman and Bordass, 2001, Wyon, 2004, Aye et al., 2005) Therefore, the general conclusion could be that people do more work on average work day if they are physically comfortable (Clements-Croome, 2000).

In the early literature, two characteristics of the indoor environment influencing the performance seem dominated: thermal conditions and lighting (Sundstrom,1986, Lorsch and Abdou, 1993, Fisk and Rosenfeld, 1997). Bedford (1949) concluded that there was a close relationship between the external temperature and the output of workers: Decreasing performance is partially attributable to heat. Kamon (1978) shows that heat can cause lethargy which not only increase the rate of accidents but also seriously affect productivity. Lighting was another important factor in early work environments, specially in manufacturing industry, since it seems to affect directly the work output. Thus, the brightness of lighting was most concerned and any other than visibility was not questioned. Performance increases with added light, however, each increment in brightness of light brings less benefit and the benefits are smallest for the least difficult task (Sundstrom, 1986). However, the industrial structure has changed from manufacturing industry to service industry, and even further to knowledge based work with the exceptional development of the information technologies. Accordingly, the term “work” has also changed and the meaning of office worker can be defined as a person who performs their tasks using office information technologies, sharing their knowledge with their colleagues. Approximately 80 percent of all tasks performed in an office are visual task by using a wide range of visual display terminals. Therefore, the brightness of lighting has become a less important factor of IEQ, but overall visual comfort including light quality eliminating discomfort and natural light and view enhancing moods and reducing work stress, has been weighed instead.

Apart from the direct connection between worker performance and IEQ, there is also the evidence of association between ventilation rates, IAQ, SBS symptoms and employee performance. Researchers have shown that productivity in the office environment is sensitive to poor IAQ, and this is linked to SBS symptoms (Abdou and Lorsch, 1994, Holcomb and Pedelty, 1994). Furthermore, perceived air quality, SBS symptoms and performance of office work were studied in a real office space at three levels of air temperature and humidity and two levels of ventilation rate. Performance of office work was not significantly affected by indoor air temperature and humidity. However, several SBS symptoms were alleviated when the subjects worked at low levels of air temperature and humidity, which implies that a longer term exposure to low indoor air temperature and humidity might help to improve the performance of office work (Fang et al., 2004).

The literature relating to the office layout has been debated on open-plan verses private offices, mainly focusing on the matching of the office environment to the work processes. It could be argued that the open-plan office has led to cost reduction and communication increase, however, there are more distractions in open-plan offices than in conventional private closed offices (Brookes and Kaplan, 1972, Canter, 1972, Hedge, 1982). Noise is the major source of distraction for employees in relation to open-plan office debates. It was found that noise coming from telephones, conversations, ventilation system, and office equipments was related to distraction and openness. Also, the potential tension that can exist in the office environment between individual work and group work is established. If the office environment is to act as a conduit for knowledge creation, and knowledge transfer, then offices need to allow both collaborative work and individual work to coexist without causing conflict between the two (Haynes, 2007).

4.2 Psychological effects and work performance

The difficulty of research exists in this area because of the complexity of defining and measuring human performance in real-world environments. There are also many other factors influencing performance beyond the physical factors, specially naturalistic features such as daylight, views and natural or urban settings with trees can bring about positive effects on employee performance. The main benefits of natural light are psychological improvements such as increasing comfort levels and reducing stress. They have broad effects on physical health, mood, behaviour and productivity, regardless of an individual’s gender, position or task. Reduced stress and a great level of comfort affect both productivity and performance. A study of daylight in schools shows that students with the most daylight in their classrooms progressed 20 to 26 percent faster on math and reading tests and were found to have 7 to 18 percent higher scores than students in rooms with the least daylight (Heschong, 2002). There is also a sizeable and growing evidence to suggest that giving office workers a view outdoors, especially a view with natural elements, is beneficial. In Biophilia, Wilson (1984) suggests that natural views play such a powerful role in the well-being of humans since the human brain evolved in a natural setting, where many significant factors played into survival. Research has shown that employees with a natural view express less job pressure and more job satisfaction, and recover from stressful situations more quickly (Bouberiki et al., 1991, Ulrich et al., 1991, Heerwagen and Wise, 1998, Leather et al., 1998, Heerwagen, 2000). Leather et al. (1998) determined that external views of natural settings helped to buffer the negative impact of job stress. Further, Stone and Irvine (1993) found that the presence of windows did not affect performance but appeared to support job task demand.

5. Comfort-Performance Evaluation Model

The following environmental comfort-performance evaluation model can be proposed based on the relevant literature. People judge their environments with subjective averaging process in order to reach their overall assessment. In this process, people judge their indoor environments according to how they feel in their environments: whether the temperature is warm or the air is fresh, not according to measuring temperature or carbon dioxide(CO_2) levels.

The theoretical framework of the environmental comfort-performance evaluation model (Figure 1) is based on the theories of environmental psychology, specially derived from Lewin's equation (1951). In principle, B=f(PE); behaviour(B) was viewed as a joint function of personal factors(P) and the perceived environment(E). In this formula, the person and the environment are interdependent variables. In the comfort-performance evaluation process, the physical comfort affects directly overall comfort and work performance as well as physiological and psychological comfort. Brunswik's lens theory (1956) can be adopted in this process, it is describing individuals' perceptual processes when making judgement in response to the environment. Brunswik emphasized the importance of the subjective or perceived environment as a determinant of behaviour and argued that complex stimuli are focused into a single perception of the environment as though through a lens.

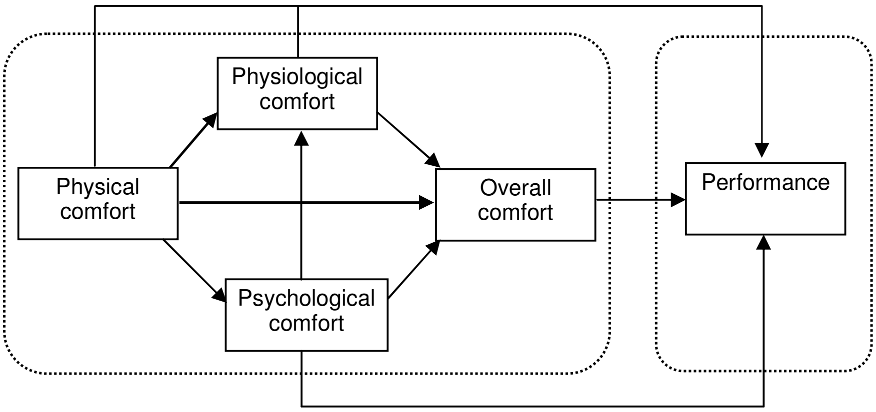

Figure 1 Comfort-Performance Evaluation Model: Theoretical Framework

Based on the literature and theoretical considerations, the following hypotheses are proposed:

H1: That thermal comfort and IAQ are dominant elements when occupants evaluate overall environmental comfort

H2: That the improvement of occupant comfort has positive effects on employees' performance

- That physical, physiological and overall environmental comfort influence employees' performance at individual level
- That psychological comfort affects employees' performance at interpersonal level

H3: That psychological factors have positive effects on occupant comfort, thus improving performance in sustainable or green buildings

6. Conclusion

In conclusion, this study attempts to examine the variables predicting environmental comfort and performance in work environments and develop the theoretical framework of the environmental comfort-performance evaluation model. The environmental comfort incorporates physical, physiological and psychological comfort, it is a concept experienced by human beings and developed in their daily interaction with the environment. Therefore, a holistic approach to understanding the issue of environmental comfort and human performance should be required to find out the way how people feel or react in the work environment. It can be an energy efficient way without sacrificing environmental comfort in buildings, thus increasing the indirect benefit from occupants' health, comfort and productivity.

Based on the literature, it could be hypothesised that there are dominant IEQ components such as thermal comfort and IAQ, thus these factors have stronger effects on overall environmental comfort than other factors. However, psychological comfort could influence occupants' comfort and performance, specially in green or sustainable buildings with more natural features. The present paper only presents a first step to evaluate buildings with post occupancy evaluation method which can be used to systematically examine building performance. Further research will be carried out to make a systematic tool based on the theoretical framework and test the validity of this comfort-performance evaluation model in field study.

Summary

The Victorian Smart Water Fund, the Department of Education and Early Childhood Development Victoria, GHD and other parties involved have funded a trial of 6 dry composting toilets and 2 waterless urinals at a new secondary school at Maryborough in Victoria. The installation was commissioned in April 2007 and results to date indicate a reasonable level of acceptance by students, good performance in terms of no odour, no fly nuisance, no operational difficulties (despite significant vandalism) and reasonably low energy use for ventilation. The paper presents data on ventilation, temperature records, energy use and quantities of residues that is difficult to find elsewhere.

To date usage has been lower than expected and quantities of urine and compost have been insufficient to undertake the proposed trial use of these materials in agriculture.

Whilst the installation cost (around 28 000 AUD/fixture in this case but potentially around 10 000 AUD/fixture) is considerably more than water flush toilets (around 4 000 AUD/fixture), it is concluded that the overall economics of dry sanitation will become favourable in a situation where water and fertiliser costs are likely to increase faster than other costs. Wider application of this sanitation approach is justified.

1. Previous Conclusions on the Feasibility of Urine-Separating Dry Composting Toilets

The UN has declared 2008 the International Year of Sanitation and there is an urgent need to assist the 2.6 billion people in the world today who lack adequate sanitation. With increasing population, declining rainfall in many areas and the need to reduce fossil fuel use, waterless sanitation systems that also recover nutrients offer a more ecologically sustainable solution than water-flushed toilets. Such systems are probably the only affordable option for those lacking sanitation and they have significant advantages in locations where there is already sewerage. Figure 1 shows the proportions of key components of domestic sewage that are contributed by each resident from the toilet. In the case of nitrogen and phosphorus, the majority of the contribution comes from urine.

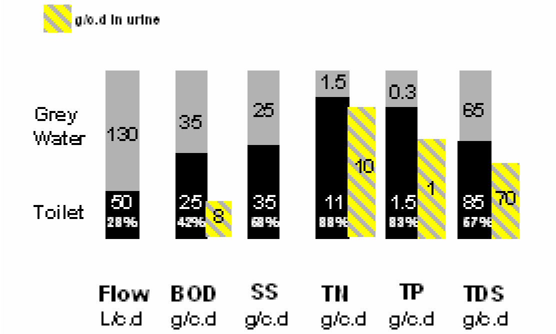

Figure 1 Load Components from Sewage & Grey Water.

There has been considerable research around the world into both urine separation and agricultural use and into composting toilets. A recent report for the Smart Water Fund (an initiative of the Victorian Government and the Victorian water industry supporting the development of innovative water conservation, water recycling and sustainable biosolids solutions) (GHD, 2003) reviewed much of this work and concluded that advantages of a dry sanitation system include:

- up to about 19% of an average household water usage (around 18 kL/c.yr saved out of 96 kL/c.yr currently used by the average Melbourne household) and up to about 28% of domestic sewage discharge would be avoided by eliminating toilet flushing.

- over 80% of the nitrogen, phosphorus and potassium, around 55% of the total salts and 25% of the BOD discharged by a household to sewer can be recovered in a transportable, stabilised and reusable form with low pathogen content.
- other technologies for reducing water use such as dual, low and vacuum flush toilets and the use of recycled grey water or roof water for flushing do not have the advantage of reducing pollutant, salt and nutrient loads to sewer.
- odour is generally not found in the toilet room because of the required ventilation of dry toilets and the overall health risks to householders and sanitation workers are assessed as being no higher than with conventional sewerage.

The report also concluded that the cost would be higher than providing water flush toilets (an additional 3 000 AUD to 6 000 AUD per fixture in an existing residential apartment block) due to the on-site equipment requirements and building construction that allows gravity fall of solids into the composters. These costs could be reduced to 1 500 AUD per fixture in new dense urban development by initially designing buildings for dry sanitation (GHD, 2003). However, the cost of dry sanitation were estimated to be comparable with conventional sanitation if overall community costs for the sewerage system were included, since dry on-site systems avoid (or reduce the size and treatment capacity required in) a municipal sewerage system.

Interest from parent representatives involved in the design of a new school in Maryborough, Victoria, spurred the Victorian Department of Education and Early Childhood Development to commission GHD to undertake a feasibility study of providing urine-separating composting toilets in schools (GHD, 2005).

This feasibility study included a comprehensive risk assessment, which concluded that only a small number of additional risks were identified for urine-separating composting toilets compared to water-flushed toilets. Of these, the health risks related to flies gaining access to the toilets were seen as potentially most significant, however there was insufficient information available to quantify this risk and monitoring of flies was identified as a key need for the trial. The risk assessment also addressed misuse and vandalism, concluding that whilst more significant for urine-separating composting toilets, these risks would be manageable. Overall it was concluded that the use of urine-separating composting toilets would not present a higher overall risk than having an on-site treatment system for conventional water-flushed toilets.

The feasibility study's final conclusion was that a trial was warranted, since there is limited data and experience from operating facilities that include both urine separation and composting of faecal matter and toilet paper. The Department of Education and Training agreed to a trial installation at the Maryborough Education Centre. A successful application was made to the Smart Water Fund for assistance with funding of this trial with other contributions coming from the Department, GHD, Oaten Stanistreet Architects and Environment Equipment Pty Ltd, the suppliers of Rotaloo® composting toilets.

2. Description of the Maryborough Education Centre Installation and Operating Experience

2.1 The Maryborough Education Centre

The secondary section of the new Maryborough Education Centre caters for about 1 000 students and contains five student toilet blocks plus staff toilets. .

Figure 2 The urine-separating dry composting toilet block and greenhouse enclosure.

Figure 3 From left: composters, leachate storage tank and urine tank.

Figure 4 One of the urine-separating pedestals.

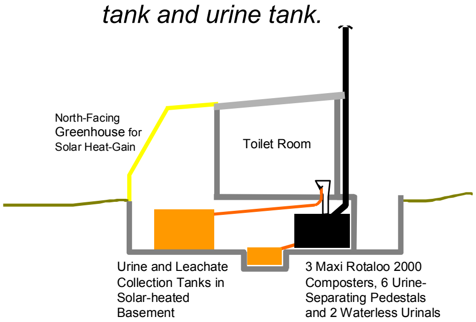

Figure 5 Cross section of the toilets.

Figure 2 shows the toilet block and its greenhouse-type west-facing structure. The three pipes pointing up from the ground on the right are from an in-ground biofilter, which removes odour from the urine and leachate tank vents. Figure 3 shows the basement below the toilet rooms with three composters on the left, the leachate tank to collect liquid from the composters in the centre (in the floor) and the edge of the separated urine tank on the far right. Figure 4 shows a urine separating pedestals. Figure 5 shows a cross section of the installation

2.2 Equipment and Capacity

The three Rotaloo® Maxi 2000 composting toilets were supplied by Environment Equipment Pty Ltd. Each has two ceramic urine-separating pedestals and eight 50 kg capacity HDPE compost bins on a carrousel within the HDPE composting container. The female toilet has four pedestals and the male toilet has two pedestals and two waterless urinals. Urine that is separated flows via PVC pipes to a 4.3 kL HDPE urine holding tank. Unseparated urine drains through the holes in the bottom of the composting bins on the carrousel, collects in the base of the composters and flows to a 2.7 kL leachate tank. The composters and tanks were sized based on the assumption that approximately 200 students over normal school hours and that, whilst at school, they would contribute 30 percent of published daily urine and faecal loads from adults. It was estimated it would take 0.5 to 1 year to fill the urine and leachate tanks and around 1 to 2 years to fill all 24 compost bins. Table 1 shows the estimated loads from this usage.

Table 1 Estimated Loads from 200 Users

Component	Yearly Loads kg/yr (based on 200 users on school days)			
	Compost	Clean Urine	Leachate	Total
Total Nitrogen	20	60	30	110
Total Phosphorus	10	10	0	20
Potasium	10	10	0	20
BOD	400	80	40	260
Organic Carbon	200	40	20	260
Total Salts	300	400	200	900
Calcium	10	0	0	10
Magnesium	0	0	1	1
Sodium"	10	20	10	40
Total Solids	500	400	200	1100
Water	200	7 400	3 500	11 100
Total Mass	700	7 800	3 700	12 200

These loads equate to 20 g of faecal matter and toilet paper per day and 320 mL of urine and leachate per day per user.

3. Experience and Quantitative Results to Date

3.1 Approvals

Current guidelines and regulations in Victoria are not established to address either urine separation or off-site use of residues on agricultural land surfaces. This meant the approval process for the installation involved several steps. Health risks were extensively researched and presented, along with details on the proposed agricultural trial and monitoring, to both the Victorian Environment Protection Authority (EPA) and the municipal council. The EPA advised that the composter type proposed was on its approved list, that this approval extended to use in schools and that it would have no objection to the trial, provided a number of conditions were met: the agricultural use of residues complied with published requirements for application of biosolids; the Chief Veterinary Officer of Department of Primary Industries had no objections; and the municipal council approved the installation and agricultural use on the nominated farm. Council required that a formal application and fee be submitted as for a septic tank permit application, although there are few similarities with a septic tank. Council also had concerns about the agricultural trial. The farmer who agreed to accept the residues for trial application was concerned about the effect on his ability to sell sheep, as farmers must complete a statutory declaration to confirm the sheep they are selling have not grazed on contaminated pastures (this largely relates to pesticide application rather than the materials from the trial).

Approvals from all stakeholders were eventually gained but the experience confirmed the feasibility study conclusion that regulation in Victoria will need modification to more appropriately regulate such installations.

3.2 Construction Costs

Table 2 sets out the estimated and actual costs for the installation and the capital cost per fixture, disregarding costs which are equivalent for composting and conventional toilets (eg toilet room, handwash basins). The actual costs do not include costs of monitoring equipment purchased purely for the trial and water metering to the hand-wash basins and to another toilet block in the school to allow comparison of water use (which added 27 000 AUD to the capital cost).

Table 2 Estimated and Actual Capital Costs (AUD)

	Urine-Separating Composting Toilets			Conventional Toilet Option (20 fixtures)
	Estimate (20 fixtures)	Actual (8 fixtures)	Estimated Minimum (20 fixtures)	
Total Capital Cost	318 000	226 000	211 000	81 400
Capital Cost per Fixture	15 900	28 000	10 600	4 000

Thus, prior to construction, it was estimated that the urine-separating composting toilets would cost around 12 000 AUD more per fixture than conventional water-flushed toilets but that, if the building arrangement had been different, this difference could reduce to around 6 600 AUD. The cost of the Rotaloos, pedestals and urinals is understood to have been only around 10 000 AUD of the 226 000 AUD actual cost.

The actual capital costs, which include an allowance of 10% for design and project management costs, were higher than estimated, 28 000 AUD/fixture or 24 000 AUD/fixture more than conventional toilets, for a number of reasons. First, the building was constructed as a slab-on-ground structure on rock. The cost of constructing and providing drainage to the basement for the composters and tanks was significant and could have been reduced if the building was constructed on sloping ground on piers, allowing sufficient under-floor space. This would have been feasible on the site but design of the buildings had progressed significantly before the trial was commissioned. Secondly, a contractor was engaged before the design was complete, which meant significant contract variations were required to complete the works. In addition, the urine and leachate tanks were custom-built by the contractor rather than using standard plastic tanks or bladders. Thirdly, the installation includes a significant number of items installed specifically for the trial, including hot and cold water hand-washing facilities in the basement, plumbing that allows later conversion to water-flush toilets if required, a natural gas supply in case supplementary heating is required and additional electrical supply for monitoring equipment. Experience to date is that the greenhouse could have been simplified and made smaller and a smaller basement could have been built if the urine and leachate tanks had been constructed below the ground outside the building. Overall, it is considered that the original estimate of the minimum capital cost or around 84 000 AUD for 7 fixtures should be achievable.

It is concluded that urine-separating composting toilets can be installed for an additional cost per fixture of somewhere between 6 000 AUD and 10 000 AUD per fixture over that of water flush toilets and possibly less in large installations with suitable building design.

3.3 User Training and Surveys

In February 2007, short information sessions were run for students and staff at the toilets during orientation tours of the new school buildings. The purpose of the information sessions and accompanying display was to explain the objectives of the trial, give insight into the installation and emphasise the importance of getting a significant level of use of the toilets. The need to keep toilet lids closed was also stressed.

Further training was undertaken with Year 8 students and staff to coincide with their Term 3 project focusing on "Sustainability in the Home". Feedback from this session was positive and the student responses indicated that a much better understanding of the urine-separating dry composting toilet installation had been gained. Additional presentations to most year levels were completed in June 2008.

User surveys have provided feedback about the level of knowledge of the trial and acceptance of the composting toilets and urine separation in general.

The first survey (distributed in March 2007 prior to any training or usage of the toilets) found that: (1) students did not have very good knowledge of and had rarely used composting toilets, urine separating systems or waterless urinals; (2) students were somewhat deterred or unsure if they would be deterred from using the facility once they knew the toilets were unconventional; and (3) staff had more knowledge and experience than students of composting toilets and waterless urinals and were generally more open to their use once they knew the toilets were unconventional.

The second survey (distributed in June 2008 after the further training had been conducted and the toilets had been in use for 15 months) found that: (1) usage of the toilets had been low, with key reasons for low usage identified as their remote location, inconsistency in being open and available for use and the fact that the toilets attract students who smoke; (2) students knew the toilets existed but did not feel they had been provided with enough information about them, although they were aware of the environmental benefits associated; and (3) students who had used the toilets found the experience to be surprisingly positive.

3.4 Operating History

The new school was opened and the installation was commissioned in April 2007 on the first day of the second school term. Since commissioning the male toilets have been open for a total of over 160 days and the female toilets for a total of over 125 days to July 2008.

There have been several periods when the toilets have been closed. A seven week closure of both male and female toilets occurred in November 2007, when heavy rain caused the leachate tank to float in the basement floor, necessitating repairs. Other closures have been in response to a few students smoking in the toilets and dropping cigarette butts and lighted paper down the toilet pedestals. Mostly, the lighted material has not caused any damage but on one occasion, the contents of a compost bin smoldered and generated significant smoke. This risk was not identified in the original risk assessment and has been exacerbated by the low use leading to drying out of the compost bin contents. Since identification of the risk, water is added daily to each of the six operating compost bins, in summer at a rate of 1.5 L/bin.day.

Throughout the trial to date there have been no complaints about flies and no complaints about odour during school hours. Regular checks and recoding have not observed flies in or emerging from the composters or pedestals or congregating in the toilet rooms. This was contrary to expectations since the author's experience is that development of Drisophila *melanogaster* (fruit flies) in compost is very common and larger flies are also attracted.

Users have not reported any toilet odour within the toilet rooms. The only toilet odour observed has been noted by the cleaners when timers controlling the ventilation fans have failed, leading to no ventilation flow in the period before school when the cleaners open the toilets. The urine and leachate tanks are sealed to prevent odour release. The urine tank inlet pipe and tank overflow pipes are equipped with a water seal. There are air vents from both tanks which discharge into the base of an odour control biofilter. Some odour has been noticed by the authors from the roof vents of the composters on cold mornings around the outside of the toilets but this has not been noted during school hours or led to complaints. There is minimal odour release when the composters are opened to inspect bins as the fans remove most of the odourous air. The urine and leachate in the holding tanks has a strong amine/ammonia odour but this is only noted when the inspection hatches are open, not when 50 mm caps are removed to take depth measurements.

Usage of the toilets has been much lower than the expected 200 students per day. The quantities of material collected (a total of around 500 L of urine and leachate and 22 kg of faecal matter and paper) have been insufficient to carry out the proposed agricultural trial of use of residues. Data on actual versus expected urine volume suggests that there has been an average only around seven uses per day (male and female combined). Data on the mass of faecal matter and paper collected suggests that there has also been an average of less than 3 uses per day. This is based on the number of days the toilets have been open and assumes that each urination contributes 0.3 L and each defecation contributes 50 g of semi-dry compost (including toilet paper) containing 30% moisture. Testing has yet to be completed to determine the actual water content of compost.

3.5 Useful Data Obtained

3.5.1 Air handling and odour control

Each composter has a 19 W mains-powered educt fan which exhausts air to a vent above the roof line. These three fans are controlled by time clocks to limit energy consumption and also to prevent drawing cold night air into the composters. Up to May 2008 they were switched on at 5 am and turned off at 6 pm with three 15 minute operations during the night. This was sufficient to prevent toilet odour within the toilet rooms but timer failures lead to some odour incidents so fans have been left on with no odour reported since.

The educt fans maintain a slight negative pressure within each composter, which draws air from an inlet as well as down through the pedestal when the lid is open. The latter air flow, the velocity of which has been measured to be around 0.2 m/s across the cross section at the level of the seat when the lid of one of the two pedestals is open, ensures that no odour from the composter is released into the toilet room. The volumetric flow of air down an open pan is approximately 0.02 m^3/s, which is around 50% to 60% of the 0.03 to 0.05 m^3/s of air flow induced by each composter educt fan. The remainder of the air flow into each composter comes from a duct system designed to draw warm air from the greenhouse roof. Some of this warmed air is transferred by a solar-powered fan and heating panel from the top of the greenhouse. This flow has been measured as up to 0.02 m^3/s or about 20% of the air total educt air flow from the three composters. The remainder of the air enters the composter via leaks and the pedestals. There is an additional mains-operated fan which draws air from the top of the greenhouse and discharges it close to the composters. This warmed air transfer fan is operated from around 8 am to 4:30 pm.

3.5.2 Monitoring program and temperature and relative humidity monitoring results to date

The following measurements are being taken as part of the project's ongoing monitoring program:

- compost, urine and leachate temperature,
- air temperature, relative humidity and velocity in various locations including each Rotaloo exhaust, air distribution box, greenhouse, solar heater inlet and outlet,
- volume and specific gravity of leachate and urine,
- mass of compost,
- water flow into the site, to the trial toilets and to a similar conventional toilet block.

Water use in the hand basins has averaged around 12 L per operating day, which suggests about 2 L/use. However there was a period of unusually high water use. The added water has amounted to a further 6 to 9 L/d. It should be noted that if flush toilets were used, the expected water usage would be of the order of 30 to 50 L/d at the current usage levels.

Figures 6 and 7 provide an example of the temperature and relative humidity results obtained from the ongoing monitoring to date covering an 8 month period. Figure 6 shows no evidence of heating due to aerobic composting. This confirms the observation that the material is desiccating rather than composting. Figure 7 shows the same diurnal temperature variations in air leaving a composter and also indicates that, even with the greenhouse in place, it is not possible to get the air temperature up to a desirable in winter to assist composting. Nor has it been possible to keep the stored urine and leachate at 20°C, which has been shown to provide rapid die off of pathogens. Trial of a heating system is now in progress.

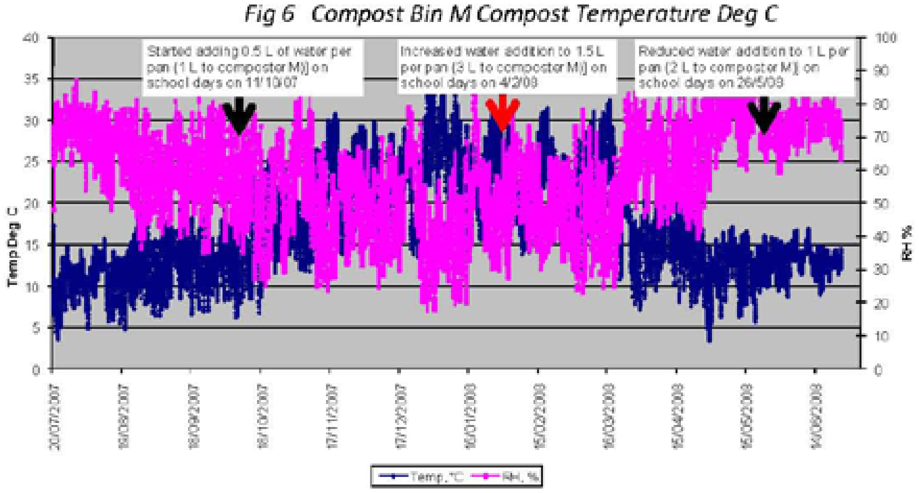

Figure 7 Male Rotaloo (M) Exit Air Temperature and Relative Humidity

3.6 Cleaning, Aesthetics, Acceptance

The operating and maintenance program was designed to ensure the toilets were pleasant and easy to keep clean. The cleaners, who also undertake some of the monitoring, keep the toilet pedestals and rooms very clean without adding water to the pedestals by using a 1:5 vinegar:water solution to wipe over seats and pedestal surfaces. The waterless urinals and other surfaces in the toilets are cleaned in a similar way. It has not yet been necessary to clean the drop pipes below the pedestals and these appear to remain clean. The cleanliness of the pedestals has been excellent with only occasional observation of faecal smears, no more and probably less than in public water-flushed toilets. This is an important factor in dry toilets, as inadequate design and inadequate cleaning results in unpleasant facilities and discourages use. However, the low usage to date means that this aspect has not been fully tested.

The architects were also requested to design the lighting so that it did not shine down the pedestals in such a way that the solids heap was visible. This objective was achieved successfully and it is difficult for users to see anything at the base of the composter drop ducts.

Further user surveys are necessary before reaching conclusions on acceptance. Reasons for low usage are not generally the fact that the toilets are non-conventional; however a minority of students have said that urine-separating composting toilets are unacceptable to them and they would not use them.

3.7 Health Risks

The low usage has delayed proposed testing of the compost, urine and leachate for indicators of pathogen presence. However, there has been no evidence of flies gaining access to the compost bins or of large fly numbers in the toilet rooms. To date, the conclusion from the risk assessment, that there was no significant risk to health, is supported by experience.

3.8 Student Behaviour

The toilet block is located at the end of a classroom pod and is hidden from view from most walkways and staffed office areas around the school. The nearest alternative toilet block has a tiled floor rather than the cheaper painted concrete in the trial toilets. The location is not ideal and there have been a number of instances of problem behavior. The only damage caused to the toilet equipment has been one broken seat and a fire that was started within one of the compost bins by dropping lit paper. It does not appear that dropping of cigarette butts into the toilets has caused the compost mass to burn. Further efforts are being made to encourage appropriate behavior and increased use of the toilets.

The conclusion from this experience is that location, design detailing, introduction of students to the toilets and ongoing discipline are major factors in the success of such a trial or permanent installation in a school environment.

4. Key Issues and Further Investigations Required

4.1 Composting versus Desiccation of Solids

The faecal matter and compost collected to date has shown no sign, either from appearance or temperature measurements, of composting. This is thought to be due to a combination of the low usage and drying by air flow. Urine separation does mean that the solid material will remain much drier than in standard composting toilets and it appears that there may be a need to add water to aid in composting. Addition of some water to maintain an non-flamable compost is desirable in any case. However, until usage increases it is not likely that the extent of composting can be fully investigated. Suppliers of continuous composters claim that the batch composting process such as that in the Rotaloo® leads to drying out of the solids once bins are moved away from below the pedestals. The indications from this trial is that in a school environment, the process may well be more desiccation of solids than composting.

4.2 Health and Aesthetic Issues with Residues

Once sufficient volume of urine, leachate and faecal matter/toilet paper is available, comprehensive physical, chemical and biological testing is planned. A key focus of this will be to check for faecal microorganism survival in both the solids and liquids and how this may vary with storage temperatures of the liquids and the storage/composting history of the solids. GHD (2003) reviewed the available literature on pathogen survival in separated urine and compost and concluded materials that could be safely used for surface application on agricultural land if the liquids were stored for 6 months or more at at least 20°C. Survival of pathogens in compost is dependent on temperature reached and since the data to date shows no elevation above air temperature, it must be concluded that pathogens are likely to have survived and the materials therefore will need further treatment before use on land.

4.3 Misuse

While the design of the facility has allowed it to operate despite some misuse, potential improvements have been identified: (1) toilets would ideally be located in areas of greater foot traffic, especially staff traffic, so they do not become a refuge for bad behaviour; (2) an automated wetting system in the compost bins using a simple garden watering spray system would be prudent, assuming that the desiccation that has been observed continues with increased usage. Alternatively or additionally, a smoke detector and spray system could be installed within each composter to guard against fire. Consideration was given to installing tobacco smoke detectors inside the toilets to detect smoker activity and alarm this locally and in a staff room. It was difficult to find suitable devices that would detect tobacco smoke; (3) the waterless urinals have a loose-fitting ceramic disk over the outlet. These discs have been occasionally been removed and dropped into the composters and clearly such loose items are undesirable; (4) signage needs to be largely out of reach and firmly attached; (5) solid padlocks are needed to resist vandalism and unauthorised entry to the equipment. Bad behavior by a few students can create an unpleasant and threatening environment in and around the toilets and that this contributes to low usage.

4.4 User Attitude and Acceptance

A further user survey will be carried out during the trial to gauge changes in attitudes and acceptance. The results of these surveys will be reported in the project report to the Smart Water Fund, which will be available on the Smart Water Fund website, probably during 2009.

4.5 Energy Use for Composting Toilets Compared to Conventional Sewerage

Conventional sewerage may be more energy-efficient than dry composting toilets installed with mains-powered ventilation fans (the current practice in most installations and the predominant method of ventilation at the Maryborough installation) (GHD, 2003). As such, energy use is being monitored during the trial and will be considered as part of an assessment of overall benefit. The need for supplementary heating in winter is being investigated and it is yet to be determined if composting (as against desiccation) ever takes place at the Maryborough installation. The need for supplementary heating in winter is being investigated and it is yet to be determined if composting (as against desiccation) ever takes place at the Maryborough installation.

Table 3 compares estimated energy use per capita of conventional sewerage with a composting toilet/grey water sewerage option for an urban area of a large city. The range for conventional sewerage relates to whether the sewage treatment plant generates some of its own energy demand from biogas or not. The range for composting toilets results from assumptions on supplemental heating and ventilation energy use.

Table 3 Estimates of Energy and Greenhouse Parameters for Sanitation Options

Energy or Greenhouse Measure	Conventional Sewerage (WC waste and flushing water)	Composting Toilets and Grey Water Sewerage
TOTAL MJ/capita.yr	248 - 540	171 - 529
Lifetime Emissions (50 years) tonnes CO_2e/capita	1.0 – 2.1	0.7 - 2.1

If mains-powered ventilation and supplementary heating is necessary to make the composting process and installation work effectively, composting toilet systems would use more energy than conventional sewerage with some energy generation from biogas at the sewage treatment plant. If ventilation fan energy is derived from solar power and if waste heat from the apartment or passive solar heat input is sufficient to keep the compost warm, then a sanitation system based on dry composting toilets with urine separation, trucking of residues up to 50 km (a 100 km round trip) and discharge of grey water to sewer will use less mains and non-renewable energy overall than a conventional system where the sewage treatment plant does not generate any of its own energy. This situation is typical of outlying areas with their own treatment plants. Further, the evaluation of energy use makes allowance for embodied energy in fertiliser saved by use of compost and urine on land.

The 19 W Rotaloo educt vent fans used on each of the composters at Maryborough were operated for 13.75 hrs per day, which was sufficient. There is one additional fan operated for 8.5 hours per day, which is used to move warm air from the top of the greenhouse down to the composter space. Thus total energy use for fans is estimated to be 290 kW.hr/yr (assuming 365 days of operation per year). If the units were installed in residential apartments they could service a population of 20 to 30 persons so the estimated annual energy use for the fans at Maryborough would be of the order of 10 kW.hr/capita.yr or 36 MJ/capita.yr which is within the assumptions used in Table 3. A solar-powered fan is used to force warmed air from the greenhouse via a heating chamber into the air distribution box for the three Rotaloos. If similar solar powered fans were used on the educt vents then fan energy use could be reduced significantly although in a normal residential situation some overnight operation would be required to control indoor odour.

5. Conclusions

Urine-separating composting toilets can easily be kept clean and properly controlled ventilation should eliminate smell from the toilet room. A biofilter on vents from urine/leachate holding tanks is recommended to remove all odour from this source. Bladders instead of tanks would avoid the need for vents.

It is feasible to turn ventilation fans off overnight if toilets are not open all the time, provided they are turned on at least 2 to 3 hours before the first use.

Trial in a residential situation would be desirable as the intermittent and low use experienced in a school limits the information that can be obtained and presents some additional challenges related to misuse.

The estimates of compost and urine/leachate volumes used in the design are probably more than adequate.

It is probable that use of rotary type batch composters coupled with urine separation will mean that desiccation rather than composting is the main mode of operation and, if so, the survival of pathogens in desiccated solids will need further investigation. An alternative may be to automatically add water to maintain moisture content in the solids closer to the optimum for composting.

For a greenhouse to effectively capture heat and keep the composters and storage tanks above the target of 20°C, it would be necessary to insulate the walls of the building (but still allow sun penetration), seal doors and other gaps to minimise drafts, and probably insulate the composters themselves. In addition, it may be necessary to reduce ventilation rates, particularly when temperature of the inlet air is less than 20°C. If desiccation is the mode of operation there would be no need for a greenhouse structure.

Urine-separating composting or desiccating toilets offer a more ecologically sustainable sanitation option than water-flush toilets and can be successfully used in schools.

Whilst the capital cost of this trial installation was very high compared to conventional water-flush toilets (an additional 24 000 AUD/fixture), a previous conclusion that urine-separating dry composting toilets can be installed for under 10 000 AUD/fixture is probably still valid. In order to minimise facility cost, the building should preferably be on sloping land and on piers or if slab on ground, with a basement design that minimises cost and uses tanks for urine and leachate that can be buried adjacent to the building.

With increasing costs of water and fertiliser, there should be no cost disadvantage. There may be cost advantages if wide-scale use of such toilets is adopted in future in school, public facility, commercial and residential settings. Such toilets already are seeing wide application in developing countries that do not have existing water-borne sewerage systems.

Keywords: smart design, bioclimatic design, climate, energy, designer's manual

Summary

The seeming abundance of high-quality energy resources and easy access to inexpensive products and labour from anywhere have made many parts in the world dependent on regions elsewhere. The ecological footprint of richer countries demonstrates how severely this process has developed. As a result of this and of economic prosperity, man has often lost the ingenuity to make optimal use of features of the local environment.

Smart and bioclimatic design encompasses an approach that deploys local characteristics into the design of buildings and urban plans. These local characteristics refer to natural circumstances (the climate, seasonal changes, variation in the weather, diurnal differences, geomorphology, etc.) yet also to man-made interventions (such as the landscape, cultural, historical and technical features, and the built surroundings). Especially, a thorough analysis of climatic conditions and the intended use of a building or urban area can lay the foundation for a smart and bioclimatic design that uses much less energy and satisfies better the needs of users.

The paper will discuss the different definitions and theory of smart design and bioclimatic design. It will present a step-by-step approach to smart and bioclimatic urban environments and buildings. This is based on years of study and teaching to students of architecture, urbanism and building technology. Moreover, the students themselves have contributed to this knowledge through an academic subject, for which they were asked to write a designer's manual on smart and bioclimatic design in general or on a specific part of it.

1. Introduction

1.1 Globalism and interdependence

There once was a time when individuals and communities had to take care of themselves on the basis of locally available or locally grown resources. Trade, first with neighbouring communities, later with settlements farther off or indirectly, through intermediate merchants, enabled growth in wealth and luxury and substitution of local provision by supply from elsewhere. This made it possible for essential resources to rely on other regions whilst providing these regions with resources they lacked. Through the centuries this has brought mankind to a thriving global economy. However, it has also given rich countries an ecological footprint many times their own area, imposed on developing regions that thereby fall behind.

Since the industrial revolution the development as described in particular affected industrial products and the fossil fuels needed for them. The world has become increasingly dependent on high-quality energy resources: natural oil and gas, coal and nuclear power. With certain reserves in depletion man is putting a lot of effort to, firstly, reduce the demand for energy and, secondly, prolongation of the provision of finite energy resources. How successful this strategy may be, it will eventually prove to be the stay of inevitable execution.

And we should not forget that the development described, supported by ineffective movements of goods across the world, has been facilitated by economic prosperity on the side of rich countries. The downfall of this prosperity would demonstrate the mutual dependence of various regions in the world and it would necessitate severe measures.

1.2 The Titanic strategy or a reconsideration of local potentials

We are at the crossroads of a principal choice. Are we going to prolong our current system, confident of new technology to win the very last reserves, until we eventually are stuck with fossil fuel quantities insufficient to produce the equipment and infrastructure for sustainable energy (the "the orchestra plays on while the Titanic sinks" strategy), or are we going to head in a different direction? Regardless of the impact on the energy market and global climate, the Titanic strategy will lead to unavailability of oil for the production of irreplaceable synthetics and other valuable purposes.

Shortage often encourages ingenuity to provide oneself with limited resources. Apart from interdependence, prosperity has made many people lose the ingenuity to make optimal use of local features. Facing the problems of fossil energy depletion, a different strategy therefore would be a reconsideration of the potentials of the regional and local environment before a demand from sources from elsewhere. This approach can be applied to different scales, of which the building scale can be described by smart and bioclimatic design.

1.3 Smart and bioclimatic design, definitions

Smart and bioclimatic design encompasses an approach that deploys local characteristics into the design of buildings and urban plans.

The *climate design* of buildings encompasses the realisation of a comfortable environment inside and outside the building, regardless of the design, engineering and technology applied. *Sustainable climate design* aims at doing this by minimal consumption of energy and mitigated environmental effects. It is an expertise that integrates the basic knowledge of building physics and building services into the area of architectural design, with a focus on sustainable solutions for energy en comfort. Due to depleting energy resources and the demand for healthier indoor and outdoor environments, there is a growing need for a more sustainable climate design. There are several approaches to this, among which smart design and bioclimatic design.

Smart design is a vague term that is perceived differently in different countries. Related to 'intelligent' (Latin: 'intelligens' = distinctive, selective) it can refer to natural or artificial intelligence (Timmeren 2001). Natural intelligence is a natural generic cognitive ability to reason underlying processes in a conventional way. Artificial intelligence is the theoretical stream in informatics and psychology that is aiming at a perfect imitation of intelligent human behaviour by a computer. In terms of building, building management systems attempt to match this cognitive reacting: through specific programming input is processed (via sensors) to a desired output (Timmeren 2001). Over the latest decades in Western Europe the meaning of smart design and specifically *smart architecture* (Hinte et al. 2003) has shifted towards sustainable designs that intelligently interact with the environment.

Bioclimatic design has a more tangible meaning. Practised through hundreds of years but introduced as a common term by the Malaysian architect Ken Yeang, it is defined as "the passive low-energy design approach that makes use of the ambient energies of the climate of the locality (including the latitude and the ecosystem, through siting, orientation, layout and construction) to create conditions of comfort for the users of the building" (Yeang 1999).

The combination of both terms – *smart and bioclimatic design* (S&BCD) – encompasses a design approach that deploys local characteristics intelligently into the sustainable design of buildings and urban plans. These local characteristics refer to natural circumstances (the climate, seasonal changes, variety of the weather, diurnal differences, geomorphology, etc.) yet also to man-made interventions (such as the landscape, cultural, historical and technical features, and the built surroundings). In particular, a thorough analysis of climatic conditions and the intended use of a building or urban area can lay the foundation for a smart and bioclimatic design that uses much less energy and satisfies the needs of users better.

1.3 An incremental approach

Smart and bioclimatic design requires an incremental approach of three basic steps, preceded by a declaration of the basic indoor requirements.

It starts with a profound study of the natural circumstances of environment of the building in question. Natural circumstances involve climate, underground and man-made interventions. Each of the circumstances define the natural potential of the building site and therefore should be studied first if one wants to make the most of an energy-efficient building design.

The second step is the synthesis of the basic knowledge acquired to starting-points and boundary conditions for the energy-efficient urban plan and building design.

In the following sections, the steps toward smart and bioclimatic design will be exemplified by the case study of the new Dutch chancellery in Canberra, Australia (Dobbelsteen et al. 2008).

2. The start: basic declaration of the indoor climate

2.1 Fanger

The demand for energy in buildings originates in the indoor environment. Since the 1970s, comfort in buildings is based on findings by Fanger (e.g. 2002), who determined deviations from a mean comfort temperature (reference score: 0) in the indoor environment by scores from minus 3 to plus 3. The comfort temperature turned out to follow a slightly increasing outdoor temperature. Temperature transgression norms have been operated for decades on the basis of Fanger's work.

2.2 Adaptive thermal comfort

Recent investigations by Linden et al. (2006) supported Fanger's findings for entirely mechanically ventilated or air-conditioned buildings ('beta buildings'). However, for cases of high outdoor temperatures, there were discrepancies with partly naturally ventilated buildings (or with mechanical exhaust air extraction, 'alpha buildings'). Linden et al. found that building occupants accept higher indoor temperatures from certain outdoor temperatures, and hence that building services could be designed for higher indoor temperatures in summer (figure 1).

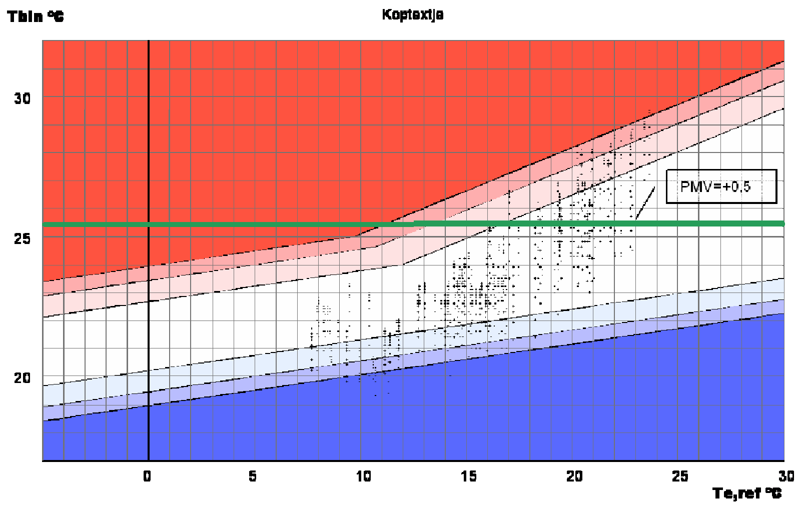

Figure 1 Comfort temperature (Tbin) at different external temperatures (Te,ref): high outdoor temperatures allow greater margins of indoor temperatures than initially perceived (Linden et al. 2006).

2.3 The importance to energy saving

Findings by Linden et al. enable less energy consuming buildings, in terms of reduced cooling demands in summer. In addition, the central climate utility in a building can be managed in such a way, that it provides with temperatures that are close to the under-margin of figure 1 in winter, and close to the upper margin in summertime, under the condition of local, individual adjustment. In this case, an optimal energy usage will be established. Moreover, occupants will not adjust temperatures contrary to the system (e.g. additional cooling when the system is heating up). This saves a lot of energy.

3. Analysis of climate, underground and surroundings

3.1 Introduction

Starting with the indoor environment and the way it needs to be managed, the demand for heat and cold in buildings is defined by the local climate. Therefore, good foundation for energy-efficient design is to be found in a thorough analysis of the local climate. The climate relates to seasonal changes, variations in the weather and diurnal differences of e.g. temperature, sun and wind. This section will mainly focus on a discussion of the analysis of climatic features.

The underground concerns the geomorphology, soil types and ground and open water. These are important as buildings connect to the underground and direct surroundings. They make storage or exchange of energy possible or impossible and they define water management features.

Many architects design as if their building could be placed anywhere, ignoring the inconvenient surroundings constituting the landscape, as well as natural, cultural, historical and technical environmental features. In contradiction, a smart and bioclimatic building can never ignore its surroundings, it should respond to them and utilise the potentials they offer to the building site.

3.2 Climatic zones, temperatures and humidity

According to Koeppen, the earth can be divided into basic climate classes (figure 2). These classes define the approach required for the energy-efficient climate design of buildings. There is no generic design for buildings: they should be based on the local features of temperatures and humidity.

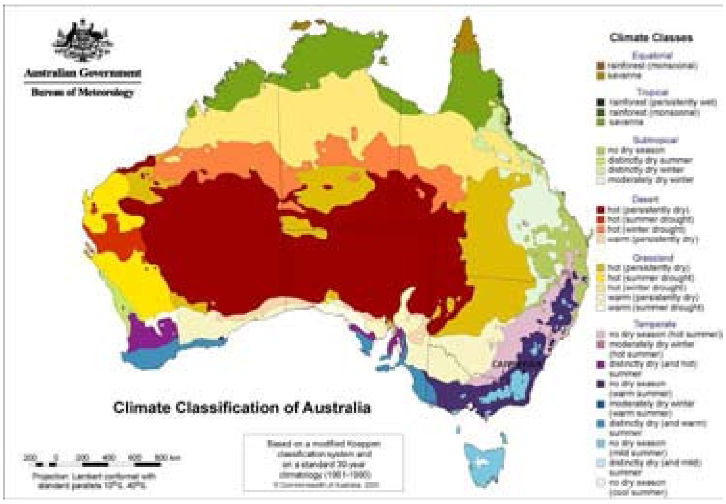

Figure 2 Climate classes according to Koeppen, period of 1961-1990 (Bureau of Meteorology 2005).

For the case study of the Dutch embassy, to Australian standards Canberra lies in a very particular zone: a temperate climate with no dry season and a mild to hot summer. The mean temperature is temperate (13 ^{o}C, relatively cool for Australia) but show relatively large seasonal and diurnal differences (table 1). This is an important feature that will influence the recommended building design.

Rainfall figures are moderate (relatively wet to Australian standards) but show a decrease over the last decades. This emphasises the importance to retain and make use of any form precipitation in the design of new buildings.

Table 1 Temperature, rainfall and solar statistics of Canberra

	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec	Annual
Mean maximum temperature (°C)	27.9	27.1	24.5	20.0	15.5	12.2	11.3	13.0	16.1	19.4	22.6	26.1	19.6
Mean minimum temperature (°C)	13.1	13.1	10.7	6.7	3.2	0.9	-0.1	1.0	3.2	6.0	8.7	11.3	6.5
Mean rainfall (mm)	59.5	56.0	51.1	46.4	45.1	41.1	41.3	46.6	52.3	62.7	64.2	52.5	618.7
Mean daily solar exposure (MJ/m^2)	26.4	23.8	19.8	15.4	11.2	8.2	8.8	11.2	15.1	20.4	23.7	25.8	17.5

3.3 The sun: north arrow and course of the sun

Table 1 also depicts the mean daily solar exposure, in energy terms. This of course is important for the yield of solar energy when making use of solar panels, solar collectors or passive solar energy.

A first simple step to smart design of buildings is putting the north arrow on every plan that is drawn. It sounds stupid but there are numerous architects who fail to acknowledge the north in their drawings, and who thereby ignore the most important energy source on our planet. No explanation needed that their buildings will not save the planet.

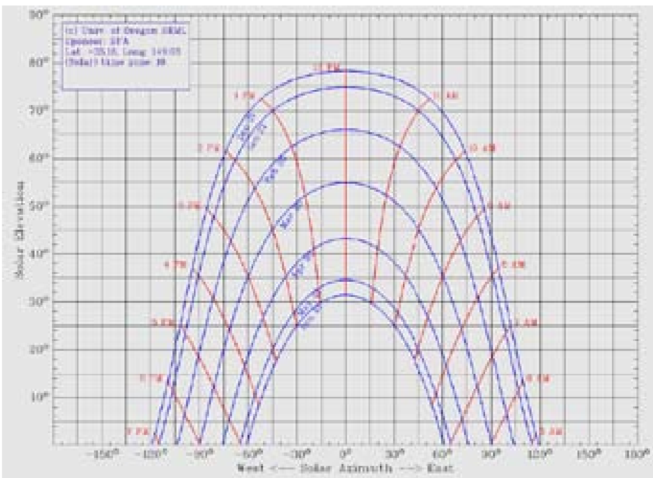

Figure 3 Solar chart for Canberra, showing the solar azimuth and elevation (University of Oregon 2007).

The designer who understands the climate features and acknowledges the course of the sun throughout the months of the year (figure 3) will be able to take appropriate measures in the envelope of the building. Table 2 for instance depicts solar properties for eight façade elevations during four typical dates of the year, at three hours of the day: the start (8 AM) and end (6 PM) of office hours and the time of the solar summit (12:04 AM in wintertime, 01:04 PM in summertime). If these data are connected to the simultaneously occurring temperatures, some indication will be gained about which solar angles to be obstructed to avoid unnecessary cooling inside the building.

Table 2 Analysis of solar characteristics on different elevations in Canberra

elevation	date	08:00 solar time			12:00 solar time			18:00 solar time

3.4 Wind: strength and direction

Next important aspect of climate is wind. Wind characteristics (strength and predominant directions) per season and with diurnal differences, combined again with temperature and humidity features, define the desired or undesired access or deployment of wind in the climate design of a building.

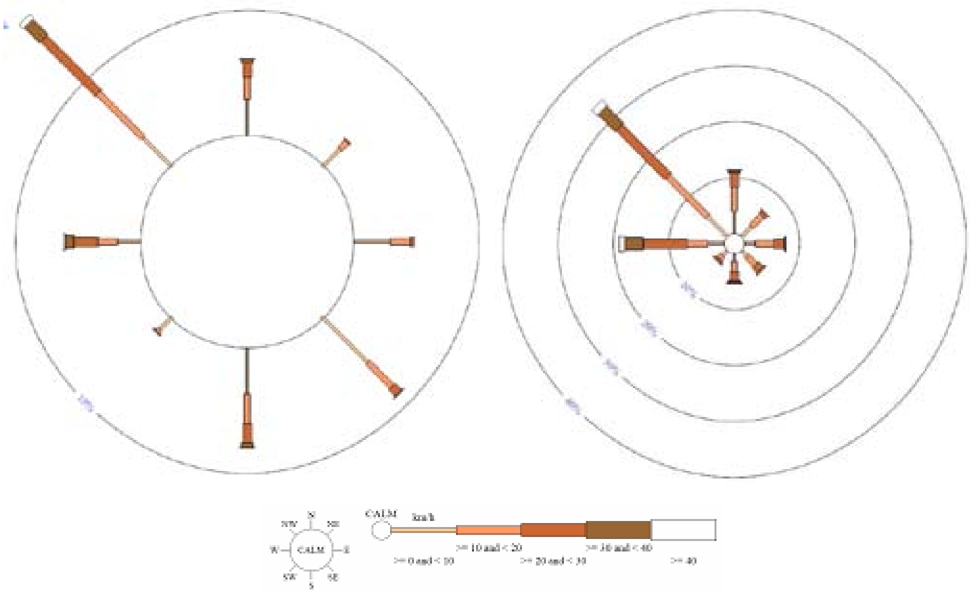

Figure 4 Wind roses for Canberra, at 9 AM (left) and 3 PM (right) (Bureau of Meteorology 2008)

Figure 4 gives average wind roses for Canberra at two times of the day. The morning is relatively still, whereas the afternoon shows a predominant north-western wind, which comes from the desert, implying hot winds in summer and cold winds in wintertime, both undesirable and hence, projecting boundary conditions for the orientation of a building.

4. Synthesis: starting-points and boundary conditions

4.1 Urban boundary conditions

The climatic analysis as discussed previously, as well as requirements imposed on the plan by authorities, can be translated into a map of the building site. Figure 5 presents the basic urban boundary conditions for the Dutch embassy in Canberra. Present trees are actually on the wrong side of the plot, considering the north sun and prevailing demand for cooling. The undesired wind from the north-west is to be obstructed or turned into an advantage since they are the only winds of any mention.

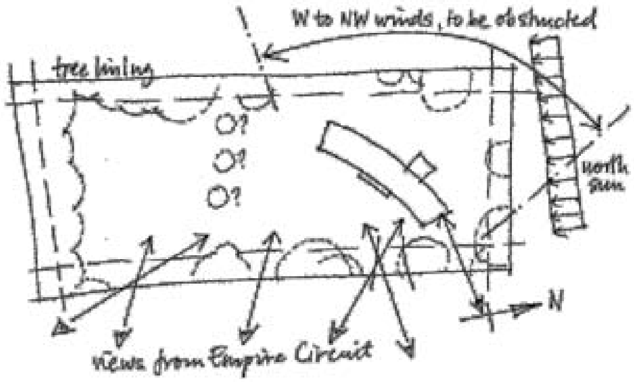

Figure 5 Urban boundary conditions for the new Dutch embassy in Canberra.

4.2 Boundary conditions for the building design

Analogue to boundary conditions for the urban setting, requirements can be made for the building design. It starts with the orientation, internal zoning, layout, and the general building shape, which in the case of Canberra would respond to the solar course by avoiding insolation from the north – which is easy, considering the high solar elevation, easily obstructed by canopies and blinds – and reducing the area of east and west facades – which are difficult, due to the low solar angles, demanding for full shading devices.

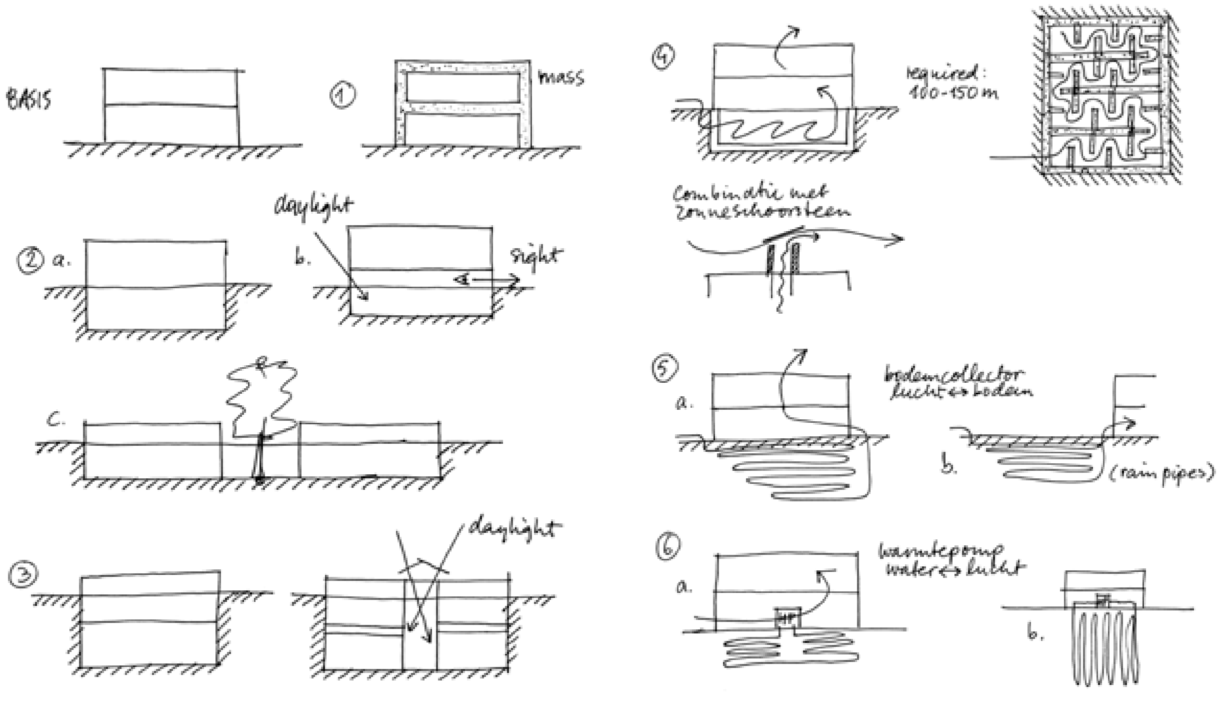

Figure 6 Possibilities to stabilise or temper the indoor climate: 1: more building mass, 2: building one layer into the ground, 3: building two layers underground, 4: using a cellar for direct cooling of fresh air, 5: using underground ducts for direct cooling of fresh air, 6: indirectly cooling the building through a soil collector and heat pump.

Within the climatic circumstances of Canberra, especially the temperature differences between night and day, winter and summer, some dimming measures are welcome. Dimming of extremes is established through mass, inside or outside the building. As the mean annual temperature is 13°C, a nearly infinite mass and the soil approximately 1.5 m below surface will reflect this average from. This means that free pre-cooling and pre-heating can be gained from the soil in summer and winter respectively. Figure 6 depicts some principal solutions – directly and indirectly – that deploy the soil in stabilising the climate inside the building.

4.3 Boundary conditions for the building envelope

The forceful solar radiation and high summer elevation of the sun in Canberra urge measures in the roof of the building. A tropical roof, an elevated light-weight roof under which the air flow can cool the building, can be an apt solution (figure 7). An upside-down wing-shaped hat can additionally provide under-pressure beneath this roof, enabling passive extraction of exhaust air from the building. This is also possible in combination with a solar chimney.

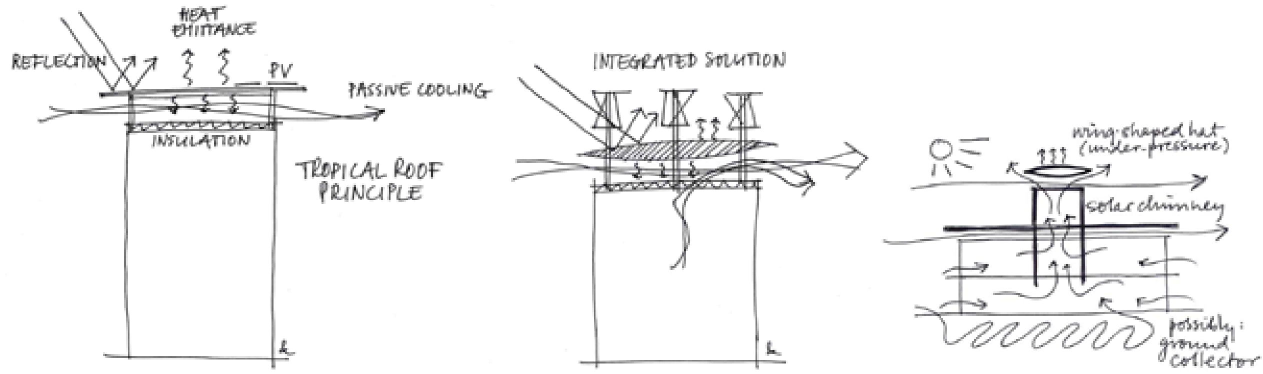

Figure 7 Tropical roof principles: the normal solution (left), an upside-down wing-shaped tropical roof (centre) and an upside down wing-shaped hat on a solar chimney (right).

Furthermore, the solar properties of table 2 can be translated to design principles for the facade, which needs to be approached differently for every orientation. Figure 8 shows three of the six elevations and their basic measures to avoid insolation.

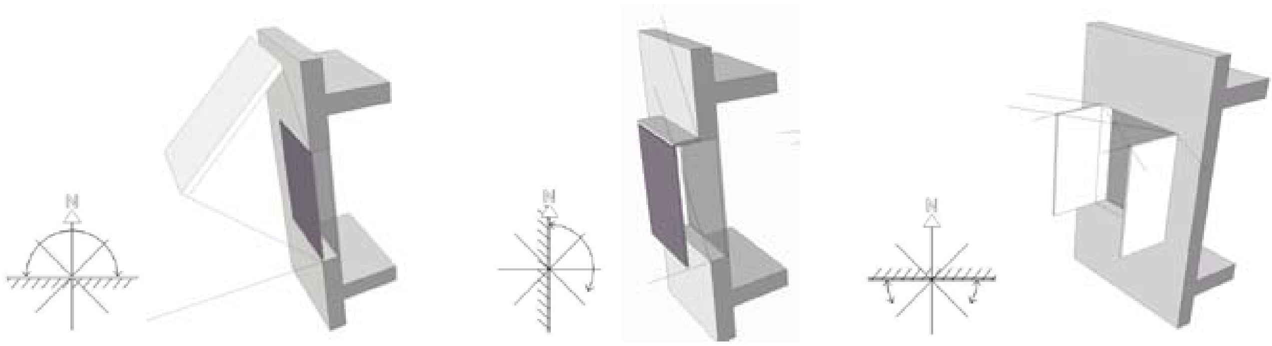

Figure 8 Solutions to avoid insolation from defined solar angles on different elevations.

5. Design proposals

A final step towards smart and bioclimatic design can be made through the elaboration of boundary conditions and design principles into an actual crude design. Creative design is a delicate process, so it should not be bound too much to restrictions, but a set of boundary conditions and principles that still allow architectural freedom can be a profound basis for sustainable architecture.

Figure 9 gives an example of just one design proposal for the chancellery in Canberra, without any architectural intention. In this sketch the old chancellery building from the 1950s is preserved (against the desire of the Ministry of Foreign Affairs and the selected architect), using it as a wind screen, open-air gallery and hosting a solar chimney that passively ventilates the new pavilion. Fresh air is let in through a ground collector beneath the new pavilion, which can basically be of any architectural expression

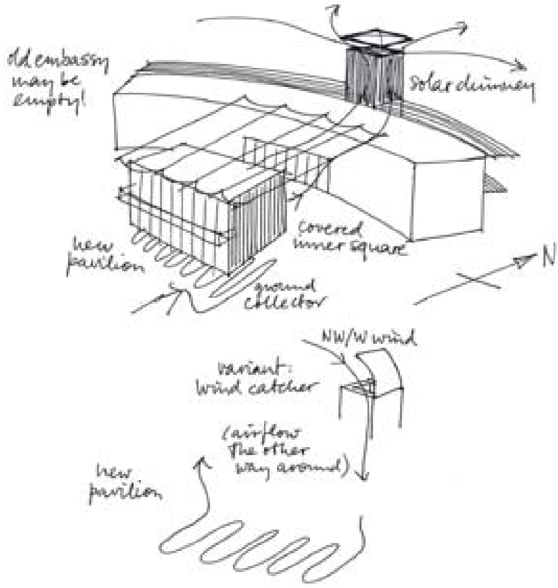

Figure 9 *Sketch of a possible solution for the new Dutch embassy in Canberra, based on bioclimatic principles and preserving the old chancellery.*

6. Conclusions and discussion

6.1 Conclusions

Despite the character of an intangible process, smart and bioclimatic design is supported by a well-structured investigation of aspects that will influence the energy performance of a building. The structured approach discussed in this paper can provide the basis for such a design that better utilises the implicit local energy potentials.

6.2 Discussion

The case study exemplifying this paper was seriously meant as a starting-point for three architects who would compete for the design of the chancellery of the Dutch embassy in Australia. Due to tight time-planning issues the Dutch ministry of Foreign Affairs however selected one architect in an early stage. This architect commenced design work while the preparative research was still ongoing. This led to suboptimal tuning of research findings and decisions on the crude design.

This demonstrated the necessity of patience in an ambitious project aiming at optimal energetic performance.

Summary

Vision for a Sustainable and Competitive Construction Sector by the European Construction Technology Platform states that "In the year 2030, Europe's built environment is designed, built and maintained by a successful knowledge- and demand driven sector, well known for its ability to satisfy all needs of its clients and society, providing a high quality of life and demonstrating its long-term responsibility to the mankind's environment." To achieve this, there are two main challenges: Meeting client requirements and reaching sustainability. Sustainable building is a comprehensive process which is able to understand user needs and requirements, to create a design that fulfils these requirements while minimising environmental impacts and life cycle costs. Understanding user needs is essential in sustainable building. However, several case studies have shown that there may be significant problems in understanding the user needs and achieving the desired usability. Systematics that support identifying user needs and requirement setting are missing; many of the existing methods rather support subsequent assessment of user satisfaction.

The paper discusses the meaning of building performance and usability as aspects of sustainable building, and gives recommendations for the development of methods that support the identification and understanding of user needs.

1 Introduction

The principles of sustainable development define the ecological, economic, social and cultural framework for the activities of communities, enterprises and individual citizens. Vision for a Sustainable and Competitive Construction Sector by the European Construction Technology Platform states (ECTP 2006) that "In the year 2030, Europe's built environment is designed, built and maintained by a successful knowledge- and demand driven sector, well known for its ability to satisfy all needs of its clients and society, providing a high quality of life and demonstrating its long-term responsibility to the mankind's environment. …In order to meet this vision, objectives and research targets are specified for two key aspects of construction: Meeting client requirements and reaching sustainability."

This paper discusses the different aspects of sustainable building. The specific focus is to try to define the significance and importance of building performance and usability as aspects of sustainable building. The specific scope of this paper is buildings as places to work.

There is a wide consensus that sustainable building is a comprehensive process which is able to understand user needs and requirements, to create design options that fulfil these requirements while minimising environmental impacts and life cycle costs. ISO TS 21929 defines that sustainable building brings about the required performance with the least unfavourable environmental impact, while encouraging economic, social and cultural improvement at a local, regional and global level.

The three main types of benefits associated with sustainable construction are environmental, economic and health and community benefits. Environmental benefits include improved air and water quality, reduced energy and water consumption and reduced waste disposal. Economic benefits include reduced operational costs, reduced maintenance costs and increase revenue (sale price or rent). Health and community benefits include enhanced occupant comfort and health, reduced absenteeism and turnover rate, and reduced liabilities (Andrews et al. 2006).

According to Cole (2005) assessment methods of buildings have overtaken other approaches for the management of sustainable building within building industry. Those methods are increasingly considered as the most potential mechanisms for affecting change while the initial intention was to ensure a specific assessment role to avoid problems from unverified claims on environmental performance. The majority of the existing assessment methods evaluate environmental performance of buildings relative to explicitly declared or implicit benchmarks. The point of view has gradually widened from sole environmental assessment to overall assessment of sustainability aspects of buildings. Existing systems are several; for example the following: BREEAM (2008) (UK BRE), LEED (2008) (US Green Building Council), Green Star (2008) (Australia), PromisE (2008) (Finland Motiva). These systems are useful not only when rating buildings but also in setting requirements. The strengths of the systems include that those are easy to use, they cover a wide range of sustainability aspects, support target setting, provide a common set of criteria. Weaknesses - on the other hand - include that the true meaning of the selected indicators is not defined, indicators may be overlapping, indicators may depend on each other and the relationship between indicators is not clearly defined. Typically, indicators concerns not only environmental performance of buildings but also functional and social performance of buildings.

Building performance is paid stronger consideration within the building sector's ongoing activities in the field of sustainable building. Performance based building and sustainable building are complementary (Sjöström and Holmgren 2005). There is a growing interest in both the public and private sectors for more sustainable approaches to buildings. Influencing factors are the need to reduce energy use, and greenhouse gases output. However, even more important than mitigating these adverse impacts may be the potential of amplifying the positive impacts of occupant satisfaction and performance (Andrews et al. 2006). Understanding and considering user needs is essential in sustainable building discussed for example in Häkkinen (2007). An integrated design approach may be a basic reason for successfulness of sustainable construction projects (Riley et al. 2004). There is a need to develop methods that support the identification and understanding of user needs, and the interpretation of these needs as requirements for building performance and spaces of building.

2 Definitions

The concepts of sustainable building have been defined variously. This section presents a summary of definitions given for sustainable building and its main aspects.

IS0 15932-2 General Principles and ISO TS 21929 define a framework for sustainable building and sustainability indicators of buildings. Environmental indicators address environmental aspects in terms of environmental loadings or impacts assessed on the basis of life cycle inventory or assessment. Environmental loadings are the use of resources and the production of waste, odours, noise and harmful emissions to land, water and air. Consequential environmental indicators express environmental impacts in terms of building performance or location either quantitatively or qualitatively.

The economic indicators indicate monetary flows connected to the building life cycle. Social indicators of buildings are used to describe how buildings interact with issues of concern related to sustainability at the community level. Community level issues that may be relevant are for example urban sprawl, mixed land use, development of brown-fields, safety, and noise and air quality. Social aspects can also be addressed on the building level like for example (ISO 2006): quality of buildings as a place to live and work, building-related effects on health and safety of users, barrier-free use of buildings, access to services needed by users of a building, user satisfaction, architectural quality of buildings and protection of cultural heritage.

The three main functions of indicators are quantification, simplification and communication. Changes over time and the development of changes in relation to stated objectives can be monitored with the help of indicators. One of the important functions of an indicator with reference to decision-making is its potential to show a trend, Indicators should be objective and the results should be repeatable. When developing and selecting indicators the starting point is the identification of the main users and user needs (Häkkinen et al. 2002).

ISO 6707-1 provides definitions for performance, performance requirement and serviceability:

- Performance - ability of a product to fulfil required functions under intended use conditions or behaviour when in use
- Performance requirement - minimum acceptable level of a critical property
- Serviceability - ability to meet or exceed relevant performance requirements

According to ISO 9241-11 usability is the extent to which a product can be used by specified users to achieve specified goals with effectiveness, efficiency and satisfaction in a specified context of use.

CIB W111 (CIB) focuses on the concept of usability of workplaces including commercial buildings and buildings for healthcare and education. Usability, with focus on the user perspective, is often a neglected aspect of building performance, but the importance is increasing as organisations seek new and more effective ways of working. Several aspects influence a building's usability. According to Nylåna (2005) usability, or functionality in use, is concerning the buildings ability to support the user organisation's economical and professional objectives. The quality of use for a building means that it is efficient in use (use of resources, productivity, effectiveness, rationality), offers the desired effect in use (increasing the value), and/or offers the desired quality in use (user satisfaction). Usability focuses on user perceptions of the ease and efficiency with which they can use the building. Serviceability, on the other hand, describes the capability of a building to provide a range of performances for which it is designed, used or required to be used, over time. While usability states a demand perspective, serviceability states a supply perspective. The CIB W060 (CIB) focuses on performance based briefing in relation to client requirements and performance indicators and in relation to sustainable building.

ISO 9001 specifies quality system requirements for achieving customer satisfaction by preventing non-conformity. ISO 9001 concerns usability because improving usability of a product is essential to quality. True quality of product design is a result of a usability process that includes measuring and improving usability (Dick 1999).

According to CIB report 'Working with the performance approach of building' (1982) performance approach is concerned with what the building is required to do, and not with describing the technical solutions i.e. how it is constructed. A prescriptive approach describes an acceptable solution while a performance approach describes the required performance. Essentially, the performance approach is the practice of thinking and working in terms of ends rather than means. Performance requirements do not say anything about the ways and means of buildings, e.g. the type of materials, the thickness, dimensions, and size of building parts, or the method of construction, but they state the required end result.

The performance approach is dual in a sense that first there is a need to identify and quantify two types of constraining sets: i) basic and intrinsic aims that the end product is expected to satisfy, ii) restraining general forces and environmental conditions (Becker 1999). It is essential to distinguish performance issues between i) design features and ii) management, operation and process issues (Cole 2000).

With reference to building performance Prior and Szigeti (2003) make a distinction between demand and supply: Demand includes descriptions of functionality needs of owners and users; Supply includes indicators of serviceability describing the performance of materials, components and structures as features of the whole asset. Based on such information it is possible to address the quality of fit, matching performance with need and analyse suitability of a building or other constructed asset to meet the required functionality of the users.

Lützkendorf et al. (2005) deal with performance as a major concept which is divided into categories including functional, technical, environmental, economic, social and process performance. Functional performance describes the suitability with planned use and it also covers aspects of accessibility and adaptability. It is closely related to the needs of the building users. Social performance refers to the health, comfort and safety of building users. Building regulations provide a base for these aspects but clients often choose to demand more.

This paper refers to the last mentioned definitions and from this point onwards uses the terms functional and social performance. This paper discusses the meaning of functional and social performance on the basis of the following definition for sustainable building: sustainable building brings about the required performance with the least unfavourable environmental impact, while encouraging economic, social and cultural improvement at a local, regional and global level.

3 Functional and social performance as a unit of reference in assessing environmental impacts

The notion of life cycle assessment (LCA) has been generally accepted within the environmental research community as the only legitimate basis on which to compare the environmental impacts of alternative products and services (Cole 2005). The approach is firmly adopted for the European environmental assessment tools. It also seems that there is a tendency to adopt the LCA approach to the sustainability assessment systems of buildings to deal with the environmental impacts of buildings. This approach has been chosen for example to the German (Schminke 2008), Australian (Green Star 2008) and Finnish systems (PromisE 2008).

LCA theory and related standards (ISO) point out the quantified performance of a product system for use as a reference unit. Within an LCA, environmental impact is always looked at in relation to the functional unit (FU) in terms of quantified performance. According Heijungs et al. (1992) the FU should be defined with the end-user in mind. Whenever possible the FU unit should be defined as a service to the user or to the process. A definition of a product is that it is of benefit to the user; it provides a service. Wenzel et al. (1997) point out that the service, the response to the user's needs, is the reason for the product's existence, and therefore the environmental impact caused by the product should be ascribed with reference to this service. To ensure that the different ways of providing a service are comparable, the service must be defined and quantified.

The service that is provided by a building or construction can be described with help of its (functional and social) performance. To fulfil the required functional and social performance (suitability for planned use including aspects of accessibility, adaptability, health, comfort and safety) there may be several alternative technical solutions. Sustainable construction should be able to choose the one that causes the minimal adverse environmental impacts. To be used as the basis of comparison, we should be able to define and quantify the performance; or if not absolutely quantify it, at least classify it so that the required service can be expressed in terms of performance classes.

World Business Council for Sustainable Development (WBCSD) first introduced the concept of eco-efficiency in its report for the UN conference on sustainable development in 1992. The meaning of eco-efficiency concept has been widely discussed ever since. The OECD (1998) has defined the term in such a way that "Eco-efficiency expresses the efficiency with which ecological resources are used to meet human needs". According to the OECD report, eco-efficiency can also be defined as a ratio of output and input so that the output represents the value of the products or services that a company produces and the input is the sum of environmental pressures caused by the production. The approach is close to life-cycle assessment approach.

By expressing the value of products or services in terms of functional and social performance, we can define that the eco-efficiency of a building expresses the efficiency with which ecological resources (and economic resources) are used to meet the user requirements concerning usability in terms of functional performance and indoor conditions. Theoretically, we can undestand eco-efficiency as a ratio of two parameters; the ratio can be improved both by increasing the numerator or decreasing the denominator.

However, at the current state of development, the ISO standards do not indicate how to derive values for building performance. According to Trinius and Sjöström (2005) the discussion of the link between performance aspects and sustainability aspects reflects the relative vagueness of the term sustainable building. The term does not relate to the establishment of a benchmark for a sustainable building, but rather to the process considering sustainability aspects during the design and operation of buildings. Watson (2005) has analysed the existing sustainable building tools in terms of their ability to support design for sustainability. Among other things Watson concludes that tools cover a wide range of issues, but do not provide a clear and consistent means of organising these.

Building regulations may provide a basis for using technical performance and basic aspects of social performance as a reference unit when comparing alternative design options in terms of environmental impacts. However, we are far from being able to quantify the overall functional and social performance. There are attempts going on and for example the Nordic CREDIT project may bring some solutions for these questions. CREDIT (2008) aims - among other things - to identify performance indicators that can be used to support clients to express user needs and that indicate the value of real estate. On the other hand, we can question the possibility - and even the meaningfulness - to define functional and social performance in such a way that it could be used and determined generally as quantified reference unit. This is because the functional and social performance (especially the suitability for planned use and comfort) depends significantly on user-specific views. In the end, it is the user who is able to prioritize and quantify. Thus the development of methods for the investigation of user views and user satisfaction might offer case specific solutions for the problem.

Whether to use functional performance as an indicator simultaneously with environmental indicators or as a reference unit for environmental assessment is problematic from the view point of current sustainable building rating systems. The majority of the systems of sustainable building indicators deal with distinct environmental parameters (like harmful emissions and the use of resources) as well as with performance aspects (like air quality, comfort and flexibility). These approaches do not define the building performance as the reference unit, but use performance aspects as indicators of environmental performance in addition to the environmental pressure indicators.

4 Functional and social performance as targets of user requirement

Sustainable building fulfils the required performance and at the same time causes the most favourable environmental impacts while encouraging economic, social and cultural improvement. On the basis of this definition, functional and social performance belongs to aspects of sustainable building, because those are essential targets of user requirements and because the user satisfaction mainly depends on functional and social performance. According to Trinius (2005) performance approach is a key element in sustainable construction: as the performance approach starts off with an expression of what is expected from a building in terms of functionality, the identification of performance requirements can perform as an anchor in other elements of sustainable construction.

In addition, functional and social performance may also be seen as aspects of sustainable building, because those have an effect on the potentiality of buildings and built environment to encourage economic, social and cultural improvement and sustainable development on the whole. Built environment and buildings may be linked to sustainable development through their ability to support work towards sustainability. Sustainable development requires changes compared to the current situation; sustainable development can be defined as an innovation process. There are different strategies to proceed towards sustainable development, but in each case innovations are needed (Gerlach 2000). Work spaces and built environment should be able to support organisations' activities in the innovation process. The meaning of functional performance from the view point of user satisfaction and productivity is more dealt with in Section 6.

5 Functional and social performance as potential means of saving resources

It can also be presented as a self-evident conclusion that the better the building corresponds to the requirements of the owner and the needs of the users and the better the coming needs have been able to foresee the longer the building can be used (after new building or refurbishment) by its users before any needs for making changes and thus needs for demolishing and rebuilding. Thus good functional, technical and social performance probably saves both economical and environmental resources and environmental loadings. This can be taken as one of the reasons for defining functional and social performance as aspects of sustainable building.

6 Functional and social performance as a compensating element for space efficiency

Organisations seek new solutions for office buildings and efficient space use in order to achieve direct benefits such as savings in energy use and costs. The development has proceeded from closed to open spaces, from personal to shared workstations, and towards telework enabled by advanced ICT. It is also possible that the threat of climate change forces the building sector to seek these solutions not only in order to save energy and costs but also primarily to save environmental impacts. In addition, if the building sector will be forced to make significant improvements, such indicators as CO_2 per square meter might not be adequate but indicators like CO_2 per employee and/or organisation or CO_2 per occupant might be more effective.

In this kind of situation functional and social performance becomes an important issue of sustainable building because it can offer compensation and potential for increasing space efficiency. Improved functional performance may enable improved efficiency in space use (and thus savings in CO_2) without impairing the quality of building.

There are a number of studies on new work space solutions and their abilities to support satisfaction and productivity (see for example the literature surveys by Häkkinen and Nuutinen 2007 and Reunanen et al. 2006). For example Haynes and Price (2004) found that the most important factors that affect productivity of work include the quality of indoor conditions, workspace structure, comfort of work spaces, flexibility, and interaction and disturbances. Similar aspects affect work satisfaction: possibilities for undisturbed work and spontaneous interaction, comfort, ergonomics, space for storing the needed equipments and documents, possibilities for chatting and good spaces for break; accessibility to needed technology, indoor conditions and possibilities to adjust (Olson 2002, Veitch et al. 2003, Charles and Veitch 2002). With regard to workspace structure, there is a general opinion that individual working rooms and individual workstations create satisfaction, while lack of those can be compensated with help of good architectural design and high quality ICT (Voordt 2004).

7 Management of functional and social performance

Functional and social performance is an important element of sustainable building and construction. Thus we need approaches and tools that enable the determination, quantification and management of functional and social performance. As already dealt with in section 3, it is doubtful, whether overall functional and social performance can be quantified in general terms, because the suitability for planned use depends on subjective views. However, improved consideration and management would be possible by developing methods and tools for identification and understanding user needs.

Different kinds of methods and standards have been developed for the management of user needs especially in terms of minimum performance levels and technical requirements. The major purpose of legislation in this field is to ensure the health and safety issues of buildings. However, many buildings are still suffering from failures and weaknesses and there is a potential for improvements. This shows that good usability cannot be ensured with help of minimum levels stated by building codes, but a better understanding is needed to improve the understanding of usability (Nylåna 2005).

Case studies have also shown (for example Häkkinen and Nuutinen 2007) that in spite of careful preparation there may be significant problems in understanding and identifying the user needs. Systematics that support requirement setting and identifying user needs in terms of functional performance and consistence with the strategic working models are missing. The existing methods mainly support subsequent assessment of user satisfaction.

Space planning is the process of optimizing the layout of a building to suit a business's needs; ideally this is done in the context of the business plan and facility management plan (Muir 2003). Conceptually the process is simple; the needs of the business and those of the employees are gathered, analysed and translated into a space plan through a design process. The success or a failure of the space planning solution can be assessed using various indicators and methods. Different kinds of user satisfaction survey instruments exist. These link user satisfaction and self-assessed productivity to the environmental factors of thermal, lighting, acoustic and spatial comfort and privacy and other issues (Wilkinson and Leifert 2003). The outlines of these kinds of surveys can also be made use of in the process of understanding user needs.

The premise is that especially the following three types of methods can be used to support the understanding of users' needs: 1) outlining functional and social performance, 2) interviews, and 3) visualisation tools. Structured outlines of functional and social performance support owners and users to express their needs. Also visualisation tools should be developed and made use of in the process of requirement management. The nature of user activities and the practical meaning of the stated strategic goals of an organisation should be understood in the early stages of project. At present, the building process lacks systematics for identification and understanding user needs from the view point of

- the consistence of workspaces with user's strategy, activities and desired ways of working,
- suitability for daily user needs and activities,
- special requirements based on specific characteristics of work,
- user's tolerance with regard to risks of non-conformity,
- compatibility with desired imago.

Section 2 introduces definitions given for usability, serviceability and building performance. We lack detailed outlining which could be made use of when investigating user needs. However, there are approaches which offer a good starting point. For example, there are building-level tools for requirement setting for building performance; these include the Finnish tool EcoProP (Huovila 2005). These methods and tools should be further developed to support the identification of space and activity specific needs. At present, the main headings of the EcoProP tool are as follows:

- Conformity: Location, Spaces, Services
- Performance: Safety, Indoor conditions, Accessibility, Adaptability; Usability; Comfort.

Usability is not divided into subheadings. REKOS (Häkkinen et al. 2002) project defined that the usability is about building spaces and their relations, ability to orientate, and the easiness to use the spaces. The connections of different kinds of spaces are essential from the view point of usability, for example the location of kitchen spaces with regard to meeting rooms, and location of corridors with regard to office rooms. The easiness to use the spaces is also important. This may depend for example on the possibilities to adjust indoor conditions, easiness to clean and operate spaces, and easiness to maintain and repair spaces. Flexibility or adaptability might also be seen as one part of usability. REKOS defined flexibility with regard to residential buildings and divided the term into the following sub headings: Usability of spaces for different kinds of use purposes (from the view point of electricity, ICT and other installations); Flexibility with regard to furnishing (ability to place furniture variedly); Ability to make changes in the image of spaces; Ability to make changes in the dimensions of spaces. Correspondingly, we can define that in addition to connections of different kinds of spaces, also the standard of installations, image, and furnishing options are of importance.

In an early design phase, the architect typically visualises various design concepts by hand sketching, or by making draft layouts and illustrations with an image processing or design tool. The visualisation is needed in order to negotiate and decide over aesthetical, functional, and technical issues. The process includes typically several iterations, which eventually converge to an optimal or widely accepted solution. An ideal support tool might be a system combining the ease of hand sketching with the accuracy and realism of a computer based system. In principle, architectural 3D models would work fine in visualisation purposes for the requirements capture. However, in spite of the obvious progress that has been made, the current design tools are not easy enough to be used for real-time conceptual visualisation and requirements capture.

In spite of the obvious progress that has been made, current CAD/3D tools are not easy enough to be use for real-time conceptual visualisation and requirements capture. However, some advances to this direction have been reported in literature. A notable work is reported in Oh et al. (2005). There the starting point for the 3D design is a 2D layout, in which an interface is provided to extrude and edit (resize, move, rotate or remove) 3D space structures. Another approach is to enable compilation of a conceptual design from a set of 3D primitive objects (basic forms), as e.g. in Virtual Lego (Oh 2004).

In principle, a specific concept description language could be developed, based e.g. on the use of a set of basic geometric patterns and graphs. Typically, 3D models are specific text files, e.g. variants of XML. Independent whether the input is textual, graphical or model based, the result needs to be converted into textual format. This needs a specific language convention to be used including a well defined vocabulary (semantics). By using specific semantics, connections and associations between spatial objects and various captured parameters, the design data can be made and stored into a database for further use. A problem is that language and its semantics depend on the user and on the purpose of use. The importance and priority of the requirements also vary and are many times both difficult to measure or quantify, and controversial with each other. The system should therefore support optimisation of the captured set of requirements according to a chosen set of cost functions (price, space, distance, functionality, etc.).

In addition to the drafting for visualisation purposes, the system should also support the storage and follow-up of the captured requirements in order to avoid the known problem of gradually drifting away from the original user requirements during various design and implementation phases (Kiviniemi 2005).

A novel possibility - especially useful for 3D visualisation in existing buildings or environments - is the use of Augmented Reality, which enables visualisation of virtual objects in physical environment. An example of an AR tool for renovation visualisation is described by Pinto et al. (2007). Augmented Reality, or more generally Mixed Reality, means computer visualisation which combines physical scenes with virtual objects. This option is particularly applicable for showing designed 3D structures in existing buildings and environments. Several other examples of using Mixed Reality in building and construction applications are given by Woodward et al. (2007).

A useful functionality in 3D visualisation is the possibility to position an animated human avatar to give realism, as well as an indication of the real scale of the 3D environment. This avatar can also be animated, and made to move according to physical rules (collision detection etc.). Animation is commonly used in computer games where even the human behaviour can been modelled. A corresponding example in Mixed Reality is to place a motioning real human into 3D environment, e.g. an architect to walk inside the 3D building model, explaining his/her reasoning behind specific architectural choices.

8 Conclusions

Functional performance and social performance are becoming more and more important aspects of sustainable building. There are several reasons for this:

1) Minimising and optimising the environmental impacts of building happens with help of comparing alternative design options. In order to compare we have to be able to define a functional unit against which the comparison takes place.

2) Functional and social performance is an essential element of sustainable building because that is a target of user requirements and because the user satisfaction mainly depends on functional and social performance. Even more extensively, we can say that the functional and social performance of buildings and the built environment affects how well the built environment (among other factors) is able to support the general innovation process that is needed in order to solve the challenges of sustainable development.

3) Good functional and social performance and conformity with users' needs probably reduces the needs to make changes and rebuild. Thus it also saves both ecological and economic resources.

4) The threats concerning the climate change will mean increasing requirements for building sector to diminish Green House Gases. This will probably mean that decreasing carbon dioxide emissions in terms of CO_2 per building volume will not be an adequate goal but absolute decreasing in terms of overall quantities is needed. This kind of development is already happening with regard to office buildings as companies seek overall savings in energy and costs with help of open space offices and effective space use. In order to remain and improve the quality of buildings as places to work and live focus has to be directed not only on decreasing environmental impact but also improving the functional performance of buildings and spaces.

Functional and social performance is an important element of sustainable building and construction; thus we need methods that enable the management of functional and social performance. It is doubtful whether the overall functional and social performance could or should be quantified in general terms, because the suitability for planned use depends on subjective views. However, improved consideration and management of functional and social performance is possible by developing methods for identification and understanding user needs. The premise is that especially the development of structured outlines for functional and social performance and visualisation tools would support understanding and consideration of user needs.

Keywords: office building, façade refurbishment strategy, HVAC concepts, feasibility evaluation

Summary

Two thirds of the office-stock in Western Europe is older than 30 years (Russig 1999). At this age façades and technical installations reach the end of their technical life-span and buildings show a bad performance in terms of user comfort and energy consumption. This situation has led to a high demand for refurbishment of office buildings constructed between 1950 and 1980.

This paper shows the four different possibilities for the refurbishment of façades and technical installations of office buildings: A simple upgrade of the façade to current needs, the application of an additional glass façade, the replacement by a façade with integrated building services, and an option in which the entire building geometry is changed. To elaborate and compare strengths, weaknesses, restrictions and opportunities of the different strategies, they have been applied to a case study of a typical German office building from the 1970s.

The results show that all different strategies generally function for the presented case study. Nevertheless they impose different restrictions to the construction process and future use of the building. By taking running costs and the interference with ongoing work into account, one can see that an appropriate refurbishment strategy creates up-to-date buildings at reasonable expenses that pay off well within the technical life-span of façade and installation-components.

1. A Case Study for Refurbishment

The assessment of case studies forms an integral part of the research project "Façade Refurbishment for Office Buildings" which is being conducted at the Faculty of Architecture at Delft Technical University. In 2007 we carried out a feasibility study for the refurbishment of the university campus building in Bielefeld, Germany. The building owner needed an overview and comparison of possible refurbishment strategies. As this building is representative of a common construction of its period, this project provided us with the opportunity to apply different refurbishment strategies developed within the research-project and evaluate them in terms of practicability, energy saving potential, and economic feasibility.

Figure 1 Aerial view of the case study project

The campus building was erected in the 1970s and contains a GFA of roughly 300 000 m². The load bearing structure is based on a grid of 7.20 m and is built of steel columns and beams. Floor slabs are made of on-site concrete and take in the structural function of horizontal stiffening. Further stiffening is realized by the staircases and elevator shafts between the actual office buildings. The major structural problems for refurbishment planning lie in the very limited load-bearing capacity of the steel skeleton and in the structural importance of the floor slabs that does not allow openings to be cut out.

The façade construction consists of pre-fabricated concrete balustrade elements that span 7.20 m and are supported by only one connection at each end. These elements carry the window frames and sun blinds. The balustrades are made of light weight concrete and are not equipped with additional insulation. The windows contain insulated glass dating from the 1970s. Hence, the façade does not comply with current energy-performance regulations. In addition to this lack of insulation, the façade shows both wind and water leaks.

A major restriction for the refurbishment process is that the concrete balustrades are difficult to remove. They were placed successively during the construction process. Today the building forms inner courtyards that are closed on all sides. Balustrades in these zones could only be reached by special cranes and would have to be lifted over building parts that are supposed to be kept in use during the refurbishment.

2 The Application of Strategies

This chapter presents four different refurbishment strategies and their adaptation for the presented building project. These range from a “minimal solution” to different approaches that aim to generate additional advantages from the refurbishment project. The evaluation and comparison of these strategies is presented in Chapter 3.

2.1 The Necessary Renovation – Ventilated Cladding

The first solution presents the necessary renovation that has to be done in order to allow the future use of the building. The aim of this ‘minimal solution’ is to achieve a proper building physical performance of the façade at minimal expenses.

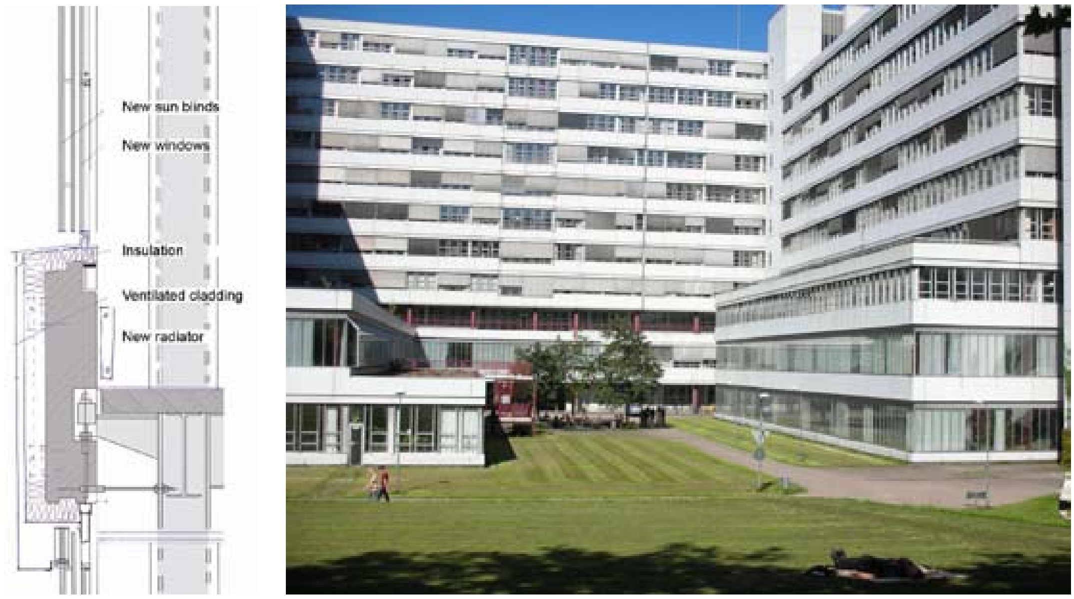

Figure 2 Principle Section of the ‘Ventilated Cladding’; Impression of the current façade

Additional insulation material is added to the outside of the balustrades in order to improve the insulation level. A ventilated metal cladding protects the insulation from weather conditions. Furthermore, the windows are replaced with new façades that provide proper wind tightness and insulation. New sun blinds reduce solar irradiation and thus cooling loads.

This concept provides a fast, easy to apply, and safe solution for the major problems of the building. It improves insulation and energy performance and includes the least construction costs. In this particular project the main restriction results from the very limited load bearing capacity of the existing balustrades, which do not allow a heavy cladding or big eccentric loads. Following this restriction we developed another solution in which at least the wind-loads on the balustrade are reduced compared to the current situation.

2.2 Twin Face Façade

It can be argued if 'Twin Face Façades' or 'Double Façades' are intelligent solutions or if they cause more problems than they solve. Nevertheless, for the task of refurbishment it is an interesting option to add a second façade layer to the outside of an existing building that prevents all weather impact to the old structure. Furthermore, the disturbance to the interior is reduced, if the existing façade is kept and all connections to dividing walls and floors do not need to be changed.

The aim for this refurbishment task is to conserve as much of the existing façade as possible, reduce the wind loads on the balustrade elements, and develop a new, energy efficient climate concept for the office rooms. In order to do so it is proposed to place a single glass screen in front of the old façade. The load bearing structure of the additional façade is suspended from new beams on top of the building that bring the loads into the main supporting columns.

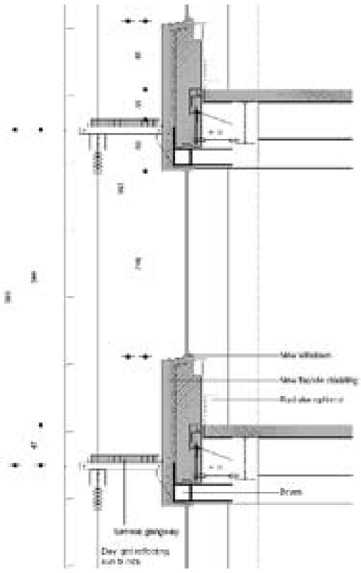

Figure 3 Principle of the 'Twin Face Façade'

The climate concept proposes using pre-conditioned air from the cavity in winter season as inlet air for the workspaces. Exhaust air needs to be let out through the central corridors and air shafts. In the summer situation the direction of the air flow is reversed. A natural updraft in the façade-cavity is used to extract exit air from the rooms. Fresh air is brought in through shafts and ducts within the building. All these technical installations have to be built, as the buildings currently are not equipped with any mechanical ventilation.

In winter the air in the façade cavity can reach very low temperatures because the cavity is used to bring in outside air to the rooms. To prevent cold bridges, condensation and heat loss, we need to improve the insulation of the inner (old) façade layer. This has to be done by new windows and additional insulation of the balustrade elements. All these efforts lead to a very complicated and expensive façade which can provide a high level of insulation and an efficient ventilation concept. But on the contrary it causes structural problems and difficulties controlling the temperature within the cavity. A bigger air volume in the cavity would reduce the range between high and low temperatures.

2.3 Winter Gardens

The shape of the existing building forms a series of courtyards and inner atria. Currently these are outdoor spaces surrounded by huge façade surfaces. By closing the courtyards and atria we can create covered spaces or 'Winter gardens' and thus reduce the façade surface of the building from 110 000 m² to 70 000 m² (including atria roofs).

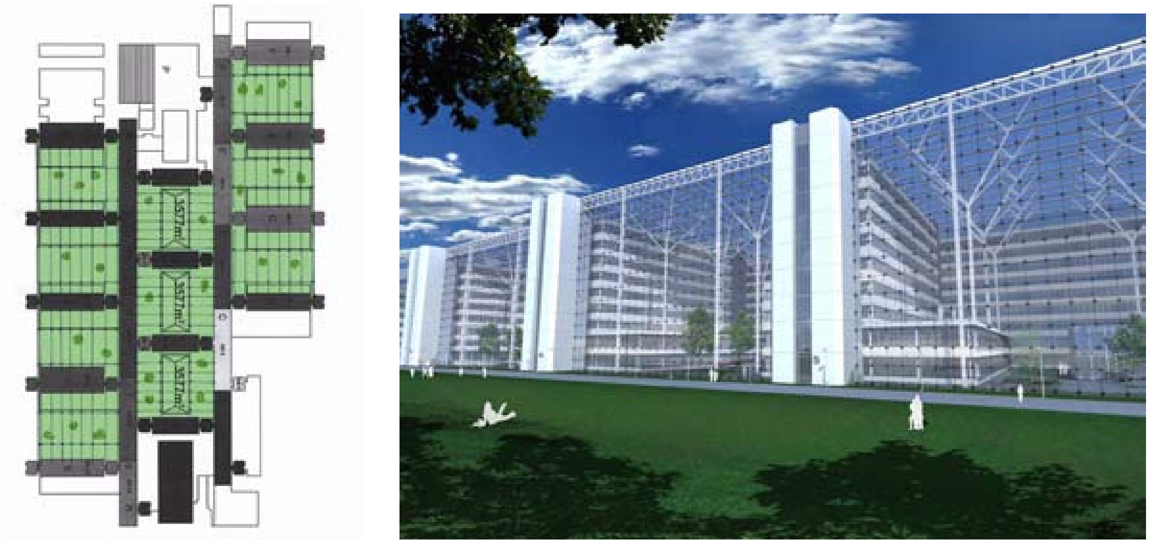

Figure 4 Principle of the 'Winter Garden' solution

The main aim of this concept is to create a buffer climate in which the air is pre-conditioned by solar radiation. Due to the big volume of the atria the air temperature will always stay above a level for which the existing façades provide enough insulation without further treatment. All office rooms get fresh air directly from the atria. The air intake for the central areas, such as libraries and auditoria, is also located in the courtyards and thus supplied with pre-conditioned air. In summer the covered atria need to be well-ventilated in order to discharge excess heat.

This concept achieves a good insulation level and a user-friendly ventilation concept in which the leaks of the old façade can be ignored. Additionally the winter gardens provide extra covered space that can be occupied by university functions. The particular problems of this concept lie in the need for new roof structures and façades for the courtyards that demand additional foundations and connections to the existing building. The ventilation concept of the atria demands special planning in order to prevent overheating in summer.

2.4 Modular Façade

So far all strategies followed the restriction of preserving the existing façade. Additionally we developed a model in which the windows and balustrade elements are removed. By removing an existing non-load-bearing façade the planner ends up with a kind of "tabula rasa" situation that allows almost any new curtain wall solution.

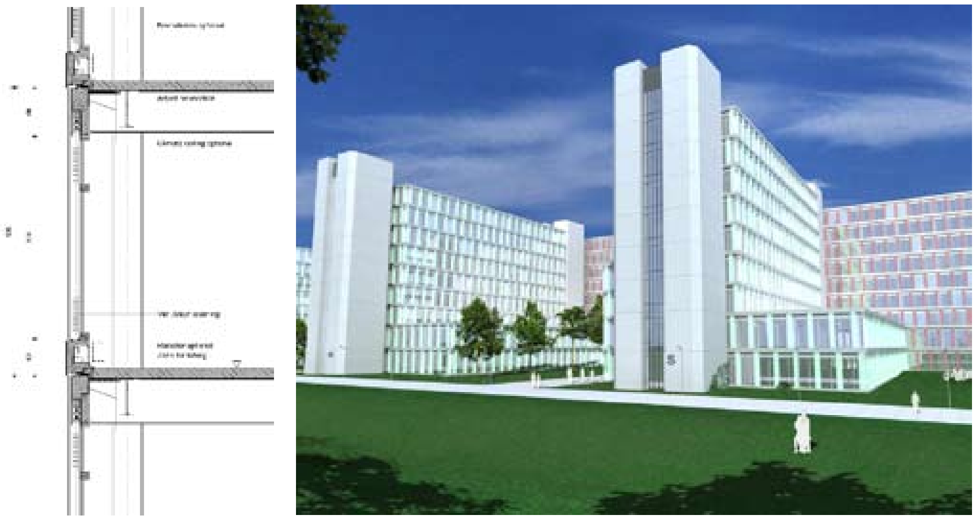

Figure 5 Principle of the 'Modular Façade'

For the university building we have created an adjustable and upgradeable concept that includes building services in the actual façade construction. This concept is based on the idea that different rooms have different demands for heating, ventilation and air conditioning depending on their use or location within a building. For example, an office room on a northern side does not need air conditioning at all, while a meeting room on the southern side does need it in summer, and a server room needs it all year round. Particularly at universities, the functions of rooms tend to be altered quite frequently.

Following this idea, we propose an element façade that provides the basic tubing for any kind of building services. In place of fixed climate components the façade supplies installation space in which different standardized components can be built in. The concept proposes that the user of a room can order his or her personal level of installation, which then can easily be installed (and billed individually). Figure 6 shows some possible HVAC concepts in sketch-form.

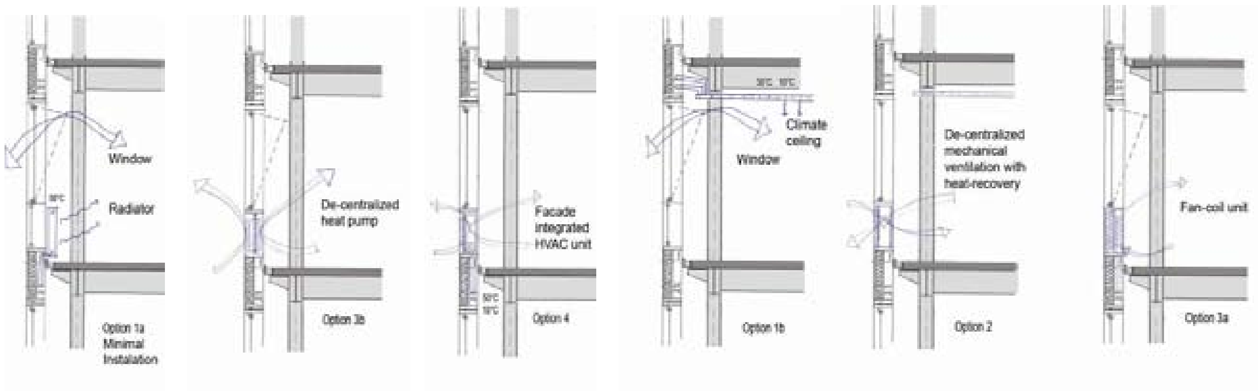

Figure 6 Different possible HVAC concepts

On the one hand, this concept provides the desired level of building services and comfort for each room. On the other hand only the absolutely necessary number of components needs to be produced and purchased. This reduces the demand of energy both in production as well as in use and allows perfect cost control. Nevertheless, this concept creates two major complications. The existing façade elements have to be removed, which is easy in the accessible outer courtyards but complicated and expensive for those courtyards that are fully surrounded by buildings. When the building is in use, this concept demands a good cooperation between building owner, user and facility manager.

3 Comparison of the different strategies

So far we have seen the description of different refurbishment concepts that show a broad variety of solutions with different levels of effort and impact. This chapter compares the four different refurbishment strategies in terms of construction cost, energy saving and life cycle cost, finally giving an impression of the possible repayment period of these concepts.

3.1 Construction Cost

To compare the investment for the different solutions, we have roughly estimated the cost for the construction of the façade and for the building services. In order to get comparable figures we estimated the costs and divided them by the square meters of the existing façade. The installation cost for building services are calculated per GFA. Table 1 shows the costs for all four solutions:

Table 1 Estimated Construction Costs

	Ventilated Cladding	Twin Face Facade	Winter Garden	Modular Facade
Façade (€ / m² Façade)	510	1130	950	890
HVAC (€/m² GFA)	60	115	95	105

The 'Ventilated Cladding' is the cheapest solution as it provides only the most necessary refurbishment. Installation costs are very low because they only cover the replacement of old radiator heating. The high investment cost for the 'Twin Face Façade' results from the complicated load bearing structure and the necessary treatment of the old façade layer. Installation costs are very high in this option, because a new ventilation system has to be installed. It is very interesting to see that the 'Winter Garden' solution is comparable to the other options. This is due to the fact that the façade surface is reduced and the existing façade needs no treatment. Installation costs in this case cover the replacement of the heating system in the rooms and the ventilation for the atria. The Construction cost for the 'Modular Façade' also covers the installation space for building services. For the installation-costs we estimated ¼ of the GFA to be fully air conditioned, while the rest is equipped with heating only.

3.2 Energy Demand

In order to determine data on the energy demand after refurbishment, we assessed one floor of the building with a thermo-dynamic simulation tool. Figure 7 shows the energy demand for heating, cooling, electric lighting and operating power in kWh per m² GFA and year. Column 'B' gives the reference data for the existing situation.

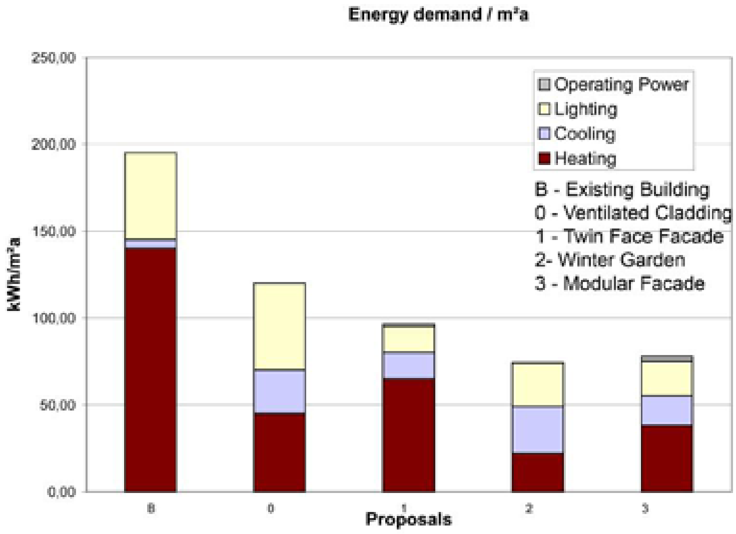

Figure 7 Energy Demand [kWh / m²$_{GFA}$ a]

Obviously the smallest refurbishment achieves the least energy saving. Nevertheless, the 'Ventilated Cladding' saves around 40% in comparison to the existing situation. The twin face façade causes a high demand for heating because the ventilation concept, based on operable windows, is difficult to control. Decentralized mechanical ventilation with heat recovery would provide a better performance, but also cause higher installation and maintenance costs. The reduction of electric lighting is achieved by daylight-reflecting sun blinds, installed in the cavity. The winter garden solution delivered interesting results: Although the old façade has not been upgraded, this solution demands the least heating energy. This shows the effect of the solar pre-conditioned climate in the atria which reduces the effect of the lack of insulation and the leaks in the old façade. A higher demand for lighting energy is caused by the shading of the roof. The Modular façade allows creating the optimal contemporary standards. By applying controlled ventilation to more than the calculated ¼ of the space, the heating demand could be reduced even further.

3.3 Running Costs

Running costs cover not only the costs for heating, cooling, electric lighting and operation of building services, but also the costs for maintaining the façade and building services, as well as window-cleaning. In the existing situation the costs for maintenance are particularly high, as it is expected that both façade and technical installations, being more than 30 years of age, demand a lot of attention. The impact of façade cleaning on the running costs becomes clear for the twin face façade. Electric lighting is an important factor for the minimal solution as this is not equipped with presence control, which on the contrary has been applied for the other proposals.

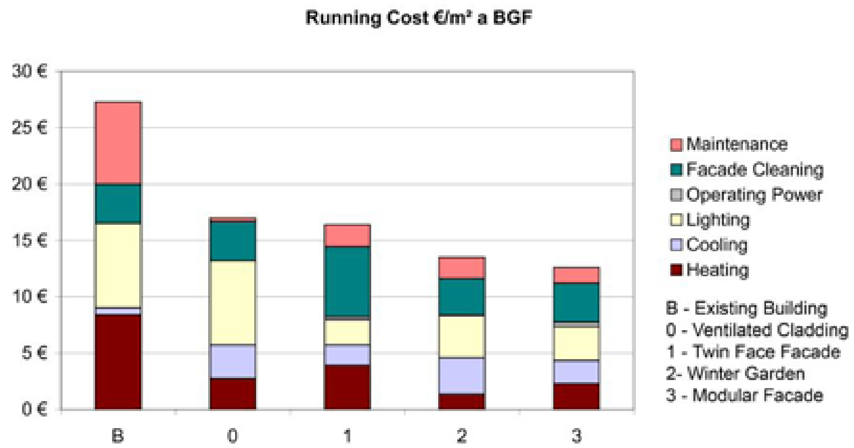

Figure 8 Running cost [Euro / m²$_{GFA}$ a]

3.4 Life Cycle Cost

Life cycle costs include the construction cost and the running costs presented before. To evaluate the future development we estimated, an increase of energy costs of 10% per year (destatis 2008). All other costs are expected to rise by 2% per year. Figure 9 shows the life cycle costs per m²$_{GFA}$.

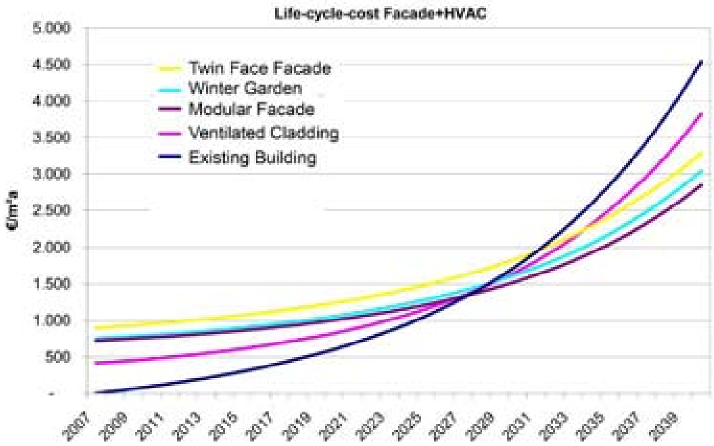

Figure 9 Life Cycle Costs [Euro / m²GFA]

All presented refurbishment strategies provide significantly lower running costs than the current situation. The graphs of all the different strategies intersect the line of the existing situation within the next 25 years. This means that any refurbishment proposal can pay off on the saving of running costs within the expected technical lifespan of façade and HVAC-components of 30 years. Under the given circumstances, the 'Ventilated Cladding' is the cheapest solution in the beginning. But, after 20 years the better performances of both the 'Modular Façade' and the 'Winter Garden' become evident. The 'Twin Face Façade' takes the longest time to pay off. A very interesting result is that the replaced 'Modular Façade' and the 'Winter Garden' are very close to each other, both in terms of construction costs as well as running costs. Keeping in mind that the 'Winter Garden' concept creates additional useable space, it is an option worth considering.

4 Applicability of the Refurbishment Concepts

The presented case study gave the opportunity to test and evaluate different refurbishment strategies. From the results generated here we have been able to conclude general results for the applicability of the different refurbishment concepts.

4.1 Ventilated Cladding

Ventilated cladding is a very common solution for the refurbishment of façades. It usually achieves a technically safe and long-lasting solution at reasonable expenses. As this kind of refurbishment is so frequently applied, it is also often criticized for the risk that buildings after renovation can lose their architectonic identity. It is the architects' task to create the best combination of good performance and appropriate appearance. A ventilated cladding always demands a sub-structure that can support new windows, insulation and the cladding. Therefore, it is mainly suitable for load bearing façades, such as massive walls with windows, or buildings with structural balustrades.

4.2 Twin Face Façade

Twin face façades can create an intelligent solution when they form an integral part of the climate concept of the building. The new cavity provides space for installation components and can make it possible to refurbish façade and building services without disturbing the interior. The load of the additional façade layer often causes structural problems. The necessary improvement of insulation and vapour tightness of the old façade layer leads to higher costs than a single façade layer. Therefore the application of an additional façade is most interesting in those special cases where the interior may not be altered, when the building has to stay in use, where the façade was originally equipped with structural service gangways, or when the HVAC-concept was based on de-centralized ventilation in the façade.

4.3 Winter Gardens

The covering of atria reduces the surface of a building, prevents weather impact on the old façade and creates a buffer climate that may make a treatment of the latter redundant. Additional values such a gain of space are further advantages. The main problems are the construction of wide-spanning roofs and the ventilation concept for the atria. This concept is particularly suitable for buildings with a convenient geometry, such as those with courtyards or feather-shaped layouts.

4.4 Modular Façade

The modular façade concept is interesting for both new and refurbishment projects. It reduces the need for HVAC equipment and allows for easy upgrades and changes in the future. Therefore it demands a complete refurbishment of façade and building services and is thus suitable for buildings that are supposed to undergo a complete retrofitting. To be successful, this HVAC-concept requires an intensive dialog between building owner, user and facility manager.

5 Conclusion

The façade is one of the most important and complex parts in construction. It creates the outer looks of a building, is the 'user-interface' between inside and outside, and it is the most important factor for the energy performance of a building. Most of the existing office buildings in Europe are older than 30 years and thus in need for refurbishment. Many interesting strategies can be considered for this task.

But, as every building is different and any refurbishment project provides different demands, no one strategy can be applied to every building type. The planner has to know the variety of possibilities. This report has shown a collection of promising solutions. It has been generated within a PhD-project that aims to provide a more comprehensive overview of refurbishment strategies, their advantages, problems and their applicability on the most common building typologies.

The presented case study shows that refurbishment design has to take into account the complete project. The integral planning of façades and building services achieves the best performance. Not only is the investment for construction important for the estimation of feasibility, but the future costs of using the building as well. This demands planners from different fields to work together with the ones, who own, use and run the building now and in the future. When all these parties collaborate, they will be able to find synergy effects that help to achieve energy and economic advantages, and they can further create a new architectural image to an old building. Refurbishment of offices makes sense and is an economically and ecologically feasible investment.

Summary

There is increasing recognition that current 'best practice' in the design, construction and management of the built environment is not enough to ensure a sustainable future. Our built environment contributes to some of Australia's most pressing environmental problems. In response, we need to push the limits and move far beyond our current conceptions of best practice. This paper puts forward a principles-based approach to sustainable design in the development industry that incorporates the concepts of ecological limits, systems thinking and responsibility for impacts. In addition, a new framework for setting targets and actions for 'restorative' developments is presented. This paper focuses on the opportunities associated with urban infill projects, examining the kind of targets required to achieve truly 'sustainable' and even 'restorative' development and the principles all developments and retrofits of the future need to embody. This analysis is done in the context of a changing regulatory and economic environment, using examples from precinct-scale Sydney developments that are currently being designed.

1. Background

The built environment contributes to some of Australia's most pressing environmental issues, such as climate change, biodiversity loss, resource depletion, pollution and social inequity. As a nation, Australia is exceeding its ecological footprint, which at 8.1 hectares per capita is 3 times the global average and far greater than the estimated sustainable footprint (1.7 hectares for every person in the world) (Commonwealth of Australia, 2005). This places Australia in the top 5 of consuming nations in the world (GFN et al., 2005) and illustrates the extent of reductions required in order to achieve a sustainable level of resource consumption. Greenhouse gas emissions (GHGE) and material consumption rates in Australia are the highest per capita in the world at 27 and 180 tonnes per capita per year, respectively. Domestic waste production is second only to the United States at 620 kilograms per capita per year. The construction industry contributes to these high statistics as construction and demolition waste is 430 kilograms per capita per year; which constitutes 40% of all solid waste disposed of to landfill (Commonwealth of Australia, 2005).

Currently, average water consumption across Australian cities is 154 kilolitres per capita per year (kL/cap/year) (Beeton et al., 2006), which is the highest national average in the world, with the U.S. falling just below this average (Commonwealth of Australia, 2005). Australia's performance in these indicators shows that vast improvements must be made to secure a sustainable future. An immediate and fundamental shift in thinking and practice is needed. In many of Australia's urban areas, energy supply, water supply and sewage disposal infrastructure is highly centralised, ageing and/or close to its capacity. These centralised systems were designed and built within a paradigm that segregated infrastructure types (e.g. energy and water) and elements within those types (e.g. water separate from wastewater). The unintended result of such systems is unwanted environmental impacts and increased costs. A different way of thinking about our infrastructure is needed, in part because infrastructure has such long life times - of the order of 20-100 years, and in part because infrastructure determines the material intensity of our lifestyles.

Current 'best practice' targets used for design and construction of the built environment have brought some progress towards the goal of sustainability; however, much greater steps need to be taken if we are to address some of the critical issues affecting our urban environment and move towards attaining the ultimate goal of sustainable development. As a highly urbanised nation, the greatest opportunity for Australia to reduce its environmental impact lies in its cities. Two thirds of Australia's population lives in cities and population growth is increasingly concentrated in urban areas. The rapid growth occurring in the inner urban areas of Australia's major cities, notably in Sydney, Melbourne and Perth (Commonwealth of Australia, 2005), presents significant challenges – and significant opportunities – for the sustainability of the built environment. Precinct-scale developments offer a particularly effective opportunity to create change in our built form and infrastructure.

This paper argues that it is time for a paradigm shift in thinking and practice, and that a principles-based approach provides an appropriate framework for this next stage in the development industry's evolution. We draw on principles for sustainability learning, because a deeper level of awareness and knowledge will be fundamental to this paradigm shift. If we are serious about a sustainable future, we need to engage more explicitly with principles such as responsibility, ecological limits and systems thinking.

2. A New Principles-Based Approach in the Development Industry

The Australian development industry has seen a considerable shift towards sustainability over the last decade. Regulatory requirements and the introduction of building rating tools have transformed mainstream awareness and have in turn resulted in changes within the building industry's supply chain. Despite this, even current leading edge practice falls short of what is needed to ensure a sustainable future. In light of the broader context outlined above, it is clear that significant changes need to be made in order to improve sustainability outcomes. The focus on harm minimisation in the development industry needs to be shifted to focus on creating sustainable and even restorative development. Concurrently, there needs to be a greater level of accountability in the way we describe development, as to date it has been common practice to describe a development as 'sustainable' when it features just a few green elements. This shift might be achieved by focusing on the principles behind sustainability and by using those principles to guide the design process.

A principles framework provides a reference point for sustainability in the development industry, ensuring industry progress towards (and beyond) sustainability is in alignment with the broader national and global picture. It reminds us of ecological limits and how we must stay within them, as well as encouraging a systems approach that will take development to a new level of synergy. A principles framework also opens up possibilities for innovation. It provides context and structure to the discourse about development of the future, whilst allowing sufficient flexibility for lateral thinking and creativity. Importantly, it supports learning for sustainability in the development industry. A deep, transdisciplinary, transformative learning approach to principles-based understanding of sustainability (e.g. Meppem and Gill 1998) empowers industry practitioners to recognise the principles that underpin truly sustainable development and apply them in new and creative ways, rather than 'following the recipe'. This is highly important for the development industry's evolution, and for reaching the long term goal of sustainability.

2.1 Principles for Sustainability Learning

This paper draws on previous research into appropriate principles for sustainability learning. The principles set out below have been drawn from many different fields of sustainability learning (Carew and Mitchell 2001) and adapted for the building and construction industry. The principles are divided into interdependence principles (systems thinking, limits and elasticity, impacts, and uncertainty and complexity) and ethical principles (responsibility, awareness and fairness) (see Figure 1). At the core of relevance to the building and construction industry are understanding limits, systems thinking, and responsibility. These are the focus of this paper.

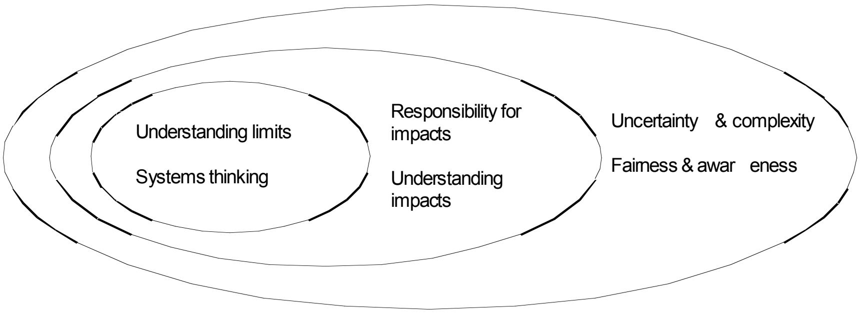

Figure 1: Principles for sustainability learning in the development industry

In the sections that follow, we first outline the principles, then demonstrate their application in various precinct scale developments in Sydney.

2.1.1 Limits

The idea of limits refers to the simple fact that all biophysical resources are limited. The planet has certain amounts of each fundamental building block - the elements - and a finite supply of energy from the sun to drive the processes that change the way those elements are combined in a myriad of ways to produce the biophysical world around us. These natural resources are all we have as potential starting materials for everything we manufacture, construct, use, and dispose. There are physical limits to the scale of these resources, ecological limits to the assimilation potential of the environment, and thermodynamic limits to the rates at which things happen. These limits and the way in which they interact are fundamental to the concept of resilience, which itself is fundamental to sustainability.

As noted earlier, we have already exceeded limits from many perspectives, and from other perspectives are close to it. Our actions have already increased atmospheric concentrations of greenhouse gases, and scientists believe we can only avoid dangerous climate change by urgently making 'deep cuts' in our greenhouse gas emissions. In water, there is a growing call to rehydrate the landscape - to return water to the catchment and source (surface or ground) from whence it was taken (Nelson 2008).

As we can see from the principles above, respecting limits is embodied in the concept of sustainability. Therefore to be considered sustainable, urban development must mirror this principle. It must itself perform within ecological limits. This may be easier to do and measure from some perspectives, such as greenhouse emissions from operational energy use, than from others, such as material intensity. However, the principle of performing within limits needs to be the goal of any sustainable development. Taking climate change as an example, urban development must deliver similar deep cuts in greenhouse emissions to those needed economy-wide to stabilise atmospheric emissions. Whilst sustainable development respects limits from a number of different perspectives, such as resource use, land disturbance and emissions, it also requires systems thinking to explore and optimise the connections between these different areas of ecological impact.

2.1.2 Systems thinking

Systems thinking is embodied in the concept of sustainability (Mitchell, 2000), and recognises we live in a highly interconnected and complex world. It considers the whole and the interrelationship of the many parts, taking into account context and multiple influences and relationships. It also creates awareness of the boundaries and assumptions used to define issues, recognises the influence of world views and perceptions, and embraces uncertainty and complexity. There are myriad examples of systems thinking in nature, yet few in the built environment. Even our approach to green development, perhaps partly as a consequence of traditional disciplinary divisions, tends to focus on one goal at the expense of another, leading to unintended perverse outcomes.

Systems thinking is not reflected in our traditional infrastructure design. Our tendency is to do what we are familiar with, which means that when an existing system is reaching its limits, we augment it with something similar. The economies of scale argument in industrialised systems makes the marginal cost of supplying one more customer look very small. However, a systems understanding of this cost that takes account of their proportion of the large scale infrastructure gives a quite different picture (Mitchell et al., 2007). The extensive economic and environmental advantages of small energy systems (Lovins et al., 2002) and small wastewater systems (Pinkham et al., 2004) are now well documented. The lack of a systems approach in engineering design has also been recently documented in wastewater systems in the USA (Etnier et al., 2007). A systems approach will lead to smaller, distributed infrastructure arrangements, focused on treatment rather than transport of commodities and capturing synergies between infrastructure systems.

Sustainability rating tools for building have played an important role in the 'mainstreaming' of green building, however they can constrain innovation at the cutting edge because they cannot adequately address systems thinking, an inherent limitation of any prescriptive tool. They prompt users to 'follow the formula' (as robust as that formula may be) instead of encouraging broader exploration. Systems thinking encourages creative new connections that allow us to do radically more with less. Emerging interest in the application of 'biomimicry' to buildings is also a recognition of the value of systems thinking. Systems thinking is key to the next paradigm shift in urban development and needs to be built into design and assessment processes.

2.1.3 Responsibility

Whilst the previous two principles are interdependence principles, responsibility is an ethical principle. Business as usual clearly has unacceptable consequences for the future, and in line with this principle all industry sectors, including the development industry, must take responsibility for its actions and accept a greater level of accountability throughout its operations.

For development industry stakeholders and practitioners, responsibility requires a shift in the level of engagement with sustainability principles and with others involved in the process. It means extending the boundaries of responsibility, similar to Covey (1990), by expanding one's area of control as well as taking action within one's influence. The Australian development industry has made significant progress in this regard e.g. It is common for developers to set up partnerships with those who will operate, manage and tenant their developments. However, there is potential for stronger and more extensive connections to be made. New institutional arrangements that facilitate these kinds of relationships will be key (Martin & Verbeek, 2006), particularly through harnessing market capital.

We need to hold ourselves accountable with respect to staying within limits. Some ecological impacts are easier to benchmark and measure than others, allowing us to more easily assess outcomes in relation to limits. For the impacts that are easier to benchmark and measure, targets can be applied as an accountability mechanism e.g. targets for greenhouse gas emission reductions or water use and effluent reductions. We also need to hold ourselves accountable with respect to systems thinking. In this regard, the quality of the outcomes achieved is largely determined by the quality of the process. It is increasingly recognised that traditional design and decision-making processes are no longer appropriate, or the traditional disciplinary roles and divisions. Integrated decision making and implementation processes are now often cited as an important way to optimise outcomes for sustainability. Therefore, it's possible to use process principles as an accountability mechanism for systems thinking.

Building rating tools such as Greenstar and the Australian Building Greenhouse Rating (ABGR) serve as our current accountability mechanism, and have made significant progress in shifting mainstream practice (Davis Langdon, 2008). However, to support the next shift, tools like these will need to be used within a broader principles-based framework that takes limits and systems thinking into account. In a similar vein, sustainability science scholars note the need for transdisciplinary thinking to deal with the issues of our time (Meppem and Gill 1998).

As it is not possible to know 'the right answers' in advance, we must move to the concept of learning, and particularly learning in new, transdisciplinary ways, as key in our planning and accountability mechanisms for sustainability.

3. Towards 'Restorative' Development In Urban Australia

To be truly sustainable, development needs to embody the principles described above. It must stay within ecological limits, and to do this from multiple perspectives a systems approach is required. This definition of sustainability is about a kind of equilibrium – development that uses only its 'sustainable' share of resources and creates only its 'sustainable' share of impacts (such as emissions, waste, effluent, etc). This is the principle of staying within limits. If all our building stock performed like this, we would have an sustainable built environment. However, performance of our existing building stock falls far short of this, and to compensate future development must aim for outcomes that go well beyond sustainability.

This is where the concept of 'restorative' development comes in. Restorative development contributes to the sustainability of the wider area, by using much less than its sustainable share of resources and creating much less than its sustainable share of outputs, or by achieving sustainability 'equilibrium' on the site and reducing the environmental impact of existing development beyond the site through, for example, export of energy with low greenhouse intensity or recycled water.

3.1. The Potential for Precinct Scale Urban Development to Lead in Restoration

Urban redevelopment provides the ideal opportunity for achieving restorative outcomes, particularly precinct scale development that, by nature of its scale and complexity, supports innovation in infrastructure design. This scale lends itself to the cost effective application of decentralised technologies for energy and water that help to minimise environmental impact and maximise efficiency and synergy. Examples include the use of trigeneration for electricity supply, heating and cooling on site, the conversion of organic waste to biogas for use on site, the use of urine separating or vacuum toilets to drastically reduce water use in conveying wastes and energy use in treatment, and improve the local nutrient and energy recovery potential. Use of these decentralised technologies helps a development to meet 'restorative' targets for minimising energy and water use, greenhouse gas emissions and effluent discharge – the principle of staying well within limits. These developments can greatly reduce their reliance on the city's ageing infrastructure, and in some cases be self sufficient and even support other development beyond the site boundaries.

Precinct scale urban development also lends itself well to a systems approach, which is key to restorative development. Developments of this scale are essentially microcosms, with the same spectrum of needs as a normal city, with residential, commercial, retail and community spaces as well as a connecting biological environment. Opportunities exist to apply systems thinking by maximising synergies between the different land and building uses. Buildings can be clustered to maximise symbiotic relationships between them and allow optimal sizing, design and staging of infrastructure.

Development of this scale and complexity provides opportunities to integrate a broader range of issues compared to single building developments, including issues related to transport, connectivity, social access and inclusion as well as the economic aspects of sustainability. This scale of development will naturally involve a larger range and number of stakeholders, meaning that multiple different perspectives and objectives need to be taken into account.

In terms of cost, precinct scale development lends itself to 'doing more with less', through the inherent economies of scale and the ability to optimise infrastructure design. This scale provides ability to bulk-purchase the most efficient products and materials (e.g. "Solaire" in New York). When there is a variety of building types and more uses (commercial, residential, retail), some infrastructure can be designed to better match supply with demand. This is certainly the case with energy, where demand profiles for heat, cooling and electricity can be better matched to supply profiles, effectively reducing the peaks in energy demand (and therefore the need to oversize infrastructure).

In terms of water, precinct scale has advantages over both highly centralised and highly decentralised - the economies of scale in treatment are realised, and the diseconomies of scale in transport are avoided (Pinkham et al 2004). Precinct scale allows potentially more cost effective integration of water cycle elements. Water is heavy, and pumping it around incurs significant energy costs. Therefore local capture, treatment and reuse at a 'cluster' scale is emerging as the means for delivering environmentally, economically, and socially preferable outcomes (Nelson 2008). Precinct scale also offers opportunities to connect effectively to other infrastructure realms. For example, shifting to a resource view of wastewater and collecting the organics in waste and wastewater and recycling those to local energy production. In the future, nutrient recovery will drive wastewater treatment processes, and this is also benefited by a precinct scale approach in terms of collection, storage, avoiding contamination and later transport.

3.2 Creating Restorative Development

In order to create a restorative development, the principles of sustainability need to be translated into specific targets for each aspect of a development, including: water, energy, waste, materials, transport and community. However, the key to restorative development is to meet individual targets and to maximise integration between systems in the built and natural environments. It is often the case that specific targets can be more easily met through synergies between systems and that these synergies can provide the means to "tunnel through the cost barrier".

3.2.1 Staying within limits – sustainable and restorative targets
Defining targets for some development aspects such as energy or water can be easier than for others, such as material intensity and community. For example, the reductions in energy use and greenhouse gas emissions (GHGE) that are required to stay within ecological limits are widely understood and universally applicable. The IPCC 4th Assessment Working Group III report argues that to achieve stabilisation of carbon dioxide at 450ppm CO2-eq, developed countries such as Australia, must reduce GHGE by 25-40% below 1990 levels by 2020 and by 80-95% below 1990 levels by 2050 (IPCC, 2007). As one of the highest per capita emitters of GHGE (WRI, 2008), Australia should arguably be aiming for the upper limit of this range and for meeting it earlier. Consequently, these society wide targets have been translated into specific targets for the building sector as shown in Table 1 below, in relation to the sustainable – restorative framework.

The sustainable level in Table 1 has been defined as meeting interim targets upfront and building in the flexibility to achieve longer-term targets. This target is derived by assuming that the upper bound of the

IPCC's 2020 target (i.e. a 40% reduction from 1990 levels) needs to be achieved upfront in new developments and that a further reduction of 10% is appropriate to account for the low cost of abatement opportunities in the building sector (Enkvist et al., 2008). The 50% reduction target is then adjusted taking into account growth in energy use in the commercial and residential sectors between 1990 and 2005 to establish reductions from 2005 (current) emissions levels. Table 1 represents an example of sustainable / restorative outcomes for greenhouse gas reductions targets for a mixed use urban renewal precinct, where targets are shown in line with their corresponding ratings in BASIX[1] and ABGR[2] as well as the measures and infrastructure required to meet these targets. Sustainable and restorative outcomes are compared with what is currently viewed within industry circles as best practice.

Table 1 – Example of Sustainable and Restorative targets for GHGE reductions and likely infrastructure requirements at a mixed use urban renewal site

Rating Tool	**Current 'best practice'**	**Sustainable Case**	**Restorative Case**
Target		40% reduction in GHGE from 1990 levels whole of society = 64% reduction in GHGE from 2005 levels for the building sector	Substantially greater than 64% reduction in GHGE
BASIX (residential)	25% BASIX score	60% BASIX score	substantially > 60% BASIX score
ABGR (commercial)	4.5 star	5 star + 40% additional CO_2-eq reductions	5 star + substantially > 40% additional CO_2-eq reductions
Measures / Infrastructure	1. Energy efficiency initiatives - average market practice in Australia, and 2. Solar hot water for residential buildings	1. Best practice energy efficiency, with some leading edge efficiency initiatives 2. Life-cycle embodied energy reductions and – Trigeneration or – Large-scale solar hot water system, – Geothermal heat exchange for space heating and cooling, and – Some on-site renewable energy	1. As for sustainable case (either path) with leading edge energy efficiency 2. Larger contribution from on-site renewable energy 3. Off-site greenhouse gas reduction initiatives

Adhering to ecological limits in the water cycle relates to the use of a sustainable yield of water that can be readily replenished locally as well as mitigating the impacts of stormwater runoff on downstream environments. Sustainability targets set for potable water substitution and stormwater management in general need to be site specific, to take into consideration the physical attributes of the site and surrounding catchment. The ecological limits concept in water extends to considering the resources in the wastewater stream - in particular, phosphorus. Phosphorus is an essential nutrient for all growth, and is currently supplied by mineral deposits that will be depleted in approximately 50-80 years. We need to move from a linear to cyclical approach to phosphorous use, by taking advantage of urine as a concentrated 'source' of phosphorus. The leading water research laboratories in Switzerland recently released a compilation of their technical, social, and economic work in this area (EAWAG 2007), and a trial of 20 urine-separating toilets is underway in Queensland (Beal et al 2008).

With respect to stormwater quality improvements, targets to create a restorative development need to reflect the sensitivities of the receiving environments downstream of the development (Barter, 2005). Natural runoff loads of phosphorous and nitrogen vary from catchment to catchment, as the natural uptake of these nutrients also varies depending on the downstream ecosystem and its condition. The most effective method to reduce adverse impacts on the downstream ecosystem is to design the development's landscape to mimic the natural environment, so that stormwater runoff is slowed and filtered to stay within natural limits of pollutant loads and flow frequency. The Sydney Metropolitan Catchment Management Authority is now recommending that the impervious area in a catchment that is directly connected to a stream by a stormwater drain be less than 2-5% of the catchment, in addition to ensuring that downstream waterways are not affected by erosion or excessive nutrients (SMCMA, 2007). This has significant implications for precinct developments and the integration of water sensitive features into landscape design. Reducing overall site imperviousness will mean an increase in green areas, including green roofs. Minimising the area of hard surfaces directly connected to drainage will mean that all hard surfaces must drain through buffer strips, grassed swales and other water sensitive landscape elements.

3.2.2 Systems thinking – a key attribute of restorative development

Ecological limits need to be respected within a development but also for the surrounding community, as for example, meeting potable water reduction targets at the expense of greater energy use in the community is not a sustainable outcome. This is where the application of the 'systems thinking' principle becomes important. Not only is it important to consider the overall balance of impacts across the different aspects of the development, but in order to make greater advances in sustainability it is vital to assess the potential for

[1] BASIX is the Building Sustainability Index tool used in NSW http://www.basix.nsw.gov.au/information/index.jsp
[2] ABGR is the Australian Building Greenhouse Rating tool http://www.abgr.com.au/

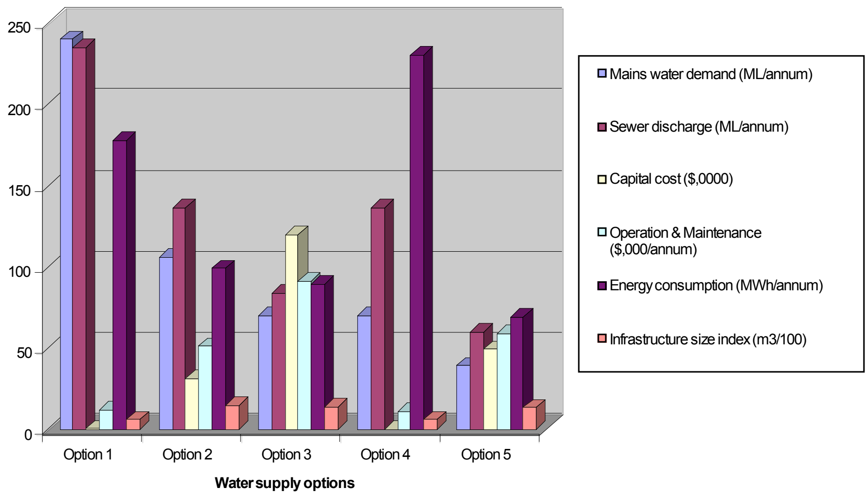
synergies between different parts of the overall system. For example, rainwater can be collected and used to cool an on-site cogeneration or trigeneration plant, which in itself reduces the site's greenhouse gas emissions; but in conjunction, the heat transferred to the rainwater produces a suitable hot water supply source for the development. Further examples of synergies between systems include: recycling biosolids and organic waste in a development for digestion and use as biogas, recycling biosolids/organics for soil conditioner, collecting urine from urine diverting toilets to recover nutrients for use as fertiliser and the use of green roofs to compensate for reduced green areas, improve water quality and provide thermal mass for a building. In this way, available resources can be used more effectively by maximising synergies.

One approach to maximising synergies between systems in a development is to use the principles of biomimicry. Biomimicry takes design inspiration from nature and encourages the incorporation of natural processes into the design of systems in the built environment (Benyus, 2002). Council House 2 is the first Australian urban building to be designed based on the principles of biomimicry (Morris-Nunn, 2007). Features of CH2 include: external sun shades made of recycled timber that pivot in response to the angle of the sun, extraction of warm air through ceiling exhaust and wind powered turbines, shower towers that use falling air and water to cool the lower levels of the building, plantings on the north façade and roof to provide shade, thermal mass in between floors to absorb excess heat as well as solar hot water, photovoltaic cells and a gas-fired co-generation plant to provide electricity (City of Melbourne, 2006).

In Berlin, UFA FABRIK and the Institute of Physics building at the Technical University of Berlin at Adlershof (Schmidt 2005) go further in connecting water and energy cycles with biological systems. Schmidt is interested in the direct connections between rainfall and energy absorption. He suggests that the lack of vegetation in our urban landscape is an insufficiently explored factor in the climate change equation that significantly shifts two variables: the nature of reflected radiation, resulting in shifts in the quantum of energy absorption potential in the atmosphere, and water and energy absorption patterns, significantly impacting heat island effects and thermal performance of buildings. The evaporation of water provides significant cooling potential - up to a theoretical maximum of 680kWh per cubic metre of water. Operational measurements are showing average figures of around 300 kWh/m2.a (Schmidt 2005).

The overall balance of sustainability outcomes is highly important when assessing options for a development. In the graph in Figure 2 below, the characteristics of a number of water demand/supply options that have been developed in accordance with the sustainable-restorative framework have been graphed for comparison. The water savings measures used in each option are explained in the key to the right of Figure 2. From left to right, each option provides a greater reduction in potable water demand; however, the associated sewer discharges and energy consumption do not uniformly decrease. In particular, the energy required for treatment and pumping of the externally sourced recycled water in option 4 is much greater than for option 3, which offers similar reductions in potable water use. The capital, operation and maintenance costs of each system and the relative size of the required infrastructure are also shown on this graph (note that capital and operating costs were unavailable for Options 1 and 4). In Option 4, mains water consumption is similar to option 3, however, energy consumption is high and in reality, the cost of this system to the community is likely to be much higher. It is clear from this graph that option 5, which maximizes efficiency, reuse of water, nutrients and biosolids and consequently incorporates synergies with natural systems, provides a more even reduction between potable water use, sewer discharge and energy consumption. This example shows very clearly that the entire system must be considered in order to achieve a balance between environmental impacts. It also shows that appropriate costing of infrastructure needs to be undertaken to reflect the real cost to the community of various options (Mitchell et al., 2007).

Figure 2 – Comparison of water demand-supply options for a precinct scale development



Option 1 - Australian best practice efficiency

Option 2 – Efficiency + rainwater + harvested stormwater

Option 3 – Efficiency + rainwater + on-site wastewater recycled

Option 4 – Efficiency + rainwater + externally sourced recycled water

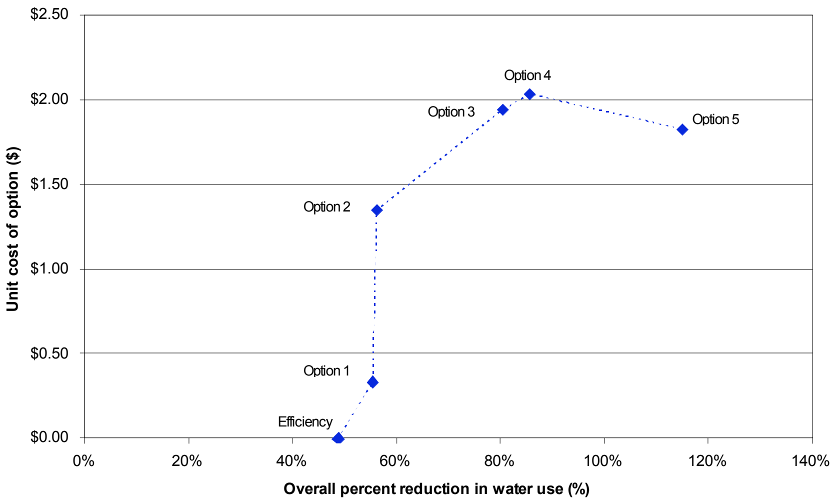
Option 5 – Greater efficiency + rainwater + greywater + collection of urine and biosolids

The graph in Figure 3 presents an example of the unit costs associated with different water demand-supply options for a precinct development. The infrastructure proposed for each option is explained in the key to the right of the graph. Options 1 to 4 illustrate the rising unit cost associated with increased water savings, however, option 5 is an example where the unit cost of water savings has reduced due to an economy of scale. This is an example of how innovative strategies and effective sizing can help to "tunnel through the cost barrier".

In practice, to ensure sustainable outcomes for a development, these sustainability principles (limits, systems thinking, responsibility) must be embedded in the design process. Collaboration between designers, planners and engineers is crucial to ensure that synergies between systems that may be simple to adopt are not overlooked. The application of explicit principles for process in urban development will help to encourage systems thinking and ensure synergies are captured. Figure 4 shows principles that have been developed specifically to guide precinct-scale urban redevelopment. The overarching principle governs outcomes – a development that is at least sustainable and ideally restorative. The other principles govern process and are in place to ensure the first principle is achieved, and in the most effective way. Using these process principles would support restorative outcomes and preclude the choice of design options such as Option 4 in Figure 2.

The examples used in this section of the paper focus on operational impacts that have been modeled for upcoming urban redevelopments in Sydney, however as the development industry moves further towards a systems approach, new concepts will be need to be assimilated. One of the emerging frontiers is the 'embodied impacts' of the materials used. These can be far ranging, and include impacts on climate change, biodiversity and other ecological health factors as well as energy and water use.

Figure 3 – Unit costs associated with water savings options for a precinct development



Efficiency - Australian Best Practice efficiency

Option 1 – Rainwater (cooling towers)

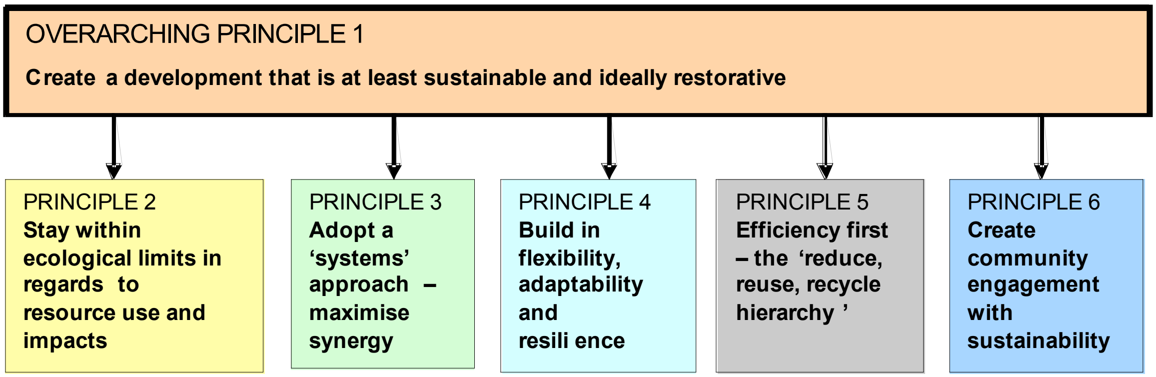
Option 2 – Rainwater (reticulated)

Option 3 – Rainwater & stormwater (reticulated)

Option 4 – Rainwater & on-site wastewater recycled

Option 5 – Rainwater & recycled wastewater from sewer main

Figure 4 – Sustainability process principles for design of precinct scale developments



4. Conclusion

Despite the increasing popularity of building sustainability rating schemes and the shifts that have been occurring in the building industry, greater changes need to occur in order for developments to become sustainable and respond to the pressing issues of climate change, material waste and water scarcity. Business as usual in the development industry and even current 'best practice' is not sufficient to address these problems. It is important that planners, designers and engineers in the industry look beyond current notions of 'best practice' and seek to create development that has a net positive impact on the environment and society. By using an overarching principles based framework, all practitioners involved in designing the built environment may be able to rethink their approach and collectively create development worthy of sustainable and even 'restorative' status, where the development has a positive impact on its environment. This paper sets out a principles framework that may be used to guide the process and outcomes of 'restorative' developments. The sustainable-restorative framework provides a means for identifying the most appropriate option in each development situation. Urban renewal sites present an excellent opportunity to apply this framework, due to the potential to create synergies between systems and the benefits gained from economies of scale. The creation of restorative developments in Australia will have a significant impact on reducing the ecological impact of urban areas, while still accommodating growth.

CALCULATING BUILDINGS' GREENHOUSE GAS EMISSIONS

Hal LEVIN[1]

[1] Building Ecology Research Group, Santa Cruz, California, USA hal.levin@buildingecology.com

Summary (*11-point Arial, bold, flush left, 11-point line spacing, style name "Heading 1*")

Increased concern about climate change has led many building designers throughout the world to focus on reducing energy use in buildings. It is often assumed that energy use is more or predictive of greenhouse gas GHG) emissions However, there are numerous time-dependent variations in building energy use and electric grid operation that result in important differences between the quantity of energy used and the related GHG emissions. These differences are not generally considered or even recognized by most designers or even regulators and others who are now striving to develop a carbon neutral economy. Efforts have begun to recognize the important factors that determine a building's GHG emissions based on its energy use, but these efforts are still in the preliminary stages. This paper identifies some of the important factors that affect the estimation of GHG emissions based on energy use data from simulations during design or from actual energy meters or purchases. These differences are being considered in a new effort to develop a tool that will more accurately predict building GHG emissions based on design alternatives, thus allowing design professionals to improve the GHG emission performance of their buildings.

Keywords: Greenhouse gas, climate change, GHG emissions, energy, design

1. Introduction

Buildings are responsible for a significant fraction (~40%) of fossil fuel consumption and related greenhouse gas (GHG) emissions globally. In the United States, buildings are responsible for 70% of total electricity use. While these factors vary from country to country and even among regions within countries, the numbers reflect the relative magnitude of building energy consumption in most of the developed world. In the developing world, the percentages are different with a shift toward combustion of biomass and less electricity use. However, the human contribution to GHG emissions is still significant and growing as developing countries gain access to modern energy-consuming technology, electricity, and a more mobile life style.

Growing concern about climate change and the human contribution to it through emissions of greenhouse gases (GHG) has led to increasing focus on reduction of GHG usually referred to as carbon dioxide equivalents (CO_2eq) using United Nations Framework Convention on Climate Change factors for global warming potentials of various atmospheric emissions. Efforts to reduce building's contributions to climate change focus on reduction of emissions of GHGs. Calculation of GHG emissions is usually done with simple conversion factors that translate fuel consumption and electricity use to GHG emissions. However, these conversion factors may not reliable inform design or building operational decisions due to potentially large influences of time and weather on actual GHG emissions compared with annual averages.

In the paper we describe the approach to GHG calculation commonly used today, some of the challenges facing those who are developing more reliable tools for such calculations, and some of the sources of uncertainty in any method for estimating GHG emissions from buildings.

1.1 Background: Global Greenhouse Gas Emissions

Emissions of GHGs have increased since the industrial revolution. The dramatic increase that began after World War II has resulted in an average annual increase in atmospheric CO_2 of 2 ppm to the present level of 383 ppm. The rate of increase has also increased in recent years. It is forecast that GHG emissions will increase by 50 percent by 2025. Emissions in developing countries are growing and are expected to continue to grow the fastest. To avoid dangerous climate change requires slowing this trend in the short term and eventually and reversing it over the coming decades.

While CO_2 comprises the majority of GHG emissions, at about 77 percent of the worldwide total (measured in global warming potentials). Methane (CH_4) and nitrous oxide (N_2O) are the next most important GHG, and methane's short term impact is dramatically larger than its longer term impact, the usual basis for comparison of global warming potentials (GWP) among the various GHGs. Fluorinated gases (SF_6, PFCs, and HFCs) have a small share of the remaining important GHGs.

In developing countries, the contributions of CH_4 and N_2O are significantly larger in and in some cases exceed those of energy-related CO_2 emissions.

GHG emissions come from almost every human activity. Because of their large contributions, key policy targets are electricity and heat, transport, buildings, industry, land-use change and forestry, and agriculture. In terms of future growth the electricity and transport sectors are particularly important sectors. In terms of potential for short-term and cost-effective reductions, buildings and transport both figure prominently.

Global emissions are dominated by a small number of countries producing the majority of global GHG emissions. Most of these are among the most populous countries and have the largest economies. However, the major emitters are comprised almost equally of developed and developing countries and some transition economies of the former Soviet Union.

Projection of emission by nations is highly uncertain, especially among developing country economies due to their volatility and vulnerability to external shocks.

Not surprisingly, most large current emitters are among the largest historic emitters.

Coal is the highest carbon fuel and it plays a dominant role in electric power generation throughout the world. Its future growth is expected to be significant. Many leaders in the building and environmental communities advocate reducing or eliminating emissions from coal-fired power plants either be carbon sequestration or by eliminating the plants altogether and stopping construction of new plants.

Avoiding dangerous climate change will require reduced coal use or geologic sequestration of coal-related emissions. Similarly, major emitting countries will need to reduce their dependence on oil, particularly in the transport sector where it has near monopoly status.

1.2 Buildings' Share of Global GHG Emissions

The proportion of total national emissions attributable to buildings ranges widely depending on the definition of building-related emissions, the accounting method used, and, of course, the level of development and energy efficiency of the national building stock. The major drivers of buildings energy demand are population growth, economic development, diffusion level of energy use equipment, size of households, square meters of buildings areas, and behavioral factors" (de la Rue du Can and Price, 2008).

In developed countries, buildings' share is relatively similar at around 25% to 35% of total national GHG emissions according to the World Resources Institute. In contrast, there is great diversity in buildings' share among developing countries ranging from around 10% (Brazil) to 40% (Poland) (Baumert et al, 2005). Where air-conditioning is common and widespread, electricity consumption will increase in non-residential buildings. In the U.S. the fraction of air conditioned homes (~70%) and commercial buildings is extremely high while in most other developed countries it is increasing in commercial buildings while in residences the penetration is strongly dependent on climate and other factors. Furthermore, the overall distribution of energy sources and the carbon intensity of the combustion fuels and electricity will be reflected in the national share of carbon emissions attributable to buildings.

"The residential sector is characterized by a striking contrast in fuel use between developed and developing countries. More than half the world's population lives in rural areas, of which more than 90% are in developing countries. The vast majority of this population is dependent upon traditional wood fuel to serve the basic need of cooking and water heating. Hence the share of biomass in the global residential final consumption represents more than 40% in 2004. In developed countries, natural gas and electricity are the most used fuel in residential buildings. While energy demand growth in residential sector was 1.4% over the period 1971–2000, growth in the commercial sector was 2.4%. Three quarters of the energy use in the commercial sector is currently consumed in developed countries. The commercial sector is characterized by a high level of electricity consumption, representing almost half of the total energy use (48%) in 2004." (de la Rue du Can and Price, 2008).

In the mid-1990s very different calculations done by the present author for buildings in the U.S. (Levin, Boerstra, and Ray, 1995) and by the World Resources Institute for buildings worldwide estimated buildings' share of total national carbon emissions at approximately 40% to 45% of total national energy consumption and a similar value for carbon emissions. Some authorities currently claim that buildings' share is even higher in the U.S. (e.g., 48% by Ed Mazria) (2008). The Levin et al estimate included building materials manufacturing, construction, operation, maintenance, renovation, and end-of-life disposal of buildings in this total. However, it should be noted that approximately 20 to 25% of building energy use is for "plug loads," that is energy used for appliances, electronics, and other devices that are not part of the building itself but that derive their energy from the same electrical source as the whole building. Therefore, their electrical consumption is measured at the electric meter and large scale data analysis and reporting often does not separate the building-related and the within-building-but-not-building-related energy uses. There remains a question as to whether devices like refrigerators, cookstoves, and plug-in lamps should be included in building-related energy uses for purposes of attribution and carbon emissions estimation

Table 1. Greenhouse gas emissions in 2004 by sector excluding land use change and forestry (source: adapted from Climate Analysis Indicators Tool (CAIT) Version 5.0. (Washington, DC: World Resources Institute, 2008).

Sector	**World %**	**United States %**	**European Union %**	**Asia %**
Energy	96.3	99.1	97.1	93.0
Electricity & Heat	45.3	45.8	39.4	46.5
Manufacturing & Construction	18.8	11.5	16.3	24.8
Transportation	19.1	30.5	23.1	10.9
Other Fuel Combustion	12.6	10.9	18.2	10.7
Fugitive Emissions	0.6	0.4	0.1	0.1
Industrial Processes	3.7	0.9	2.9	7.0
Total ($MtCO_2$)	**29,319.4%**	**5.873.8**	**4,013.1**	**9,968.1**

As can be seen in Table 1, the dominant source of human GHG emissions throughout the world is energy consumption with somewhere between 40 and 50% attributable to buildings. If construction and demolition are added to the total, buildings share is well over half. However, much of the electricity used in buildings is not to operate the building itself but is attributable to "plug loads' including appliances, electronics, etc. Nevertheless, building services uses of energy are approaching half of total energy use in developing countries.

Of course there are many ways of classifying the users of energy and of doing the accounting. According to the World Resources Institute (see Table 1), buildings account for only 15% of global GHGs. Of that amount, 65% is residential, 35% commercial. Within the residential sector, public electricity is 43%, District heat is 12%, and direct fuel combustion is 45%. In the commercial building sector, 65% is electricity, 4% is district heat, and 31% is direct fuel combustion. It is not clear whether the

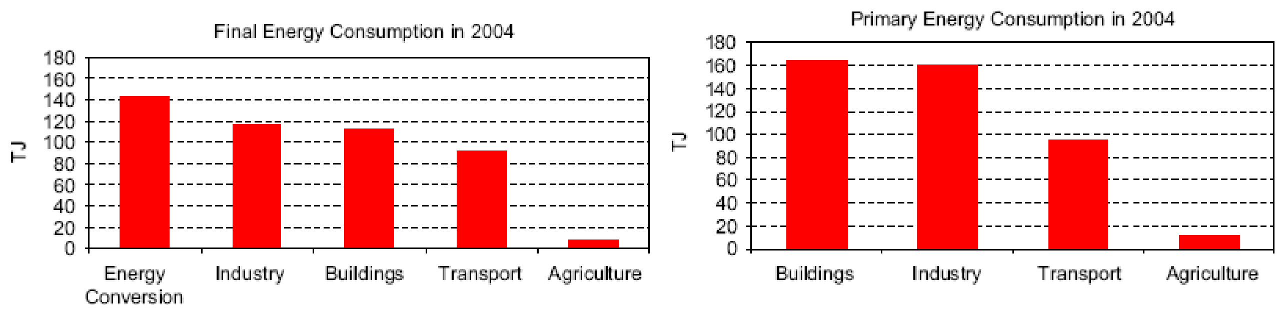

Figure 1. Final and Primary Energy Consumption by Sector in 2004 (source: de la Rue du Can and Price, 2008).

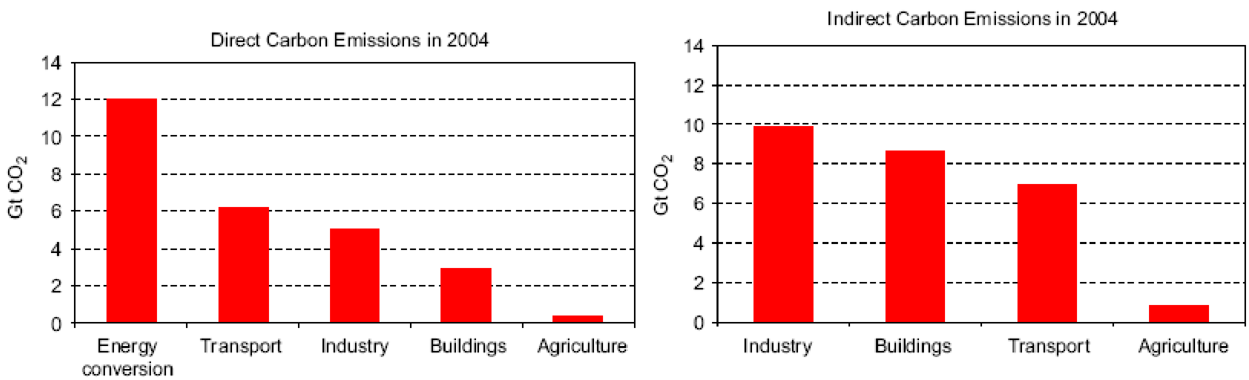

Figure 2. Direct and Indirect Carbon Dioxide Emissions in 2004 (source: de la Rue du Can and Price, 2008).

Regardless of the precise quantity of its share of global GHG emissions, it is clear that buildings are important sources of GHG emissions. It is also important to note that the range of building energy efficiencies and of potential sources of energy for buildings major consumption categories suggest that buildings can be far more energy efficient and emit far less GHGs. It may also be true that careful selection of energy efficiency measures can ensure optimization of both energy conservation goals as well as GHG emission reduction goals. However, since there is not a one-to-one relationship between energy use and GHG emissions, it is important to understand the GHG emissions implications of various alternative technologies to reduce energy use. For example, electricity from coal-fired power plants is associated with roughly twice the GHG emissions as that from natural gas-fired plants. Hydroelectric and wind electric energy plants are responsible for far less GHG emissions, although their construction, operation, and ultimate disposal do have GHG emission implications as does the transmission of electricity from any plant to the site where it is used. Large-scale concentrating solar electricity generation is viewed as one of the potentially viable renewable sources of future electricity, but it too has GHG emissions associated with its construction, operation, and electricity distribution. On site photovoltaic electric generation eliminates the transmission losses but does have a several-year payback for the energy required to manufacture and install the system. Even passive solar heating and cooling where high performance glass, shading, thermal storage, and other components are included in order to improve system performance still must be accounted for in total GHG emissions required to install and "operate" for their entire life cycles.

Conversion of building energy use data to GHG emissions

Following are definitions of some basic terms and some background information on greenhouse gases that are useful for those calculating greenhouse gas emissions.

Carbon sequestration: The fixation of atmospheric carbon dioxide in a carbon sink through biological or physical processes.

Carbon sink: A reservoir that absorbs or takes up released carbon from another part of the carbon cycle. The four sinks, which are regions of the Earth within which carbon behaves in a systematic manner, are the atmosphere, terrestrial biosphere (usually including freshwater systems), oceans, and sediments (including fossil fuels).

Global warming potential (GWP): An index used to compare the relative radiative forcing of different gases without directly calculating the changes in atmospheric concentrations. GWPs are calculated as the ratio of the radiative forcing that would result from the emission of one kilogram of a greenhouse gas to that from the emission of one kilogram of carbon dioxide over a fixed period of time, such as 100 years.

Greenhouse gases: Those gases, such as water vapor, carbon dioxide, nitrous oxide, methane, hydrofluorocarbons (HFCs), perfluorocarbons (PFCs) and sulfur hexafluoride, that are transparent to solar (short-wave) radiation but opaque to long-wave (infrared) radiation, thus preventing long-wave radiant energy from leaving the Earth's atmosphere. The net effect is a trapping of absorbed radiation and a tendency to warm the planet's surface.

Greenhouse effect: The result of water vapor, carbon dioxide, and other atmospheric gases trapping radiant (infrared) energy, thereby keeping the earth's surface warmer than it would otherwise be. Greenhouse gases within the lower levels of the atmosphere trap this radiation, which would otherwise escape into space, and subsequent re-radiation of some of this energy back to the Earth maintains higher surface temperatures than would occur if the gases were absent. See Greenhouse gases.

Radiative forcing: a measure of how the energy balance of the Earth-atmosphere system is influenced when factors that affect climate are altered. The word radiative arises because these factors change the balance between incoming solar radiation and outgoing infrared radiation within the Earth's atmosphere. This radiative balance controls the Earth's surface temperature. The term forcing is used to indicate that Earth's radiative balance is being pushed away from its normal state.

The principal greenhouse gases are shown in Table 2. From the table it is possible to see the growth in concentrations between pre-industrial atmospheric concentrations and those observed in 1998. Note that the atmospheric lifetimes of these gases vary greatly and are part of the reason that the time required for stabilizing climate and eventually reversing climate change through control of the concentrations of releases of these gases.

Table 2. Global atmospheric concentration (ppm unless otherwise specified), rate of concentration change (ppb/year) and atmospheric lifetime (years) of selected greenhouse gases

Atmospheric Variable	CO_2	CH_4	N_2O	SF_6 [a]	CF_4 [a]
Pre-industrial atmospheric concentration	278	0.700	0.270	0	40
Atmospheric concentration (1998)	365	1.745	0.314	4.2	80
Rate of concentration change[b]	1.5c	0.007[c]	0.0008	0.24	1.0
Atmospheric Lifetime	50-200[d]	12[e]	114[e]	3,200	>50,000

[a] Concentrations in parts per trillion (ppt) and rate of concentration change in ppt/year.

[b] Rate is calculated over the period 1990 to 1999.

[c] Rate has fluctuated between 0.9 and 2.8 ppm per year for CO_2 and between 0 and 0.013 ppm per year for CH_4 over the period 1990 to 1999

[d] No single lifetime can be defined for CO_2 because of the different rates of uptake by different removal process removal processes.

[e] This lifetime has been defined as an "adjustment time" that takes into account the indirect effect of the gas on its own residence time.

1.2. Basics of GHG Emission Calculations

It is common practice in most developed countries to use annual average conversion factors for calculating GHG emissions based on electricity consumption. These factors may vary greatly within and among countries due to differences in the composition or inventory of electricity generating plants. There is a substantial range of emissions depending on the combustion fuel used or other source of energy to produce electricity. For example, electricity produced in coal-fired power plants result in approximately twice the CO_2 emissions compared with natural gas fired electric power plants.

A general practice is to calculate a building's greenhouse gas emissions relatively simply. This involves using readily available conversion factors for each form of energy used annually. An alternative that may be somewhat more accurate is to modify fuel use data by the efficiency of the device consuming the fuel and other factors to convert the fuel consumption to emissions of each to the mass of the greenhouse gases. Then, using global warming potentials (GWP) of each pollutant emitted, the total GWP is given in carbon dioxide equivalents (CO_2e).

Currently, building design professionals estimate the annual energy consumption (e.g. kWh) that will be required to operate the building, and then apply actual average annual carbon emission factors (e.g., tons of CO_2 per kWh or per therm) to those estimates in order to estimate the annual carbon emissions associated with the building's operation (e.g. tons of CO_2 = kWh * tons of CO_2/kWh). The carbon emission factors applied to electricity to be purchased from the grid are based upon various sources within the building design professions today. There is not standard practice for selecting and applying carbon emission factors applied to electricity whether purchased from a utility or produced on-site. Combustion on-site is more reliably converted to emissions using standard factors although inclusion of 'embodied' emissions related to use of the fuel is not common.

Limitations of current methods for estimating GHG emissions

There are at least four aspects of the current method that may lead to less than sufficiently accurate estimates of carbon emissions associated with buildings.

Limited scope

The current emission factors for the carbon emissions associated with the generation of electricity, i.e., predominantly from the emissions from combustion of a fuel to produce electricity, do not reflect the emissions associated with the extraction and transportation of the fuels used to generate that electricity. It is also possible that these factors have not been fully adjusted to reflect the energy losses on the transmission and distribution grid between the point of generation and the point of consumption, i.e., the building. Similarly, emission factors for on-site combustion do not include the so-called 'embodied' emissions associated with extraction, transportation, and storage of the fuels.

No differentiation by time period

Annual average emission factors for electricity purchased from the grid can mask significant variations in emissions by time of day, day of the week and/or season, and therefore may not produce a sufficiently accurate estimate. This is a major reason for this project. Energy consumption and GHG emissions do not map one-to-one due to the diversity of electricity generation on the grid and its geographical and temporal variations. The question then is whether the estimate of carbon emissions would be materially improved if building design professionals could evaluate the time-dependent energy consumption at the site using emission factors based upon the corresponding time-dependent output of the electric grid providing electricity to that that site.

No differentiation by weather

There are two potential concerns in this regard. The first is similar to, if not the same as, the lack of time differentiation. Annual average emission factors for electricity purchased from the grid can mask significant variations in emissions within the year due to variations in weather conditions. In other words, electricity generation emissions under extreme weather conditions such as heat waves and cold waves are different from emissions under annual average weather. The second relates to potential mismatches between the weather assumptions underlying the estimates of building energy consumption and the weather assumptions underlying the carbon emission factors. Building energy simulations are performed using average annual weather data (Typical Meteorological Year – TMY). Therefore the estimates of energy consumption produced by those simulations reflect that weather assumption. In contrast, actual carbon emission factors for grid electricity reflect actual weather in the relevant year while projected carbon emission factors reflect the weather assumptions used in the simulation of the electric grid. Thus, there is a possibility of a mismatch between the estimates of energy consumption and the carbon emission factors being applied to those estimates.

Actual versus projected emission factors

The current emission factors for electricity purchased from the grid are based upon emissions associated with actual generation of electricity in a recent year. The concern here is whether those factors provide a sufficiently accurate estimate of the emissions that will be associated with the future mix of generation over the life of the building.

In addition to evaluating the accuracy implications of each of those aspects of the current carbon estimation methodology, the accuracy of the energy use estimates to which those factors are being applied must be considered. Research indicates that the actual levels and patterns of building energy use can be very different from the estimates of use from simulation models made during the design process. These differences between estimated and actual building energy use arise because building energy simulations rely upon assumptions about key factors such as building occupancy, use, and operation. Actual occupancy, usage and operation of the building are often very different from those assumptions.

ASHRAE's Carbon Tool Development Project

The American Society of Heating, Refrigerating, and Air-conditioning Engineers (ASHRAE) has embarked on a project to development a more robust and accurate tool for estimating building's carbon emissions to enable designers, building operators, and others to make decisions that will improve the carbon emissions performance of a building and to account for the emissions that have occurred in an existing building. The tool will weigh the accuracy of the building energy use estimates when considering the value of developing more accurate estimates of carbon emissions to be applied to those energy estimates.

While the uncertainties are very large in any prospective estimate of carbon emissions based on forecasts and historical data as well as building simulations, by identifying and characterizing the sources of uncertainty and incorporating means to reflect them in an estimating tool will provide "realistic" data as an improved basis for design and operation.

Discussion and Conclusion

The present inaccurate methods of estimating buildings' carbon emissions leave building design and operational professionals with inadequate information to make decisions that actually result in lower greenhouse gas emissions. The assumption that a decision resulting in less energy use is always the lower GHG emission strategy is potentially costly both to the building operator as well as to the global climate. It is important to improve on currently available estimation tools and reduce the uncertainty in decision-making around a building's carbon footprint. While the data available currently is a major constraint on the development of accurate tools, investigation and improvement of the performance of current tools can help identify the most important data needs and the value in improving data quality. ASHRAE's current efforts are unique as far as is known by the author, and they are certain to create increased awareness of the problems and means of addressing them. It is hoped that the tool itself will be a major step toward broader recognition of the most important factors related to buildings' GHG emissions and that this recognition will enable more rapid progress toward net zero GHG emission buildings.

Table A1: Global Warming Potentials (GWP) (Relative to Carbon dioxide = 1) and Atmospheric Lifetimes (Years) IPCC 1996 values.

Gas	Atmospheric Lifetime	100-year GWPa	20-year GWP	500-year GWP
Methane (CH_4)b	12.3	21	56	6.5
Nitrous oxide (N_2O)	120	310	280	170
HFC-23	264	11,700	9,100	9,800
HFC-125	32.6	2,800	4,600	920
HFC-134a	14.6	1,300	3,400	420
HFC-143a	48.3	3,800	5,000	1,400
HFC-152a	1.5	140	460	42
HFC-227ea	36.5	2,900	4,300	950
HFC-236fa	209	6,300	5,100	4,700
HFC-4310mee	17.1	1,300	3,000	400
CF4	50,000	6,500	4,400	10,000
C2F6	10,000	9,200	6,200	14,000
C4F10	2,600	7,000	4,800	10,100
C6F14	3,200	7,400	5,000	10,700
SF6	3,200	23,900	16,300	34,900

These values were modified for the IPCC's Third Assessment Report (TAR) released in 2001 as shown in Table A2.

Table A2. Conversion Factors for Global Warming Potentials (source: 2001 IPCC GWP)

Gas	2001 IPCC GWP
Carbon Dioxide	1
Methane	23
Nitrous Oxide	296
HFC-23	12,000
HFC-125	3,400
HFC-134a	1,300
HFC-143a	4,300
HFC-152a	120
HFC-227	3,500
HFC-236	9,400
Perfluoromethane (CF_4)	5,700
Perfluoromethane (C_2F_6)	11,900
Sulfur Hexafluoride (SF_6)	22,200

Table A3 from L2, Approved document L2A emissions factors (source: UK, 2006)

Fuel	**CO_2 emission factor $kgCO_2/kWh$**
	UK
Natural gas	0.194
LPG	0.234
Biogas	0.025
Oil	0.265
Coal	0.291
Anthracite	0.317
Smokeless fuel (including coke)	0.392
Dual fuel appliances (mineral and wood)	0.187
Biomass	0.025
Grid supplied electricity	0.422
Grid displaced electricity[1]	0.568
Waste heat[2]	0.018

Notes:

1. Grid displaced electricity comprises all electricity generated in or on the building premises by, for instance, PV panels, wind-powered generators, combined heat and power (CHP), etc. The associated CO_2 emissions are deducted from the total CO_2 emissions for the building before determining the BER. CO_2 emissions arising from fuels used by the building's power generation system (.e.g., to power CHP engine) must be included in the building CO_2 emissions calculations.
2. This includes waste heat from industrial processes and power stations rated at more than 10 MWe and with a power efficiency > 35%.

ACCURACY OF SOME EPBD IMPLEMENTED THERMAL PERFORMANCE CALCULATION PROCEDURES

Summary

The driving force of the thermal regulations revision in the European Union (EU) was the European Directive for the Energy Performance of Buildings – EPBD (European Commission, 2003). The main objectives of the EPBD are the harmonization of all thermal regulations in the EU and the optimization of buildings energy performance, taking into account the climatic conditions, indoor comfort conditions and economic viability, for both new and existing buildings.

In order to be efficient and effective, the thermal regulations must lead to an accurate estimation of the energy performance of buildings allowing the energy certification to become a useful tool to compare results obtained in different countries. Having this fact in mind, the results obtained with the Portuguese calculation methodology, together with the results obtained with the methodologies used in two other countries (UK and Belgium), will be put side by side and also compared with the results obtained with a dynamic simulation tool for the energy performance estimation - VisualDOE.

This case study will be based on the heating and cooling needs estimation of some Test Cells built in the School of Engineering of the University of Minho. The simulated results obtained using the simplified calculation models established in the mentioned three countries thermal regulations and by VisualDOE.

1. Introduction

One of the main challenges that nowadays humankind has to face is the climatic changes and environmental depletion. It is known that these challenges are closely related to the energy consumption. In the EU 15, there are about 164 million buildings, responsible for 40% of the final energy demand and 1/3 of the greenhouse gas emissions. So, in order to promote the reduction of energy consumption, it is fundamental to apply sustainable development principles in the construction sector (Tzikopoulos et al, 2005; Eyckmans and Cornillie, 2002).

There are several measures that can be applied in order to reduce the buildings energy consumption, since the appeal of the consumers' consciousness to environmental problems, to the development of new construction solutions, more energy efficient.

One of the larger impact measures is the implementation of more restrictive thermal regulations. One of the new Portuguese thermal regulations, the RCCTE 2006, is applied to residential buildings and imposes a higher quality of the envelope, promotes the use of renewable energy and supports the use of certified materials.

The driving force of the thermal regulation revision was the European Energy Performance of Buildings Directive (European Commission, 2003). The main objectives of the EPBD are the harmonization of all thermal regulations in the European Union and the increase of buildings energy performance, taking into account the climatic conditions, indoor comfort and economic viability, for both new and existing buildings.

All the EU thermal regulations have methodologies that can, effectively, estimate the energy performance of standard buildings allowing a much more energy efficient design and thus an effective reduction of the energy consumption. The harmonization of methodologies and the subsequent building energy certification can allow comparing the European building stock in a more effective way.

The goal of this paper is to assess and compare different European thermal regulation methodologies, based on the EPBD. Three methodologies were applied to estimate the heating and cooling needs of a case study: the Portuguese (RCCTE, 2006), United Kingdom (SBEM, 2007) and Belgium – Walloon Region

(CWATUPE, 2007) thermal regulations. The heating and cooling needs were also determined by means of a dynamic simulation tool – VisualDOE – in each climate (Portugal, United Kingdom and Belgium). The case study used was the Test Cells built in the School of Engineering of the University of Minho, Portugal.

2. Building description

The Test Cells used in this study have three compartments: a Sustainable Test Cell (STC), a Conventional Test Cell (CTC) and a Passys Test Cell (PTC). However, this study focuses only the STC and the CTC, in order to guarantee that the Portuguese, the Belgium and the United Kingdom thermal regulations calculation methodologies can estimate with good accuracy the thermal behaviour of both conventional and non-conventional solutions.

2.1 Sustainable Test Cell

The Sustainable Test Cell (STC) contains two rooms (Figure1):

- Room 1 (simulates a bedroom) – It has a massive envelope with compacted earth walls (Goodhew & Griffiths, 2005) and an opening in the south façade. The high thermal inertia combined with an opening equipped with exterior horizontal and vertical shading devices - in order to avoid overheating in summer - is a passive solar technique. To improve the sustainability of the solution, the room' exterior walls were built with a locally available material - earth;
- Room 2 (simulates an office) – It is an insulated lightweight construction with a large opening in the north façade in order to promote the daylighting and thus reduce the energy consumption in lighting.

Between the two rooms of this Test Cell there is a movable partition that allows testing the performance of the whole Test Cell space or of the two distinct rooms (Silva, 2006).

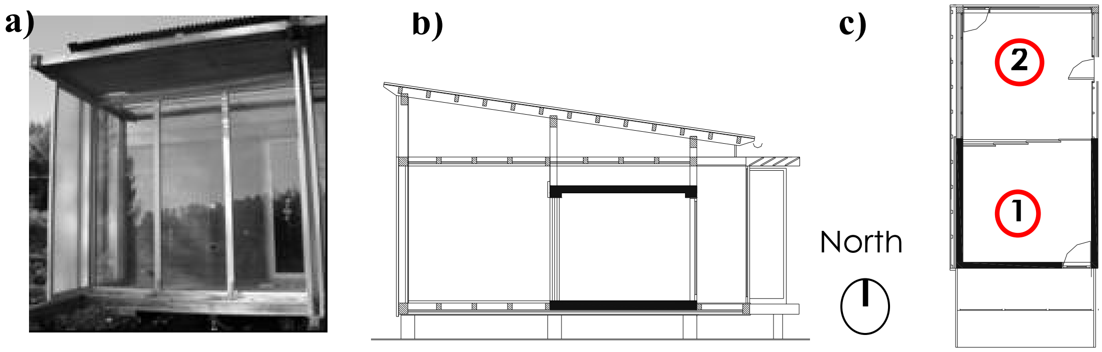

Figure 1 Sustainable Test Cell: a) Photo; b) lateral view; c) plan view

2.2 Conventional Test Cell

The Conventional Test Cell (CTC), shown in Figure 2, contains three rooms: the room 1 simulates a bedroom; room 2 simulates a bathroom; room 3 simulates a hall. The CTC was built with a double pane hollow brick wall with extruded expanded polystyrene in the air gap. This Test Cell is representative of the conventional Portuguese Construction (Mendonça, 2003).

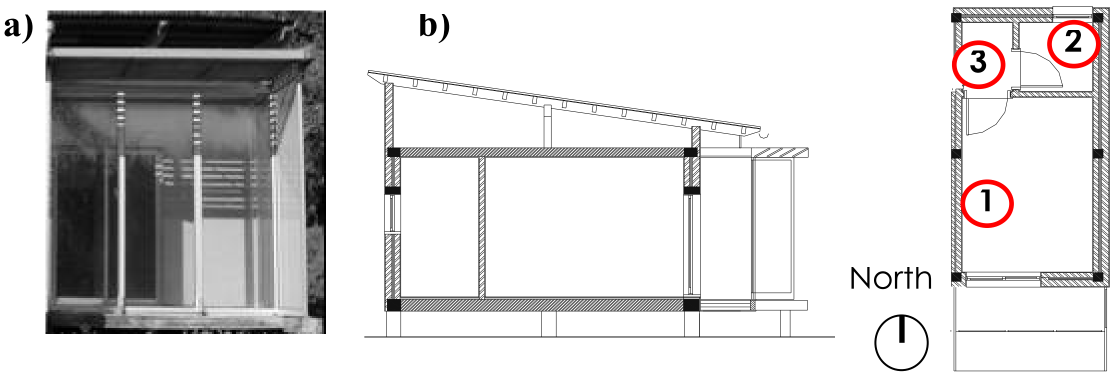

Figure 2 Conventional Test Cell: a) Photo; b) lateral view; c) plan view

3. Estimation methods

3.1 Portuguese thermal regulation - RCCTE

RCCTE is the Portuguese thermal regulation targeted to residential buildings and office buildings without HVAC systems. The objectives of this regulation are: guarantee that the heating and cooling requirements for thermal comfort, the ventilation requirements for indoor air quality and the hot water requirements are satisfied without an excessive energy consumption; Minimize the pathologies in the construction elements due to condensation.

This regulation defines values for the heating needs (N_{ic}) and cooling needs (N_{vc}). The N_{ic} and N_{vc} are obtained using the following equations:

$$N_{ic} = \frac{0{,}024.GD.(U.A_e + U.A_i.\ \tau + \sum \Psi B_s + \sum \Psi B_j + (0{,}34 * Rph + Ap * Pd) - \eta_H (qi.M.Ap\ 0{,}720 + G_{Sul} \sum_j [X_j \sum_n A_{snj}].M)}{A_p} \quad (1)$$

$$N_{vc} = \frac{(1-\eta_C)\left[\left[2{,}928\ U.A.(\theta_m - \theta_i) + U.A.(\frac{\alpha.Ir}{h_e})\right] + \sum_j \left[Ir_j \sum_n A_{snj}\right] + \left[2{,}928\,(0{,}34.Rph.Ap\,Pd)\right] + 2{,}928\,qi.Ap\right]}{A_p} \quad (2)$$

Where: A_p is the useful floor area; GD is the number of degree-day of heating for a 20ºC base; U is the thermal transmittance (U-value, e - for elements of the external envelope and i – for elements of the internal envelope); A_e is the area of the elements of the external envelope; A_i is the area of the elements of the internal envelope; τ is the coefficient of reduction of the thermal losses to non-heated spaces; Ψ_s is the linear thermal transmittance of the elements in contact with the soil; B_s is the length of the elements in contact with the soil; Ψ_j is the linear thermal transmittance of the linear thermal bridge; B_j is the length of linear thermal bridges; R_{ph} are the hourly air flow rate; P_d is the ceiling height; η_H is the dimensionless gain utilisation factor; η_C is the dimensionless utilisation factor for heat losses; qi are the internal heat gains (4 W/m^2 for residential buildings); M is the duration of heating period; G_{Sul} is the average mensal value of the solar energy hitting on a vertical surface south oriented of a unitary area during the heating season; X_j is the orientation factor; A_{snj} is the effective collecting area of the solar radiation (n – surface; j – orientation); θ_m is the average external air temperature for the cooling season; θ_i is the internal air temperature; α is the coefficient of absorption of solar radiation of the outside surface of the element; I_r is the average Intensity of the total solar energy hitting on the surfaces, per orientation, for all the cooling season; h_e is the external thermal superficial conductance of the envelope element (25 W/m^2.ºC).

3.2 United kingdom thermal regulation

In the United Kingdom the Energy Heating Needs are defined:

$$Q_{NH} = \sum\left[(\sum_i A_i U_i + \sum_k l_k \Psi_k).(\theta_i - \theta_{e,k})\right].t.\mathrm{f} + \rho_a.\mathrm{C_a}.\mathrm{U_{v\text{-}heat}}.A.(\theta_i - \theta_e).n.0.0864$$
$$-\eta_{\mathrm{G,H}} \cdot \left[Q_i + \sum_j (q_{sun,j}.\mathrm{f}_{sh,j}.\mathrm{f}_{sun,j}.g_j.\mathrm{f_f}) + \sum_j (\mathrm{f}_{ab}.q_{sun,j}.U_{c,j}.A_{\mathrm{c,j}})\right] \quad (3)$$

And the Energy Cooling Needs are obtained:

$$Q_{NC} = \sum\left[(\sum_i A_i U_i + \sum_k l_k \Psi_k).(\theta_i - \theta_{e,k})\right].t.\mathrm{f} + \rho_a.\mathrm{C_a}.\mathrm{U_{V\text{-}Cool}}.A.(\theta_i - \theta_e^{'}).n.0.0864$$
$$-\eta_{\mathrm{L,C}} \cdot \left[Q_i + \sum_j (q_{sun,j}.\mathrm{f}_{sh,j}.\mathrm{f}_{sun,j}.g_j.\mathrm{f_f}) + \sum_j (\mathrm{f}_{ab}.q_{sun,j}.U_{c,j}.A_{\mathrm{c,j}})\right] \quad (4)$$

Where: A_i is the area of the element i of the building envelope; U_i is the thermal transmittance (U-value) of the element i of the building envelope; l_k is the length of the linear thermal bridge k; Ψ_k is the linear thermal transmittance of the linear thermal bridge k; θ_i is the internal temperature of the building zone (heating set point); $\theta_{e,k}$ is the external temperature (the monthly average temperature) of element k; t is the duration of the calculation period; f is a factor for conversion from Wh to MJ; ρ_a . C_a is the specific air heat capacity (1.2 kJ/m^3); $U_{v\text{-}heat}$ is the air flow rate through the conditioned space, for heating; $U_{v\text{-}cool}$ is the air flow rate through the conditioned space, for cooling; A is the zone floor area; θ_i is the internal temperature of the building zone (heating set point); θ_e is the external temperature (the monthly average temperature); θ'_e is the modified external air temperature; n is the number of days within a month; $\eta_{G,H}$ is the dimensionless gain utilisation factor; $\eta_{L,C}$ is the dimensionless utilisation factor for heat losses; Q_i is the sum of internal heat sources (occupants, appliances and lighting) over a given period; $q_{sun,j}$ is the quantity of solar radiation per month on the plane, for weather location an orientation of window j; $f_{sh,j}$ is the shading correction factor of the window j; $f_{sun,j}$ is the reduction factor for moveable solar protection for window j; g_j is the total solar energy transmittance, for window j; $A_{r,j}$ is the area of window j, including the frame; $\mathrm{f_f}$ is the computation value for the frame factor (taken as 0.75); $\mathrm{f_{ab}}$ is the dimensionless absorption coefficient for solar radiation of the opaque construction multiplied by the external surface heat resistance (0.9X0.05= 0.045); $q_{sun,j}$ is the quantity of solar radiation per month on the plane, for weather location and orientation of construction part j; $U_{c,j}$ is the thermal transmittance of construction part j; $A_{c,j}$ is the area of construction part j.

3.3 Belgium, Walloon thermal regulation

The Belgium Walloon region regulation also defines the heating and cooling needs, as presented in the following expressions:

$$Q_{heat,\ final,\ m} = \frac{Q_{heat,\ gross,\ m}}{\eta_{ger,\ heat}} \quad (5)$$

$$Q_{heat,\ gross,\ m} = \frac{A_T \cdot K_S \cdot (18-\theta_{e,m}) \cdot t_m + H_{V,heati} \cdot (18-\theta_{e,m}) \cdot t_m + \eta_{util,heat,m} \cdot (Qi + 0.95 . g_j . A_{g,j} . I_{s,m,j,shad})}{\eta_{sys,\ heat,\ m}} \quad (6)$$

The cooling needs are obtained:

$$Q_{cool,\ final,\ m} = \frac{\max\left\{0, \min\left(\frac{I2-I1}{I3-I1}, 1\right)\right\} \cdot Q_{excess,cool,m}}{8.1} \quad (7)$$

Where: $\eta_{ger,heat}$ is the efficiency of the mensal energy production for heating; $\eta_{sys,heat,m}$ is the efficiency of the heating system; A_T is the total envelope area; K_S is the average thermal transmittance (average U-value); $\theta_{e,m}$ is the mensal external average temperature; t_m- is the duration of the heating period; $H_{v,heat}$ are the thermal losses due to ventilation and infiltration; Q_i is the sum of internal heat sources (occupants, appliances and lighting); g is the solar factor; Window area; $I_{s,m,j,shad}$ is the incident solar radiation having in account the effect of the fixed obstacles; $\eta_{util,heat,m}$ is the thermal gains utilization factor; I_1, I_2 and I_3 can be obtained from Figure 3; $Q_{excess.cool.m}$ are the excessive heat gains comparatively to the comfort temperature (23ºC).

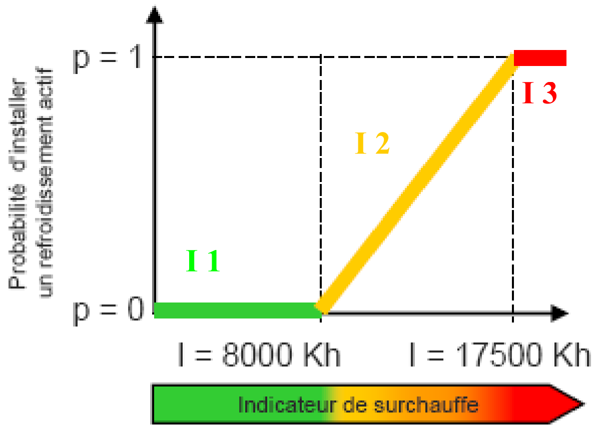

Figure 3 Probability of installing an active, conventional cooling system

3.4 VisualDOE

VisualDOE is a WindowsTM application that can estimate the buildings energy performance. The calculation engine used in this tool is the very well known and tested DOE2.1E. However, only the 3rd version of this tool (VisualDOE 3.1) can be considered as a Graphical User Interface of the DOE engine, as it allows a good control of the introduction of geometrical elements, in real-time, through the pictures of the model produced by the tool and it has the possibility of editing the model simply by clicking with the mouse in an element. This tool can be used without any knowledge of the source engine (Green Design Tools, 2001).

To estimate the buildings energy performance with VisualDOE it is necessary to follow 3 steps:

- Project data introduction;
- Execution of the simulation;
- Results analysis.

The project data introduction begins with the definition of all the VisualDOE databases containing the elements applied into the building – Glazing, Openings, Materials, Constructions, Occupancy, Schedules and Utility rates – and afterwards with the introduction of the model and project data that is formed by 6 folders – Project, Blocks, Rooms, Façade, Systems, Zones. As VisualDOE was created for the WindowsTM platform, the databases are easily updated with new materials and constructions through a graphical interface, as shown in Figure 4.

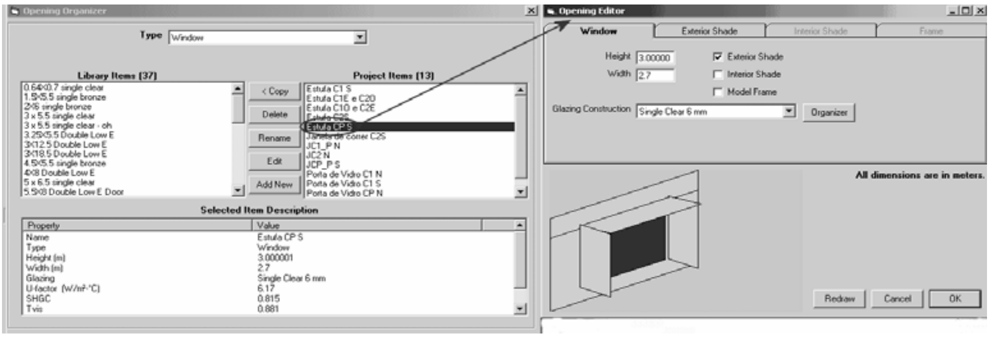

Figure 4 Openings definition in VisualDOE databases

In the 2nd step there will be present three folders – Simulation, Standard DOE-2 Reports and Hourly Reports – where we can define the base case, the alternatives (if necessary) and all the reports needed (hourly, daily, monthly or yearly results) for each specific study.

For the results analysis there are two main groups of data – the VisualDOE graphs and reports and the DOE-2 reports. The main difference between these sets of result is that the ones obtained with VisualDOE follow the WindowsTM platform (allows exporting results to other tools) while the DOE-2 reports follow a DOS platform.

The Test Cells were modelled and calibrated following the procedure shown in Silva *et al* (2006) in order to apply the model to VisualDOE. The final model is shown in Figure 5.

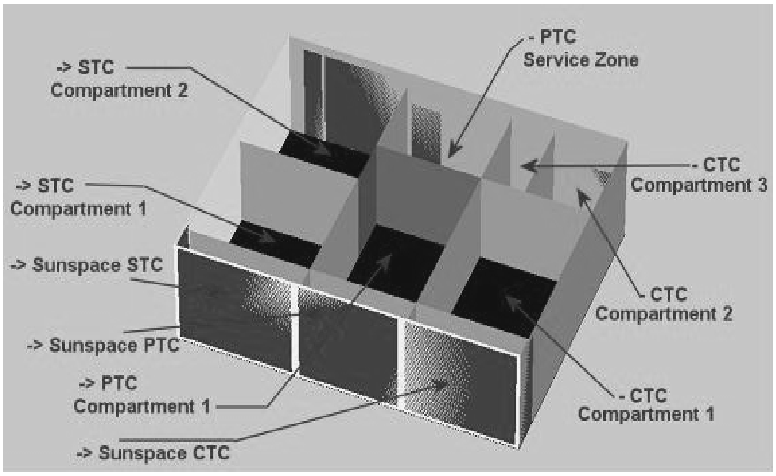

Figure 5 Model of the Test Cells

4. Simulations

This study was executed following three building energy performance calculation methodologies, all based on the EPBD (Energy Performance of Buildings Directive):

- The Portuguese methodology – RCCTE – Regulation of the Thermal Behaviour of Buildings;
- The Belgium methodology (Walloon region) – CWATUPE – Walloon Code of the Territory Development, Urban Planning, Heritage and Energy;
- The UK methodology – NCM – National Calculation Methodology;

Since the different methodologies enclose different input data, like the climatic data, heating and cooling set points and others, they can not be compared directly. Then, it was applied a dynamic simulation tool – VisualDOE – in order to put side by side with all the methodologies, in each case with the same input data.

4.1 Portuguese thermal regulation - RCCTE

The Portuguese regulation was assessed using the calculation model of the RCCTE to obtain the energy needs of the case study, with the following input data:

- City: Guimarães (41º27'N, 8º17'W));
- Heating set point: 20ºC;
- Cooling set point: 25ºC.

The results obtained with RCCTE and VisualDOE are expressed in Table 1.

Table 1 Heating and Cooling needs from RCCTE and VisualDOE

Test Cells		Heating Needs (kwh/m^2.year)		Cooling Needs (kwh/m^2.year)		Total Needs (kwh/m^2.year)	
		RCCTE	VisualDOE	RCCTE	VisualDOE	RCCTE	VisualDOE
With Sunspace	STC	127.7	124.7	49.5	41.9	177.2	166.6
	CTC	100.9	120.5	13.8	13.6	114.7	134.1
Without Sunspace	STC	139.8	135.2	51.3	42.5	191.1	177.7
	CTC	129.4	149.8	30.3	32.3	159.7	182.1

4.2 United Kingdom thermal regulation - NCM

In the case of the UK regulation, it was applied the basic user interface iSBEM Version 3.0 (Simplified Building Energy Model) in order to obtain the case study energy needs, with the following input data:

- City: London (51º30'N, 0º7'W);
- Heating set point: 18ºC;
- Cooling set point: 25ºC.

The results obtained with NCM and VisualDOE are expressed in Table 2.

Table 2 Heating and Cooling needs from NCM and VisualDOE

Test Cells		Heating Needs (kwh/m^2.year)		Cooling Needs (kwh/m^2.year)		Total Needs (kwh/m^2.year)	
		SBEM	VisualDOE	SBEM	VisualDOE	SBEM	VisualDOE
With Sunspace	STC	346.41	366.2	17.6	6.4	364.0	372.6
	CTC	355.2	359.1	10.0	1.2	365.2	360.3
Without Sunspace	STC	384.12	383.2	27.2	5.4	411.3	388.6
	CTC	403.04	383.5	37.5	4.8	440.6	388.3

4.3 Belgium, Walloon region thermal regulation - CWATUPE

For the Belgian regulation (Walloon region) it was applied the tool CALE Version 1.3 (Built with the Energy – Construire Avec L'Energie) in order to obtain the case study energy needs, with the following input data:

- City: Saint Hubert (50º1'N, 5º22'E);
- Heating set point: 18ºC;
- Cooling set point: 23ºC.

The results obtained with CWATUPE and VisualDOE are expressed in Table 3.

Table 3 Heating and Cooling needs from CWATUPE and VisualDOE

Test Cells		Heating Needs (kwh/m^2.year)		Cooling Needs (kwh/m^2.year)		Total Needs (kwh/m^2.year)	
		CWATUPE	VisualDOE	CWATUPE	VisualDOE	CWATUPE	VisualDOE
With Sunspace	STC	402.8	405.7	10.7	1.5	413.5	407.2
	CTC	379.4	379.4	10.8	0.0	390.2	379.4
Without Sunspace	STC	402.8	426.7	10.7	1.6	413.5	428.3
	CTC	435.0	479.0	10.0	1.1	445.0	480.1

5 Results

With the energy needs estimated following each of the Energy Performance Regulations presented before, and with the simulations performed with VisualDOE using, in each case, a similar input data, it is now possible to compare the performance of the different regulations. However, it is necessary to have in mind that the Portuguese model should have a more efficient calibration, as the climatic input data used for the

RCCTE calculation was retrieved from the "*in-situ*" Climatic File, obtained as shown in Silva *et al* (2006), applied in VisualDOE. Although, the rest of the model calibration, like the U values, is similar in all the models.

5.1 RCCTE Vs VisualDOE

The results of the RCCTE calculation methodology were compared with the ones obtained with VisualDOE. The variation between the two estimation methods is presented in Table 4.

Table 4 Differences between RCCTE and VisualDOE estimation

Test Cells		Heating Needs	Cooling Needs (kwh/m^2.year) (%)	Total Needs
Guimarães, Portugal				
With Sunspace	STC	3.0 (2.3%)	7.6 (15.4%)	10.6 (6.0%)
	CTC	19.6 (16.3%)	0.2 (1.4%)	19.4 (14.5%)
Without Sunspace	STC	4.6 (3.3%)	8.8 (17.2%)	13.4 (7.0%)
	CTC	20.4 (13.6%)	2.0 (6.2%)	22.4 (12.3%)
Total error in the average energy needs estimation of all models				**13.1 (2.7%)**

From Table 4 it can be concluded that there is a good approximation between the STC total needs estimated with RCCTE and with VisualDOE, with only an average errpr of 6.5% in the total needs (average between STC with and without sunspace). This fact should be due to a good calculation methodology from the RCCTE associated to a good calibration of the models. The higher variation in the estimation of CTC total needs, 13.4% (average between CTC with and without sunspace), is due to the heating needs contribution. This fact can be explained by a higher south oriented glazing area in this Test Cell that can lead to very high solar gains. This could have led to an overestimation of the thermal gains in the RCCTE methodology.

4.7 NCM Vs VisualDOE

The results of the NCM methodology were compared with the ones obtained with VisualDOE. The variation between the two estimation methods is presented in Table 5.

Table 5 Differences between NCM and VisualDOE estimation

Test Cells		Heating Needs	Cooling Needs (kwh/m^2.year) (%)	Total Needs
London, United Kingdom				
With Sunspace	STC	19.8 (5.4%)	11.2 (63.6%)	8.5 (6.0%)
	CTC	3.9 (1.1%)	8.8 (88.0%)	4.9 (1.3%)
Without Sunspace	STC	1.0 (0.2%)	21.8 (80.1%)	22.8 (5.5%)
	CTC	19.5 (4.8%)	32.7 (87.2%)	52.2 (11.9%)
Total error in the average energy needs estimation of all models				**22.1 (4.5%)**

As Table 5 shows there is a high approximation between the CTC with sunspace and STC without sunspace heating needs estimated with NCM and with VisualDOE. It can be observed that the heating needs have a very good approximation between both the estimation methods, however the cooling needs appears to be overestimated by the NCM methodology.

5.3 CWATUPE Vs VisualDOE

The results of the CWATUPE methodology were compared with the ones obtained with VisualDOE. The variation between the two estimation methods is presented in Table 6.

Table 6 Differences between CWATUPE and VisualDOE estimation

Test Cells		Heating Needs	Cooling Needs (kwh/m^2.year) (%)	Total Needs
Saint Hubert, Belgium				
With Sunspace	STC	2.9 (0.7%)	9.2 (86.0%)	6.2 (1.5%)
	CTC	0.01 (0.0%)	10.8 (100%)	10.8 (2.8%)
Without Sunspace	STC	23.9 (5.6%)	9.1 (85.0%)	14.8 (3.5%)
	CTC	44.0 (9.2%)	9.1 (89.0%)	35.1 (7.3%)
Total error in the average energy needs estimation of all models				**16.7 (1.9%)**

From Table 6 it can be concluded that there is a very high approximation between the CTC, with sunspace, heating needs estimated with CALE and with VisualDOE. It can be observed that the heating needs have a very good approximation between both the estimation methods, however the cooling needs appears also to be overestimated by the NCM methodology.

6. Conclusions

The objective of this study was to evaluate and compare the precision of the Portuguese thermal regulation calculation methodology and some other countries calculation models. Therefore, the RCCTE, CWATUPE and NCM heating and cooling needs estimation methodologies were put side by side with the ones calculated with the dynamic simulation tool VisualDOE.

From this evaluation it can be said that all the calculation methodologies have a good precision, better than one could expect, as they are simple steady state methods. All the methods just appear to have a higher difficulty in estimating accurately the heating needs of buildings with large openings. Also, the Belgium and UK methodology have problems in the cooling needs estimation, overestimating them.

The three methodologies show similar errors, being the Belgium one the most accurate and the UK methodology the least accurate.

Then, it can be said that all the studied thermal codes can produce good results in what concerns energy needs. Thus, as they correctly foresee the energy performance of buildings, the buildings energy certification will allow that the comparisons of the certified building stock of each country can be more meaningful.

THE A,B,C'S OF SUSTAINABLE SCHOOLS

Katrina SHUM MILLER [1]

[1] Green Building Services Incorporated, Portland, Oregon, USA, katrina@greenbuildingservices.com

Keywords: school, pedagogy, high performance, design, operations

Summary

This paper focuses on the A, B, C's of creating and operating a sustainable educational facility, based on the examples of schools in the United States of America. These schools include public and private schools, from elementary schools, to high schools, day-only to shared community-use facilities. The paper firstly covers the "A" or attributes of a sustainable school, with an emphasis on the characteristics of the learning and working environment. The paper then identifies the "B" or benefits of sustainable schools, including the pedagogical opportunities. The "C" or challenges associated with designing, constructing and operating a sustainable school are also then discussed. Drawing from lessons learnt from the various schools, the paper identifies the essential steps in adopting sustainability goals for schools, and concludes with a focus on the educational opportunity this presents for our current generation.

1. "A" is for Attributes

Sustainable schools can be defined as "high performance" schools, where the buildings and site have been designed and constructed to create optimal, healthy learning environments; while consuming a minimum of resources and producing a minimum of waste. The attributes of a sustainable school can be succinctly described as follows:

- Provides Healthy and Productive Environments
  - Learning and working spaces are designed to have high levels of thermal, visual and acoustical comfort
  - Superior indoor environment throughout, with high quality air and natural daylight

- Operates in a Cost-Effective Manner
  - Energy performance is optimized and a life-cycle cost approach is adopted for decision making
  - Building commissioning and re-commissioning is standard practice

- Conforms to Sustainable Design and Operations
  - Efficient and effective use of resources (energy, water, materials) during the creation and operations of the school
  - Environmentally responsive site activities and landscape
  - The building is a teaching tool featuring examples of sustainable strategies

Until the late 1990's, the notion of a sustainable school was open to interpretation and there was no common metric in place to validate the claims of a sustainable school. Several sustainable frameworks have since been developed in the United States to address the design, construction and operations of sustainable educational facilities in a holistic manner. The US Green Building Council created the LEED (Leadership in Energy and Environmental Design) rating system in 2001, as a third-party certification program, and a school specific program, LEED for Schools, was launched in 2007. The Collaborative of High Performance Schools (CHPS) introduced their program in 2002, with a focus on the California school market, but is now being adopted by various other states. The CHPS program started as a self-certifying program, but in 2007 introduced a third-party certification option.

The rating system or framework establishes a defined standard for what a sustainable school should be like. It is a valuable tool for guiding the design team on sustainable decision making, dictates how the construction practices will happen, and informs the operational policies and practices of the school. Similar to an academic program, the process of certification itself provides rigor to the design process and construction practices, and enables a greater level of accountability between all players. It provides a common language and reference point for all, as well as facilitates the integrated design process. For example, sustainable strategies such as rainwater harvesting for irrigation and waste conveyance will necessitate the early involvement of the architect, the plumbing engineer, the landscape designer and civil engineer; with each working towards a common goal.

2. "B" is for Benefits

A sustainable school can result in significant benefits in terms of the performance and operations of the building. These benefits include both tangible and intangible benefits, including:

2.1 Optimized Learning and Working Environments

2.1.1 Thermal, Visual and Acoustical Comfort

Studies have shown that the student learning performance can be enhanced by the physical learning environment itself. The effects from the introduction of controlled natural daylight to classrooms, along with allowing views to the outdoors, were analyzed in the 'Daylighting in Schools' and 'Windows and Classrooms' studies (1999, 2003) conducted by the Heschong Mahone Group. The study showed an increase in student achievement by up to 26%, compared with statistical control groups. Other studies indicate that daylight in classrooms can have an impact on reducing illness and absenteeism, and in improving student behavior.

The ability to have environmental controls to adjust the comfort levels of the classroom or offices are also crucial components in an optimized environment. Studies indicate that teachers have a basic expectation of being able to dictate light levels, mitigate sun penetration and adjust for audio visual needs, regulate the temperature and ventilation in their classrooms.

The optimized environments will positively improve satisfaction and morale at sustainable schools, especially among the teaching staff, leading to direct benefits in improved teaching performance, as well as retaining and recruiting teachers.

(Image courtesy of Moseley Architects)

Fig.4 Gymnasium at Clackamas High School
(Image courtesy of Boora Architects)

2.1.2 Indoor Air Quality

Improved indoor air quality has also been found to contribute to student performance and health. With a sharp increase of asthma in school-aged children today, the need for good indoor air quality is critical. Poor indoor air quality will result in sickness and absenteeism. Clearly, if kids are sick or not in school, they will not learn or perform as well as those who are attentive, well and present on a regular basis.

Similarly, schools designed for good indoor air quality provide benefits to the staff, and demonstrates that the school administrative body is vested in the health and well-being of all employees and students. This fosters staff retention, and creates a positive image in the community as a responsible employee.

Indoor air quality is an issue that needs continual attention, and starts with good design followed by on-going indoor air quality management measures. The adoption of a green cleaning policy and practices, along with an integrated pest management policy, can further ensure good indoor air quality (in the interior and exterior) is maintained during the operations and maintenance of the building.

2.2 Financial Benefits

2.2.1 Design and Construction Cost

While sustainable schools can incur a premium in design and construction cost, there can also be opportunities for cost savings when innovative approaches are taken to systems and materials. For example, at Clackamas High School (Portland, Oregon), the chiller system was down-sized, as the school recognized that based on the scheduling of events, the auditorium and gymnasium would not typically be used concurrently. The chiller was then designed to serve one of the spaces, and could switch to serve the other space as needed. In the Londonderry School (Harrisburg, Pennsylvania), a low-cost heating and cooling system was selected using a baseboard heat system with basic controls located in each classroom, along with the use of natural ventilation (via operable windows). This also reduced the amount of resources used in terms of materials, by omitting heating and cooling mechanical equipment and ductwork.

The reduction of finish materials can also result in cost savings, with block walls left unpainted or concrete floors sealed without needing a top layer floor finish. The exterior walls of The Dalles Middle School (The Dalles, Oregon) were stained concrete tilt-up slabs, which were efficient to construct, and reduced the need for costly maintenance such as repainting. Cost saving were also achieved with the extensive use of salvaged materials for the Willow School (Gladstone, New Jersey). Salvaged timber frames were used for the structure, pickle barrels were used for window trim, and felled trees on-site were used for the furniture.

Fig.5 Exterior of The Dalles Middle School

Fig.6 Furniture at Willow School
(Image courtesy of Willow School)

2.2.2 Operating Cost

One of the most significant benefits of a sustainable school is the resultant operating cost reductions, particularly in the areas of energy and water use. The adoption of passive systems, coupled with energy efficient systems, result in a reduction in electrical and gas consumption, along with the associated cost savings. Similarly, the use of water efficient plumbing fixtures and efficient irrigation strategies or xeriscaping provides further cost savings. The water savings for plumbing can be accounted for both in terms of water supplied and also in terms of a reduction in sewage conveyance charges. Managing the stormwater on-site could also result in a reduction of stormwater charges, and adopting waste recycling practices can also reduce the waste utility charges as well.

At Third Creek Elementary School (Raleigh, North Carolina), the projected energy savings based on the energy model was $25,600 or 22.89% compared to the baseline case. Over a period of five years, the building has in fact achieved a total savings of $171,400, based on normalized energy rates, which exceeds the projected amount. In terms of water, the calculated per student use is about 27% less compared to other schools in the school district, and was achieved through the use of waterless urinals and low-flow faucets.

2.3 Community and Cultural Alignment

2.3.2 Expression of the Cultural Values

The concept of a sustainable school is often aligned with the cultural values of the community. The Baca/Dlo'ay Community School (Prewitt, New Mexico) is a Native American school that embraced sustainable design and construction as an outward expression of their values in terms of respect for the land. The Punahou School's new Kindergarten-First Grade School (Honolulu, Hawaii) is currently in the design phase, and borrows sustainable ideas from the "ahupua'a", which describes the manner within which the native Hawaiians lived, and represented land divisions that were complete ecological and economic production systems. The project is expected to have an on-site photovoltaic system that will off-set over 50% of its electrical needs. There will also be rainwater harvesting and stormwater swales, to manage the water resources on the site. These measures allow the new school to be partially self-sustaining, similar in concept to the "ahupua'a".

2.3.2 Responsibility to the Community

A sustainable approach to schools will show the community that school districts are putting the best efforts possible into improving the facilities where their kids spend so much of their formative years. The reduction in operating costs is also a visible demonstration of a school district's efforts to conserve financial resources. This focus will reflect favorably on school districts and will help it to achieve national recognition as a leader in sustainable schools.

A sustainable school also manages its resources wisely, to ensure it does not drain the local resources. A school district is often one of the largest local users of energy and water, and generates a significant amount of waste. In some cases, the school itself can service the community with the introduction of a recycling center on its campus, or convert cooking oil into biodiesel for community use. A photo-voltaic system on a school can generate electrical back to the grid during the summer months when school is out. The use of local materials and resources for the school can also help generate a healthy local economy.

In partnership with the community, shared use educational facilities can reduce the need for additional new buildings, while maximizing the use of the school and its associated spaces. The Langston-Brown High School Continuation and Community Center (Arlington, Virginia) consist of a continuing education high school, a community recreation center, and an early education center. This school has successfully become the new community hub, and effectively reduced the need for further new construction and infrastructure based on centralizing the three uses. Similarly, the Rosa Parks School (Portland, Oregon) houses both an elementary school and an after-school Boys and Girls Club program, drawings kids from the community, while showcasing sustainable strategies.

2.4 Pedagogical Opportunities

2.4.1 Using the Building as a Teaching Tool

The integration of visible sustainable elements can provide an interactive and experiential learning environment for the students and the community. Elements such as on-site stormwater management systems, native landscaping and xeriscaping, wind turbines, photovoltaic systems, shading devices, or green roofs; can be designed to be highly visible and accessible for the students, staff and the community. The use of signage or data on the school's website can further be used to educate the students, staff and the community about sustainability.

The Twenhofel Middle School (Independence, Kentucky) installed a large plasma screen information center in the building lobby to monitor the energy efficient systems. The data includes information about the energy use of different classroom wings, the amount of rainwater stored in the cistern, and details about the performance of the on-site photovoltaic system. Using the data for the different classroom wings, the energy efficiency efforts can also be recognized and rewarded via a friendly competition between the wings. This encourages each classroom to be mindful of their daily energy usage. The data, which has been named 'Vital Signs', is also available on their website (www.twhvac.kenton.kyschools.us), and through this means, has the potential to educate an extensive global audience.

At Rosa Parks School (Portland, Oregon), a monitoring system offers students real-time data on the building's photovoltaic panel's energy generation and several bioswales around the building teach kids about on-site stormwater treatment. At Roy Lee Walker Elementary School (McKinney, Texas), the wind turbine and rainwater cisterns are clearly visible sustainable elements, and act in conjunction with each other, to supply the irrigation needs for the site.

Fig.8 Wind turbine and cistern at Roy Lee Walker Elementary School
(Image courtesy of SHW Group)

2.4.2. Integration into the Curriculum

The various elements of a sustainable school can be featured as part of the educational curriculum. For example, statistical data from the on-site photovoltaic system can be used for a mathematics exercise, or data about the sun movement can be incorporated into the science lesson. These bring home the message in a direct and effective manner.

At Kersey Creek Elementary School (Hanover County, Virginia), the project architects, Moseley Architects, worked together with the school faculty to write curriculum about project strategies that promote environmental responsibility. Lessons might feature an assignment on how the building materials were made using recycled products, or students may perform measurements on the temperature differences between black asphalt surfaces, white concrete surfaces, and shaded vegetated surfaces. At Case Middle School, part of Punahou School (Honolulu, Hawaii), students do a research project on the three ice-making plants that are a part of the air-conditioning system, and learn about the photovoltaic system on the roof.

3. "C" is for Challenges

While the benefits of sustainable schools are compelling, most schools face some challenges in the process of adopting and applying their sustainable goals, both in the design phase and in the operations of the building. Some schools have been designed to meet a high level of green certification, with significant design effort and analysis performed to ensure a high performance building is built. However, once the building is occupied and in operation, the projected energy savings are not realized, and the building does not perform in a sustainable manner. Some of the challenges associated with designing, constructing and operating a sustainable school include:

3.1 Juxtaposition of Goals

3.1.1 Conflicts in Performance

Many sustainable schools aspire to have a natural ventilated building, and provide operable windows in the classrooms and offices. The desire however to have a high level of acoustical performance in the same space can be minimized when the windows are open. Careful analysis of the exterior noise level and consideration of the natural ventilation methods should be taken into account early in the design stage to mitigate this conflict. At Baker Prairie Middle School (Canby, Oregon) and Clackamas High School (Portland, Oregon), ventilation louvers located below the windows in the exterior wall, are tempered with acoustical baffles, and allow natural ventilation without significant exterior noise transfer.

Teaching methods and equipment needs are also evolving over time, and the use of computers and audio visual equipment has significantly increased. The lighting levels required for this can at times be in conflict with the provision of a day-lit classroom. The use of blinds can allow for controlled daylight levels, and as needed, be supplemented by electrical lighting.

3.1.2 Code Constraints

At times, the local code requirements can be at odds with the sustainable goals of a project. For example, in certain states in the United States, plumbing and water codes limit or prohibit the use of captured rainwater for flushing toilets or limit the use of certain types of plumbing fixtures, such as waterless urinals. Restrictions on height limits can at times result in a larger building footprint with more site impacts, or may preclude the use of wind turbines. Green roofs or the use of photovoltaic panels may be prohibited in certain neighborhoods with defined code requirements for aesthetics and regulated material use. The application for special use permits or exemptions takes time and expense, but it may be possible to partner with the local authorities to use the school as a demonstration or case study for new technology or strategies.

3.2 Financial Constraints

3.2.1 Capital Budget versus Operations Budget

A common challenge for schools is the segregation of the capital budget versus the operations budget. These budgets can constraint the opportunities up-front for selecting efficient mechanical systems, which can be more expensive, even though there are apparent long-term operations savings. For some public and private projects, the budget is determined several years before the final construction occurs, as the bond approval process or fund raising efforts can take a long time. When the project is finally bid, the budget may then be inadequate for the project, and often sustainable strategies are the first items to be eliminated in a cost cutting exercise. However, carefully considered design will integrate sustainable elements to ensure that these elements are integral to the success of the building, and are less likely to be eliminated.

During the operations of a school, cost constraints can again be a factor in limiting the manner in which a school performs. The availability of skilled staff and time may preclude appropriate monitoring of a building, and preventative measures may be overlooked as a consequence.

To fund the up-front cost of some sustainable strategies, schools in the United States can seek out various funding opportunities and grant partnerships that could be pursued to assist with off-setting the cost of specific sustainable strategies. Some states have energy efficiency incentives, or special funding for projects pursuing LEED or CHPS certification. Shared-use educational facilities are also likely to trigger other funding sources, with potential collaboration between the school, the community and local businesses. The additional funding could be directed towards sustainable elements that directly educate or benefit the community, such as a photovoltaic system or a rainwater harvesting cistern.

3.2.2 Perceived Costs

For many schools incorporating sustainability for the first time, there can be a fear associated with the cost of building a sustainable school, and this perceived cost may deter them from pursuing a sustainable school. This fear is often not founded on factual information or is a misunderstanding of building costs. For example, some may consider the full cost of a high performance glazing system as associated with this sustainable strategy, instead of the incremental cost over a conventional glazing system.

Having a clear understanding of cost is vital and where possible, life cycle cost should also be factored into the decision making. There often is a cost premium in building a sustainable school, in part due to the soft cost of additional design and analysis, as well as the selection of efficient equipment and fixtures. The study completed by Capital E's Gregory Kats, "Greening America's Schools – Cost and Benefits" (2006) noted cost premiums were typically less than 2%, but in some cases, sustainable schools cost less than a conventional design. When project budgets are determined, consideration must be given to ensure that both cost escalation and the potential premium in building a sustainable school is accounted for.

Taking consideration of the long-term benefits of sustainable schools, Ohio Schools Facilities Commission (OSFC) mandated that all new schools must meet a minimum LEED for Schools rating of Silver certification and should be targeting the Gold level. At least 250 buildings will meet these requirements over the next two years, with an estimated $1.4 billion return on investment over 40 years for the state.

3.3 Knowledge Base and Knowledge Transfer

3.3.1 Receptiveness to Sustainability

The idea of building and operating a sustainable school can be a new concept for some of the school's stakeholders, as this may new or unfamiliar territory. The design team may not be as familiar with designing and implementing sustainable concepts and strategies, or the contractor may be reluctant to install certain types of new products, if they have not used them before. The facilities department may be comfortable with the use of certain controls, mechanical systems or materials, and may resist changing out to new options, even if it is more efficient or sustainable. There may be concerns over the need to hire a specialist (possibly at considerable expense) when the mechanical system needs maintenance, or replacement parts may not be available locally or in a timely manner. There may also be concerns over adopting new technologies that may not have been tested and proven in applications like schools, and are "bleeding edge" rather than "leading edge". There can also be concerns about the desired occupant comfort levels versus the use of passive systems, which typically result in less control over the comfort levels.

In order to overcome these barriers, it is vital to engage all key stakeholders early in the design process, and often an "eco-charrette' is a great way to get everyone involved. This facilitated brainstorming event can generate sustainable goals and identify strategies for the project, with the input from everyone involved. In terms of implementing sustainable measures in the operations of schools, one successful approach in changing the mind-set of those "nay-sayers" is to firstly evaluate current policies and practices, and identifying what is already being done. In many instances, the school may already have adopted sustainable practices, and with minor modifications, will be well on their way towards operating a more efficient, environmentally responsive school.

3.3.2 On-going Performance Monitoring

A high performance building needs to be operated and maintained well to ensure on-going performance. The knowledge of how the building works needs to transfer between one facility manager to another. This can be challenging as there may not be overlapping time between the transition of the managers, or the operations manuals or policies may not be in place to provide the appropriate record and guidance on how to successfully operate the school. It may also be that the facility manager is not tasked with tracking and monitoring the performance of the building, but rather is focused on maintenance issues instead. In some cases, unskilled staff may be responsible for managing a sophisticated control and mechanical system, without clear instructions or knowledge on how to optimize the systems. A well designed high performance building can suffer from poor performance if there is no one at the helm guiding the efficiency efforts.

Commissioning new schools and re-commissioning existing schools on a periodic basis are excellent ways to identify any issues, course correct defects, and enhance the performance of the building. These services can be performed by in-house experts, or external consultants can be engaged to complete the work. While there is cost associated with this work, any improvements to the efficiency of the system are likely to generate energy savings, which can off-set the cost for performing this work.

In order to facilitate the adoption of sustainable strategies, it is beneficial to have a sustainable "champion" on board. In Montgomery County Public Schools, the in-house sustainable champion is known as the Green Building Manager, and is a part of the Division of Construction. The Green Building Manager facilitates the sustainable task force, with representatives from each division, such as building maintenance, transportation, and finance. Each brings their own unique concerns to the forefront, and collectively common policies and practices can be established. Other school districts or schools may have a resource conservation manager or an energy manager in-house, who can be vital in guiding the sustainability efforts for the district or school.

3.4 Occupant Patterns of Use

3.4.1 "Old Habits Die Hard "

Many sustainable schools are designed to achieve good daylight, augmented with electrical lighting, and use natural ventilation, supplemented by mechanical ventilation and heating. The best designed schools will however not perform well if the occupants are not mindful of their responsibilities in ensuring the building operates the way it is intended. For example, in many schools, the lights are turned on when one enters the classroom, even if the daylight levels are adequate without artificial lighting. The lights may be left on even when the classroom is empty, or every lighting zone may be turned on even if only part of the classroom needs the artificial lighting or is in use. The blinds on the windows may be lowered for an audio visual presentation, and not raised after the presentation, so daylight is blocked out of the classroom, resulting in the need for artificial lighting. Windows may be open when the weather is not conducive for natural ventilation, or the window ledge may be used as book shelves, and as such, the windows cannot be opened.

There are automatic controls that can be installed to mitigate some of these scenarios, but it is important to have simple instructions available on how to operate the classroom as intended. When The Dalles Middle School was first opened, the design team conducted a training session on how to maximize the use of daylight and natural ventilation in the classrooms. An instruction sheet was included in each classroom for reference, and would then inform future occupants of how to operate the classroom. At the Londonderry School, classrooms are equipped with a red/green light to indicate when the climatic conditions are optimum for opening the windows.

3.4.2 Expectations of Occupants

The expectations of the occupants can eliminate sustainable strategies from the design concept of a sustainable school. The desire to have air conditioned spaces in lieu of natural ventilation and passive cooling is often a major point of discussion in schools, even in more temperate climates. If another existing school has an air conditioning system, the future occupants of the new school will often want a comparable system, even if the climatic conditions are suitable for passive cooling. In one school district, the idea of installing skylights in the upper level classrooms was omitted as the school felt they needed to create equitable spaces on all levels, and variations in daylight levels could be misconstrued as a demonstration of favoritism.

Different spaces may also have different comfort needs based on the activities of the space, and a "one size fits all" concept may not be appropriate in terms of heating, cooling and ventilation. These unique needs should be identified early in the design phase, to both manage the expectations for comfort, and also to ensure that appropriate systems are selected to meet these demands.

4. Getting from "A" to "Z"

Based on the experiences and lessons learned from several sustainable schools, the following steps were identified as being crucial in the adoption and implementation of sustainable design, construction and operations strategies:

- Aim High, Start Early
    - Aspire for great things, with clear, mutual goals
    - Identify a champion to keep the sustainable goals in the forefront
    - Bring all players to the table early
- Setting The Passing Mark
    - Determine the priorities for the project
    - Establish the standards
        - Create design and construction guidelines, and use an established framework
        - Implement sustainable operating protocols
    - For new construction and renovations, select the right design and construction team
    - Test out ideas with a prototype building before adopting the strategies for all projects
- Use Lessons from History
    - Learn from the occupants of existing schools in the district with post occupancy evaluations
    - Indentify what works and what doesn't work with existing schools
    - Evaluate comparable sustainable schools, and identify strategies to adopt
- Do the Math
    - Establish realistic budgets and timeframes
    - Consider cost holistically – upfront expenses can result in long terms savings
    - Value the intangible – staff retention and attraction, student well-being and test scores, can all have indirect financial impacts
    - Seek out funding sources, and get buy-in early

- Excel in Geography and Science
  - Design and construct appropriate to the context – consider climatic conditions and site
  - Think Global, Act Local – seek out local partnership opportunities, use local resources wisely, and mitigate impacts on the local infrastructure

- Establish the Curriculum
  - Use the school to educate not just the students, but all occupants and the community at large
  - Establish clear protocols for knowledge transfer to ensure smooth operations of a sustainable school

5. Conclusions

Schools are educational facilities, centered on educating the children of their respective communities. A sustainable school is also an opportunity to educate and inform not just the students, but also the staff, parents, and the community, about sustainable design, construction and operations.

A sustainable school takes consideration of sustainability as defined by the World Commission on Environment and Development (Bruntland Commission) in 1987 as "Development that meets the needs of the present without compromising the ability of future generations to meet their needs." Sustainable schools play a critical role in educating and equipping our future leaders with the awareness, expectation, knowledge, and skills to help mould a sustainable future for all.

Keywords: LCA, Building, Embodied energy, Global Warming Potential, eco-design

Summary

The path to sustainable cities goes trough detailed studies concerning the energy and the environmental performances of buildings. In particular, the buildings should be analyzed following a life-cycle approach, including the energy flows and the environmental burdens that arise during all the life cycle steps.
The paper presents a Life Cycle Assessment of an Italian mono-familiar house in the Mediterranean area. All the main stages of the building useful life have been investigated including: design, production of raw materials and building components, energy and materials supply, construction and installations, maintenance, demolition and debris disposal.
The aim of the study is to locate the building components that are responsible of the higher burdens and to state the incidence of each component and phase. The assessment showed that the largest impacts are located in the use stage, but significant environmental impacts are due to manufacture and transport of materials. It resulted that the studied building had low impacts compared to other case-studies in the central and Northern Europe. Energy for winter air conditioning is significant but not dominant; the contribution of the electricity utilized for households and other equipments resulted, instead, very significant.
The study is a part of the Italian research project “Genius Loci” about the role of the building sector on the climate changes.

1. Introduction

Traditional environmental analyses generally focus on a restricted number of life cycle steps according to the contest of the investigation. In the building sector, for example, a household or plant producer generally focuses the attention on the products use stage, aiming to give to the consumer information about final energy consumption and other consumables.

Furthermore, analysts often focus their attention on direct environmental impacts more than external and indirect impacts due to suppliers, retailers and consumers activities.

The Life Cycle Assessment (LCA) is a methodology voted to analyze and assess the environmental impact of materials, products or services throughout their entire life cycle, from the origin of raw materials to their disposal. The LCA can be applied to every typology of good or service defining their eco-profile. This approach allows to perform a scientific environmental balance between the benefits and the drawbacks related to the product’s use. In comparison to traditional environmental analyses, the LCA allows to avoid partial or wrong assessments concerning the products environmental performances.

Besides information regarding the environmental impacts due to manufacturing of construction materials, maintenance or disposal of the buildings are generally not sufficiently investigated or even neglected.

Dealing with the building sector (Council Directive 89/106/EEC) several Member States have set and developed approaches aimed to integrate the environmental criteria in the design and construction of buildings. The LCA could therefore become a support methodology for designers and decision makers into the defining and the realisation of strategies and solutions for ecological buildings with high energy and environmental performances.

Finally we underline the role of LCA of buildings into the definition of environmental certification of buildings. In particular, the European Commission is debating about the possibility to extend the European Ecolabel (European Commission, 2000) to buildings. LCA studies on exemplary case studies could address the work of decision makers into the definition of environmental criteria for the certification of constructions.

1.1 Life Cycle Assessment of a building

There are many benefits for businesses activities adopting the LCA approach to the evaluation of buildings, including:

- Assessing, on the basis of a internationally agreed scientific procedure, the components and the life cycle steps that are responsible of the most significant environmental impacts;
- Identifying the most efficient and cost effective options to increase the environmental performance of the building, more desirable to consumers;
- Assessing the company's operations and production processes to identify opportunities for efficiency improvements, while reducing financial costs;
- Reducing greenhouse emissions and other environmental burdens throughout every life-cycle step, in accordance with national and international laws and agreements;
- Utilising the LCA results as the basis to develop an Environmental Management System (EMS) or to obtain environmental label and product certifications;
- Comparing the performances of replaceable products in terms of environmental performances or life cycle costs.

The LCA of a building should be developed according to the following scheme:

1. <u>Qualitative and quantitative analysis of building components</u> including the main construction materials and the main equipments;
2. <u>Analysis of the construction phase</u> including material origin and transport, the use of construction machineries, installation steps, environmental impacts due to the construction (as land use, soil removal, air and water emissions, wastes, noise levels), etc.;
3. <u>Reference analysis</u> to collect information regarding the construction materials and plant's components. When available, it is generally suggested to refer to local producers; otherwise the analyst could refer to national or international data and statistics;
4. <u>Detailed analysis of the use phase</u>, computing the yearly energy employed for lighting, air conditioning, sanitary water heating, food cooking, etc.;
5. <u>Analysis of maintenance operations</u>. For new buildings the analyst could refer to experiences of previous buildings or to local and national statistics. This step should include the qualitative and quantitative analysis of utilised materials and environmental impacts due to the maintenance (following a similar approach as that performed for the building construction analysis);
6. <u>Analysis of disposal phase</u>. That should include the energy and the environmental impacts related to the building demolition (energy employed by machineries, air and water emissions, etc.) and the exhausted materials disposal or recovery. Being generally not possible to exactly foresee and describe the disposal phase before accomplishing it, the analysis should be based on different disposal scenarios. These scenarios have to describe different disposal assumptions and technologies (i.e. material totally moved to landfill or partially reused and recycled, energy recovery, etc.);
7. <u>Data regarding each life cycle step have to be processed</u> in order to obtain global environmental indexes that synthesize the environmental performances of the building;

8. Analysis of all the previous steps to locate hot spots (components of the system with the higher environmental burdens) that are further investigated in order to reach the desired level of precision and reliability of the results. Assumptions concerning hot spot have to be discussed in a sensitivity analysis.

1.2 Global environmental impacts of building

Several studies have been performed worldwide concerning the LCA of buildings and construction.

An interesting Swiss study was performed to assess the energy consumption of the construction sector (Wüest&Partner, 1994; Zimmermann et. al., 2005). It was estimated that the construction sector is responsible of the consumption of about 50% of the primary energy in Swiss. Specific average energy consumption for different building typologies are: mono-familiar houses resulted the most energy consuming (1.5 $\frac{GJ}{m^2 year}$), followed by multi-familiar houses (1.15 $\frac{GJ}{m^2 year}$) and offices (0.82 $\frac{GJ}{m^2 year}$). Such consumption are mainly related to the indoor air-conditioning and sanitary warm water demand (50% - 70% of the global consumption), and to the production of building materials (10% - 20%).

Another interesting comparative study among different residential buildings has been presented by the European Commission (2003). Sixth semi-detached house typologies commonly employed in the central Europe, with a living surface are from 176 m^2 to 185 m^2, have been analysed, supposing an average useful life of 80 years. The study shows that respect to a common reference building, the adoption of high efficiency design solutions (with better insulations, high efficiency plants, low energy materials, etc.) sensibly decrease the global energy demands. Global primary energy consumption can sensibly vary from $6 \cdot 10^3$ GJ to $12 \cdot 10^3$ GJ. Worse performances are generally related to bad insulated construction or to the use of electricity for the building heating.

A component detail of the LCA of a building is presented by Thormark (2003). The analysis regarded a "good performing" residential building in Sweden and it includes energy for material's production, building installation and maintenance and replacement. The Energy requirement for heating has been estimated to be 45 kWh/m^2. The author shows that the energy consumption due to embodied energy of materials could be sensible decreased by employing recycled materials and about 35 - 40 % of the building embodied energy can be saved through the recycling. The global energy consumption during the use phase amounts to about *8.2* GJ/m^2; the consumption for other life-cycle steps (materials manufacture, transports, construction, maintenance, and demolition) amounts to *7* GJ/m^2. It shows that, concerning a "*low energy*" building with good performance, the energy consumption for plants is approximately comparable to the consumptions during the other phases. On the other side, in bad performing building energy consumption for the plants could represent till up the 90% of the consumption. The author finally shows the great importance of the *design for recycling* and *design for disassembly*: it is expected that the reuse/recycle of material could allow to save up to 30% - 40% of the energy used to manufacture building materials and components.

2. Application of the LCA methodology to an exemplary construction: an Italian case study

In the following paragraphs a study of LCA applied to an Italian exemplary mono-familiar house is presented. The house can be considered as a representative Italian construction of the Mediterranean area (Figure 1). The house is occupied by a three member family.

The studied area is characterized by a temperate climate, with mild winters and hot summers. Such conditions influence significantly the energy performances of the building. In fact, compared to Northern case study, the energy consumptions for air-conditioning are reduced during the winter time, while sensibly increased are the consumptions for the indoor cooling in the hot seasons. The house is isolated and no neighbouring constructions modify the direct sun radiation.

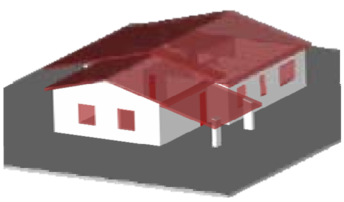

Figure 1 Structural layer of the case-study building

The structure has been realized with reinforced concrete pillars and body bolsters; external walls include 20 cm bricks with a 9 cm cavity filled with insulating expanded vermiculite; the building is equipped with wooden double-glazed insulated windows; floors are 20 cm width, including perforated brick and prefabricated reinforced concrete rafters. Roof is constituted by a wooden structure with composite materials and clay roof tiles cover. The basement rests on a reinforced concrete structure and a layer of cave crushed stones. Bitumen sheets are used as water proof barriers.

The heating system consists of a Liquid Petroleum Gas boiler, steel radiant radiators and insulated steel pipes. The boiler provides also warm water for sanitary demand. Gas is purchased by local companies, transported in small trucks and stored in an autonomous 1000 litres tank. Summer air conditioning is granted by electrical heat pumps installed into main rooms.

The house is equipped with normal electrical and sanitary water lines.

2.1 LCA phases: Goal and scope definition

The Functional Unit is a single level structure with of an overall surface of 108 m^2, located in the municipality of Palermo. The house has been built in the last decade. The aim of the research is to evaluate the global environmental impacts of an exemplary mono-familiar house of the Mediterranean area. The scopes are:

- to locate components that are responsible of largest impacts (key issues);
- to assess incidence of each life-cycle steps and, in particular of phases generally not adequately investigated (incidence on the global environmental balance of construction materials, maintenance cycles, transports, etc.);
- to focus the attention on components that are responsible of significant impacts in a prospective of an environmental design of the residential buildings.

Results can represent a scientific basis useful for the definition of criteria concerning the energy and the environmental certification (Ecolabel) of buildings.

2.2 LCA phases: Inventory phase

Data collection has been structured as following;

- Analysis of design plans: collection of structural information and calculation and assessment of the quantity of used construction materials;
- Analysis of building components: technical sheet of building components (windows, plants, pipe lines, etc.) have been analysed in order to detail their composition and performances;
- Reference survey: LCA databases (Boustead, 2001; PE International 2006; Pré-Consultants, 2006) have been consulted in order to acquire information regarding the eco-profile of construction materials, components and plants;
- Inventory of construction phase: at the time of the study, being the case-study house already existing, it was not possible to compute impacts during the construction. A similar mono familiar house in construction has been studied, in order to estimate main impacts due to construction machines and transports;
- Use phase: electricity, LPG and water consumptions of the case-study house have been monthly monitored for two years.
- Maintenance: the consumptions due to the renovation of plants and house components have been calculated on the basis of information of the owners concerning the house life. Further information have been asked to the building company, concerning their experience on the buildings maintenance cycles;
- Demolition and Disposal: the life-time of the building is supposed to be 50 years. The end-life scenario of the house has been assessed jointly with the construction company. Exhausted inert materials are supposed to be addressed to a sorting plant, wood and plastic components to incinerators, steel to recycling. Secondary components are disposed in landfills.

Details of main building materials and components utilized during construction (Table 1) and of average consumptions during the use (Table 2) is following shown.

Table 1 Detail of main construction materials and components

Material	Unit	
Concrete	[10^3 kg]	276,5
Clay bricks	[10^3 kg]	33,0
Roof tiles	[10^3 kg]	13,6
Ceramic tiles	[10^3 kg]	6,5
Plaster	[10^3 kg]	4,7
Wood boards	[10^3 kg]	4,6
Steel	[10^3 kg]	4,0
Composite membrane	[10^3 kg]	1,0
Galvanized steel	[10 kg]	221
Sanitary ceramics	[10 kg]	151
Glass	[10 kg]	115
PVC	[10 kg]	23
Copper wires	[10 kg]	10

Table 2 Average yearly consumption during the use phase

Consumption	Unit	
Electricity	[kWh]	3,944
LPG	[MJ]	22,122
Water	[m^3]	318

2.3 LCA phases: Impact assessment

The energy and the environmental impacts have been assessed on the basis of declaration scheme and characterization factors utilized in the EPD system (Swedish Environmental Management Council, 2000). Results are showed in Table 3 and figure 2.

Table 3 Life-cycle Impacts

Impact Category		Total
Global Warming Potential (GWP)	[kg $CO_{2\ eq}$]	327.406
Ozone Depletion Potential (ODP)	[kg $CFC_{11\ eq}$]	0,05
Photochemical Ozone Creation Potential (POCP)	[kg C_2H_4]	68
Acidification Potential (AP)	[kg $SO_{2\ eq}$]	1.551
Nutrification Potential (NP)	[kg $PO_{4---\ eq}$]	145

It is possible to observe that:

- The GER amounts to about 4.58 $\cdot 10^3$ GJ of primary energy. Yearly specific consumption per unit of area is 0.63 $\frac{GJ}{m^2 year}$. Such values are lower than reference values reported in the previous paragraphs. This is mainly due to good energy performances of the house but also to mild climate conditions (that decrease sensibly the consumptions for winter air conditioning) and the particular care of users to the energy save;
- Concerning ODP, impacts are almost negligible. The highest incidence is related to the production and transport of construction materials;
- As expected, the usage is the phase that causes the largest impacts (Figure 2). It is responsible, for each environmental index, of about 50-70% of the global impacts.
- The incidence of the construction phase is considerable, moving from 20% (GER) to 30% (NP);
- Other phases are responsible of about 6% of the GER. Higher percentage have been observed considering the other indexes, till up a weight of 20% in the NP index;

- The GER consumption is mostly represented by non renewable energy sources. Small quantity of renewable energy are related to the use of electricity, following Italian power energy generation mix, and to the utilization of renewable materials into the construction components;
- A detail of the use phase (Figure 3) shows that the largest impacts are due to the use of electricity. The consumptions for the winter heating and for the sanitary warm water demand are almost the same.

	Construction	Use	Maintenance	End-Life
■ Renewable (GJ)	30	228	12	2
□ Non renewable (GJ)	826	3.198	193	94

Figure 2 Details of Global Energy Requirements (GER)

	Water supply	Electricity	LPG (heating)	LPG (sanitary warm water)	LPG (cooking)
■ Renewable (GJ)	19	209	0	0	0
□ Non renewable (GJ)	73	2.029	500	478	118

Figure 3 Detail of energy life-cycle consumption during the use phase

From a more detailed analysis, it resulted that the energy consumption for summer air conditioning is about 20% of global summer electricity input, corresponding to about 7% of the yearly consumption, as about 157 GJ of primary energy consumption during the life-cycle of the building.

It's interesting to note that energy consumption due to air conditioning are relevant but not dominant, as shown by other authors concerning case-studies in the central and northern Europe. The summer air conditioning is also significant but comparable to the energy consumption for the cooking. Very relevant are other consumption almost equally distributed along the year, as energy for water heating and electricity for households. This last component is responsible of about 45% of the GER during the entire house life-cycle. It means that the application of good practises in the household use and the purchase of high energy performing devices could reduce sensibly the energy consumptions and the related environmental impacts.

2.4 LCA phases: Life cycle interpretation

The previous paragraphs showed that the use phase is critical in the global environmental analysis of the case-study house. Therefore attention has been focused on such life-cycle step.

First of all, being electricity a dominant factor, it has been carried out a sensitivity analysis by changing the eco-profile of power energy production mix. The previous assessment, based on Ecoinvent energy data (Swiss Centre for Life Cycle Inventories, 2000), has been modified supposing to use data from ETH concerning the national average energy mix (Frischknecht, 1996). As result, we observed little modifies on the GER index (less than 1%) due to the ETH data, with a small increase of the incidence of renewable energy use in the global energy balance. Higher modifies (from 10 to 30%) has been observed in the GWP and NP indexes. ODP index is totally modified: considering input data form ETH, ODP resulted about ten times higher. These large variations are ascribable to different air emissions included in the inventory phase. We underline that those data are quite aged, especially data from ETH that referred to the last decade, and their quality is therefore low. A further analysis should be performed with updated eco-profile and, possibly, using data related to the regional context with a higher geographical representativeness.

The next step in the analysis was the house simulation of the energy consumptions by means of specialist software. Such analysis is described in the following paragraph. Finally, we observe that a large part of the energy consumptions are due to the use of households and to the behaviors of the house habitants. That represents a limit of such typology of analysis, being the results strictly dependent of the case-study peculiarities and not plenty transferable to a more general context.

2.4.1 Energy simulation of the building

The energy simulation of the house has been performed with the *TRaNsient SYstem Simulation Program - TRNSYS* (Klein et al., 1976). The software has been applied to the case study building. Input data to the model included: building input description (structural components, material thermal performances, orientation, internal thermal loads), characteristics of system components (plants, windows and other transparent modules) and manner in which components are interconnected and local weather data (temperatures, humidity, wind and solar radiation).

Simulations have been performed with a 1 hour time-step. Design assumptions were: internal temperature enclosed in the range 20-26 °C and humidity in the range 40-60%. The aim of the simulation has been:

- to assess the energy winter and summer loads, and to compare results with monitored data;
- to assess the variability of results on the basis of initial assumption.

As example of simulations, Figures 4 shows the yearly trends of the sensible heat loads of the building. However, the estimated results have been very different from monitored consumptions, showing even in this case a discrepancy between assumptions and real users' behaviors

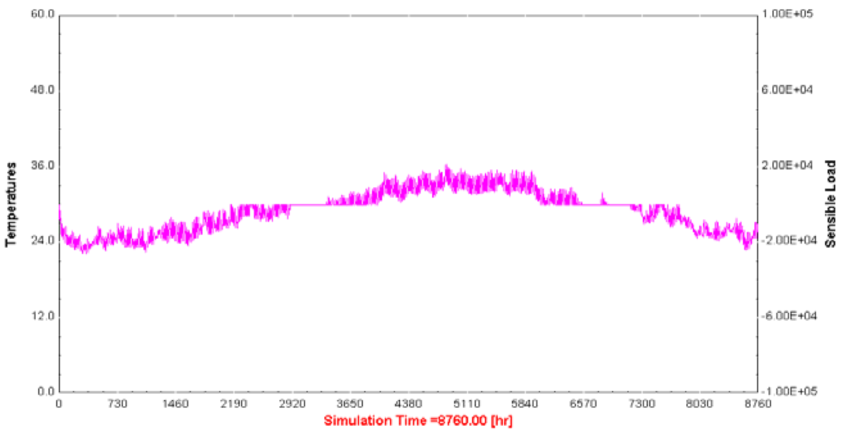

Figure 4 Yearly trends of sensible heat load

3. Conclusions

The paper presented a Life Cycle Assessment study of a mono-familiar house in Italy. The construction can be assumed as representative case-study building of the Italian Mediterranean area. The study is a part of the Italian research project "Genius Loci" about the role of the building sector on the climate changes. It is expected that the results could be employed for the definition of criteria for the energy and environmental certification scheme of the building.

The analysis was performed collecting and estimating data from each life-cycle step of the building including: design phase, production of construction materials and components, energy and water supply, construction and installation of plant, use, maintenance and management of the building end-life. Data concerning the building have been directly measured or estimated in collaboration with the construction company. Data regarding the eco-profile of construction materials, plants and energy sources have been referred to international LCA databases.

The results showed the large incidence of the use phase in almost all the considered energy and environmental indexes. In particular, concerning the primary energy consumptions, the use phase is responsible of about 75% of the GER index. Other phases, as in particular the use of construction materials and components, have a significant incidence (from 20% to 40%).

A more detailed analysis of the use phase showed that the utilization of electricity is dominant, followed by the use of LPG for house winter heating, warm water demand and cooking.

The global and specific energy indexes of the studied building are, however, lower than reference data related to other case-studies in the central and northern Europe. Energy consumption for air conditioning, in fact, is low due to both mild winter weather conditions and an energy saving behaviours of the building users. On the other side, a large part of the consumptions are related to the use of households and other electrical equipments. It means that the eco-profile of a house is strictly depending on the activities of families and the conductions of plants.

A sensitivity analysis was performed on the incidence of electricity eco-profile, showing significant variations especially on non-energy indexes. Finally it has been performed an energy simulation of the building with the TRNSYS software, supposing to maintain in the rooms the indoor comfort values of the thermal parameters. The results have been however very different from monitored consumptions, showing even in this case a discrepancy between assumptions and real users behaviours.

Key words: BCS, CASBEE, building, assessment, questionnaire, survey, results, outlook

Summary

Every year since 2004, the Building Contractors Society (BCS), an industry organization (public service corporation) of general contractors working in building construction throughout Japan, has conducted a questionnaire survey of 23 member companies having in-house architectural design divisions with regard to the Comprehensive Assessment System for Building Environmental Efficiency (CASBEE). The questionnaire covers a wide range of topics, including the projects subject to assessment, reasons for introducing CASBEE, in-house education, targets if any, numbers of buildings evaluated, assessment results, opinions concerning positive and negative aspects of CASBEE, time spent on assessment work, and the future outlook. Through these surveys, we have learned that many companies are actively introducing CASBEE, and that some are using CASBEE to evaluate all of the buildings they design. The unstructured comments from survey respondents are taken into consideration when deciding how to further promote the use of this assessment tool in the future.

1. About CASBEE

CASBEE• Comprehensive Assessment System for Building Environmental Efficiency•• has been developed since 2001 in Japan with the support by Ministry of Land, Infrastructure and Transport. CASBEE distinguishes environmental load (L) and quality of building performance (Q) as the major assessment targets, and applied the concept of eco-efficiency as BEE (Building Environmental Efficiency). Give L and Q, BEE is defined as Q/L to indicate the overall result of environmental assessment of buildings.

2. About BCS

2.1 Building Contractors Society (BCS) and its design and construction activities

The Building Contractors Society (BCS) is an industry organization (public service corporation) of general contractors working in building construction throughout Japan. It has 69 member companies (as of March 2008), which employ a total of about 122,000 employees (as of July 2007) and handle approximately ¥14,660.068 billion in construction orders (FY 2006, including civil engineering projects), about three-quarters of which consists of building construction orders (approximately ¥10,853.015 billion).

One important characteristic of Japan's large-scale construction companies is that they include in-house architectural design divisions. With this kind of corporate organization, they can provide design and construction in so-called "full turnkey" services according to the client's preferences. The architectural design divisions of BCS member companies are involved in the design of 44% of all of the building construction orders they handle. The buildings designed by BCS member companies include some architecturally and technologically outstanding buildings which have won a variety of awards. For example, about 17% of the buildings in "Selected Architectural Design 2007" by the Architectural Institute of Japan (AIJ) were designed and built by leading companies which are members of BCS.

2.2 Promotion by BCS of environmental responsibility throughout a building's life cycle

BCS has adopted an action plan indicating its goals and the role of its activities with regard to society; and is implementing this plan in collaboration with member companies. The second of five goals under the BCS action plan is "to contribute to the global environment through sustainable architecture." To protect the global environment, it is essential to implement environmental measures throughout a building's life cycle. Because BCS is involved not only in construction, but also in planning, design, and operation after a building is completed, it is taking the following three specific actions to achieve this goal: promoting environmentally friendly planning, programming, and design; pursuing environmentally friendly construction processes; and promoting improved environmental performance at the operational stage. Many BCS member companies have in-house architectural design divisions and are capable of involvement for the sake of environmental responsibility at all stages, having organizations that facilitate the effective application of lessons learned through experiences and information at each stage.

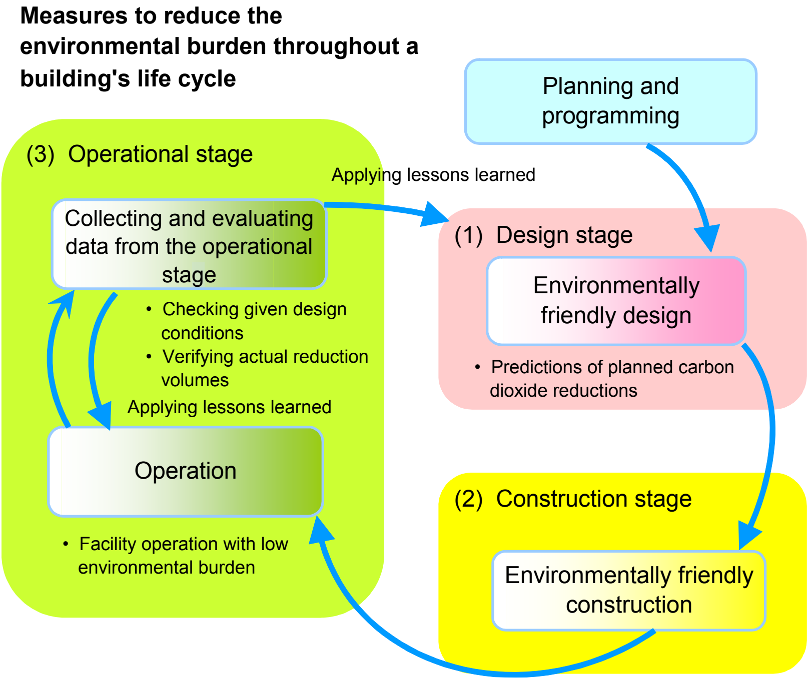

Figure 1. Measures to reduce the environmental burden throughout a building's life cycle

2.3 Survey of BCS companies regarding CASBEE utilization

Considering the Comprehensive Assessment System for Building Environmental Efficiency (CASBEE) to be an effective tool for promoting environmentally friendly planning, programming, and design, BCS believes that the widespread adoption of CASBEE is important, not only among its member companies but also in society at large. Therefore, every year since 2004, BCS has used questionnaires to survey 23 of its member companies with regard to CASBEE. The 23 surveyed firms have active in-house architectural design divisions. The volume of building design and construction orders taken by these 23 companies accounts for over 90% of the total handled by these BCS member companies.

The questionnaire covers a wide range of topics, including the projects subject to assessment (voluntary decision or based on administrative guidance), reasons for introducing this assessment system, acquisition of evaluator qualifications, in-house training, targets, the evaluated properties (about 500 buildings) categorized by purpose of use and assessment results, opinions concerning positive and negative aspects of CASBEE, time spent on assessment work, increases in assessment staffing, and future expectations.

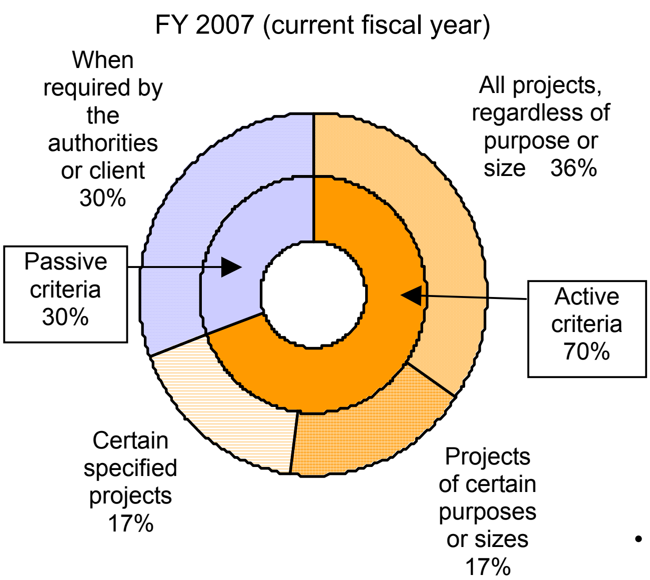
Here, we report the findings from surveys conducted over the past four years. When no fiscal year is specified, the results from the FY 2006 survey are indicated.

3. Survey results

The survey results are reported in four categories: situation of CASBEE use, analysis of past assessment records, opinions concerning the assessment system, and unstructured comments.

3.1 Situation of CASBEE use

Several local governments in Japan (12 local governments as of January 2008) require CASBEE evaluations for construction projects above a certain size; and some clients specify the use of CASBEE. In addition, 16 of the 23 surveyed companies (70%) actively utilize CASBEE based on their own criteria, even without these external factors. These companies have established a wide variety of criteria, including the use of CASBEE for certain specified projects (e.g., based on annual target numbers of projects), or for projects of certain purposes or sizes (e.g., at least 5,000 square meters of total floor area). Also, four companies stated that they use CASBEE for all their projects. (Figure 2)



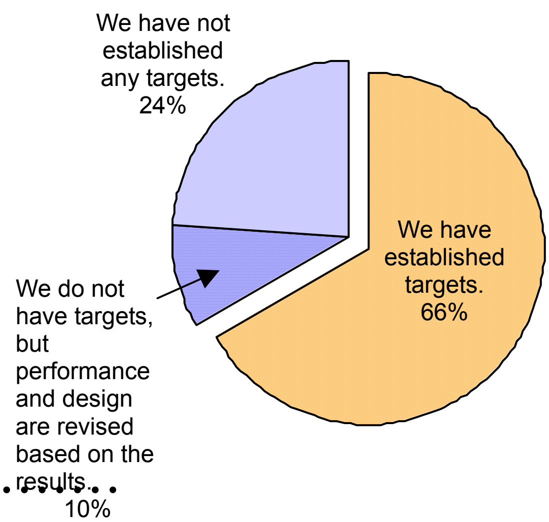


Figure 2. Criteria for conducting CASBEE evaluations *Figure 3. Targets for assessment results*

14 companies (66%) have established targets regarding CASBEE evaluation results. Seven companies have no targets, but two of these companies revise performance and design in some cases according to the results obtained. This means that the companies conduct design with an awareness of CASBEE evaluations. Eight companies have selected targets of a certain rank (at least B+, or BEE scores of at least 1.0, etc.), and four companies establish targets according to the project. (Figure 3)

Concerning internal measures for the implementation of CASBEE evaluations, 18 companies recommend or encourage the acquisition of evaluator qualifications; 12 companies participate in external training sessions; nine companies incorporate this into internal programs such as ISO 14001; and nine companies hold in-house training sessions.

22 of the 23 companies surveyed have environmentally friendly design tools and include them in ISO 14001 documentation. Ten companies correlate these environmentally friendly design tools with CASBEE or plan to do so in the future; and eight of these companies use the simplified edition of CASBEE as is.

3.2 Analysis of past CASBEE evaluation records

Figure 4 shows trends in the numbers of properties evaluated using CASBEE by the surveyed companies since CASBEE was first published. There were 591 properties in FY 2006, bringing the cumulative total up to 1,090 properties. About 1.5 times as many properties were evaluated using CASBEE in FY 2006 as in FY 2005.

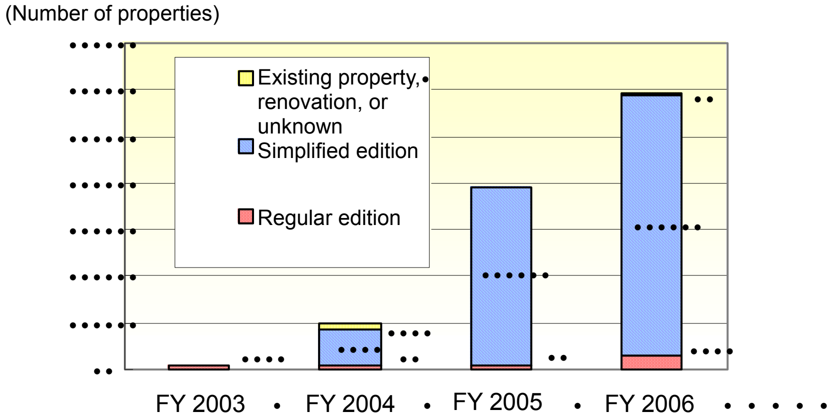

Figure 4. Trends in numbers of assessments by year

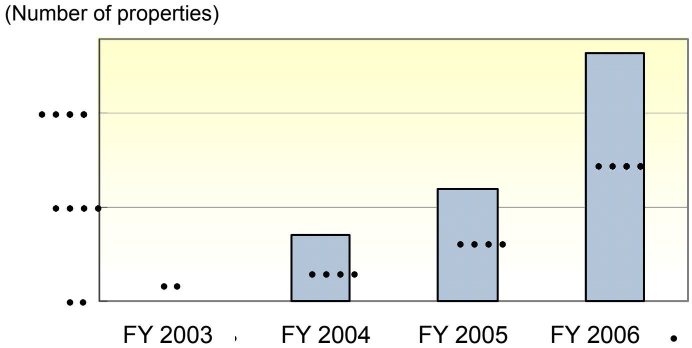

Figure 5. Trends in numbers of assessments submitted to local governments

Figure 5 shows annual trends in the numbers of assessments submitted to local governments. Reflecting the increasing number of local governments that have adopted environmentally friendly programs using CASBEE, twice as many assessments were submitted to local governments in FY 2006 as in FY 2005.

Figure 6 shows past CASBEE evaluations by rank. The most frequent rank has been B+ at over 40%, and nearly as many properties have been ranked A. Ranks of B+ or higher account for about 90% of the total.

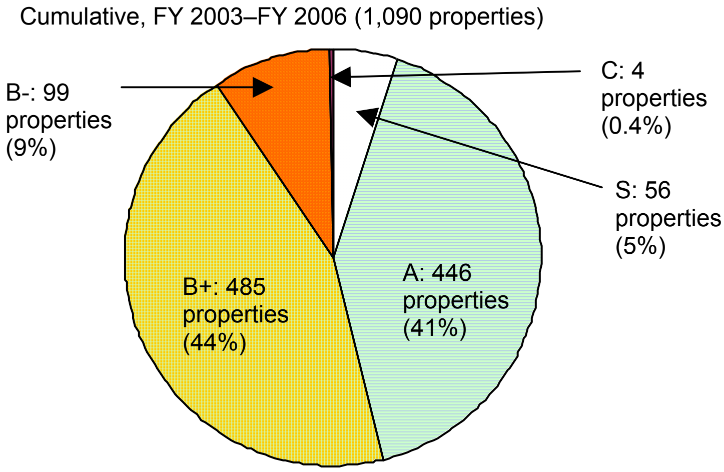

Figure 6. Breakdown of evaluated result by rank

Figure 7 is a scatter plot of environmental efficiency rates (Q/L) in FY 2006. Most (87%) earned a rank of A or B+, and about 4% were ranked S. About 9% were ranked B-, and practically none were ranked C. The number of points plotted rises sharply for environmental efficiency rates (Q/L) of 1.0 and higher, implying efforts at the design stage to meet a standard of at least 1.0.

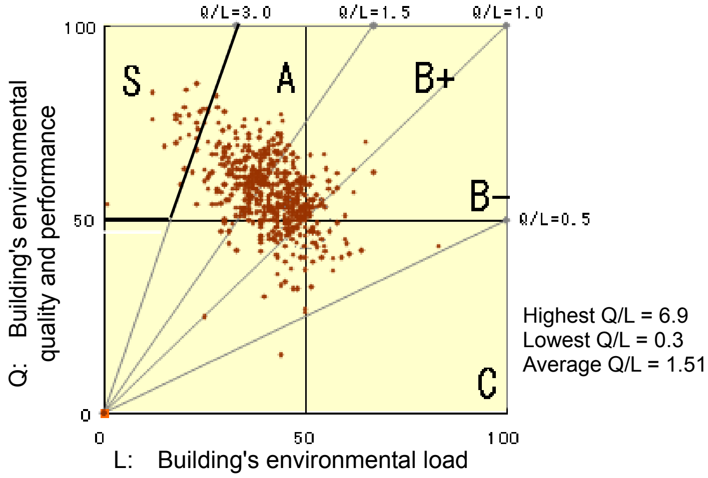

Figure 7. Q/L scatter plot

Figure 8 shows the assessment results of the past four years classified by the building's purpose of use. Schools and assembly halls have tended to earn high CASBEE scores. Apartment buildings and factories account for the largest numbers of projects, but fewer than half of them earned scores of A or higher, a lower proportion than other purposes of use. This could be attributed to the greater difficulty of obtaining a high score in these purposes of use; nevertheless, further improvement is needed in the environmental performance of buildings for these purposes of use in the future.

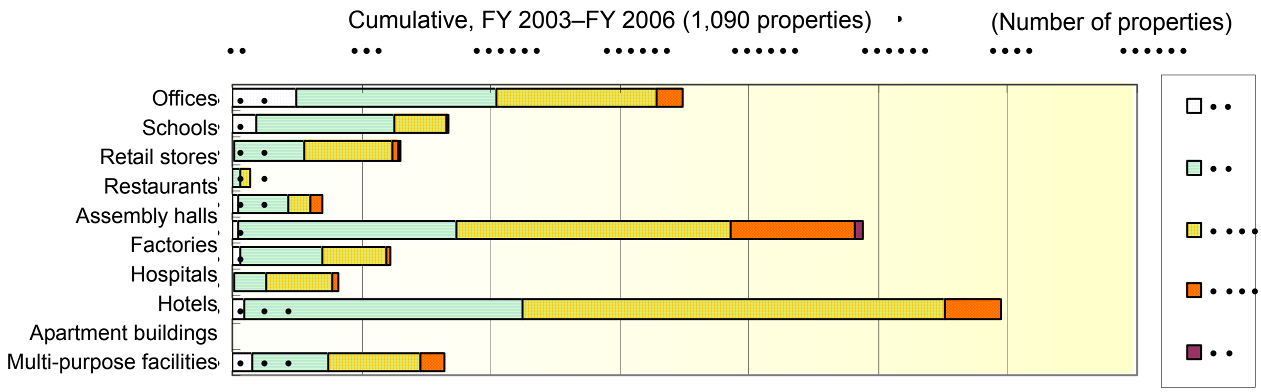

Figure 8. Assessment results by purpose of use

Figure 9 shows the assessment results of the past four years classified by the building's total floor area. Larger-size buildings have tended to achieve better assessment results, with a higher proportion of S and A ranks. Some companies use 2,000 square meters as the cutoff point for deciding whether to perform a CASBEE evaluation. There is a trend toward lower ranks among buildings of less than 2,000 square meters.

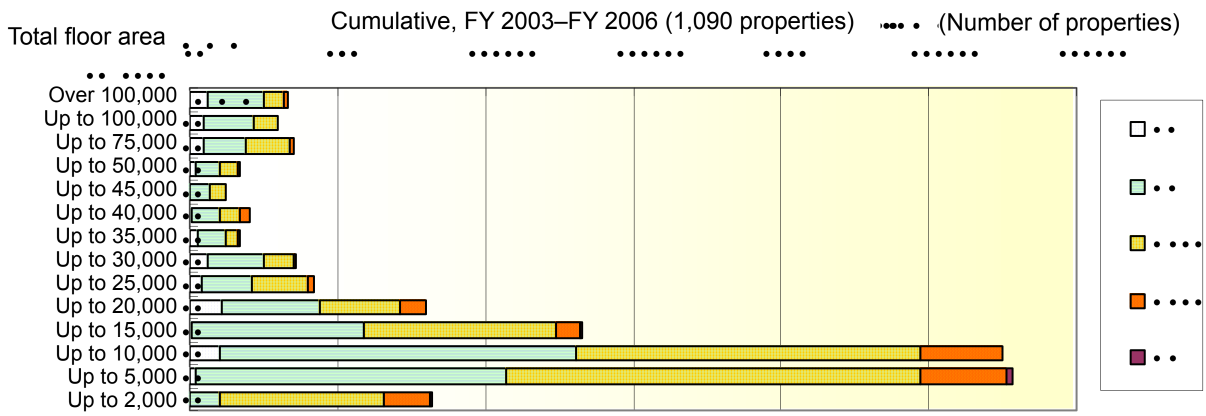

Figure 9. Assessment results by size

3.3 Opinions concerning the CASBEE evaluation system

Among the 16 companies which have actively incorporated CASBEE evaluation, 11 firms said the most important reason was that they consider CASBEE to be an effective tool for promoting environmentally friendly design.

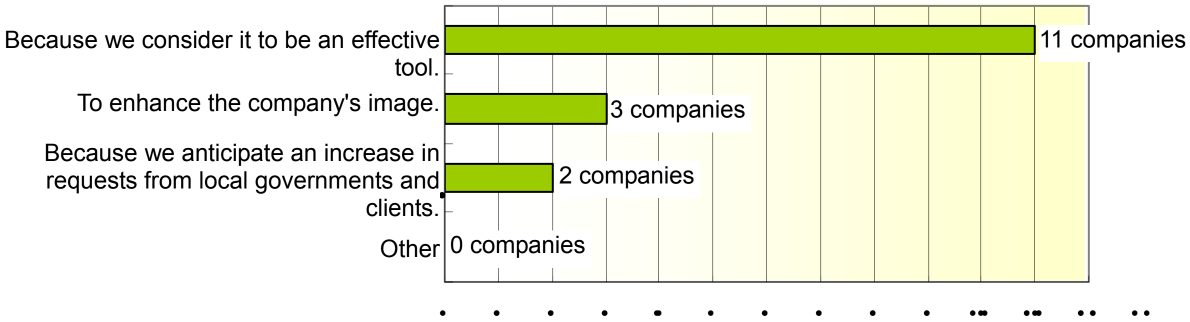

Figure 10. Reasons for actively incorporating CASBEE evaluation

Figure 11 shows the positive aspects of CASBEE evaluations, with the greatest number of respondents indicating the fact that results of environmentally friendly design can be expressed in numerical terms, followed by the facts that it helps to educate architects with regard to environmentally friendly design, and that the evaluation is relatively simple.

Figure 12 shows the negative aspects of CASBEE evaluations, with the greatest number of respondents indicating the difficulty of subjective evaluation judgments, followed by the burden on architects, and the lack of quantification of the reduction in carbon dioxide emissions.

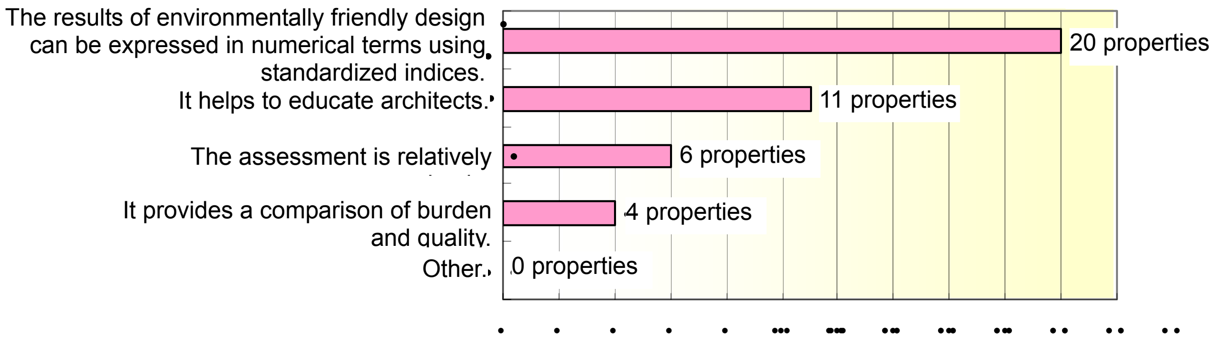

Figure 11. Positive aspects of CASBEE evaluations

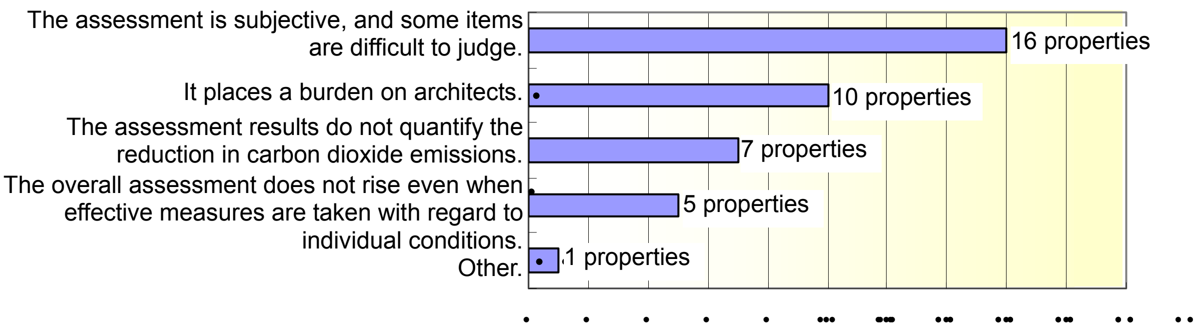

Figure 12. Negative aspects of CASBEE evaluations

Figure 13 indicates the approximate working hours required for CASBEE evaluations (assuming that PAL and CEC data are already in place at the time of CASBEE evaluation work). The simplified edition is indicated as requiring about two hours, but in fact, 60% spent half a day and 20% spent an entire day, while only about 10% completed it within about two hours (no non-responders). Among the eight companies responding that they spent either about eight hours or more than eight hours, the most time-consuming tasks were understanding the manual and gathering back data. Under "other," responses included document preparation, coordination with the architectural and M&E divisions, discussions and guidance from the authorities concerning documents to be submitted and the resulting additional document preparation time, and coordination regarding the views of government authorities.

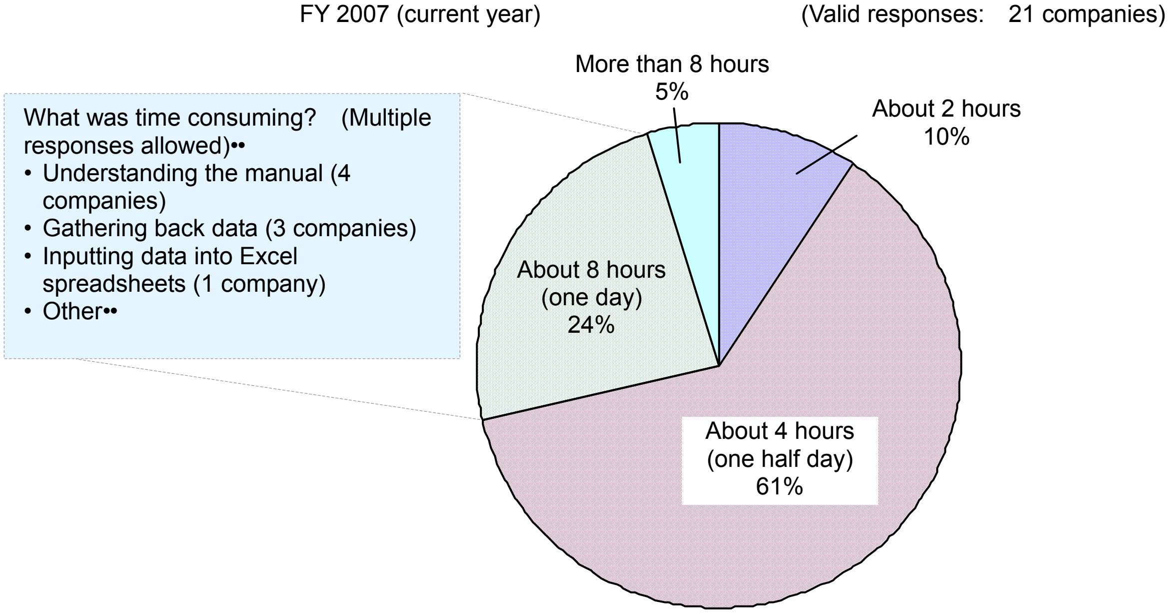

Figure 13. Working hours for "CASBEE, New Construction: Simplified Edition"

3.4 Unstructured comments concerning CASBEE

Table 1 shows the unstructured comments of 23 companies in the BCS design subcommittee regarding CASBEE this fiscal year, by category. The following were the most frequent types of responses:

[1] The CASBEE evaluation system should clarify the effects with regard to reducing carbon dioxide emissions, etc.

[2] Efforts should be made to promote dissemination among a wide range of interested parties including clients, managers, and financial institutions.

[3] Building facility engineers should also be permitted to take the CASBEE evaluator examination.

[4] The local government editions of CASBEE should use the same tools in order to allow the work to be standardized, from the applicant's standpoint.

Regarding item [1], the developer of CASBEE (Japan Sustainable Building Consortium) published "CASBEE, New Construction" (FY 2007 Provisional Edition) in September 2007, clearly indicating evaluation items for the prevention of global warming and incorporating a standard method for calculating life-cycle carbon dioxide emissions. The official edition is scheduled to appear in July 2008.

Many CASBEE users within BCS would agree with items [2] and [3]. Item [4] reflects some level of apprehension regarding the differences in CASBEE content among different local governments which require these assessments.

Table 1

<u>Wishes regarding the CASBEE evaluation system:</u> • The assessment does not clearly indicate the extent of effects regarding the prevention of global warming. A clear indication is desirable, such as stating the amount of reduction in carbon dioxide emissions resulting from a certain assessment rank. • The layout and composition of the evaluation sheet should be improved to allow the input work to be handled mechanically. • Some items, such as consideration for scenic aesthetics, are subjective and difficult to evaluate, and this should be improved if possible.

<u>Wishes regarding promotion and dissemination:</u>

- Although CASBEE is becoming more prevalent in the building industry, most clients still do not understand CASBEE evaluations. Measures should be taken to provide benefits to clients, in addition to encouraging local governments to adopt CASBEE.
- Widespread adoption and utilization of CASBEE should be promoted not only among government authorities and the building industry (design, construction, and manufacturing), but also among clients, end users, maintenance and management providers, and financial institutions.
- Eligibility for CASBEE evaluator testing is limited to first class architects, but it should be opened to building facility engineers as well.

<u>Wishes regarding local governments:</u>

- Different local governments use different standards regarding the size of buildings to be evaluated. The trend toward widely varying approaches among local governments is problematic in terms of the reputation of CASBEE.

<u>Other</u>

- Environmentally friendly design should be actively promoted in competitions for energy efficient and environmentally friendly buildings, based on assessment results.

4. Future outlook

No other organization in Japan conducts a survey that rivals the BCS survey regarding CASBEE, excluding certain local governments. In this survey, the third annual survey since its full-scale launch, we see that CASBEE is becoming increasingly prevalent among BCS member companies. The number of buildings evaluated has also increased to nearly 600 per year, including many certified buildings and buildings published by local governments. It is becoming possible to measure progress in the prevalence of CASBEE by means of these large numbers of cases and assessment results.

This survey has been discussed at symposia held by the CASBEE development committee, and it is also noted by the Ministry of Land, Infrastructure and Transport, financial institutions, and real estate appraisal organizations. BCS will continue to actively communicate these findings to all types of stakeholders (CASBEE development committee, local governments, builders, financial institutions, real estate appraisal organizations, end users, etc.) and listen to their reactions.

Some of the future issues are included under the summary of unstructured responses. Another important future issue is to increase assessments of existing buildings.

Today, there is growing demand for truly effective performance from buildings that are planned with an eye to preventing global warming. In other words, it is becoming imperative to measure energy consumption in completed buildings, publish these figures, and promote further reductions.This suggests the importance of assessments under the "CASBEE, Existing Buildings" edition. It is important for BCS to increase the number of properties evaluated in this way. Meanwhile, it is also important for CASBEE tools to include ways to evaluate the performance of existing buildings.

5. Acknowledgment

This article is based on the BCS's research conducted by a committee of BCS. We are grateful to the following members for their efforts."Working Panel for Environment Issues" in Design Committee of BCS -Panel Chair: Kenichi KAJIMOTO(Maeda Corporation), Vice-Chair: Tadayuki SUZUKI(Toda Corporation), Members: Yasuhiro IMAI(Obayashi Corporation), Kunihiko KAGAWA(Kumagai Gumi), Masaru KIKUIRI(Tokyu Construction), Tomonori MIYAZAKI(Tekken Corporation), Hiroshi MIYAHARA(Sumitomo Mitsui Construction), Hisayoshi SAKUMA(Taisei Corporation), Hiroaki TAKAI(Takenaka Corporation), Masaki TAKEUCHI(Shimizu Corporation), Akira TOKESHI(Hazama Corporation)

INTEGRATED SUSTAINABILITY ASSESSMENT OF URBAN DEVELOPMENT AND INFRASTRUCTURE: COMPLEMENTARITIES AND CONTRADICTIONS

Summary

The context of this paper is the Green Growth agenda of the United Nations which has highlighted the challenge of the developing world to achieve economic growth but with less resource use and lower social and environmental impacts compared with Western nations. Urban infrastructure systems, including transport, water, energy, education, health and housing, and associated land use patterns, are important elements of achieving Green Growth as they consume significant resources, establish consumption patterns for decades and have major socio-economic impacts.

As part of a longer term project to develop a model for the integrated assessment of urban sustainability, this concept paper discusses various theories and approaches from economic, social and environmental sustainability perspectives, exploring opportunities for integration. Using a case study of a proposed transit-oriented development in a growing urban centre near Adelaide, South Australia, it examines how more compact and dense urban development may be planned and assessed from an integrated sustainability viewpoint. It is intended that the results of this work will inform policy and urban development and infrastructure decisions across a wide range of urban locations, including rapidly growing urban areas within the Asia-Pacific.

1. Introduction

The world's high rate of urbanization has potentially catastrophic consequences for the planet, in terms of consumption of resources, degradation of the natural environment, the waste and emissions generated, and effect upon human health. Some have claimed it is the most important cause of greenhouse gas emissions and climate change, coupled with increases in ecological footprint (Von Weizsacker 2007). Urban societies have footprints of around 7-10 global hectares per inhabitant, compared with a world average of about 2.2, and a biological carrying capacity of 1.7 available worldwide (WWF International 2006; Rees & Wackernagel 1996). In addition, whilst urbanization brings increased wealth for some, it can be characterized by inequalities, severe poverty and social problems. Thus, the challenge is to achieve urban development that is not only environmentally sustainable, but also economically and socially advantageous, to meet the UN Millennium Development Goals and the UN 'Green Growth' agenda (ESCAP 2006).

It is therefore imperative that a way is found for the urban areas of developing nations to grow in a more sustainable manner, avoiding the high consumption patterns of western cities. Moreover, it is incumbent on cities of the west to reduce dramatically their own consumption of scarce resources and develop new more sustainable modes of growth, which may be emulated by cities in developing nations.

The paper firstly outlines the challenge to develop rapidly growing urban areas in a more sustainable manner, introducing the concept of transit oriented urban development (TOD), and highlighting the need to consider the relative merits of compact, more dense configurations of development (such as TODs) and more dispersed, lower density patterns.

Various efficiency-related principles from the economic, social and environmental disciplines are examined, including allocative and resource efficiency, with opportunities for integrated thinking being explored.

The literature on urban sustainability assessment is then reviewed, firstly from the economic, environmental, and social perspectives of sustainability and, secondly, in terms of the intersections and associated contradictions and complementarities.

Reference is then made to a planned case study of an urban centre to the south of Adelaide, with some preliminary thoughts on new patterns of integrated and sustainable urban development. More dense and compact patterns are compared with lower density, dispersed modes, based upon the current state of knowledge. Means of integrated assessment of urban sustainability are also examined.

Finally, some indication is given of how the principles and techniques being trialed in Adelaide may be adapted and extended to cities in developing countries.

2. The challenges

2.1 Sustainable urban development and infrastructure

The provision of engineering and social infrastructure to provide increased services for rapidly increasing urban populations is a challenge faced by urban planners and developers in most Australian cities and elsewhere. Engineering infrastructure includes transport, energy and water services, whilst social infrastructure includes health, education and other government services, including public housing.

Recognising the substantial contribution of infrastructure and associated urban developments to greenhouse gas emissions and ecological footprint (Ness 2007), especially given its long life, increased attention has been given to its sustainability. At a recent UN Expert Group Meeting, a sustainable infrastructure system was seen as one that facilitates the delivery of transport, energy, water and other services to support social and economic development in an integrated, resource efficient and socially inclusive manner. It was recognized that infrastructure systems are central to economic and social development, as they support economic growth and deliver services to communities, and are also critical determinants of environmental impacts as they lock in consumption patterns for decades. Infrastructure was seen as not only very costly and having a long life, but also as very intensive in resource use, including energy, water, materials and land (ESCAP 2007).

Within Australia, state and local planning authorities are increasingly favouring urban developments characterised by mixed use, higher density and proximity to existing or new public transport systems as a way of reducing the consumption of scarce resources and environmental impacts. The current interest in Transit Oriented Developments (TODs) by the South Australian Government is a case in point. Such compact developments can be considered to be manifestations of 'new urbanism', a planning theory which suggests that urban sprawl might be contained by rebuilding inner cities around attractive streetscapes, walkable town centres and public transport hubs (Scheurer 2004). 'New urbanist' developments typically have higher population densities than in suburban localities. For example, Gordon and Vipond's (2005) study of a new urbanist development in Markham, Ontario suggests gross densities twice that of traditional suburbs might be achieved.

Some planners have previously expressed simplistic arguments in favour of more densification in urban development. However, these need to be balanced with what is achievable in the existing urban structure and with regard to social preferences.

2.2 The need for tools

Our ability to assess the sustainability of forms of urban development as described above is limited and the tools to do so have yet to be coherently brought together, with many existing tools and approaches being uni-dimensional. Tools are required to undertake a more integrated analysis than is currently available (Rotmans 2006; Davidson 2007) and to evaluate and guide development and infrastructure decisions. These tools should have the capacity to assess alternative development proposals and compare them on the basis of their sustainability, in addition to the normal financial feasibility assessments.

In addition, interdisciplinary research is required, in recognition of the complexities of urban systems, and to draw together diverse lines of enquiry to form coherent, integrated theory and practice.

3. Literature review

3.1 Economic welfare/well-being

Economists propose goods, services and outcomes that society most prefer/want/need, delivered with the best/most appropriate use of resources. The former is known as 'allocative efficiency', sometimes called '*doing the right things*', whilst the latter is known as 'productive efficiency', sometimes called '*doing things right*'.

The economic concept of 'allocative efficiency' aligns with the needs and preferences of urban dwellers for space, privacy, housing type, appropriate noise levels, to name a few. In Australian society, the market plays a key role in delivering those needs, but government can also play an important role in identifying market failures (e.g. inequitable outcomes, unsafe construction, etc) and considering options for overcoming those failures.

In relation to the related concept of 'productive efficiency', economists look for the cost minimising mix of resource use to deliver any given outcomes – this should include full costing of resources, including environmental and social costs. This means minimising negative impacts but, of course, positive impacts are very welcome.

'Tradeoffs' are a core issue in the dialogue about sustainability (SA Government 2005). In discussing trade-offs, the concepts of 'weak' and 'strong' sustainability can be helpful (see Neumayer 2003). These concepts relate to the substitutability or trade-off between economic and environmental capital. Strong sustainability requires that economic capital should only be increased provided there is no reduction in environmental capital. On the other hand, weak sustainability allows for environmental capital to be decreased whilst economic capital is increased, provided the gain in economic capital is greater than the loss of environmental capital. In an ideal world, sustainability would involve no trade-offs i.e. strong sustainability. However, the real world consists of many situations involving tradeoffs, where weak sustainability can play a role. In this regard, Rotmans (2006) acknowledges the unavoidable conflicts and tradeoffs that are required for a sustainable future.

3.2 Environmental sustainability and urban density

A transition to higher levels of residential density within cities is seen as a means of achieving a number of key environmental objectives. According to Newton (2006), 'medium density housing has approximately two thirds the material intensity of detached single family housing'. Similarly, Schiller noted 'a strong correlation between material consumption and building density', concluding that the parameter 'cost efficiency' is an argument for more dense and less resource-intensive settlement structures (Schiller 2007). Newton (2006) acknowledges that more compact styles of development are the subject of debate in respect of the perceived benefits in areas other than resource consumption – namely neighbourhood character and amenity. Other aspects of consumer preference could be added to this list, such as preference for private space and privacy.

Salat (2007) has called for action on more efficient engineering infrastructure complemented by more compact forms of urban development, with a focus on the relationship between energy and density. In this regard, the mapping of energy consumption in the urban environment offers the potential for determining more energy efficient urban forms, monitoring energy efficiency improvements and complying with targets for greenhouse gas emissions (Troy & Smith 2000; Jones et al. 2001; Gupta 2005; Matsumoto et al. 2006). The life cycle energy consumption of the built environment includes a number of components including the embodied energy of the materials from which buildings are constructed as well as the operational energy for running buildings. Research is being carried out to depict both the embodied energy of residential buildings in the Adelaide metropolitan area in a spatial format (Pullen 2007) and the operational energy used in specific areas (Hamilton et al. 2008).

The model for spatially representing the embodied energy consumption of residential areas has three components - embodied energy theory, property register data and geographical information software (GIS) – that can be integrated to provide maps (Pullen 2007). The advantage of using GIS as the mapping medium is that ultimately other forms of energy consumption in the urban environment can be overlayed and accumulated to allow a more comprehensive representation of urban energy usage.

In this regard, the consumption of energy and other resources (land, materials and water) can be considered not only in relation to residential areas, but also associated with engineering infrastructure for transport and utilities and social infrastructure for government services. Sharing and co-location of infrastructure and facilities, for example, can lead to higher resource productivity – delivering more services with less use of embodied and operational (fossil fuel) energy and other scarce resources, less environmental impact and less cost. An example is the use of a road corridor for water collection and harvesting and as a linear solar energy source to serve adjacent housing (Ness 2007, 2008).

The modelling and measurement of energy consumption, which takes into account embodied energy, can also provide a means for valuing the existing built form and accounting for saved energy in the re-use or recycling of construction materials in the redevelopment of existing urban areas (Pullen 2007). This provides a more holistic analysis of energy consumption and indicates the significance of the embodied energy component of overall life cycle energy consumption. The analysis of operational energy demonstrates that different forms of residential development at different densities display differing energy profiles (Perkins & Hamnett 2005; Perkins et al. 2007). These spill over into transport energy, since density is often related to location and proximity to services. Therefore, even within a discrete area of study such as urban energy demand, we can identify relationships which need to be made explicit in any analysis of the sustainability of urban form.

3.3 Social sustainability and urban density

Despite the interest in transit oriented developments in Australia, Crabtree (2005: 333) notes that 'we seem to know what needs doing to move towards sustainability' but the uptake of new urbanist projects has been slow. Crabtree (2005) lays the blame for this on a neo-liberal planning agenda, which avoids what she terms the substantial challenges of 'ecocity design and community based enterprise'. Whilst she argues there is a demand for such developments, her case study of the Pinakarri co-housing community in Perth suggests local resistance to urban designs of this nature might arise when such developments are imposed on communities by housing authorities.

Much of the thinking on urban intensification in Australia as in other parts of the world seems to focus on the notion that residents can be induced into choosing higher density living options in preference to low density suburban locations (Skaburkis 2006). It assumes that consumers will accept giving up backyards and using public transport in place of cars to access work and shopping because it will create 'socially sustainable communities'.

It is almost forty years since Arnstein (1969) drew attention to the relationship between inclusive, resilient communities and the degree of control local people have over institutional decisions that affect their lives. If we accept Arnstein's argument it is clear that the degree to which residents are able to address their preferences for the style of housing they wish to live in and the choices they have in relation to the location of their homes have implications for the sustainability of a community. That is, urban developments are more likely to be sustainable if residents are satisfied with the design of their housing, the density of their local area and the accessibility of work, shopping and social institutions. Hence a model that wishes to measure the sustainability of urban developments should consider not only the types of housing and relative urban densities that might be supplied but public demand for such developments. We might begin by asking if actors in the housing market will increasingly accept compact city living in mixed use, higher density communities as assumed by many policy makers and planners.

The planning literature on consumer preferences for new urbanist living is limited but a recent British study by Senior et al. (2006) examined the acceptability to relocating households of higher density living in mixed land use land areas in redeveloped dockland, inner urban and city centre locations. Relocation has been encouraged in the UK by policies to address social exclusion through the creation of sustainable, mixed income communities (Silverman et al. 2005). Senior et al. (2006) surveyed the housing preferences of owner occupier residents of Cardiff, Wales who were selling or had sold their homes to relocate. Their study found a continuing preference for detached properties in suburban locations rather than in higher density, inner city locations. Such preferences were strong among families with children of pre-school age. Those of retirement age were even less likely to opt for inner urban locations. Senior et al. (2006) noted a significant general aversion to living in areas where residents were perceived to be of lower socio-economic status. Their respondents also expressed an aversion to neighbourhoods where residents were considered to be of a higher social status than themselves. First time home buyers with financial constraints indicated they would look at affordable options in the inner city. However, once on the housing ownership ladder, most first home buyers said they would prefer to move to suburban locations and detached housing once they had established some equity. Most respondents expressed a preference for socially homogenous communities where they might live among people similar to themselves.

A similar survey by Skaburkis (2006) of residents of a new urbanist development in Cornell, Ontario tends to support the findings of Senior et al. (2006). At the time of Skaburkis' study, 37 percent of homes in Cornell were detached houses with the rest a mix of units and townhouses. While almost all of Cornell residents expressed satisfaction with their housing and their community, 88.6 percent said they would move to a detached house if they could. Skaburkis noted that while housing density in Cornell was twice as high as in surrounding suburbs, many residents were beginning their housing careers in relatively cheap, attached housing and were likely to move to detached housing when it became affordable to them. Skaburkis (2006) did find that residents who wished to move from attached to detached housing were keen to retain a new urbanist lifestyle and would accept living on smaller blocks if that lifestyle could be maintained. Nevertheless, the net effect on urban density of developments such as Cornell might be much less than crude measures of gross density suggest.

4. Towards integrated concepts and assessment

4.1 Integrated concepts

The need for at least a Factor 4 improvement in resource productivity, doubling wealth whilst halving resource use, has been highlighted by authors such as von Weizsacker et al. (1998). In addition, the UN (ESCAP 2006), the Wuppertal Institute (Rithoff et al. 2002) and the WBCSD (2000) have promoted the concepts of eco or resource efficiency. As discussed at the aforementioned UN meeting on sustainable infrastructure development (ESCAP 2007), eco-efficient and sustainable infrastructure systems should, among other objectives, deliver economically viable goods and services, be financially viable, be socially inclusive, and minimize resource use and ecological impacts throughout the life cycle.

To date, however, a strong link has not been made between 'eco-efficiency' and related 'efficiency' concepts in the economic field. The economic concept of allocative efficiency, or doing the right things, aligns closely with the preferences of urban dwellers that receive the attention of social planners. On the other hand, the concept of productive efficiency, or doing things right, is closely related to resource efficiency.

Thus, the notion of providing more services with less resource use, less environmental impact and less cost may be expressed in economic, social and environmental terms, namely: more services and outcomes that people prefer/want/need, with improved/best use of all resources (land, materials, energy and water, labour, capital), leading to reduced negative, and increased positive economic, social and environmental impacts.

4.2 Integrated assessment

The challenge here is to develop a framework tool that is capable of assessing sustainability using reliable and widely accepted measures across a broad spectrum ranging from physical inputs of concrete, steel and energy, through environmental factors such as water quality, biodiversity and habitat protection to social cohesion, service delivery, quality of life, and the preferences of residents and the community.

The UK government's sustainability indicators suite provides one such attempt. Developmental work on formal techniques of Sustainability Appraisal and Integrated Assessment also provide useful starting points. There remains a significant intellectual challenge, in both identifying the key indicators and building a robust framework tool which, crucially, includes suitable trade offs between social, economic and environmental factors.

A model that seeks to assess new urban developments in terms of their capacity to reduce consumption of material resources and energy without having differential impacts on the sustainability of communities should, at a minimum, incorporate a mechanism to assess consumer preferences in terms of housing (e.g. style and location) and mode of transport and hence relative demand. A mechanism is required that has the capacity to unpack the housing and other preferences of residents and the implications of these preferences for the nature and sustainability of the local communities that will form around new developments. The mechanism might be integrated with tools to measure resource efficiency so that an assessment of the relative environmental impacts can be considered in relation to the social sustainability of new developments and with economic measures to evaluate economic allocative efficiency as well.

Resource efficiency can be measured in terms of Material Input Per Service unit (MIPS or MI/S), a concept developed by Schmidt-Bleek (1993) that has a strong relationship to Factor 4. The reciprocal of MIPS (i.e. S/MI) is known as 'resource productivity'. Although the MIPS concept has been mainly applied to measuring resource efficiency at a product or company level it is, potentially, a very useful indicator of the relative resource efficiency of various patterns of infrastructure development (Ritthoff et al. 2002).

Wallbaum and Buerkin (2003) have noted that resource efficiency is only one important path towards sustainability. In the broader context of sustainable development there are also economic targets, environmental targets and social targets (e.g. employee satisfaction over low unemployment rate, overall stability in society) that have to be addressed.

Consideration could be given to extending the MIPS concept to include not only material input, but also social, environmental and economic outputs per unit of service. Thus, it may be possible to assess various configurations of infrastructure and associated urban development not only in terms of their ability to meet service demands with greater resource efficiency and with recognition to the key issues of public acceptability and social performance. Thus, urban areas may be sustainable and efficient in terms of 'allocative efficiency' and 'productive efficiency', including resource efficiency.

5. Exploration and application of theoretical concepts using a case study

5.1 Aims

Our aim is to examine the intersections between environmental, social and economic sustainability, and how these may influence forms of urban development and infrastructure provision, through a case study of an urban centre near Adelaide. The study of single exemplars has been rigorously supported by Flyvberg (2004) as a valid approach for undertaking qualitative research.

The study comprises the first phase of a proposed longer-term research programme, leading to the development of an integrated model for the assessment of urban sustainability, aimed at the level of new urban Master Planned communities.

TODs and similar developments are normally considered in terms of integrating land use and transport (Cervero 2005). This study and research seeks to extend the analysis, considering the inter-relationship of various forms of 'economic' infrastructure systems and services, including transport, energy, water, and the 'social' infrastructure of affordable housing, education, health and welfare.

The study/research seeks to answer questions including the following:

- How do compact, dense and 'urbanised' patterns of infrastructure development (including TODs) perform in terms of cost, resource efficiency and allocative efficiency, compared with more dispersed 'suburbanised' patterns?
- Can they deliver community well being and social sustainability in comparison with dispersed 'suburbanised' developments?
- How can we assess the relative social, economic and environmental impact of urbanised and suburbanised developments?

5.2 Noarlunga regional centre

This regional centre (see Figure 1) is projected to grow significantly in future, in accordance with South Australia's population policy (Department of Premier and Cabinet 2004).

However, this needs to occur in much more environmentally sustainable manner, with more efficient use of resources e.g. water, energy, land and materials plus less emissions and waste. In addition, the pattern of development must recognise social preferences and address housing affordability. Land within the area is poorly utilised at present, and includes a shopping centre with extensive car parking, underutilised government land, a transport interchange, and disconnected facilities such as a hospital, technical and further education centre (TAFE), technical college, public high school and private school, sports centre, cinema, offices, and police station and courthouse.

At present, the centre is surrounded by low density public and private housing, with no residences within the centre itself. In this regard, the SA Government and the local council envisage that the centre should accommodate 6000 residents by 2050, adding to its current 7000 working population.

In terms of its demographic characteristics, 30 per cent of the existing households in the vicinity are single parent, with relatively low incomes and declining affordability of houses. Car ownership is low compared with other parts of South Australia, with 50 per cent of residents having none or one car. The aged proportion of the population is increasing.

Figure 1 Noarlunga Regional Centre

The government/council vision for the Noarlunga Centre is of a vibrant, dense community focused on the transit interchange and with connected and integrated land uses. Housing densities of up to 40-50 dwellings per hectare are envisaged, with at least 15 per cent of housing being 'affordable housing', including 5 per cent 'high needs'. At least 12.5 per cent open space is required as part of new development. The area has targets for water conservation and reuse, for reducing emissions (the state target being to reduce emissions by 60 per cent by 2050), for reducing its ecological footprint (by 30 per cent by 2050) and for biodiversity.

5.3 Possible scenarios: complementarities and contradictions

The area is currently the subject of a consultant study, with the aim of developing a 'structure plan' and guidelines to accelerate transit-oriented urban development'. Whilst this study is yet to be completed, it is clear that a residential population of over 5000 can be accommodated within the centre confines, at densities ranging from 30 to 55 dwellings per hectare and with a choice of housing types. Lower densities are likely to be more affordable.

A market study by the consultants indicated that residents for higher density forms of housing would need to be attracted from outside the area. However, this could be viable, given the present scarcity of this form of housing in the southern part of Adelaide and the availability of shopping, government services and retail development.

One option is for higher density residential development to be clustered around the transport nodes, including the interchange, surrounded by the lower density development. Currently dispersed car parking could be consolidated into compact, multi-deck structures, enabling the land to be used more efficiently e.g. urbanised built form of several stories could be constructed along new shopping streets, with retail at street level and offices and residential uses above.

However, whilst there may be savings in energy, materials and cost deriving from higher densities, this may imply problems of privacy, access to open space or excessive levels of noise in the urban environment leading to social stress.

In the Noarlunga example, the land adjacent the transport nodes and with increased access to services is likely to be more expensive. This poses a problem for the 50 per cent of the current population in the area who have access to one or no car, or who are single parent households, many of whom are struggling to pay their rent or mortgages. Similarly, the aged and infirm, who require access to services and transport, will need to be located at or near ground level – otherwise lifts will be required which will detract from the affordability of housing for the aged, low income population. Such contradications represent 'weak sustainability' and will require tradeoffs.

On the other hand, there are examples of possible complementarities and synergies that represent 'strong sustainability' ('win-win' situations). Various government services will need to expand to meet projected population growth, and facilities could be shared and co-located, leading not only to improved services but also to reduced ecological footprint and emissions. For example, educational services (e.g. high school, technical and further education) could share additional teaching space, accompanied by more efficient use of existing facilities through connectivity. Community health care, with general practitioners and health promotion, could be co-located with family and community support services related to housing, disability, financial support/advice and the like, all in close proximity to transport, retail and commercial hubs. Similarly, landscaped open space penetrating the centre may be used for water detention and treatment, recreation, walking and cycling routes, food cultivation, and promotion of biodiversity. Thus, application of 'systems thinking' enables connections and synergies between various elements of the urban system to be explored and optimised, resulting in provision of more services but in a resource efficient manner.

The above case study of the Noarlunga Regional Centre has revealed that, while some examples of strong sustainability can be identified, others represent 'weak sustainability' and will require tradeoffs between economic, social and environmental factors.

6. Application to urban areas in developing countries

It is incumbent on developed nations such as Australia to demonstrate how urban areas may grow in an environmentally sustainable manner and, at the same time, address social disadvantage and differing cultural and other preferences. This could require major shifts in western patterns of consumption of scarce resources and forms of urban development.

Whilst the Australian case study context is vastly different from urban areas in developing countries, it is expected that the broad principles and methodology for integrated sustainability assessment will be transferable, with appropriate adaptation to particular cultural and other circumstances. The methodology will require testing in a developing country urban context, after the model has been constructed, with comparisons to Australian applications and findings.

7. Closing remarks

This 'concept paper' has indicated a direction towards urban sustainability, integrating the economic, environmental and social dimensions and recognising the intersections and tensions. Decisions on urban sustainability will usually require tradeoffs.

It has also highlighted the relationship between allocative efficiency and social preferences, and between productive efficiency and resource efficiency.

Whilst compact, more dense forms of urban development such as TODs may be more resource efficient, this will need to be balanced against possible disadvantages in terms of allocative efficiency. The achievement of overall sustainability, balancing the economic, environmental and social dimensions, is a complex process that may have been over-simplified in the past. This requires a multi-disciplinary team approach such as represented by the authors of this paper.

The findings are indicative only, and more in depth research is required to develop the integrated model and to test this in practice using Noarlunga and other 'small area' case studies.

Whilst based on an Australian case study, the methodology we are developing is intended to be broadly applicable in different cultural settings, with appropriate adaptation.

THE SUSTAINABLE BUILDING ASSESSMENT TOOL: INTEGRATING SUSTAINABILITY INTO CURRENT DESIGN AND BUILDING PROCESSES

Jeremy GIBBERD.[1]
CSIR, Pretoria, South Africa

1 CSIR, Pretoria, South Africa, jgibberd@csir.co.za

Keywords: sustainable building, assessment tool

Summary

The Sustainable Building Assessment Tool (SBAT) was developed to ascertain the performance of buildings in terms of their contribution to sustainable development. In particular, the tool focuses on a developing country context and includes social and economic criteria as well as environmental indicators. The paper reviews definitions of sustainable development and current measures of global and national sustainability performance and compares this to criteria used in the SBAT. It shows that the SBAT is reasonably well aligned with these definitions and measures and identifies a number of areas where alignment could be improved.

The paper suggests that the tool is reflects progress within the wider field of sustainability performance measurement. Here, environmental sustainability performance measurement is now well defined and can be ascertained in objective and detailed ways through ecological footprints and carbon emissions measurement and calculations. Social and economic sustainability measurement however is still difficult to measure and there are a range of competing systems such as the Human Development Index (HDI) and the Genuine Progress Indicator (GPI).

While there is no general consensus and appropriate measurement system for social and economic sustainability at global or national scale it will be difficult to finalize these aspects in assessment tools that aim to measure sustainability in buildings. The paper argues however that this should not be an excuse to leave out social and economic indicators in building sustainability assessment tools. It suggests instead that these criteria are important and should be developed, particularly in developing countries, as buildings and construction can make substantial contributions to local economic and social sustainable development.

1. Sustainable Development

What is sustainable development? There are many definitions of sustainable development. These generally describe a 'state' to be aspired to, and a recommended route to this. This state is defined in terms of its ability 'to maintain services and quality of natural resources', 'to live within carrying capacities of supporting ecosystems', 'to meet future generations needs and aspirations'. The recommended route to this state in these definitions expresses a concern about current populations and aims to ensure that 'current needs' are met, and the 'net benefits of economic benefit are maximised' and the 'quality of human life is improved'. Examples of definitions that reflect this are outlined below.

…development that meets the needs of current generations without compromising the ability of future generations to meet their needs and aspirations. (World Commission on the Environment and Development 1987)

…maximising the net benefits of economic development, subject to maintaining the services and quality of natural resources over time. (Pearce and Turner 1990)

…. development that improves the quality of human life while living within the carrying capacity of supporting ecosystems. (International Union for Conservation of Nature 1991)

These definitions focus on what Wackernagel and Yount call the "socio-economic" and "ecological imperatives" of sustainability (Wackernagel et al, 2000). Measuring progress towards sustainability therefore requires accounting tools that measure progress in terms of the socio-economic and ecological imperatives. Two well known tools for measuring progress in these areas are the Human Development Index (socio-economic) and Ecological Footprints (ecological)

1.1 The Human Development Index

The Human Development Index was developed as an alternative to economic progress indicators and aimed to provide a broader measure that defined human development as a process of enlarging people's choices and enhancing human capabilities. The measure is based on

- A long healthy life, measured by life expectancy at birth

- Knowledge, measured by the adult literacy rate and combined primary, secondary, and tertiary gross enrolment ratio
- A decent standard of living, as measure by the GDP per capital in purchasing power parity (PPP) in terms of US dollars

1.2 Ecological Footprint

An Ecological Footprint is an estimate of the amount of biologically productive land and sea required to provide the resources a human population consumes and absorb the corresponding waste. These estimates are based on consumption and production of waste in the following areas:

- Food, measured in type and amount of food consumed
- Shelter, measured in size, utilization and energy consumption
- Mobility, measured in type of transport used and distances traveled
- Goods, measured in type and quantity consumed
- Services, measured in type and quantity consumed

Figures from these measures have been combined in graph developed by the World Wildlife Fund (WWF), shown below. This shows that countries in Europe and North America tend to have very high ecological footprints and acceptable human development indexes (above 0.8), while countries in Asia and Africa tend to have unacceptably low human development indexes (below 0.8) but have ecological footprints within the biosphere's average capacity per person.

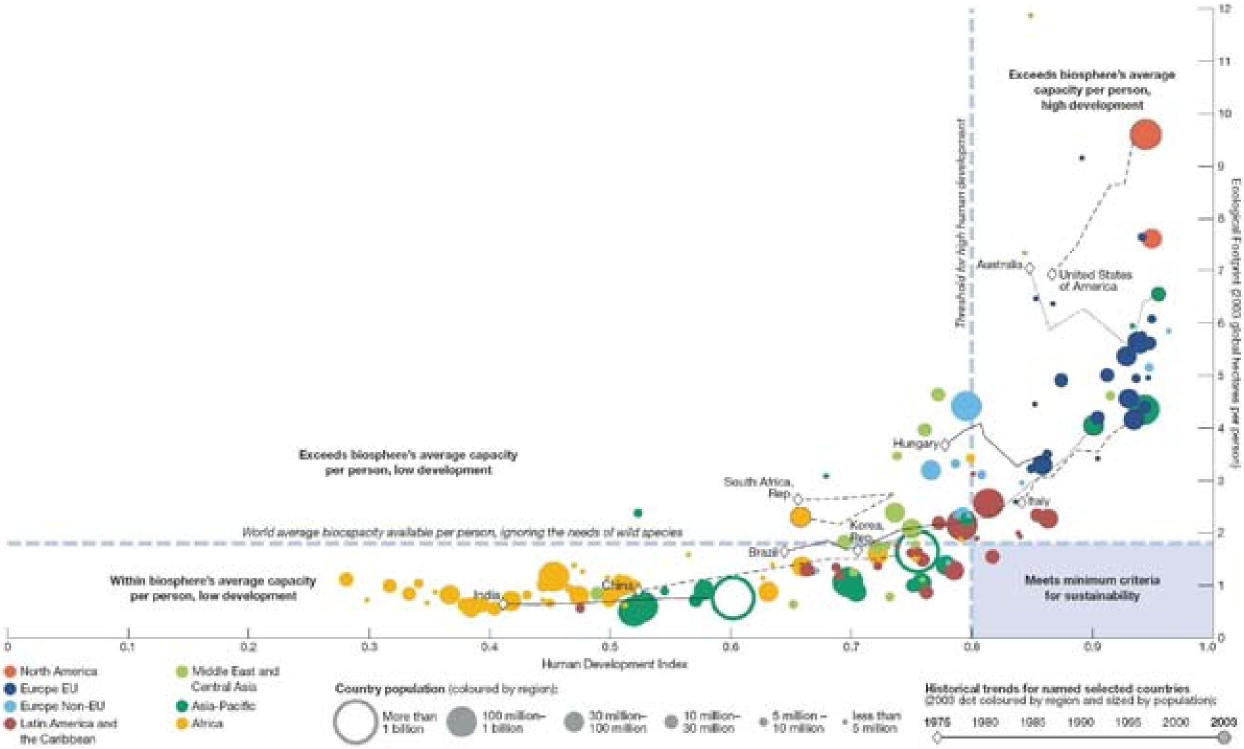

Figure 1 Human development and ecological footprints 2003 (from the Living Planet Report)

The figure is interesting in that it suggest that only one country (in Latin America and the Caribbean) meets the minimum criteria for sustainability. The clustering of countries from Latin America and the Caribbean (brown dots) around the minimum sustainability criteria for sustainability box suggests that these countries have development models that should be emulated.

2. Implications for buildings

The definitions of sustainable development described above have implications for the planning, design and management of the built environment. In particular, they suggest that the built environment should contribute to the socio-economic and ecological imperatives of sustainability. Assessment systems designed to measure a building's performance in terms of sustainability therefore must measure performance in terms of the extent to which a building contributes to these socio-economic and ecological imperatives.

Most building environmental impact assessments have focused on the shelter and, to a less extent, the mobility aspects described above. The Sustainable Building Assessment Tool has had a broader focus and aims to capture social and economic impacts of the built environment

3. The Sustainable Building Assessment Tool

The Sustainable Building Assessment Tool (SBAT) measures sustainability performance in the built environment against 15 social, economic and environmental criteria, as outlined below.

3. 1 Social

- SO1: Occupant comfort
- SO2: Inclusive environments
- SO3: Access to facilities
- S04: Participation and control
- S05: Education, health and safety

Economic

- EC1: Local economy
- EC2: Efficiency
- EC3: Adaptability
- EC4: Ongoing costs
- EC5: Capital costs

Environmental

- EN1: Water
- EN2: Energy
- EN3: Waste
- EN4: Site
- EN5: Materials and components

Performance in each of these areas is measured out of 5 and presented on a radar diagram, see below. This enables performance in the different areas to be 'read' quickly and the 'balance' of the approach between social, economic and environmental performance to be ascertained.

Figure 2 SBAT report

SBAT criteria were developed through a process of describing, and understanding, buildings in terms of their relationship to social, economic and environmental systems Gibberd (2001). Different environmental and economic and social systems have different levels of sustainability and the approach used to develop the

SBAT aimed to assess not only the performance of buildings in terms of sustainability but also assess the extent of the building's contribution to supporting and developing more sustainable systems around it.

This aspect can be illustrated through the example of the **Local Economy** set of criteria in the Tool. This suggests that a strong and diversified local economy is important for sustainability. A local emphasis supports sustainability in a very simple way by reducing the need for transportation and therefore limits the consumption of non-renewable resources and pollution. A more subtle aspect of this concept is the way it draws on the connections between people and their environments. The local emphasis encourages people to adopt more sustainable practices by ensuring that people experience, and suffer the negative consequences of their actions (Ekins 1992). Buildings can also have a positive impact on the economy of an area by being designed, constructed and managed to stimulate, and support, a local, diversified economy and create local employment. In order to establish the extent and type of impact a building makes on the local economy the SBAT uses the following measures.

- **Local Contractors:** The extent to which local contractors and labour is used to construct the building
- **Local Building Material Supply**: the extent to which local materials is used in the building
- **Local Components, Fittings and Furniture:** The extent to which local components, fittings and furniture are used for the building
- **Small Business Support:** The extent to which small business such as contractors, manufacturers or retailers are supported through the construction process (i.e. through construction and business administration training) or in the completed building (i.e. through outsourcing, low or no cost access to space and facilities).
- **Maintenance:** The extent to which the building and its system is maintained locally.

4. Discussion

A review of sustainable development definitions and measures raise a number of questions for the development of tools that aim to measure sustainability performance in the built environment. These questions include:

A. Does the sustainable building assessment tool measure aspects related to human development or quality of life (as measured for instance by the Human Development Index)?
B. Does the tool measure the key factors related carrying capacity and ecological footprint?
C. What should be the balance of weighting **between** 'human development' measures and 'ecological foot print' criteria?
D. What should be the balance of weighting **within** the 'human development' and 'ecological footprint criteria'?

Applying the first two questions to the SBAT reveals a number of interesting findings. It shows that for each of the Human Development Index (HDI) criteria there, there are at least two relevant SBAT criteria. The SBAT criteria however are not directly related to the HDI criteria. Where the built environment was being used as mechanism to support human development, it could be argued that these measures should be more closely aligned. For instance, SBAT criteria could measure the labour intensity of building operation as well as labour intensity in construction (measured as person years of employment created per R million construction costs) and check that remuneration provided enabled a reasonable quality of life in terms of Purchasing Power Parity (PPP). The HDI measures with relevant SBAT criteria are shown.

Table 1 Alignment between HDI measures and SBAT criteria

HDI sustainability measure	**SBAT criteria**
A long and healthy life	SO1, SO5
Knowledge	SO3, SO4
A decent standard of living	EC1, SO3

Checking alignment of SBAT criteria with Ecological Footprint measures reveals an expected strong alignment for the Shelter measure. It also reveals weak alignment with the Services measure and no alignment with the Food measure, as indicated below.

Table 2 Alignment between Ecological Footprint measures and SBAT critiera

Ecological foot print Sustainability measure	**SBAT criteria**
Food	
Shelter	EN1, EN2, EN5 EN4, EN5, EC3, EC4, EC5
Mobility	EN2, SO3, EC3
Goods	EC1, EC2, EN5
Services	EC

The weak alignment for the Food and Services criteria is a result of the SBAT's focus on design rather than operational issues. To strengthen alignment there should be a stronger emphasis on operational issues. Specifically, criteria on the availability of 'low ecological footprint food' such as vegetarian meals in buildings as well as criteria that aim to minimize the ecological footprint of goods consumed and services used in buildings should be included.

The SBAT addresses the problem of weighting (Question C) by encouraging a responsive approach in which environmental, social and economic performance targets of the building relate to the building type, the owner of the building and the local context in terms local needs and opportunities. The Sustainable Building Lifecycle (SBL), the process by which the SBAT is used to integrate sustainability into buildings therefore recommends that background research is carried out of the local area at an early stage of the development of the building in order to ensure that this informs the development of the building. Thus, if this research revealed that there was high unemployment and an unreliable water supply in the area, targets within the Local economy and Water SBAT criteria should be challenging. This process can work well, for instance in the Thuba Makote project, however in many cases owners and professional teams are not willing to make the required investment in time to carry out these early studies and do not see local economic and social impact as part of their remit (Gibberd 2005).

The weighting of indicators within the social, economic and environment relate to the 'internal' performance and impact of buildings. The review (Question D) suggests that perhaps the weighting should reflect the balance found in the human development index and ecological footprint measures. Thus the weighting distributed to 'health', 'knowledge' and 'standard of living' in the Human Development Index should be reflected in the weighting of indicators supporting these measures in the SBAT.

5. Recommendations

Assessment tools that measure sustainability performance of buildings need to be aligned more closely to internationally accepted sustainability performance measures such as the Human Development Index and Ecological footprint. In order to do this the design and development of assessment tools should aim to incorporate the following issues:

- **Context responsive:** The design of tools and procedures used to apply assessment should take into account the local context. Where the ecological footprint of the country is well above 2 global hectares per person, the tool should have a strong weighting on criteria that measure environment impact. If however, the human development index of the country is well below 0.8 there should be a strong weighting on social and economic criteria in buildings that support human development.
- **Building-human interface**: An understanding of how the built environment can influence and structure human behavior should inform the design of assessment tools. For instance, easy access to 'low ecological' footprint food such as vegetarian meals and to facilities that support education and health could play a significant role in supporting sustainable development and should be included as measured criteria.
- **Operational issues:** Design of assessment tools should have a strong focus on operational issues. In particular, criteria measuring the ongoing contribution of buildings to human development and to reducing ecological footprints should be set and measured.

STUDY ON DYNAMIC EVALUATION SYSTEM OF GREEN-EFFICIENCY OF RURAL COMMUNITIES IN CHINA

Yang WANG Ph.D Candidate
Xiaoming WANG Ph.D Prof.
Fan YANG Ph.D Candidate

School of Civil Engineering & Mechanics, Huazhong University of Science &Technology, Wuhan, Hubei, China, wangyang.hust@yahoo.com.cn

Keywords: rural green community; green-efficiency; evaluation; system dynamics; simulation

Summary

The traditional high-energy approach of community construction and operation has resulted in serious problems in fields of economy, environment and society. The purpose of this paper is to discuss a new way to evaluate green-efficiency of rural community construction and operation by system dynamics. The approach followed in the paper is a comparative study on characteristics between rural and urban community, and dynamic feedback loops and quantitative relationships in rural community, extended by a case study. Findings are that ecological environment is still fragile in rural community though the initial environment is excellent, and emissions of domestic sewage and refuse is the most important environmental issue, also, the value of green-efficiency of rural community should maintain at a certain level instead of a initial one. Further research should concentrate on the detailed analysis of factors. Practical implications are an increased embedding of system dynamics in rural community development. The originality of the paper lies in its focus and discussion of a new approach of green-efficiency assessment.

1. Introduction

1.1 Development and Problems of Green Community and Rural Community

Human society, developing from the hunting civilization to the agricultural civilization, then to the industrial civilization, has accumulated a great deal of wealth and a highly developed spirit and culture. On the other hand, the rapid economic development with growing world's population and accelerating urbanization process, especially in the industrial civilization drives more people to settle down in community which speeds up the process of urbanization in the end. It leads to (1) high density of human settlement, pollution of domestic refuses and sewage, emissions from large industrial enterprises in terms of various pollutants and serious damage to the environment and ecosystem eventually; (2) that management of sewage treatment and the facilities in city are lagged behind compared to the rapid increase of urban population when people swarm into cities who are lack of attribution to the city identity and often damage the urban environment and ecosystem; (3) and that family structure, educational background, cultural qualities, living habits, nature of the work and the economic situation for the people living in cities are totally changed, which inevitably results in imbalances and conflicts. And in China, nearly half of the 1.3 billion people are still living in rural communities and the construction and operation in rural areas should not be taken the pattern as that of the old days. How to build rural green communities and improve the living environment and conditions of farmers becomes one of the major problems in the community construction in China.

In recent years, the implementation of sustainable development of communities has been the focus all over the world. Green Community, also known as sustainable community or ecological community, refers to the community which has the facilities meeting the requirements of environmental protection and establishes and maintains long-term community environmental management system and public participation in environmental protection mechanism. (State Environmental Protection Administration of China 2005). Western scholars propose that Green Community, as a non-profit, community-based organization, functions to advocate environmental actions, changes environmental activities, and promotes green products and green services. Each Green Community has its own board of directors, budget and professionals. Furthermore, Green Community construction has become an important and effective form for the strategy of sustainable development and environmental protection in western countries (Li Jiusheng *et al*. 2003). The contents of Green Community basically relates to three themes: firstly, reducing the load and passive impact onto the resources and environment; secondly, creating a healthy and comfortable living environment; thirdly, promoting the renewal of the existing patterns to live, produce and consume according to the natural environment (Zhang Linying *et al.* 2006). The goal for building urban Green Community is to strengthen the functions of community as the human survival and development base by enhancing the community's self-organization, self-regulation and self-control ability to use material, energy and information rationally and efficiently and improving the environmental standards of life quality to fully adapt to the social development needs, so as to ultimately create the optimal residential place for human beings that fully integrates technology and natural environment from both the aspects of natural ecology and social psychology (Shi Wenxin *et al.* 2002).

Rural Community is the regional social life community consisting of farmers mainly engaging in agricultural activities. With the overall environmental changes, Rural Community has been put forward in the direction of "quasi-city", which forces us to consider the carrying capacity of environment while exploring the economic development in communities. Through systematic observing and analyzing, we can form the inner function of Rural Community by five aspects namely, community land utilization, community life characteristics, community environmental resources, community culture and community tourism, and deduce the dialectical functional relationship based on sustainable development model (Weng Zhengkai *et al.* 2007).

1.2 Evaluation of Green-efficiency of Community

Green-efficiency analysis, also called eco-efficiency analysis, emerges as a valuable tool towards the target of sustainable development. The World Business Council for Sustainable Development defined that "Eco-efficiency is reached by the delivery of competitively priced goods and services that satisfy human needs and bring life quality, while progressively reducing the impacts to environment and resource intensity throughout the life cycle to a level at least in line with the earth's estimated carrying capacity" (NRTEE 2001; E. Syrrakou 2006). Since its original academic development, the approach has been refined during the last decade and applied to a multitude of projects (Andreas Kicherer *et al.* 2008) and there are some new approaches (Landsiedel R. *et al.* 2002; Zhongsheng Hua *et al.* 2007; J. Quariguasi Frota Neto *et al.* 2008; Pil-Ju Park *et al.* 2008).

In the field of evaluation of green-efficiency of community, eco-efficiency and industrial symbiosis method have been used to analyze the development of a mining community (Olli Salmi 2007). In the business community, people pay more attention to promote sustainable consumption in the way of improving eco-efficiency (L. Michaelis 2003), and the Model Sustainable Agricultural Complex (MSAC) is applied in experimental farm to monitor and manage resource efficiency so as to promote long-term environmental improvement (Charles C. Reith 2003). Several testing criteria of Green Community have been put forward in the mid-1990s in China, including "National commendation and assessment criteria for the Green Community (2005)" by State Environmental Protection Administration and various local criteria, such as Commendation and assessment criteria for the Green Community in Hubei province, which is calculated by scores to promote the construction and development of urban green communities. However, the construction standards of Green Community do not reach a complete and accurate conclusion and China's Ministry of Construction and Housing Industry Promotion Centre in 2001 introduced "Construction key points and technical guidelines for Green Community (for trial implementation) ", giving nine subsystems proposed to design indexes of energy, water, gas, sound, light, heat, virescence, waste treatment and management of green construction materials, and offered as the technical criteria to help China's development of green eco-community system. So far, this guideline is still the only official, authoritative and comprehensive technology index system to guide construction of green communities (Zhang Linying *et al.* 2006).

At the same time, assessment criteria for rural green communities are not involved, and evaluation criteria classified by scores is not fit for rural Green Community which has its own characteristics.

1.3 Evaluation of Green-efficiency of Rural Community with a System Dynamics Approach

The construction of rural Green community is affected by many factors related to social, economic, environmental factors and local development level of technology and so on. These factors are complicated, involving not only the Green Community itself, but also affecting the external environment. The combined effects of various elements will influence the effectiveness of Green Community construction in the end. There will be a large number of unpredictable factors during the construction of Green Community, the interaction of these factors leads to different results, which may be far from that of comparing with these factors alone and ultimately affect projects' objectives. It is precisely because the characteristics of complex nonlinear and feedback loops in community construction, the evaluation of green-efficiency of community can not be decided by scores or linear indexes simply. Therefore, we introduce system dynamics methodology to evaluate the green-efficiency of rural community in order to solve the complex and dynamics in the process of rural community construction (Wang Yang *et al*. 2007).

2. Dynamic Evaluation System Model of Green-efficiency of Rural Community

2.1 Subsystems of Rural Green Community and Their Interaction

There are two basic sources of the dynamics that impinge upon a project system: planned activities and uncertainties. Planned activities, namely attended dynamic, include established operational programmes, arranged daily duties and planned material and plant operations and so on. These activities are designed to initiate the progress of construction while the characteristics of unattended dynamics are represented by unexpected events or uncertainties causing changes to a project system which potentially affect the overall performance of the system (P.E.D. Lovea *et al.* 2002). Within each subsystem, the internal factors will change as time changes and these changes call for the policy-makers of projects to make quick and effective responses. Such responses should be appropriate, strategy adjusted to achieve the original targets by reducing the loss of the unpredictable events. Generally speaking, these factors will have either positive correlation or negative correlation effects on the target system as a whole. For those leading to the strengthening influences onto the system, we call as positive correlation effects and negative correlation effects for dwindling influences. Figure 1 below shows the project dynamic system (P.E.D. Lovea *et al.* 2002). Taking the project as a system, apart from its own changes after the influence, the impact of changes in system 1 will be transmitted to the system 2, which will affect both of the two systems eventually. Furthermore, the impact of changes in system 2 will be transmitted to system i in turn and such cycle.

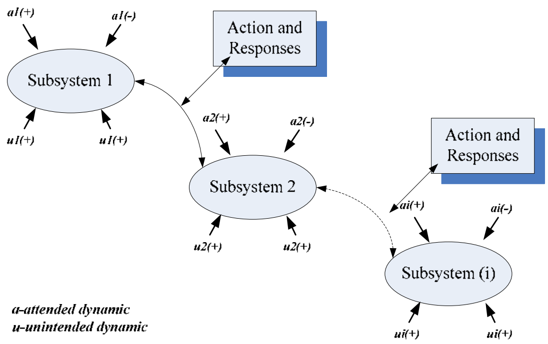

Figure 1 Dynamics of the project management system

Turning our focuses onto the Green Community, from the viewpoint of system theory, rural green community can also be divided into several sub-systems, such as economic, social, environmental and construction systems. These subsystems are relatively independent on each other while each evolves according to its own characteristics. And relative factors known and unknown affect the changes and development. Meanwhile, there are various interactions among the subsystems, as the changes in a subsystem may influence the others and bring the impacts like the domino effect.

2.2 Analysis of Feedback Loops of Dynamic Evaluation System of Green Rural Community

Compared with the green urban community, the green rural community in China has its own characteristics.

Firstly, in regard to the environment, the green rural community maintains a good condition compared with that of urban areas. The green rural community has better environmental capacity, better recoverability of environment and the pollution index is relatively low because it rarely or little, if ever, involves industrial production with damages to the environment at a lower level.

Secondly, compared with the urban green community, the economic structure of rural Green Community is still underdeveloped and the economic level relatively low as the income sources of rural households mainly rely on family-based farming and aquaculture. Housing is not only for the residential life but also for the production and the economic conditions form a strong contrast between rural community and urban community. Therefore, a common kind of farm tourism that people living in cities go to the rural communities for tourism and relax has been developed for the past decades. And this phenomenon becomes more and more popular and such kind of tourism takes an important part in the economic system of rural community.

Finally, after a relatively long period of growth of population in rural communities, the increase and decrease of it are close to a balance, which causes the population in rural community now to be in a stable way. So we can suppose that the increase of housing area is nearly all because of the growing tourism demands.

As the above-mentioned characteristics, we suppose that construction and operational system of rural community in China consists of three reinforcing feedback causal loops and another three balancing feedback causal loops as shown in Figure 2.

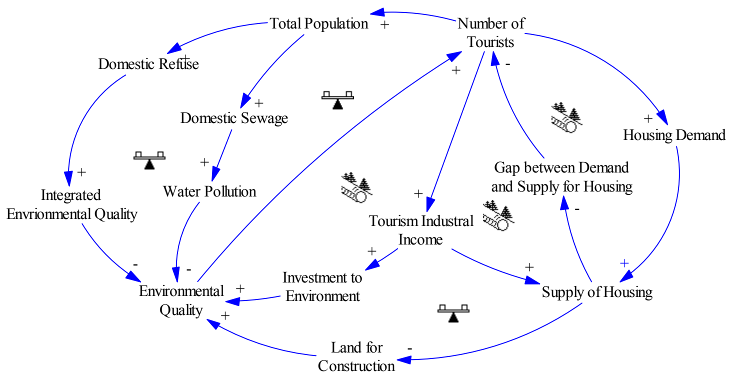

Figure 2 Feedback loop diagram of green rural community construction and operational system

There is the interaction between environmental subsystem and economic subsystem. With the development of tourism in rural community, the incomes from tourism industry increase which leads the increase of the investment to environment. The related facilities for domestic refuse classification, transportation and treatment, and establishment of domestic sewage will be built to improve the environmental quality in rural community eventually, so that the community becomes more attractive to tourists. This reinforcing feedback causal loop is shown in Figure 3 (the left one).

The middle one in Figure 3 is for the interaction between economic subsystem and construction subsystem As the number of tourists increases while the population in local community is relatively stable, the housing demands from tourism industry will increases which will lead to the increase of supply of housing by greater numbers of housing construction. Then the gap between the demand and supply will be narrowed which pushes on the increase of tourists as shown in Figure 3 (the middle one).

And the right one in Figure 3 is also for the interaction between economic subsystem and construction subsystem. The increase of tourists drives the increase of income from the tourism industry and new housing construction as well, and the gap between housing demand and supply is releasing, also leading to the growth of tourists. These three causal loops are shown the reinforcing strength to the entire construction and operational system of rural Green Community.

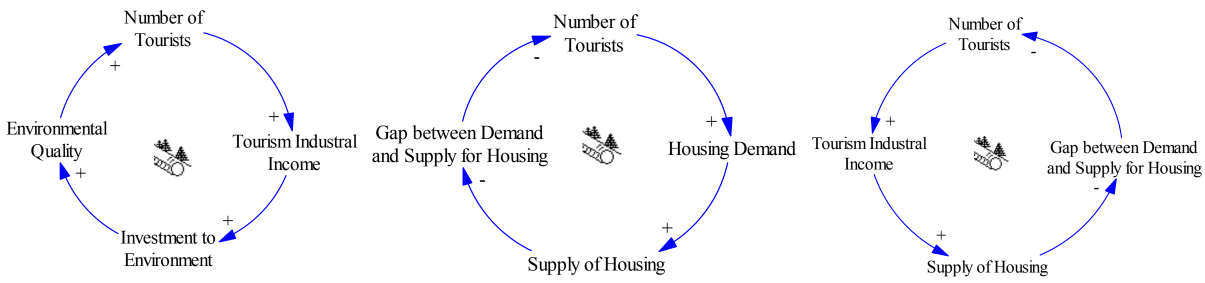

Figure 3 Diagram of reinforcing feedback causal loops in the green rural community construction and operational system

There is not only reinforcing feedback causal loops but also balancing ones in the construction and operational system of rural Green Community, shown in Figure 4. Some tangible limits in the model causes the feedback loops balancing and they were what we now call "environmental": limited natural resources, limited agricultural land, limited pollution absorption (Jorgen Randers 2000). The growth of tourists pushes up the demand and actual increase of new housing construction, which leads to decrease of land for construction and the environmental carrying capability. And the environmental deterioration will relatively restrain the growth of tourists because the environment then is out of attractiveness, the dynamics as shown in Figure 4 (the left one). The increase of number of tourists which are part of the total population in the community, given that the per capita of domestic sewage and refuse is constant, will increase the domestic sewage and refuse in the community and the environmental quality gets worse which inhibits the growth of tourists, as shown in Figure 4 (the middle and right one in respective). And these latter two dynamics is the most significant environmental menace in the rural communities.

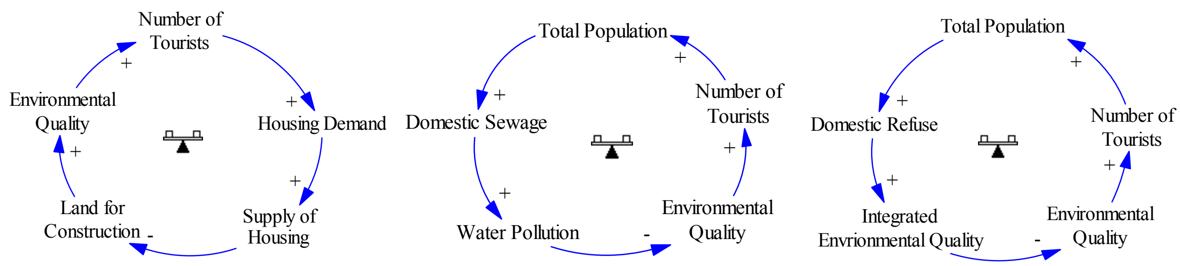

Figure 4 Diagram of balancing feedback loops in the green rural community construction and operational system

3. Modeling and Case Study

3.1 Assumptions

There is certainly a certain distance between the reality and the mathematical model of the construction and operational system of rural Green Community, which should include systematic timing delay and other factors which cannot be quantified. And for easy analysis, we put forward the modeling assumptions as follows:

(1) Not every rural community has developed an economic part of tourism, but in view of its popularization and good trends in China, we assume that there is tourism development in the model.

(2) We suppose that the environmental impact onto travel time stays can be shown immediately, that is to say, the travel time could be decided to prolong or shorten without difficulties during the trip. Meanwhile, the average consumption of tourist is a constant neglecting the effect of environmental impact.

(3) There are of course, various factors affecting the quality of rural community and in this model we only choose the domestic refuse and sewage which is the most representative and sensitive kind with the stock at the very beginning is set to be zero.

(4) Disposable income is largely from the industry or tourism and it is assumed in the model that the income of farmers from scattered farming and production is just to meet their needs and the tourism income is all of the disposable income we will calculate for the growth in rural community at this stage.

3.2 Case Introduction

Yanhe Village is located in the north of Hubei province, a typical representative of hilly type rural communities in the central China and its environmental condition is very excellent. The area of Yanhe Village is about 1.2 square kilometers and there are 222 families with 840 residents. The average income of farmers there reaches 3400 yuan per person in the year of 2005 and the total revenue of the village is about 5 million yuan. There are 440,000 m^2 of housing, and the land for construction purpose is about one square kilometers.

3.3 Simulation Analysis

3.3.1 Environmental Subsystem Simulation and Evaluation Analysis

As shown in Figure 5 below, the assumptive initial stock value of domestic sewage is zero and for the first three years, the stock of domestic sewage will peak up at a high level quickly. But after the period of approximate three years, the stock value will be slightly adjusted declining and ultimately reaches balanced at about 2200 tons while the stock of domestic refuse has been with a nonlinear increase to reach about the balance till the year 2020.

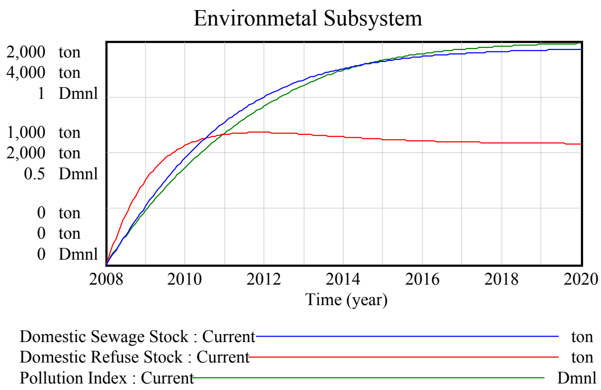

Figure 5 Simulation results of environmental subsystem

For the pollution index, we have selected the more sensitive one in rural community between domestic sewage index and refuse index as its value. That's to say, if the domestic sewage or refuse exceeds its environmental capability in the case of the worse of the environment quality, we choose the one which is greater as the value of the pollution index and there is the formula:

$$\text{Pollution Index} = \frac{\text{Max (Domestic refuse index, Domestic sewage index)}}{\text{Environmental carrying capacity} \times \text{Impact of the land area reduction}} \quad (1)$$

Of which:

$$\text{Domestic Sewage Index} = \frac{\text{Domestic Sewage Stock}}{\text{Total Population} \times \text{Per Capita Domestic Sewage Carrying Capacity}} \quad (2)$$

$$\text{Domestic Refuse Index} = \frac{\text{Domestic Refuse Stock}}{\text{Total Population} \times \text{Per Capita Domestic Refuse Carrying Capacity}} \quad (3)$$

As Figure 5 shows that the pollution index is much more related to domestic refuse index, which indicates that the emissions of domestic refuse have greater impact on the environment of community and are more sensitive. Meanwhile, the pollution index is not entirely consistent with the domestic refuse index and that's because the decrease of the community land for construction purpose mitigates the pollution so that the environmental pollution is getting worse.

3.3.2 Economic Subsystem Simulation and Evaluation Analysis

As shown in Figure 6, development of the tourism in rural community promotes the development of economy so that the disposable income of farmers can be substantially increased. After a period of about six years, the income peaks to achieve a smooth level and this is because that the environmental and housing conditions are considered to be growing in accordance with the number of tourists reaching to a certain level of balance. The model assumes that the ratios of the capital input to the treatment of domestic sewage, refuse pollution and housing construction in the community are all constants respectively. And we can see that the behaviors of capital input to the integrated environment (domestic refuse), water environment and the housing construction are as well as that of income of industry or tourism.

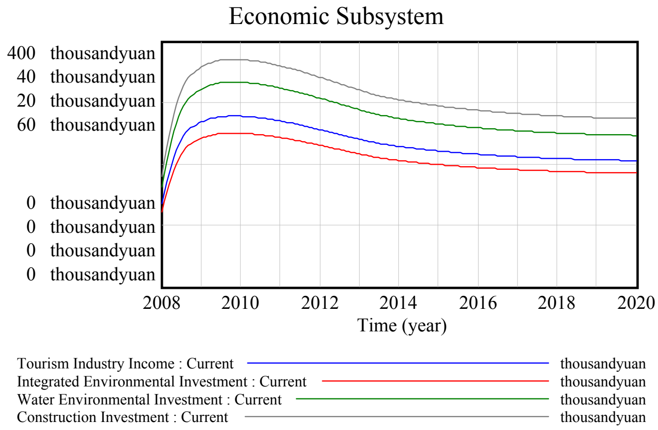

Figure 6 Simulation results of economic subsystem

3.3.3 Construction Subsystem Simulation and Evaluation Analysis

As shown in Figure 7, the construction of housing will reach a peak during the development of tourism industry in the first six or seven years and slightly downwards to a balanced level and the amount of land available for new housing construction will drop down. Conversely the area of housing in community is increasing from the original 44,000 m^2 to about 45000 m^2 and the situation is similar to the investigation we have done in the case area before.

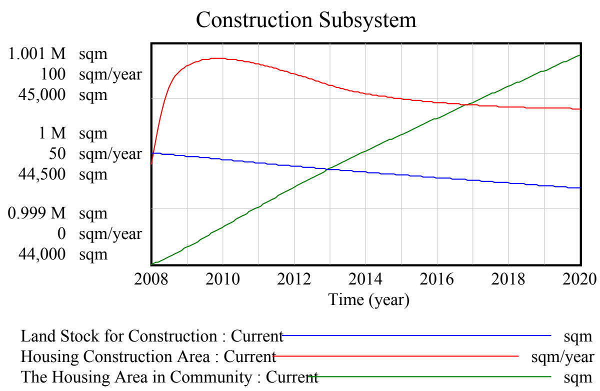

Figure 7 Performance simulation results of construction subsystem

3.3.4 Simulation and Evaluation Analysis of Green-efficiency

Green-efficiency, also the eco-efficiency as we said before, means using fewer natural resources and less environmental impact to create greater economic value (Dicksen Tanzil *et al.* 2006). In this paper, green-efficiency in the model is defined as the ratio of economic value to environmental costs as:

$$\text{Green-efficiency} = \text{Industry Income} / \text{Environmental Degradation Index} \quad (4)$$

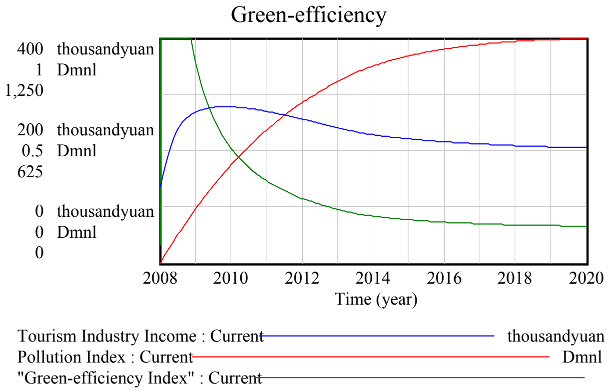

Figure 8 Simulation results of green-efficiency

As shown in Figure 8, the high development of tourism industry greatly enhances disposable income, but with the further increase of the pressure on the environment, deterioration of the environment is getting worse and green-efficiency of economy and environment is declining seriously. The deterioration of the environment doesn't reach to a balance until the industry income is stable and the trend of green-efficiency is from getting down to a balance in the end.

4. Conclusions and Following Research

(1) The ecological environment is still fragile in rural community in China, though the original condition is excellent. The solution to damage and impact from people to the environment relying solely on its own recoverability is not far from enough and financial and technological efforts are strongly needed so that part of economic inputs can monish the environmental impact.

(2) The emissions of domestic sewage and refuse in rural community in China is the most important environmental issue and we should try to change people's customs to decrease the amount of per capita emission and use technical means to reduce the impact, especially those from domestic sewage and refuse.

(3) As shown in the model, environmental degradation index is zero without development and green-efficiency is infinite, which is the idealism what we want. While in the process of development, green-efficiency is inevitably gradual declining. For a rural community in China, an area with relatively backward economic conditions, we should get the economic development at the cost of part of the quality of environment and we should consider the issue in a correct view. While eco-efficiency is certainly an important element of sustainability, it is by no means a representation of the whole picture. (Dicksen Tanzil *et al.* 2006).

We cannot ignore that kind of trade-off. Almost every step of development will bring the decline of the quality of the environment and how to make the balance between development and the quality of environment is always a worthwhile research topic. As formulated above, how to accurate the table functions from technology and fund to environment is the following issue of our research. Meanwhile, in the field of green-efficiency evaluation, how to measure and choose a proper initial value of green-efficiency may be a vital path to establish the evaluation system and method of green-efficiency to assess sustainability of economic and social development accurately and objectively.

Keywords: sustainability, rating, tool, building

Summary

Building sustainability assessment involves various relations between built, natural and social systems. Therefore it comprises hundreds of parameters, most of them interrelated and partly contradictory. To cope with this complexity and to support the sustainable building design, a systematic, holistic and practical approach is proposed in this paper.

The main goal of this paper is to present a methodology for the sustainability assessment of new, built or renovated buildings that is adapted to the Portuguese context. This paper contributes to the evolution of generic methodology and international understanding by introducing an approach to take the traditions and social aspects into account. It is expected that the methodology to assess the weight of the social parameters will contribute for a more consensual and objective distribution of social weights. The presented methodology assesses the performance of a building within the three dimensions of the sustainable development (environment, society and economy).

1. Introduction

Construction and real estate sector affects each three dimensions (environment, societal and economy) of sustainable development. In a sustainable building, each bottom line dimension is considered as well as the interaction with its surroundings. In common, the sustainability issues cope with reducing use of non-renewable energy, materials and water as well as production of emissions, waste and pollutants. The following goals can be found in several agendas: optimization of site potential, preservation of regional and cultural identity, minimization of energy consumption, protection and conservation of water resources, use of environmentally friendly materials and products, healthy and convenient indoor climate and optimized operational and maintenance practices.

The purpose of a sustainability assessment is to gather and report information for decision-making during different phases of construction, design and use of a building. The sustainability scores or profiles based on indicators result from a process in which the relevant phenomena are identified, analyzed and valued. Following a life-cycle-analysis or performance analysis of chosen indicators, a building can be rated and certified. The benefits of rating tools are that various kinds of sustainability and performance issues can be included in the assessment criteria and their use is in common user-friendly, to the extent that self-evaluation tools are available in the Internet.

A variety of sustainability assessment tools is available on the construction market, and they are widely used as a basis for environmental product declarations. The majority of tools for building level assessment has then been developed by summing up results of building materials and components to a building. When the environmental impacts are considered, this approach can be regarded as justified as a starting point and providing that the interface issues of a system are taken into account. When an assessment includes functionalities of the whole building including energy demand, this approach has been criticised by several researches (Kohler 1997, Erlandsson & Borg 2003). There are LCA-based tools available that are especially developed to address the building as whole, like e.g. Eco-Quantum (Netherlands), EcoEffect (Sweden), ENVEST (U.K.), BEES (U.S.), ATHENA (Canada) and LCA House (Finland). A comparison of contextual and methodological aspects of tools has been made e.g. by Forsberg and Malmborg (2004).

Three major building rating and certification systems are providing the basis for the other applications throughout the world. They are Building Research Establishment Environmental Assessment Method

BREEAM, developed in U.K.; Sustainable Building Challenge Framework SBTool, developed by the collaborative work of the international initiative for Sustainable Building iiSBE; and Leadership in Energy and Environmental design LEED, developed in U.S.A.

In the Sustainable Building Tool (SBTool) the approach is to weight different criteria, considering weighting factors that are fixed at national level. Each "score" results from the comparison between the studied building and national reference. This scheme allows an international comparison of buildings from different countries. Other tools, like for instance BREEAM and LEED, are based upon credits. The maximum number of credits available for each indicator it is related to its weight in the overall score, that is expressed by a rating (e.g. from Pass to Excellent in BREEAM).

The problems of the sustainability rating tools are similar with those of the sustainability assessment methods: At first, they embrace and compromise tens of parameters which turn implementation very time consuming. Secondly, the subjective qualitative evaluation turns the reliability of the results very limited.

This paper presents a novel approach to develop building sustainability assessment and rating. The main objective of a systematic methodology is to support building design that achieves the most appropriate balance between the different sustainability dimensions, and that is at the same time practical, transparent and flexible enough to be easily adapted to different kinds of buildings and to technology. This new approach can be used in the assessment of new, built and renovated residential buildings.

2. Scope and objectives of a new Building Sustainability Assessment

The scope of the research work performed in the University of Minho, Portugal, was to develop and propose a generic methodology to assess the sustainability of existing, new and renovated buildings in the urban areas and especially in the Portuguese context. It is intended to foster the awareness of the Portuguese construction market stakeholders and to allow adequate policy implementation on sustainable construction.

The objectives of the research work were to analyze the applicability of various generic methods to actual building projects and to develop methods to incorporate the influences of local regulations, technologies and traditions to the building sustainability assessment.

As a first step, a methodology to assess the sustainability of residential buildings has been developed. Reasoning for this priority is due to the fact that most of the impacts related to the construction sector are related to the housing sector. The acronym of the methodology is MARS-H (from the Portuguese name *"Metodologia de Avaliação Relativa da Sustentabilidade de Edifícios de Habitação"*).

The following priorities were stated in the development of the MARS-H:

- List of parameters wide enough to be meaningful and to comprise the most relevant building impacts and at the same time limited enough to be practical (fifty parameters at maximum);
- Building-level assessment, based upon the state-of-the-art of methodologies and considering ongoing standardization;
- Balancing between all different dimensions of sustainable development (environment, societal and economics);
- Limitation or exclusion of subjective and/or qualitative criteria that is hard to validate (e.g. aesthetics and technical innovation);
- Improved reliability through the use of accepted LCA methods for environmental performance;
- Assessment output and certification label that is easy for building users to interpret and understand but is also one which clients and designers can work with.
- Validation of the work by the development of a prototype tool and test it on case study buildings.

As a result of the research work, the MARS-H is based in the SBTool approach and is harmonized with the CEN/TC350 draft standards "Sustainability of Construction Works – Assessment of Environmental Performance of Buildings". This methodology allows future rating and labelling of buildings, in analogy with the Energy Performance of Buildings Directive.

Although the interaction between a building and its surroundings is of importance for sustainability (e.g. energy performance, social indicators) it was decided to exclude this aspect. The main reason was that in an urban environment, the decisions concerning the surroundings and networks of a site are mostly made by the local and regional authorities. However, some publications have concluded that restricted scales of study (corresponding for a single building for example) are too limited to take into account sustainable development objectives correctly (Bussemey-Buhe, 1997).

3. Development of the Building Sustainability Assessment

3.1 General

The research and development project on the new Building Sustainability Assessment methodology was undertaken by literature survey of the state-of-the-art, development and feasibility studies of indicators and weighting factors as well as case-studies and interviews of stake-holders.

Due to the scope and objectives of the research work, the focus of the studies was in the development of weighting factors that would take into account the local environmental, socio-economic and legal reality as well as the type of building.

The system boundaries were chosen to include the building itself with all structures and the building site. The impacts of the building to the surroundings and in urban environment won't be assessed. This way, the methodology excludes construction works outside of the site location and construction of the different networks for communication, energy and transportation outside of the site location.

The time boundary should represent the whole life cycle stages of the building. In a new building it will consider all life-cycle stages, from construction to final disposal and in existing buildings the time boundary will start from the moment of the intervention to the final disposal.

After defining the methodology's time and physical boundaries the next step is to choose the categories, indicators and related parameters within the three sustainable development dimensions that are going to be used to assess the objectives of a project. According to Kurtz et al (2001) a parameters is a sign or a signal that relay a complex message, from potentially numerous sources, in a simple and useful manner. Therefore the main three objectives of the parameters are: simplification, quantification and communication (Geissler, 2001). Indicators and related parameters are the basis of the methodology, since objectives and results will be conditioned by them.

After selecting the parameters it is necessary to proceed with their quantification. Quantification means linking the environmental information to the actual designs of a building. The quantification method should be anticipated. There are several quantification methods: previous studies results, simulation and other software tools, expert's opinions, databases processing, etc. (Cherqui, 2004). At the level of the quantification of the environmental parameters, there are some aspects to overcome, mainly regarding to the availability of local data for the life-cycle inventory (LCI).

There is a growing number of voluntary Environmental Product Declarations (EPD), and their information can be used in quantification. The Environmental Product Declarations are based in the product categories rules (PCR) which established the rules for developing the environmental data and predetermined parameters for that product category, in compliance with the ISO standards ISO DIS 21930, ISO FDIS 14025 and ISO 14040. The EPD presents data that has been aggregated over the life cycle stages "Product stage", "Building stage" and "End of life stage" or relevant portions of it.

3.2 Categories, Indicators and Parameters

Figure 1 presents the categories and indicators considered in the MARS-H methodology. There are 9 categories, 35 indicators and 44 parameters. The complete list of categories, indicators and parameters can be found in the iiSBE Portugal webpage (www.iiSBEPortugal.org).

In the evaluation of the environmental performance, the commonly accepted LCA methodologies were adopted. Analysing the different LCA methodologies it was possible to observe that the number of environmental categories undertaken to access the embodied impacts of the building materials usually varies from 8 to 10. To access the embodied impacts related to the building materials, MARS-H uses the same environmental parameters declared in the Environmental Product Declarations. The list of environmental categories and environmental parameters was extended in order that, in a holistic approach, would be possible to access the other life-cycle environmental impacts related to the operation phase of the building, according to the national priorities.

In societal performance assessment, only the parameters related to the health and comfort were chosen, and they were assessed especially during the use and operation of a building. The methodology doesn't consider parameters that could raise some kind of complexity and subjectivity in the assessment, in order to facilitate its use by all Portuguese construction market's actors. The list of societal parameters presented in Figure 2 reflects the functional requirements of a residential building, according to national building codes.

The economic performance indicators were defined in order to include all costs related to building's life-cycle, from cradle to grave. This performance also considers the possibility to adapt, in the future, the building for other types of uses, factor that increases its value.

3.3 Quantification of Parameters

In order to potentiate their use, MARS-H uses the same parameters that are declared in the Environmental Product Declarations. At the moment, there are limitations with this approach due to the small number of EPD's.

Other solution is to import the results that come from the use of external LCA tools and methods (e.g. SimaPro tool and CML2 baseline 2000 method to assess the *Mid Point* impact categories and the Cumulative Energy Demand method for the embodied primary energy). One important drawback of this method is that LCA procedures are very time consuming and complex and therefore, in most times, limited to experts and academics.

The best way is to develop and use databases with the environmental data of the most used building technologies. In order to facilitate the quantification of the environmental parameters, a database that gathers the same parameters declared in the EPD is being developed. This database will cover the most used building technologies for each building element (walls, floors, windows, doors, etc.) and will be built-in the MARS-H methodology. The database covers the parameters presented in Table 1. The values of the parameters are presented for two life-cycle stages: “cradle to gate” and “demolition/disposal”.

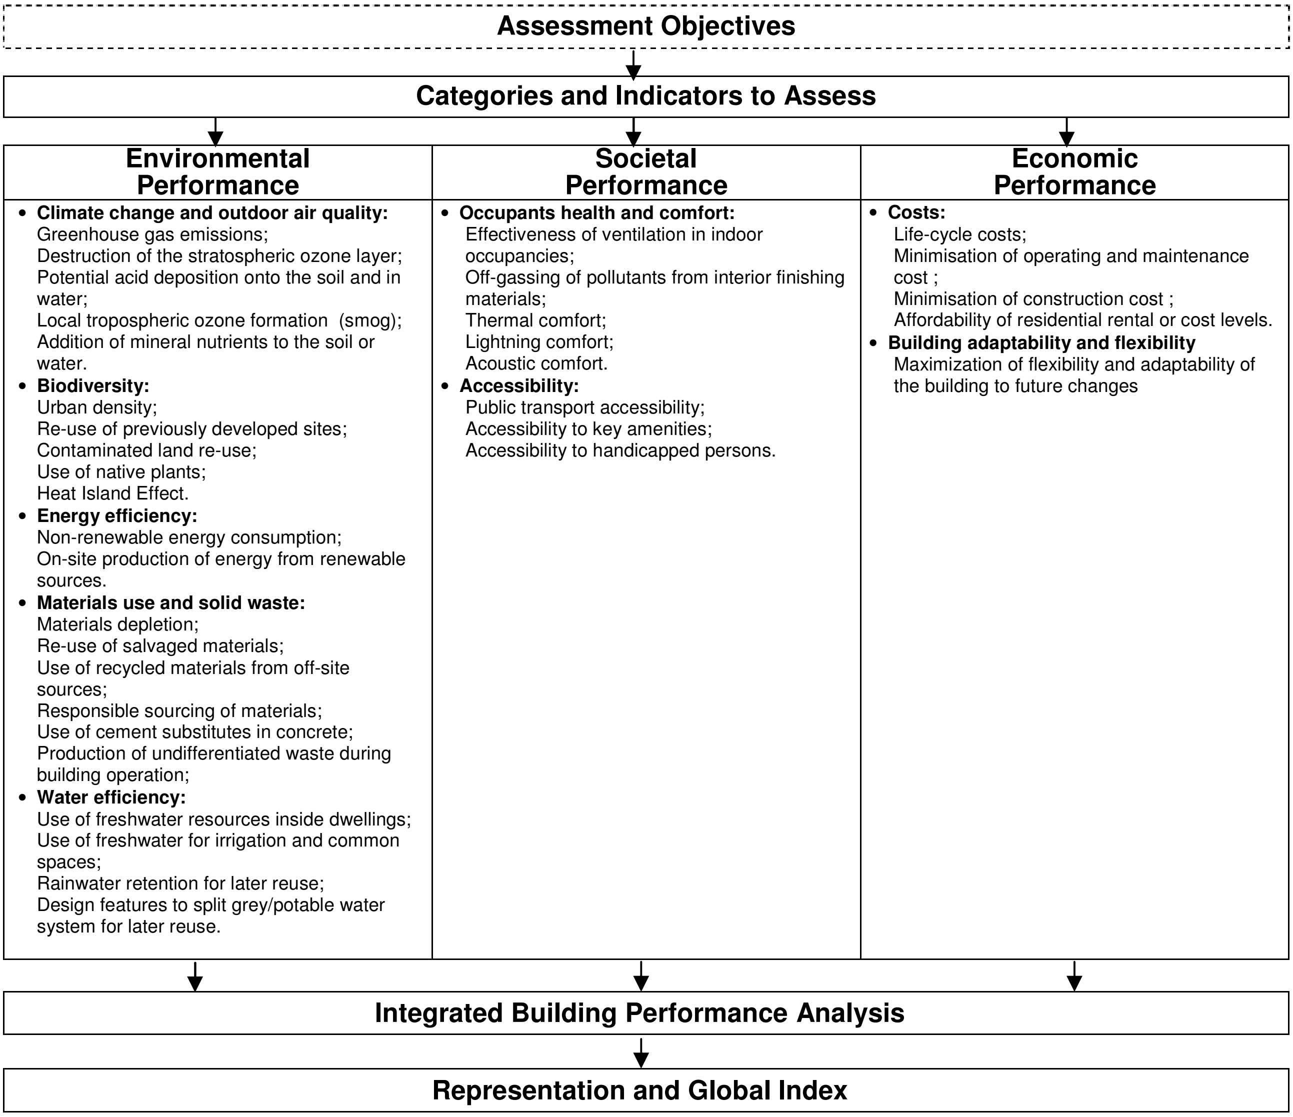

Figure 2 Indicators and related parameters considered in the MARS-H methodology.

At the level of the societal performance, it is possible to use one of the available analytical methods to quantify the parameters. If the object of assessment is a built building one can use the results of the experimental monitoring of it to evaluate the performance.

Measuring the economic performance of a building is more straightforward than measuring the environmental performance. Standardized methodologies and quantitative published data are readily available for the Portuguese context. The biggest problem is to foresee the maintenance costs, since the durability of the finishing and building solutions are quite dependable on external factors, like for instance, climatic conditions.

3.4 Normalization, Aggregation and Weights

The objective of the normalization of parameters is to avoid the scale effects in the aggregation of parameters inside each indicator and to solve the problem that some parameters are of the type “higher is better” and others “lower is better”. Normalization is done using the Diaz-Balteiro *et al.* (2004) Equation 1.

$$\overline{P_i} = \frac{P_i - P_{*i}}{P_i^* - P_{*i}} \forall_i \quad (1)$$

In this equation, P_i is the value of i^{th} parameter. P^*_i and P_{*i} are the best and worst value of the i^{th} sustainable parameter. The best value of a parameter represents the best practice available and the worst value represents the standard practice or the minimum legal requirement.

Table 1 Parameters declared in the built-in LCA database for building technologies

Parameter	Unit/declared unit	Source
Depletion of abiotic resources	[kg Sb equiv.]	CML 2 baseline 2000
Global warming potential (GWP)	[Kg CO_2 equiv.]	IPCC 2001 GWP 100a
Destruction of atmospheric ozone (ODP)	[Kg CFC-11 equiv.]	CML 2 baseline 2000
Acidification potential (AP)	[Kg SO_2 equiv.]	CML 2 baseline 2000
Eutrophication potential (NP)	[Kg PO_4 equiv.]	CML 2 baseline 2000
Photochemical Ozone Creation (POCP)	[Kg C_2H_4 equiv.]	CML 2 baseline 2000
Non-renewable primary energy	[MJ equiv.]	Cumulative Energy Demand
Renewable primary energy	[MJ equiv.]	Cumulative Energy Demand

Normalization in addition to turning dimensionless the value of the parameters considered in the assessment, converts the values between best and conventional/reference practices into a scale bounded between 0 (worst value) and 1 (best value). Excellent practices will have a score above 1 and performances bellow the reference will have a negative normalized value. This equation is valid for both situations: “higher is better” and “lower is better”.

For example, the normalization of the primary energy used for heating (hot water heating included) is done as presented in Table 2 and Equation 2.

Table 2 Example of benchmarking for normalization

Parameter	Primary energy used for heating (hot water heating include)
Notation	Eh
Unit	kWh/m²/year
Value	100
Reference value	140
Best practice	35

$$\overline{Eh} = \frac{Eh - Eh_*}{Eh^* - Eh_*} = \frac{100 - 140}{35 - 140} = 0{,}38 \quad (2)$$

In order to facilitate the interpretation of results, the normalized values of each parameter are converted in a graded scale, as presented in Table 3.

Table 3 Conversion of the quantitative normalized parameters into a qualitative graded scale

Grade	Values
A+ (Above best practice)	$\overline{P_i} > 1{,}00$
A	$0{,}90 < \overline{P_i} \leq 1{,}00$
B	$0{,}70 < \overline{P_i} \leq 0{,}90$
C	$0{,}50 < \overline{P_i} \leq 0{,}70$
D	$0{,}30 < \overline{P_i} \leq 0{,}50$
E	$0{,}10 < \overline{P_i} \leq 0{,}30$
F (Reference practice)	$0{,}00 < \overline{P_i} \leq 0{,}10$
G (Bellow reference)	$\overline{P_i} \leq 0{,}00$

Although building sustainability assessment across different fields and involves the use of numerous indicators and tens of parameters, a long list of parameters with its associated values won’t be useful to assess a solution. The best way is to combine parameters with each other inside each dimension in order to obtain the performance of the solution in each indicator (Allard, 2004).

The methodology uses a complete aggregation method for each indicator, according to Equation 3.

$$I_j = \sum_{i=1}^{n} w_i . \overline{P_i} \tag{3}$$

The indicator I_j is the result of the weighting average of all the normalized parameters $\overline{P_i}$.

w_i is the weight of the i^{th} parameter. The sum of all weights must be equal to 1.

Difficulties in this method lie in setting the weight of each parameter and in the possible compensation between parameters. Since weights are strongly linked to the objectives of the project and to the relative importance of each parameter in the assessment of each indicator, higher weights must be adopted for parameters of major importance in the project.

In what concerns to the weights of the environmental parameters, there aren't national impacts scores for each environmental parameter, according to its relative importance to overall performance. Additionally, European Environment Agency doesn't studied it yet. However, there are some international accepted studies that allow an almost clear definition of it. Two of the most consensual lists of values are based on the US Environmental Protection Agency's Science Advisory Board study (TRACI) and a Harvard University study (Norberg-Bohm, 1992). MARS-H uses the TRACI approach, allocating the considered environmental parameters in the impact categories of that method. Table 4 presents the relative importance of each impact category, according to the US EPA's Science Advisory Board study.

Table 4 Relative importance weight (%) of each impact category according to TRACI method (EPA, 2000)

Impact category	Relative importance weight (%) 8 impacts	12 impacts
Global warming	24	16
Acidification	8	5
Eutrophication	8	5
Fossil fuel depletion	8	5
Indoor air quality	16	11
Habitat alteration	24	16
Water intake	4	3
Criteria air pollutants		6
Smog		6
Ecological toxicity		11
Ozone depletion		5
Human health		11

In spite of being easy to quantify the functional parameters, the way as each parameter influences the functional performance and therefore the sustainability isn't consensual. This assessment involves subjective rating and depends, above all, on the type of solution and on the valuator's social-cultural and economic status. Several building sustainability assessment methodologies consider an empirical distribution of weights to assess the social performance. In order to overcome this situation a scientific-based methodology was developed in order to study the relative importance (w_i) of the most important comfort stressors - thermal environment (P_{tc}), acoustics (P_{ac}), air quality (P_{aq}) and visual comfort (P_{vc}) - in the perceived global comfort (G_c), as presented in Equation 4.

$$G_c = P_{tc}.w_{tc} + P_{ac}.w_{ac} + P_{aq}.w_{aq} + P_{vc}.w_{vc} \tag{4}$$

The methodology involves subjective evaluation (questionnaires to building users) and parallel experimental evaluations. During the experimental evaluations, the method assesses four parameters: resultant temperature (T_r), average illuminace (lx), CO_2 concentration (ppm) and weight A equivalent continuous noise level (L_{eq}). Collected data is processed using a multivariable linear regression and an artificial neural network method. Results, so far, show the distribution of weights presented in Table 5.

Table 5 Relative importance weight (%) of health and comfort impact categories considered in MARS-H

Category	Weight (%)
Thermal comfort	38
Visual comfort	27
Indoor air quality	22
Acoustic comfort	13

3.5 Representation and global assessment of a project

Normally, the majority of the stakeholders would like to see a single, graded scale measure representing the overall building score. Such score should be easily for building occupants to understand and interpret but also one which clients, designers and other stakeholders can work with.

Having this in mind, in MARS-H the overall performance of the building is represented by a single score in a graded scale. The methodology adopted a similar approach to the one used in the existing labeling schemes such as the EU energy labeling scheme for white goods and the European DisplayTM Campaign posters. However, due to the possible compensation between categories, the global performance of a building is not communicated using only the overall score. This way, the performance of a building is measured against each category, sustainable dimension and global score (sustainable score) and will be ranked on a scale from A to G. Figures 3 e 4 represents the outputs of the MARS-H methodology for a hypothetical case study.

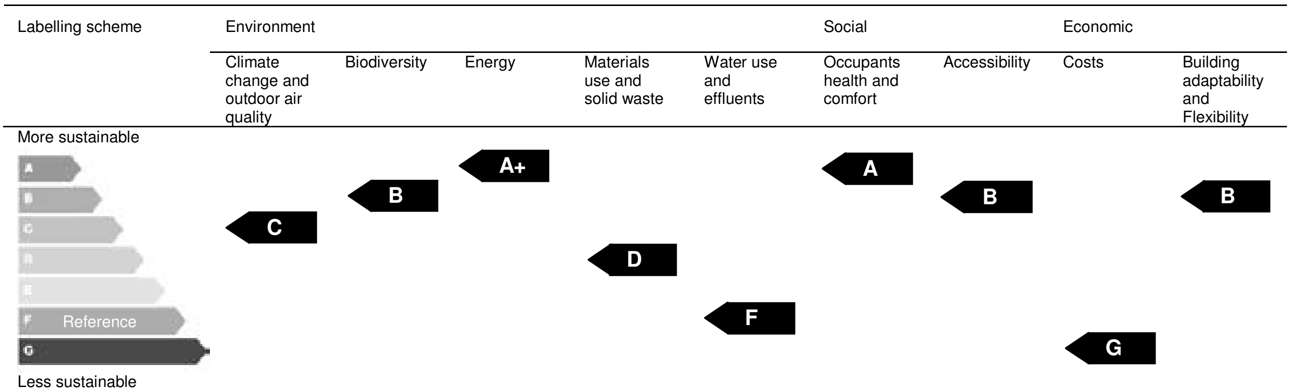

Figure 3 MARS-H output for a hypothetical building - performance of the solution presented at the level of the different categories.

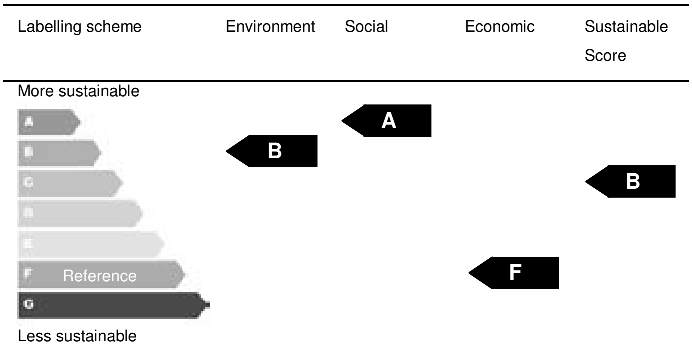

Figure 4 MARS-H output for a hypothetical building - performance of the solution presented at the level of the three sustainable dimensions and sustainable score.

From the outputs of this building sustainability assessment method it is possible to monitor and compare the performance of the solution in study with the reference solution (F grade). Nearest to the grade A is the performance of the solution, more sustainable it is. If the solution has a grade G at one parameter or category it means that special attention should be given to that issue, since it has a worst performance that the reference solution at that level.

The assessment of a project will not come only from the sustainable score grade, but mainly from the visualization of all categories. Analysing Figure 4 it is possible to verify that the analysed solution is more sustainable than the reference one. Nevertheless it is only possible to see what are the advantages and disadvantages of the solution when the performance at the level of each category is analysed (Figure 3). According to Figure 3, although the solution has higher performance in the major part of the categories, it has a lower performance in the costs category. In order to improve the overall performance the design team will have to check and try to improve the parameters that are negatively influencing the cost category.

4. Conclusions

Sustainable design, construction and use of buildings are based on the evaluation of the environmental pressure (related to the environmental impacts), social aspects (related to the users comfort and other social benefits) and economic aspects (related to the life-cycle costs). The sustainable design searches for higher compatibility between the artificial and the natural environments without compromising the functional requirements of the buildings and the associated costs.

Despite of numerous studies about the building sustainability assessment, there is a lack of a commonly accepted methodology to assist the architects and engineers in the design, production and refurbishing stages of a building. Nevertheless, in spite of the limitations of different methods, the widespread of assessment methods is having several direct and indirect impacts in the sustainable building design. The actual LCA methods and building rating tools have a positive contribution in the fulfilment of sustainable developing aims.

Many countries are either having or being in the process of developing domestic assessment methods, and therefore the international exchanges and coordination is increasingly needed. This paper contributes to the evolution of generic methodology and international understanding by introducing an approach to take the traditions and social aspects into account. It is expected that the methodology to assess the weight of the social parameters will contribute for a more consensual and objective distribution of social weights.

The building assessment and rating tool that is being developed in Portugal supports steps toward the sustainable design and construction, through the definition of a list of objectives that are easily understandable by all intervenient in construction market and compatible with the Portuguese construction technology background. Although the list of indicators and parameters is partially based on the framework for assessment of integrated building performance (CEN/TC 350), further work includes its validation in Portugal through its application to case studies.

Keywords: climate change, vernacular planning, backtracking, energy potential mapping, low-exergy design, heat cascading

Summary

Energy depletion and climate change require an approach to spatial planning that is radically different from what we are used to. For developed countries, with an ecological footprint exceeding their national territory, it is a moral question to not just depend on supply of energy from elsewhere. For developing countries an economy relying mainly on smart deployment of local qualities will enable sustainable growth without the changeable support of richer countries.

The principle of smart vernacular planning is based on a thorough analysis of local characteristics that can be used in the management of energy, water and other resources. These features can be translated to potential maps depicting, for instance, the opportunities to generate power from local resources.

Furthermore, the depletion of fossil energy requires optimal management of the energy chain: use of sustainable resources (supply) and low-exergy design (demand). At present much waste energy (mainly heat) is emitted unused into the air, water and soil. In addition, high-quality energy is now used for low-grade purposes for which waste energy of a lower quality would suffice. Cascading spatial functions that tune supply and demand would satisfy the principle of effectiveness, creating greater effect than energy efficiency.

A next creative step in smart vernacular planning is the translation of the information gained into interventions in an already existing built, or unbuilt, environment. This process requires ingenuity, knowledge of planning process and, above all, political courage. It is the only way towards a sustainable future within shifting boundary conditions of climate and available resources.

In the paper we will elaborate on the methods of energy potential mapping and matching, energy cascading and climate- and energy-inclusive planning, all of which form the building blocks of smart vernacular planning. We will discuss recent studies that applied this principle.

1. Introduction

1.1 Need for a different approach to energy

While dramatic changes are taking place to our climate, one of its probable causes, consumption of fossil fuel is becoming an uncertain asset in the near future. Natural oil and gas reserves are depleting, or their extraction is becoming complex and expensive. This will make the availability of energy uncertain and very expensive, which will probably affect developing countries the hardest.

The tendency to widely use coal again for the generation of electricity – for instance in China and the Western world – will have a devastating impact on greenhouse emissions and pollutions that seemed to have been banished. Many countries now seek refuge to nuclear power but uranium is also depleting. Meanwhile, sustainable energy may be expensive yet abundant: based on the potential for energy from the sun, wind and water, Jong et al. (2004) calculated that the Netherlands alone could already sufficiently provide the global economy with energy. However, at this instant local potentials are not effectively seized.

1.2 Sustainable development

Paradoxically, the threats of climate change and energy depletion can be used as a catalyst for sustainable redevelopment. A new paradigm can be found in responding to the inevitable changes in climate rather than fighting them. Spatial planning can be based on local energy potentials and in accordance with an optimal usage of the energy cycle by means of the low-exergy principle. The local potentials for energy generation can be investigated by means of analyses of climatic conditions, landscape and land use typology, local natural, cultural and technical features, and existing 'hotspots' of energy and heat generation.

This new approach to sustainable regional planning leads to 'energy potential maps', depicting the local potentials for energy provision. These can be combined to a map of interventions proposed from an energetic point of view.

1.3 Need for a different approach to energy

Energy depletion and climate change require an approach to spatial planning that is radically different from what we are used to. For developed countries, with an ecological footprint exceeding their national territory, it is a moral question to not just depend on supply of energy from elsewhere. For developing countries an economy relying mainly on smart deployment of local qualities will enable sustainable growth without the changeable support of richer countries. Local strengths therefore should be better used, and vernacular solutions were primarily based on the deployment of these local characteristics, so they will be most helpful.

In addition, we need to acknowledge that many of the current energy systems are close to 100% energy efficiency. Nevertheless, we still seem far off from the desired sustainable development. Energy efficiency, as it seems, is not the solution for a sustainable society. This can be made understandable by the exergy concept, which is rather about effectiveness than efficiency and which will be discussed further on.

2. Smart vernacular planning

2.1 Backtracking, revaluating vernacular solutions in a traditional sense

In order to set the path for future sustainable developments, there are different time-based approaches (figure 1, Dobbelsteen et al. 2006).

- *Forecasting* is needed when we want to estimate the consequences of current developments and our own intervention on long-term effects, such as the issues of climate change and depletion of resources.
- *Backcasting* involves the description of a desired future state (sustainable and based on the needs that need to be met), translating this state back to strategies and measures we need to develop now.
- By means of *backtracking*, solutions are based on historical circumstances at the time when there still was a sustainable equilibrium. This sustainable past may be an instance for planning directions, for which perhaps certain valuable historical, natural or cultural features or circumstances can be brought back to new design.

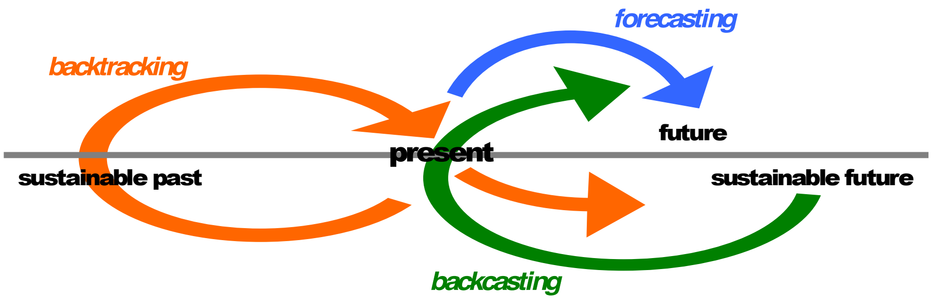

Figure 1 Graphical explanation of the forecasting, backcasting and backtracking methods.

Forecasting is useful to predict trends that have developed over some time already, but is not very effective to establish a great leap toward a sustainable future. A better, more effective method for substantial change is backcasting, but one could consider this method rather detached from real life and how it evolved throughout the centuries. Therefore, backtracking can be used to link the present to qualities of the past, embodied by vernacular principles. Backtracking would revaluate vernacular solutions that in itself sustained a way of living in equilibrium with the environs.

None of the methods presented should be applied alone. We found that the simultaneous use of all three of them means synergy, picking the best solutions from history, the present, and the imagined and desirable future.

2.2 Incremental approach to new vernacular principles

Apart from local historical principles, smart vernacular planning needs to be based on a profound analysis of local characteristics that can be used in the management of energy, water and other resources. Therefore, basic information is collected of climate, historical developments, topography, soil and underground, landscape, land use and infrastructure. For instance, the local climate is essential for the determination of potentials of solar and wind energy, and land use gives a clue to the possibilities of biomass.

This basic information then is translated to energy potential maps for fuel, electricity, heat and cold, and CO_2 capture. These maps evolve through a process of deduction, association and creativity. The depletion of fossil energy requires optimal management of the energy chain: use of sustainable resources (supply) and low-exergy design (demand). At present waste energy (mainly heat) is usually emitted unused into the air, water and soil. In addition, high-quality energy is now used for low-grade purposes for which waste energy of a lower quality would suffice. Cascading spatial functions that tune supply and demand would satisfy the principle of effectiveness, creating greater effect than energy efficiency.

A next creative step in smart vernacular planning is the translation of the information gained into interventions in an already existing built, or unbuilt, environment. This process requires ingenuity, knowledge of the planning process and, above all, political courage. It is the only way towards a sustainable future within shifting boundary conditions of climate and available resources.

Figure 2 depicts this generic methodology for charting energy potentials and interventions therefrom.

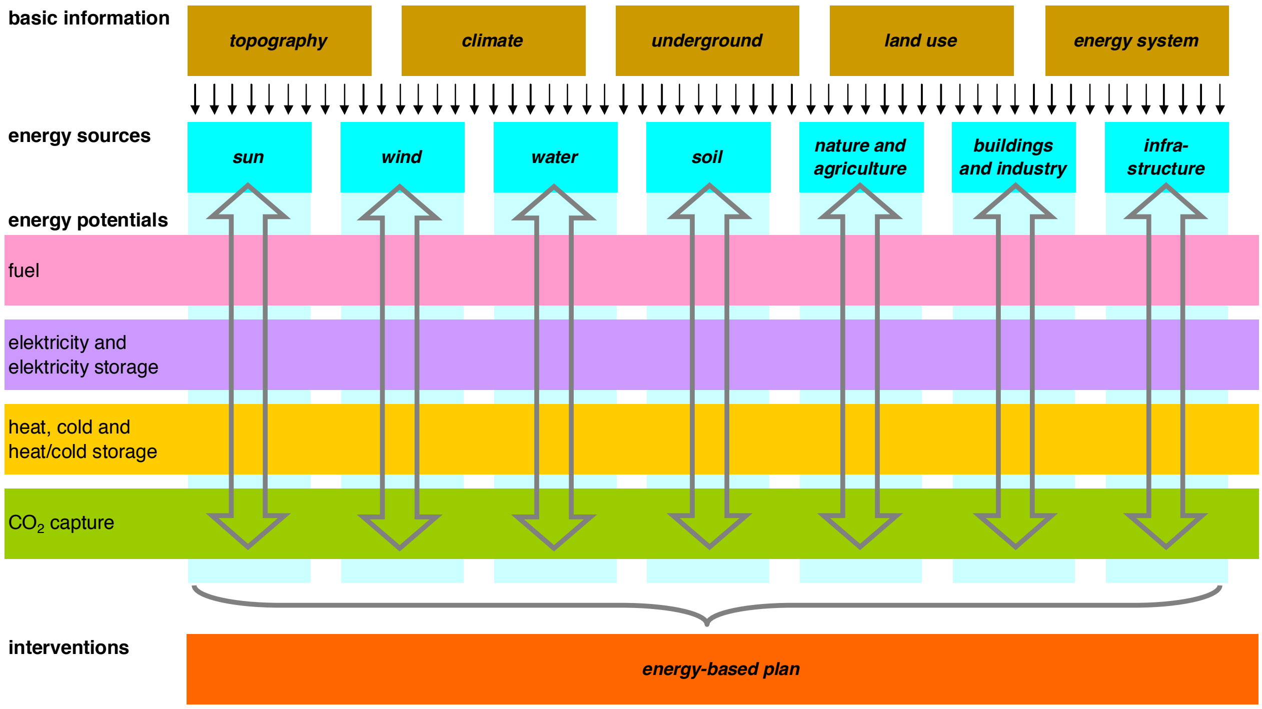

Figure 2 Methodology of the energy potential mapping.

3 Heat cascading

3.1 Exergy

The First Law of Thermodynamics states that energy is never lost, whereas the Second Law describes that processes develop towards a state of increasing entropy. Hence, entropy embodies the non-useful waste energy evolving during processes. Exergy is the useful part, the part that can perform work. It is a measure of energy quality.

As already stated, processes can be energy-efficient but in terms of exergy this efficiency can be totally different if the initial exergy level is predominantly converted to entropy. For instance, a contemporary boiler may have an energetic efficiency of 95%, but considering the gas flame of 1500^{o}C, a lot more can be done with it than just heating up houses to 20^{o}C. The exergetic efficiency is approximately 10%. If the gas flame heat were used in the metal industry, the exergetic efficiency would approximate 100%. Therefore, energy of a high-quality level should be used for high-grade functions before it transforms into a lower-quality state, which can still be useful to low-grade functions.

3.2 The low-ex approach

The current energy system of a region (figure 3, left) is characterised by an influx of primary energy – fossil fuel – into every function present in the area. A power plant, which is also fuelled by fossil energy, generates electricity and every function produces waste and waste heat. The latter is emitted into the air and water. In this system each step requires high-quality input of exergy.

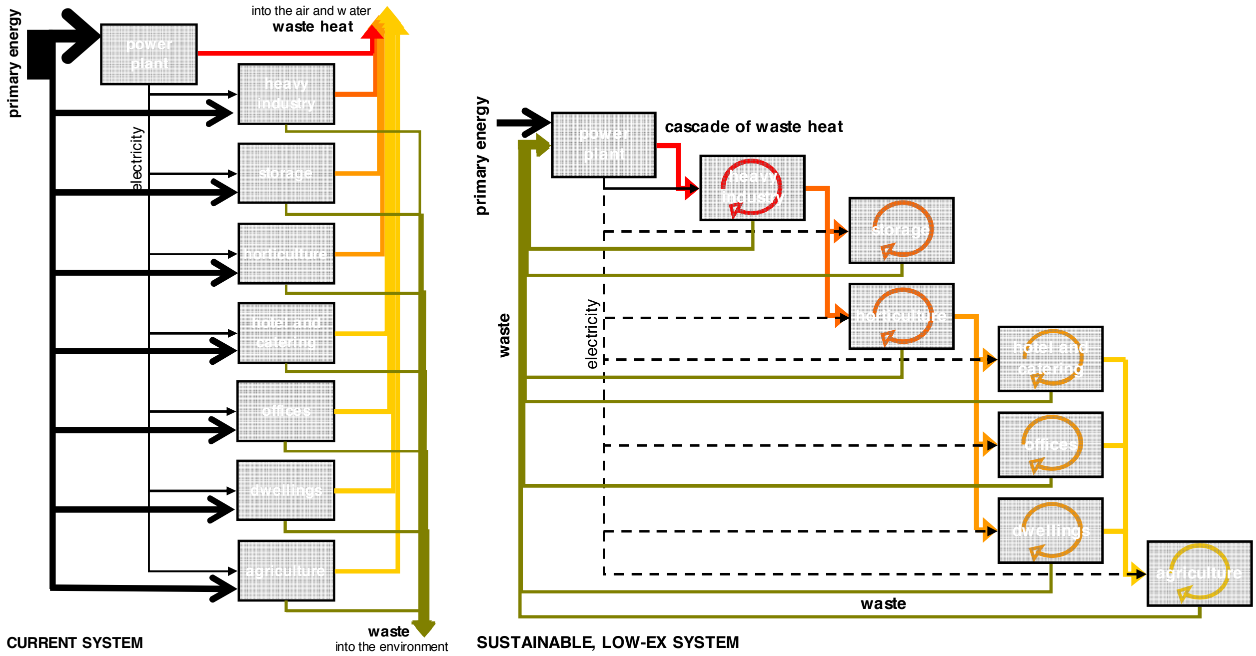

Figure 3 Graphical example of energy provision in the current system (left) and in a more sustainable, low-exergy system that uses heat cascading (right).

The low-exergy (low-ex) approach (figure 3, right) limits exergy losses between and during process steps. This would imply feeding an exergy quality close to the demanded level, losing little exergy during the process and finding a secondary function that can make use of the output level. High temperatures would only be used in heavy industrial processes, of which waste heat could be used in lower-grade functions such as manufacturing processes, horticulture, and subsequently for residential heating. Residences and agriculture can eventually again 'feed' the power plant with biomass and waste.

Thus, four to seven instead of just one purpose would be served by the same amount of primary energy.

3.3 An uncommon inventory

In order to get the full picture of heat cascading potentials, a survey needs to be executed of all regional functions, their exact location, temperature levels required for their processes, the demand of energy and the supply of waste energy and other products. In order to make the inventory feasible, for some of these functions – e.g. housing and offices – one may use generic values of energy demand and supply. Specific industrial functions however require individual study of internal processes and energy characteristics. Not every company is willing to give this information, but regional administrations often need the same data for environmental licences, and one can use these in the energy survey.

After the collection of data, the exact location of heat and cold supply and demand can be charted. This will visualise areas with excess and lack of energy, and evoke measures to be taken for closing the heat chain.

3.4 Right form, right place, right time

In order to make heat cascading possible, there is a question of the right energy form needing to be in the right place at the right time (Gommans & Dobbelsteen 2007).

3.4.1 The right energy form

For the mapping of (waste) energy potentials it is necessary to know which forms of (waste) energy can be harvested and for which use. The energy required for certain processes is not always available in the desired form, in which case conversion is necessary. Practical expertise is necessary of this conversion process, including knowledge of efficiency, costs and space requirements. This sometimes requires innovation. For instance, the bio-technology industry still regularly finds new ways, assisted by enzymes and bacteria, to convert certain materials into usable carriers of energy (TI-KVIV 2007). An overview of existing energy conversion processes will clarify which forms of (waste) energy can be converted to a usable form, and provide basic information about the associated costs and practical aspects of the conversion process.

3.4.2 The right place

On the regional scale the low-ex principle has implications for planning. Low-caloric heat cannot be transported over long distances: heat losses would be too big. Therefore, spatial functions should be concentrated and mixed: horticulture near industry, residences near horticulture. The SREX research project (Roo et al. 2005) focuses on this synergy of space and exergy.

Each method of transporting energy has characteristic features. Electrical energy can be transported at high voltage over large distances with relatively little losses. Transport of heat over larger distances however quickly reaches a point where the energy losses exceed the energy content. The losses are partly transmission losses to the environment and partly losses incurred by displacing the energy carrier (e.g. pump losses). Energy carriers in a solid or fluid state (e.g. wood products or liquid gas) can be transported by road, rail or waterways. Every method of transport has a price.

The right place to generate electricity may be disputed. Should this be the place where, for example, biomass is available? Or is it the place where biomass or some other fuel can be easily delivered? Or should it be close to areas of living, where waste heat can be used for space heating? Or should it be at some location in-between? Every location has its pros and cons in terms of logistics, efficiency, public inconvenience, transport losses etc. For a well-deliberated decision on the matching of supply and demand of energy and the location of conversion, it is essential that the characteristics of the possible methods of transport are known.

3.4.3 The right time

Finally, timing can be an obstacle in realising a working energy system. Usable energy may be available in the right amount at the right place, but at the wrong time, necessitating energy storage for a short or long term. For instance, photovoltaic systems may require an overnight storage for electricity generated during the day, for use at night (e.g. lighting). Long-term seasonal energy storage will meet the demand for space heating in winter, with excess solar energy captured during summer. Similarly, waste heat continuously produced by industrial processes may be usable only in winter.

Storing energy is always associated with energy losses and, besides, costs, space and energy (for loading and unloading). Each form of storage has its own characteristics. Fuels such as fossil fuels, plant-based oils, bio-ethanol, but also biomass in general are the highest form of exergy. They essentially are chemical stores from which energy can be released by combustion or in another way. As a result of their energy density they require relatively little space. There are many ways to store heat, such as in the thermal mass of buildings or underground heat buffers. Storage of electricity is more difficult than of heat. The electrical grid is sometimes used, but this is only possible as long as the changeable power from wind turbines or solar systems is relatively limited. An increasing share of electrical energy produced by the sun and wind will require a different solution for storage, possibly hydrogen. The selection of an appropriate energy storage method is determined to a large extent by the form of the energy required and by the duration of storage. Locations and regions will vary in their particular requirements and potentials for storage.

4. Using local features at different scales, two examples

4.1 The regional scale: the province of Groningen

Following the investigation of a new regional plan for the Northern Netherlands (Roggema et al. 2006) based on a sustainable energy system, the northern province of Groningen commissioned an energy potential study. The findings of this study, presented in e.g. Dobbelsteen et al. (2007), would be included in the new provincial development plan, for which climate change was also one of the steering principles.

Figure 4a shows the map of all potentials for electricity generation. It gives the best location for wind parks, a tidal plant and a few 'blue energy' plants along the coast, for a biomass-based industrial cluster in the centre, and for a new type of plant: an inundation plant for occasional flooding of the deepest polders in case of emergency. Furthermore, there are small decentralised bio-digestion installations with combined heat and power (CHP) generation, spread through the country-side which contains many isolated farms and villages. Energy values of solar radiation showed little variance over the province, so use of photovoltaic panels is possible anywhere. For large-scale solar plants, the energy properties of a northern place as Groningen are unfavourable. Local self-supply, however, can be helped by solar panels, as well as small wind turbines.

Figure 4b is the overlay map of heat and cold potentials. The map depicts the potentials of geothermal heat from aquifers at 3000 meters of depth, to be deployed through empty gas fields, shown as grey grids. The drill-holes of gas locations are indicated by small blue triangles. The small dotted areas depict reasonable to good potential for heat and cold storage in shallow aquifers (30 tot 150 meters deep). Hollow circles are heat (red) and cold (blue) demand within the municipalities, whereas full circles pinpoint major sites of excess of heat or cold, which can be considered sources of supply. The excess of heat in industrial areas is evident. Nevertheless, the largest producer of heat, the Eems harbour area, now has no heat-demanding function close to it. This can be altered through spatial planning that takes these heat potentials into account.

Solar heat, again, is available anywhere and should be seized when possible. This also applies to local exchange of heat and cold with exhaust air, the soil and open water.

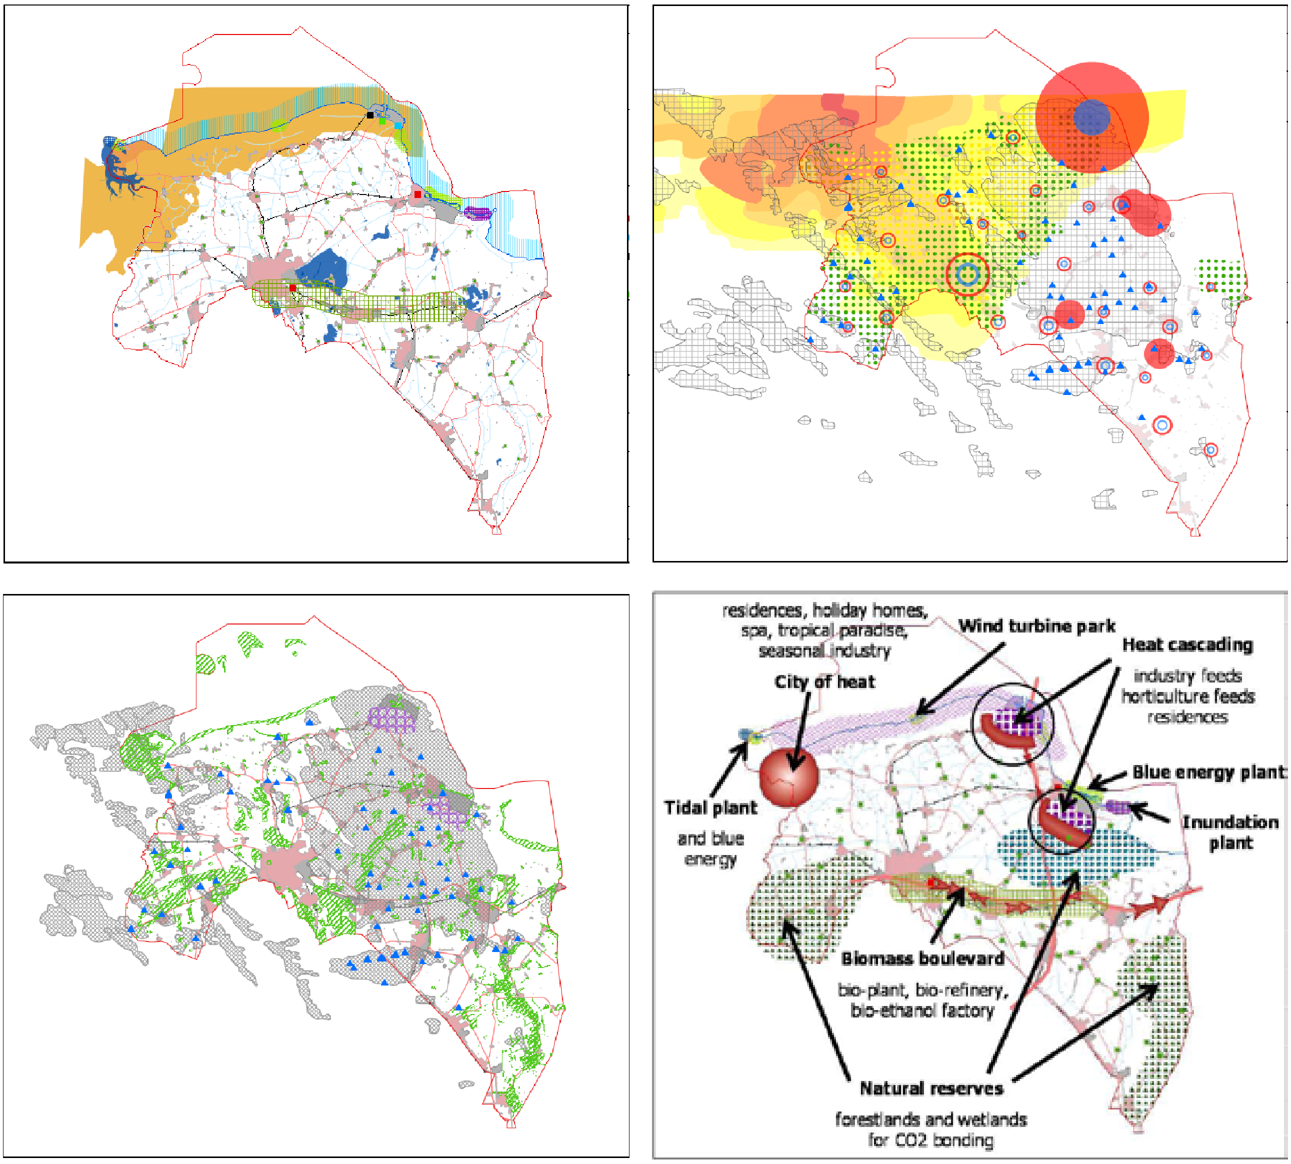

Figure 4 Overlay maps of energy potentials of Groningen for the generation of electricity (a, top left), the provision of heat and cold (b, top right) and for CO_2 use in greenhouses, compensation by plants and storage in gas fields (c, bottom left), as well as the map with proposed interventions (d, bottom right) (Dobbelsteen et al. 2007).

The principle of human influence on the climate is quite simple: prehistoric lush jungles that captured carbon dioxide (CO_2) over millions of years evolved into fossil fuels, which are again converted into CO_2 in a time period of two centuries. To compensate for that, new jungles should thrive another couple of million years, but this time man obstructs the natural regeneration of plants. A four-steps strategy may be (1) avoid emission of CO_2 by energy-saving and sustainable energy resources, (2) make CO_2 useful in industrial and horticultural processes, (3) compensate for CO_2 emissions by planting trees and other green absorbers, and finally (4) storing CO_2 underground. This last option is possible in emptying gas fields that are not watered out after abandonment. Figure 4c summarises the last three options for the province of Groningen. The gas drill-holes are again given.

Figure 4d finally represents the interventions proposed on the basis of energy potentials. These proposals involved a wind park, a tidal plant, blue energy (osmosis) plants, an inundation plant, a cluster of biomass-related industrial activities, heat cascading solutions by horticulture and housing developments against industry, and wet biotopes for CO_2 bonding.

4.2 The urban to district scale: Almere East

Almere, a new town near Amsterdam established in the 1970s has gradually grown, to Dutch standards, to middle-sized proportions but continues to grow with the increasing demand for space for living in the Amsterdam metropolitan area. The municipality of Almere intends to make a 'scale leap' to twice the size of today and therefore is planning three new districts and an upgrade of the inner-city. One of the new districts will be Almere East, to be realised in a predominantly agricultural environment.

Almere has expressed and put into their general policy that all new developments be done in a sustainable way. On April 9th of 2008 they even presented their 'Almere Principles', seven guidelines based on the philosophy of Cradle to Cradle (McDonough & Braungart 2002). Fitting into this town-wide supported ideal was amongst others the study of energy potentials for the new area of Almere East.

The methodology applied to this energy potential study (Dobbelsteen et al. 2008) follows the generic approach presented in this paper. On the basis of fundamental information energy potential maps were drawn, of which figure 5 gives two examples.

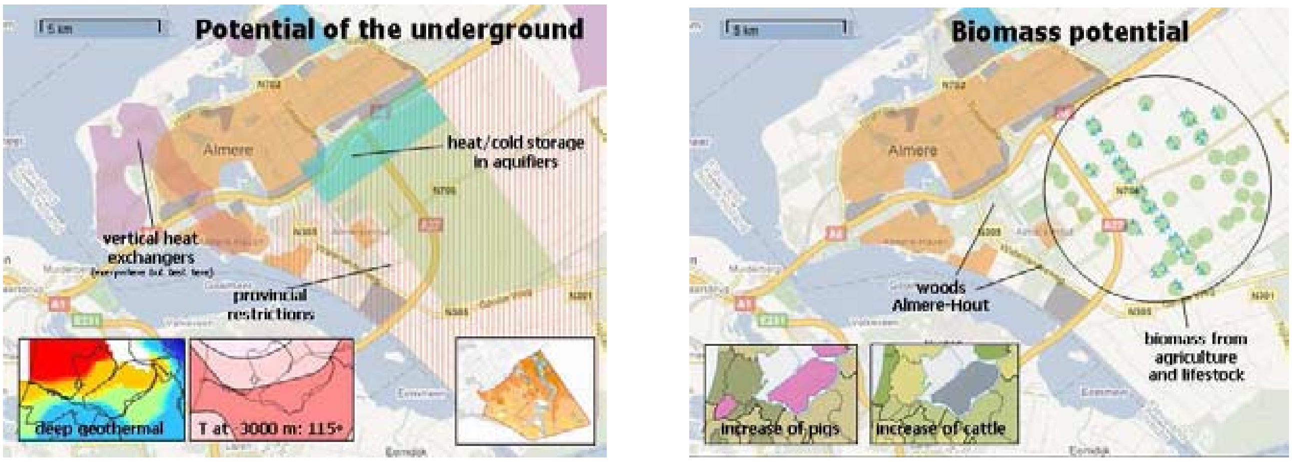

Figure 5 Examples of the energy potential maps for the new district Almere East: potentials of the underground (left) and potentials of biomass (right) (Dobbelsteen et al. 2008).

Using the findings of the energy potentials, two maps with spatial interventions were drawn (figure 6).

The measures proposed for the north side of Almere East in the picture on the left encompass intensive developments alongside the A6 motorway with industry and housing (for the exchange of heat and cold), extension of the heat and cold network from Almere-City and the use of open heat and cold storage in aquifers. The approach for this dense area can be described as heteronomous (Timmeren 2006). For the open agricultural area of Almere East, autonomous clusters are proposed around farms: low-temperature heating dwellings with greenhouses, bio-fermentation with bio CHP, small wind turbines and PV. Alongside the A27 motorway, large windmills will provide additional sustainable power and reed fields will purify water of the area.

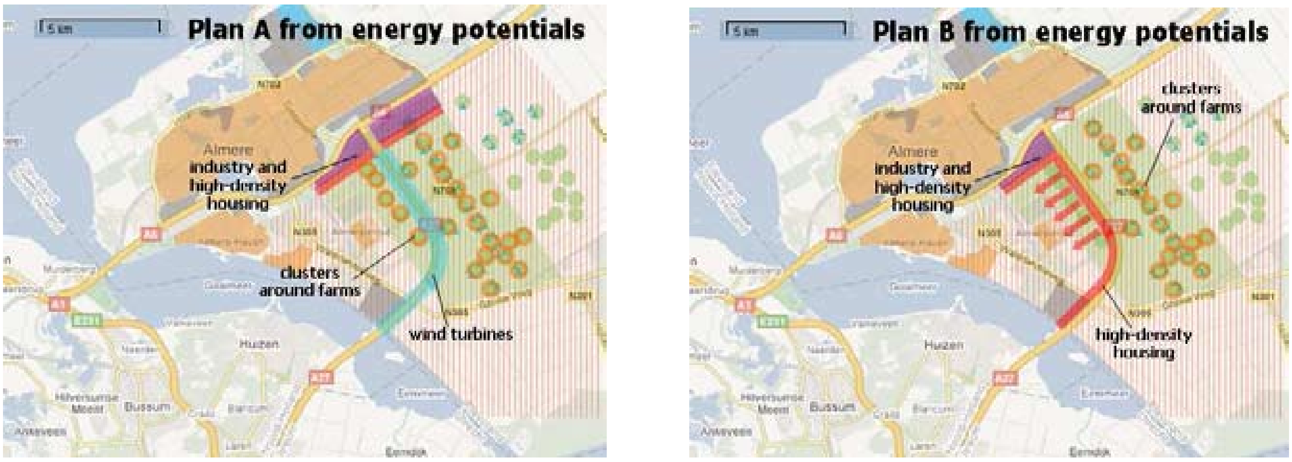

Figure 6 Two possible plans for Almere East that optimally use the energy potentials (Dobbelsteen et al. 2008).

As another option (figure 56, right), only the part west of the A27 motorway is developed, with highly intensive housing against the A27 (noise wall) with a centralised energy infrastructure, and less dense housing towards the west.

These proposals are currently taken into account for the elaboration of Almere East. An energy potential study of the whole Almere region is ongoing, and new studies are expected for two additional new areas for development.

5. Conclusions and discussion

5.1 Conclusions

In this era of energy depletion and climate change, regions throughout the world have become inter-dependent on energy whilst losing the ingenuity to deploy regional and local features in energy-effective planning systems. Smart vernacular planning enables better use of local potentials of energy provision. Energy potential mapping, on the basis of a profound study of local characteristics and possibilities of reusing waste energy flows, will support this smart vernacular planning, as two case studies demonstrated. The methodology for this is generic yet applicable to different scales, from the region to the building scale. It may be combined with potential maps related to social and economical issues. Studies indicated that significant improvements to energy performance can be achieved where efficiency increases to our current system lead to marginal improvements.

5.2 Consideration

The approach presented in this paper implicitly presumes a direct relationship of spatial planning with meticulously located energy potentials. Submitting to this approach would therefore imply direct spatial consequences to found energy properties. A society based thereon could be considered site-bound. Although drastic in its impact to current plans, with the current developments in energy provision this vernacular planning seems an appropriate shift from the old paradigm of disconnecting functions and planning regardless of place and time, made possible through site-independent fossil fuels. In the near future however society may head in a different direction when a substitute is found for fossil fuels, e.g. sustainably produced hydrogen. In such a situation planning can again be 'footloose' and disconnected from its energetic underground.

These are two entirely different scenarios that lead to fundamentally different spatial planning needs. An intermediate scenario is most probable as the footloose society on e.g. hydrogen will at least partly be tied to the local generation of sustainable energy.

5.3 A message of urgency

The Stone Age did not stop because man ran out of stones; it stopped because man found better material for tools. Likewise, the Fossil Age will not stop because of the depletion of fossil fuels; it will find an ending through better solutions for energy. Our current generation has the great honour to make this transition. We hope the methodology presented in this paper can contribute to that.

Abstract
Green building practices are revolutionizing the building sector by changing the way that buildings are designed, built, and operated. This trend is expanding from its initial emphasis on the performance of individual structures to the characteristics of **neighborhoods and entire communities**. The design of green buildings has often been closely associated with increasingly sophisticated modeling approaches. These tools can represent and integrate the performance of mechanical, electrical, water, and waste systems. These tools work well for individual structures, but they typically cannot be used directly at neighborhood or community-scales.

This paper describes the application of an innovative information technology called the CTG Sustainable Communities Model ® (SCM), a software application using a systems-based modeling approach to analyze the costs, benefits, and sustainability implications of design alternatives for community developments. SCM has been used as the basis for the design of communities consisting of thousands of individual homes, commercial buildings, infrastructure and open space. This paper provides examples of several such developments and the types of design decisions enabled by the use of the SCM tool.

Keywords: communities, sustainable, modeling, decision tool, metrics, case studies

1. Introduction

Green building practices are revolutionizing the building sector by changing the way that buildings are designed, built, and operated. The design of green buildings has often been closely associated with sophisticated computer modeling approaches to optimize the performance of proposed building designs. Such tools include: DOE-2, eQuest, Ecotect, IES, and Green Building Studio. These tools can represent and integrate the performance of mechanical, electrical, water, and waste systems. These tools work well for individual structures, but they typically cannot be used directly at neighborhood or community-scales. There are also a number of modeling tools that function at the community scale, for traffic and transportation (e.g. URBEMIS), storm water and hydrology (SG Water), air pollution (EMFAC), and other civil engineering analyses. However, these tools only look at the large-scale performance of the individual systems modeled, without regard to the interactions with other systems or the impacts of building-scale systems. A third class of modeling tool is one that looks at the conceptual layout of a proposed community design, and evaluates certain urban planning metrics (such as walkability, adjacencies of related functions, etc.).

Each of these modeling tools has a useful application in the analysis of new buildings and communities, but there has been a missing capability which tied the multiple scales (building, community, infrastructure) together into a single set of metrics which could interact and allow alternative design scenarios to be evaluated. In other words, a system-based modeling environment was needed; something that could bring together disparate information sources and facilitate quantitative evaluation and comparison. It was this missing capability which drove the development by CTG Energetics of its information technology called the CTG Sustainable Communities Model ® (CTG SCM). In the same way that the energy modeling tools can be thought of as "whole building modeling", the CTG SCM enables "whole-community sustainability modeling" and optimization.

The CTG SCM is a calculation engine using a systems-based modeling approach to analyze the costs, benefits, and sustainability implications of design alternatives for community developments. The CTG SCM has been used as the basis for the design of communities consisting of thousands of individual homes, commercial buildings, infrastructure, and open space. The most significant contribution of this tool is its ability to quantify the evaluation and comparison of design options at different scales at the same time, and to compare multiple options on the basis of both economic and environmental impacts. This capability enables users to evaluate various sustainability features and their relative cost (both construction cost and operating costs), so as to be able to select features that provide the maximum environmental benefit for a given level of economic investment.

The CTG SCM is differentiated by its ability to provide an integrative environment that facilities quantitative, systems-based analysis of whole community performance. The CTG SCM provides a flexible platform for the analysis of project alternatives with exceptional capability to accommodate a range of project detail (e.g. increasing project specification during entitlement and design). These features distinguish the CTG SCM from compliance-oriented tools that focus on subsets of issues or rigid “default” assumptions. For example, there are tools that evaluate the degree to which a proposed community design conforms to “smart growth” concepts, but they do not quantify either the actual environmental loadings generated by the design options or the relative economic performance of those options which it evaluates. There are also rule-based tools, such as LEED for Neighborhood Developments™, which is an assessment system which provides a set of pre-requisites and credits which can be used to evaluate a proposed community design. But again, it provides no quantitative metrics other than the “LEED Rating” which is a single number which conveys no actual quantitative significance, either environmentally or economically. Thus, these types of tools are seen as more of a compliance evaluation tool than a design optimization tool.

This paper provides examples of the types of design optimization decisions enabled by the use of the CTG SCM tool for some recent projects.

2. The CTG Sustainable Communities Model

The authors developed the CTG SCM model with the following goals in mind:

- To quantify the relative environmental impacts and linkages of various development design decisions
- To analyze environmental impacts, economic costs, savings, synergies and trade-offs
- To enable optimization of community design based on a variety of sustainability metrics.

The CTG SCM models a community from the ground-up, using detailed sub-models for each element of a community, including residential, commercial, public and other buildings; parks and other open-space; physical roadways and streetscaping; transportation systems (car trips, bus trips, etc.), stormwater systems, onsite energy generation systems, landscaping pallet and irrigation; domestic water usage, etc. The types of elements which can be modeled are described in Figure 1 below.

Figure 1 Elements of the SCM modeling vocabulary.

Figure 2 below shows an example of the elements which might make up a typical neighborhood modeled as part of a community model.

Figure 2 Elements of an SCM Neighborhood

The environmental performance of each of these elements is individually variable, and can be modeled using industry-standard modeling tools and techniques for each. For example, the energy performance of each type of building in the neighborhood can be modeled using DOE-2, Energy 10 or other energy modeling software, the outputs of which become inputs to the CTG SCM at an element level. Alternatively, building performance information can be derived from statistical data, such as the California Building Energy Reference Tool or the Commercial Building Energy Consumption Survey (CBECS). Similar kinds of modeling or statistical analyses can be done for water usage, solar energy, materials usage, etc., with the calculated outputs of those building-level models becoming the input to the various CTG SCM scenarios which will be evaluated. This can be separately modeled for every different building condition or configuration in the neighborhood. For infrastructure scale features, similar kinds of external modeling can be performed for transportation systems, hydrology, stormwater, etc., with the results used as inputs to the CTG SCM.

One major advantage of using industry-standard modeling tools as inputs to the community-scale analysis done by the CTG SCM is that those tools are familiar to the various design disciplines working on a community plan. The models have typically been subjected to peer review and use over extended periods of time. The analysis is often done as a standard part of work by the appropriate subject-matter experts on a design team, both to optimize their various discrete sub-systems and to document discrete environmental loadings as required for various permitting programs. Thus, these analyses which were already being performed for a project can be utilized as inputs to the CTG SCM to enable the community-wide assessment of whole-community sustainability optimization.

Individual elements are combined to form neighborhoods as shown in Figure 2 above. Neighborhoods can then be aggregated together, along with additional infrastructure elements, to form larger planning areas, districts, and communities, as shown in Figure 3 below.

Figure 3 Elements of an SCM community

From a data flow perspective, the types of inputs and outputs of the CTG SCM are shown in the block diagram of Figure 4 below. From left to right in the diagram:

1. The inputs are detailed description of the various elements of the neighborhoods and community elements in the terms in which they are typically described. Thus, energy inputs are described in typical energy modeler's terms, transportation in typical transportation modeling terms, etc.
2. The computations by the model are all based upon peer-reviewed publicly available algorithms and data, which can be reviewed and revised as new or better data become available.
3. Finally, the outputs are presented in an aggregated form which enables the quantitative assessment of the whole community on a variety of environmental and economic metrics.

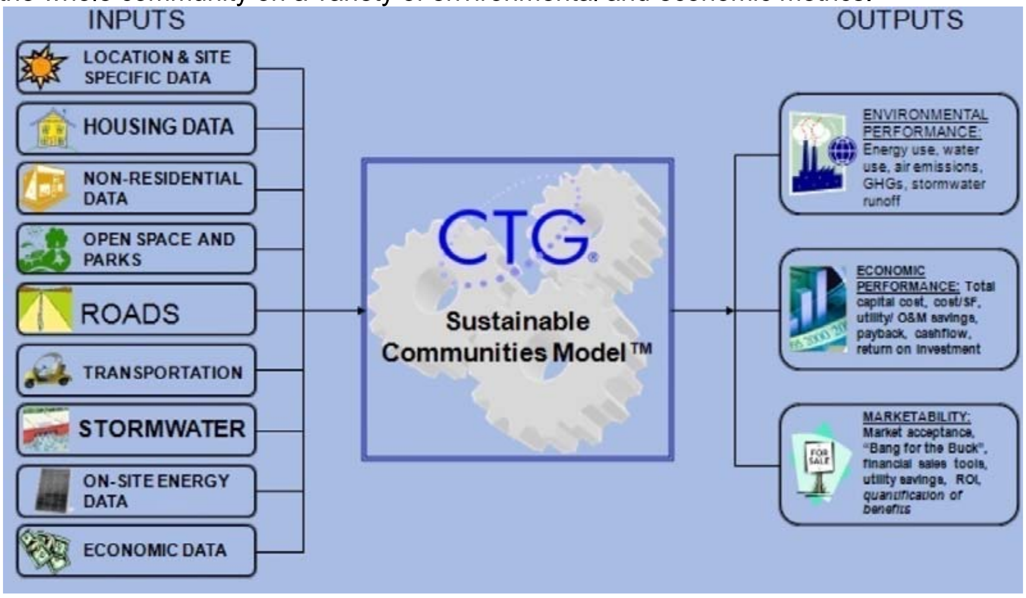

Figure 4 CTG SCM input-output block diagram.

The CTG SCM model links together all of the various "system interactions" and upstream and downstream resource flows. For example, the embodied energy in water pumping, treatment and distribution are modeled. The energy usage, air emissions, carbon footprint, stormwater pollutants, potable water usage, etc. are all modeled quantitatively at the same time. Thus, the model captures synergies and tradeoffs between various design alternatives, and helps determine the designs that provide the best benefit-cost relationship.

3. Case Studies Using the CTG Sustainable Communities Model

This paper shows examples of the types of analysis and decisions enabled by the CTG SCM for two new mixed-use development projects in Southern California, USA. The first is the Rancho Mission Viejo Ranch Plan, a large mixed use development in Orange County including15,000 dwelling units and 4 million SF of non-residential buildings (shopping plazas, restaurants, business parks, and civic facilities) and a multimodal transportation system on a total developed area of 6,000 Acres. The SCM was used as the basis for numerous sustainability design decisions as part of a "…regional, comprehensive master plan for Rancho Mission Viejo that will be developed in phases over the next 20 to 25 years". The second project is the Heritage Park project by Lennar Corp. in the City of Irvine, CA, also a large mixed-use project but on a brownfield site (the redevelopment of the old El Toro military base). This project encompasses 3,900 dwelling units and 5 million SF of non-residential buildings on 2,200 Acres of developed land. The balance of this paper shows examples of the types of analysis performed by the SCM and the decisions thus enabled for these two case study projects (the data are not ascribed to specific projects, due to confidentiality concerns of the project developers).

An example of the value of the integration of multiple systems described above for Figure 4 is that it enables the design team to ascertain where the most significant environmental impacts are for the "whole community", as a guide to where to focus attention on mitigation. Figure 5 below shows the set of base case metrics for an example community on multiple environmental impact criteria. These base case data enable the design team to identify which elements of the community are having the most impact on the various environmental impacts. For example, it is clear that transportation has the single biggest energy impact, much more than either the residential or commercial buildings. This is even more striking in the air pollution metrics, where transportation represents 90% of the total community impacts. By contrast, for stormwater impact, the commercial buildings are far and away the largest impact, due to relatively large roof areas and parking lots. Which impacts are most important to minimize will depend upon the local environmental conditions and upon the goals of the project team.

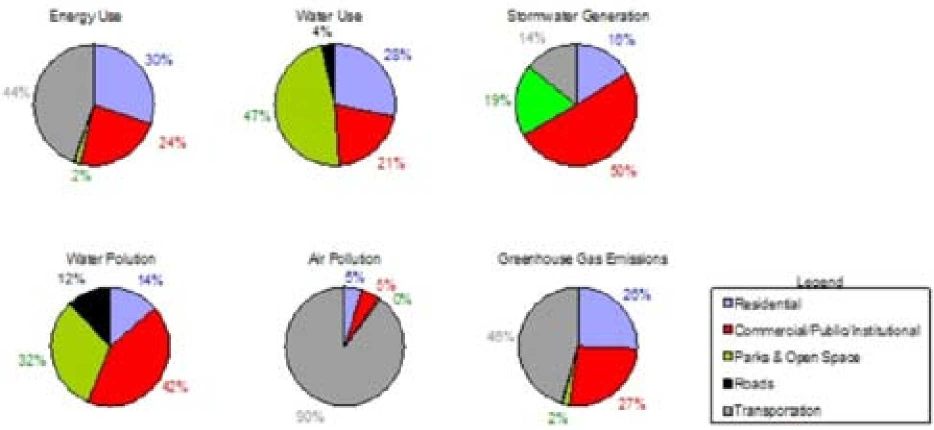

Figure 5 Integrated environmental metrics.

An example of how the inputs from the many different systems can be aggregated into a combined set of integrated end-use summary metrics is shown in Figure 6 below. This enables buildings, landscaping, transportation systems, and other infrastructure features to be combined to see their total demand upon various resources.

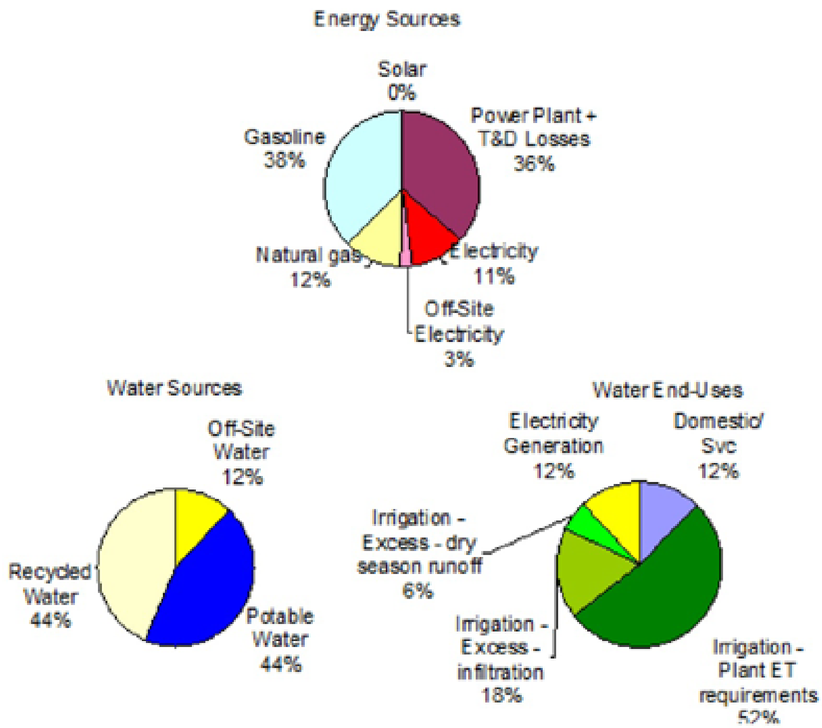

Figure 6 Aggregated end-use analysis

One useful analysis is to focus on a single set of design decisions and look at all of the environmental impacts associated with those decisions. In Figure 7 below, the residential design optimization was done looking at a wide range of sustainability measures, in this case with and without PV Solar power on the dwellings; both options are compared to the Base Case of standard code-compliant design.

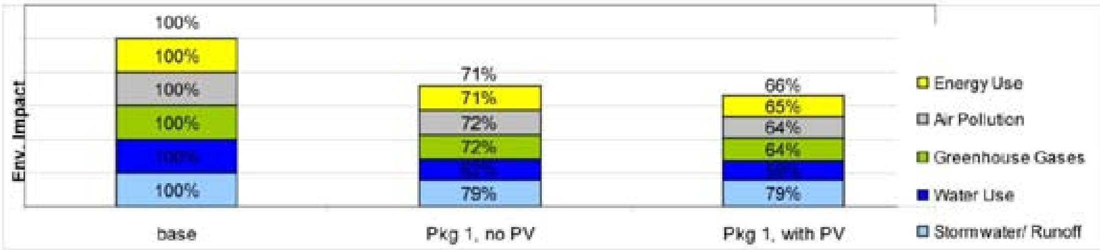

Figure 7 Residential Optimization.

In this case, the environmental impacts in each category (energy use, air pollution, etc.) were totaled and for the base case were assumed to be 100%. The impacts of each category were then stacked. The combined set of design alternatives resulted in a percent reduction from the baseline. The advantage of this representation is that it avoids subjective weighting between the impact categories and assumes each to be equal.

Another way to apply the tool is to look at a single environmental metric and evaluate the potential impact on that metric by various design choices. Figure 8 below shows the analysis of all buildings in the community on the basis of annual GHG emissions.

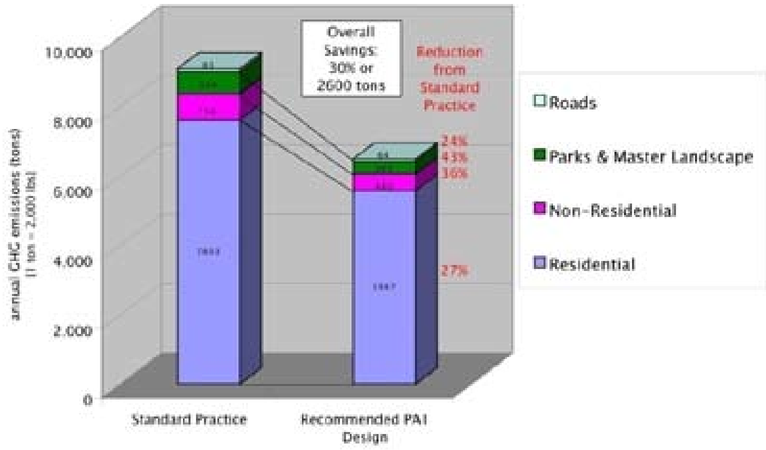

Figure 8 Annual GHG Emissions.

Still another useful approach is to compare the environmental impacts to the construction costs of various measures, and to the Return-on-Investment (ROI) of the measures (the annual rate of return on economic savings from the analyzed sustainability measures). An example of this multi-variate analysis is shown in Figure 9 below.

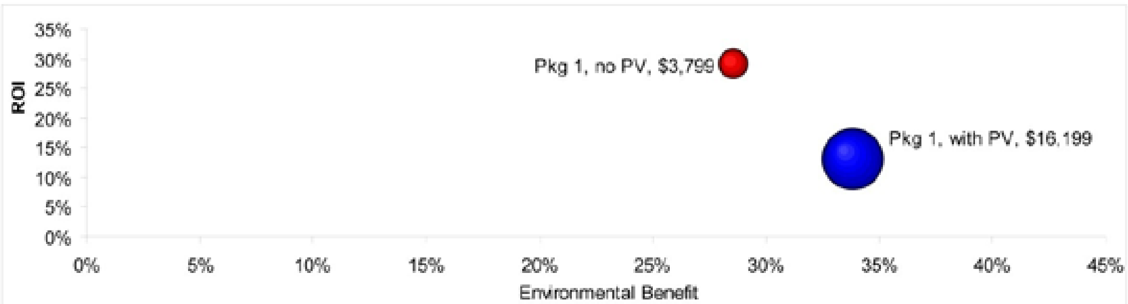

Figure 9 Environmental Impact vs Economic Returns.

One of the most interesting abilities of the model is the comparison of the total environmental impact of different sustainability measures which are otherwise not commensurable. This is accomplished by computing the total environmental impacts of the community with and without the specified measure. The impact here is measured as the percentage reduction of the sum of energy consumption, water consumption, air pollution emissions, stormwater runoff. This can be done with or without a weighting scheme to vary the effect of each separate environmental element. In Figure 10 below, an example output graph is shown for a project in which no weighting is used (i.e. all environmental impacts are considered of equal weight); a discussion of the possible impacts of weightings is beyond the scope of this paper. Thus, in Figure 10 the measures with the highest impact are shown towards the left end of the X-axis, with declining impacts as one moves further to the right of the graph. As a separate data point on the graph, the absolute cost of each sustainability measure is shown as a diamond on the graph.

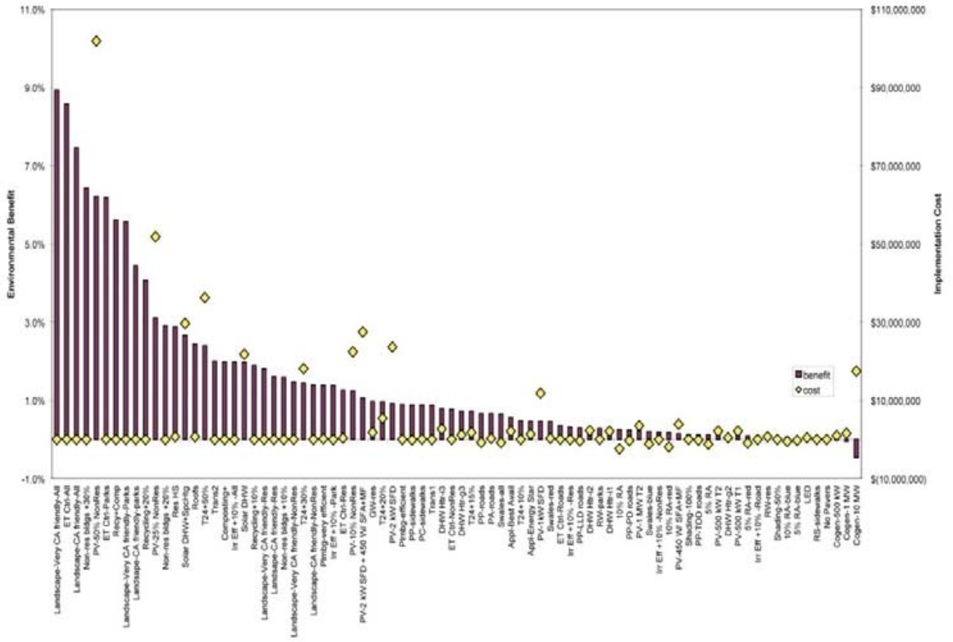

Figure 10 Environmental Impacts and Costs.

Perhaps a more useful way to look at the combination of the impact and cost of each sustainability measure is as shown in Figure 11, which is the "Cost-Savings Ratio" for each measure. This is computed as the ratio of the Environmental Impact Reduction (the left-hand axis of Figure 10) to the First Cost of each measure (the right-hand axis of Figure 10). Thus, measures with higher impact and/or lower cost will appear to the left of the X-axis on Figure 11, whereas measures with lower impact and/or higher cost will appear towards the right. Note that the first 14 measures shown at the left end of the X-axis actually have a cost *savings* for the measure, so that there is both an environmental benefit *and* an economic benefit to those measures.

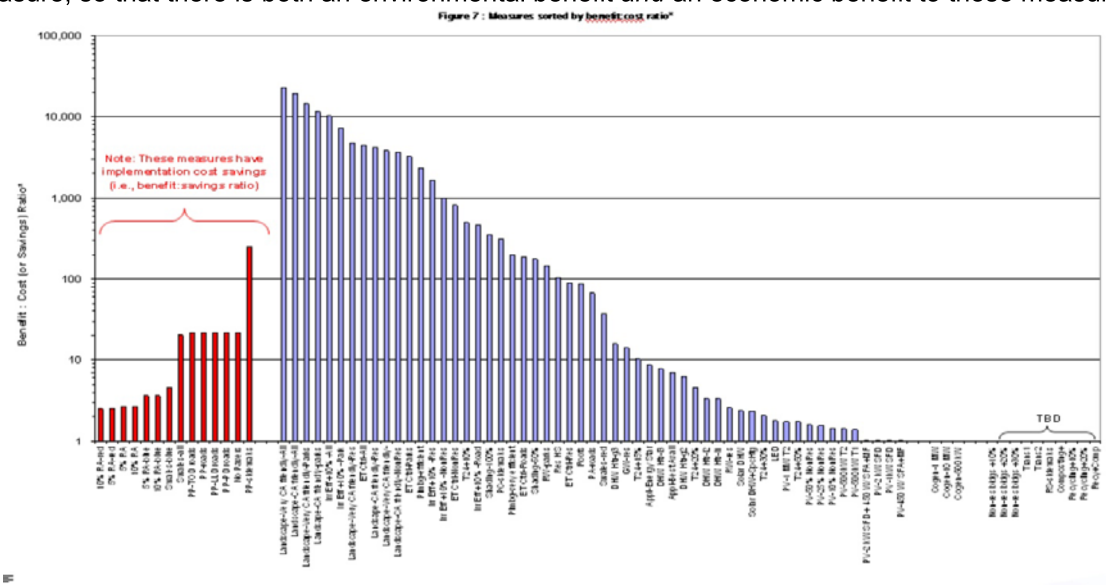

Figure 11. Measures Sorted by Benefit-Cost Ratio.

The types of decisions enabled by using the SCM include the following:

- Trade-offs of building energy conservation vs. transportation options to minimize total carbon footprint of community for a given capital cost.
- Design of "smart streets" that combine traffic calming, stormwater control, landscaped rights of way, reduced paving areas, etc. in a way that optimizes the total environmental benefits.

- Development of community greenhouse gas reduction goals to comply with environmental review requirements under the California Environmental Quality Act (CEQA).
- Justification for increased density and increased number of residential units by demonstrating that the environmental performance of the community overall and compared to key metrics would be reduced (on both a total and per capita basis).

The tool also enables evaluation of the impacts of different information on different decisions by different stakeholders:

- For Policy Makers:
  - The opportunities for environmental impact mitigation through various policy options.
  - Quantification of the environmental impacts from real project design options.
- For Developers:
  - The costs and benefits of project infrastructure design
  - The potential impacts of design guidelines for the buildings
  - Setting measurable quantified goals for sustainability of the project.
- For Builders (of the buildings):
  - The costs and impacts of specific design decisions on building performance.
  - The ability to quantify value of cost increases to prospective home-buyers.
- For Homebuyers and Tenants:
  - The potential savings and returns of any increased “green” premiums on buildings.
  - Quantified environmental impacts in terms they can understand.

Box 1. Challenges for Sustainable Projects that are Facilitated by the CTG SCM

- High construction & housing costs
  - utility savings, improved cash flow, energy efficient mortgages,
- Slowing housing market
  - sustainable developments = competitive advantage
- Bewildering array of competing & confusing “Green” programs
  - Need a project-specific analysis of what makes sense.
- Daunting number of “sustainability” decisions & tradeoffs
  - Quantify benefits, utility savings, and environmental impacts
- Limited money to implement
  - Optimize “Bang for the Buck”
- Consumer education & buy-in
  - Translate vague undefined “green” to real dollars saved, tons of air pollution reduced, gallons of stormwater reduced, etc.
- Need to identify and defend project design features and mitigation measures that save energy and reduce greenhouse gas emissions
  - Identify cost-effective features to reduce greenhouse gas emissions
  - Evaluate community-wide goals based on feasible packages of features

4. Conclusions

The CTG SCM is a systems-based, integrated modeling environment which has been developed for and applied to the real-world development planning process for major mixed use development projects pursuing cost-effective and measurable sustainability goals. The SCM provides the flexibility needed to accommodate changes in the level of detail and specification common to design processes. Early in the planning phases, the SCM helps project teams understand the “big picture” by supporting scoping and schematic analyses. As project specifications become known, the SCM can answer progressively more complex and nuanced questions. Late in the process, the SCM can inform critical design trade-offs with quantitative analysis about their cross-cutting implications. As projects transition into sales and operations, the SCM can evolve to support marketing, education, and performance monitoring. This provides the ability to support an entire sustainable community planning and design process for developers, builders, homeowners, and even public policy makers.

EVALUATION ON SUSTAINABILITY OF URBAN ENERGY SYSTEM BY ENERGY FLOW ANALYSIS

Keywords: Energy Flow, Sustainability Index, Residential Sector, Urban Heat Island.

Summary

In this paper, the urban energy flow of Osaka City, Japan is estimated. The energy flow consists of supply, conversion, consumption and discharge of energy. Since Osaka City is the third largest city in Japan, it provides a base for further urban energy investigations. The energy flow in the residential and non-residential sector is estimated by a detailed end-use simulation model. For the residential sector, this simulation model considers the diversity of households and building types in the city. For the non-residential sector, energy consumption in the city is estimated from district energy uses classified by district characteristics (e.g. central business district, commercial district, residential district, etc.). For the industrial sector, energy flow is estimated from 1997 data by considering the reduction of factories, shut down of blast furnaces and power plants. For the transportation sector, the latest statistics are used for estimation. The estimated energy flow chart of Osaka City for 2005 is made and compared with the energy flows in 1997.

In the latter part of this paper, an index for evaluating sustainability of urban energy flow is discussed. In addition the impact on the atmospheric environment, global environment, urban heat island, non-renewable resource consumption, eco-efficiency are evaluated. In addition, exergy flow of the residential sector is estimated for evaluating the thermodynamic efficiency of energy consumption.

1. Introduction

Activities in modern cities are supported by enormous artificial flows of material, energy and water. These flows cause various kinds of impacts on urban, regional, and global environments. For example, an expansion of energy flow means an increase in consumption of non-renewable resources and an increase in emissions of CO_2, other air pollutant and waste heat, which is one of the important factors of urban heat island phenomenon. The residential and non-residential sectors especially have considerable percentages of energy flows in urban areas and their energy flows have close relationships with other sectors. Therefore, it is very important to estimate the potential of energy saving measures of building stocks on total urban environment by clarifying total energy metabolism in the city. In addition, since energy flows of residential and non-residential sectors indicate the average energy efficiency of the building stock in the city, appropriate measures for improving existing buildings' energy efficiency can be discussed by evaluating energy flows.

The authors (Shimoda et. al. 2000a and Shimoda et. al. 2002) estimated energy flows of Osaka City (Population: 2.6million [Third largest in Japan], Area: 209km^2) as of 1997 for industrial, transportation, residential and non-residential sector and evaluated the energy flow from the viewpoint of environmental impacts on urban heat island, global warming and local/regional atmosphere.

In this paper, energy flow of Osaka City as of 2005 is estimated and compared with the energy flows in 1997. The energy flow in residential and non-residential sector is estimated by detailed end-use simulation model. These models enable us to estimate energy flows of each end-use, to estimate the effects of energy saving measures for appliances and buildings, and to evaluate energy flows by thermodynamic (exergy) efficiency.

In the latter part of this paper, an index for evaluating sustainability of urban energy system is discussed. Sustainability of energy system is a synthetic concept and may consist of several aspects: environmental load on inside/outside the city; rate of non-renewable resource consumption; efficient utilization of energy for required and appropriate amount of service. In this paper, quantification methods for these indexes are investigated.

Bose et. al (1996) optimized the energy flow in Delhi, India for the objectives include minimizing energy demand, maximizing capacity utilization, minimizing energy expenditure, minimizing emissions of pollutants and minimizing energy resources. Ivancic (2004) analyzed and diagnosed energy flow in Barcelona, Spain. Energy and Environmental Balance Simulator of the city is developed and it was used for future perspectives and scenario analysis. For estimating energy flow of residential sector, a geographical information system and cooling and heating load simulator were used.

2. Estimation of Energy Flow in Osaka City.

An urban energy flow chart consists of energy inflow classified by energy source, energy conversion (electricity generation), energy use classified by sectors and end-uses and anthropogenic heat release. Since the climate condition during summer in Osaka is severe, energy flow must be evaluated from the viewpoint of heat island phenomena caused by anthropogenic heat release. Therefore, the anthropogenic heat release is classified into sensible heat, latent heat and waste heat to water system respectively since these impacts on air temperature are quite different.

2.1 Industrial Sector

Energy consumption in the industrial sector is evaluated from the survey results for large facilities and estimates for the other facilities as of 1997. The change of energy flows due to shut down of facilities in the last decade are estimated. In addition, the change of energy flows due to the change of blast furnaces to electric furnaces in steel plants is also considered. Energy flow in power plants is modified using the data of 2005.

2.2 Transportation Sector

In the transportation sector, gasoline and diesel oil consumption by automobiles, trucks, busses and electricity consumption by trains are estimated from the statistics of 2006.

2.3 Residential Sector

Energy consumption in the residential sector is estimated by the detailed energy end-use simulation model developed by the authors (Shimoda et. al, 2007). This simulation model considers the diversity of household and building types in the city. For each category of household, energy consumption is simulated by the aggregation of each appliance's energy use schedule based on occupant's behavior. Energy use for heating, cooling and hot water use is calculated from the heat load calculation. Figure 1 shows the estimated energy flow. Such a detailed estimation enables us to evaluate the energy metabolism with understanding for which purpose and by which appliance energy is utilized and with which form of anthropogenic heat is discharged to environment as shown in figure 1.

In the residential sector of Japan, most of the energy is used for heat consumption such as heating and hot water supply. Among home electric appliances, energy use for refrigerator is largest.

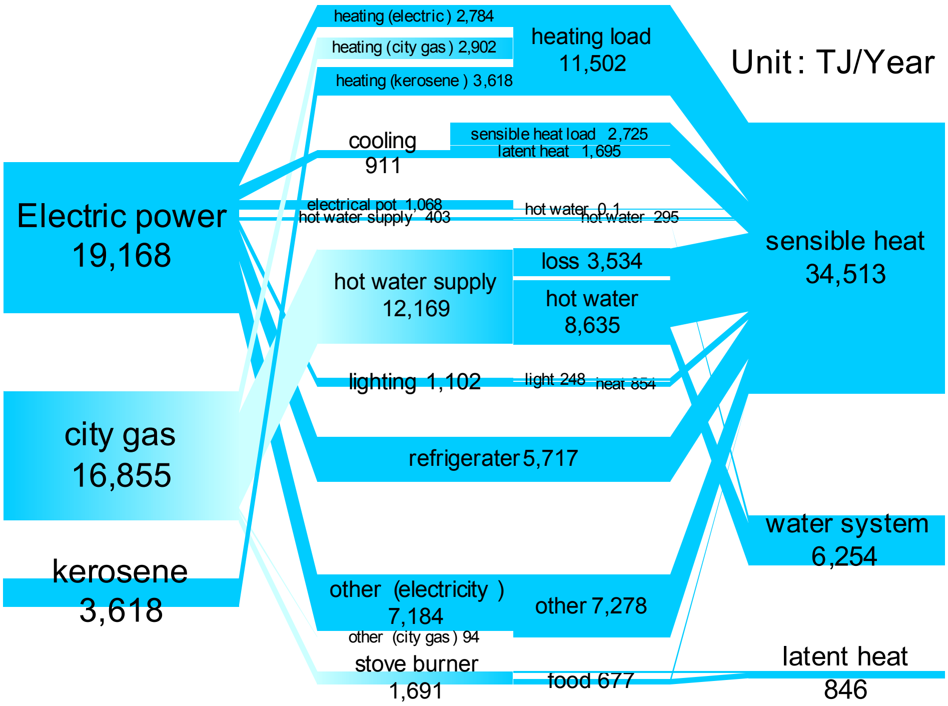

Figure 1 Energy flow in residential sector.

2.4 Non-residential Sector

For the non-residential sector, energy consumption in the city is estimated from energy use of the district classified by its district characteristics (e.g. central business district, commercial district, residential district, etc.) (Yamaguchi et. al. 2007). For each district, energy consumption is estimated by aggregation of each building's energy simulation which includes bottom-up simulation of equipment energy use and dynamic heat load calculation. Figure 2 shows the estimated energy flow for non-residential sector in Osaka City. The central business district, which is only 2.5% of total city area, consumes 27% of total energy use of non-residential sector.

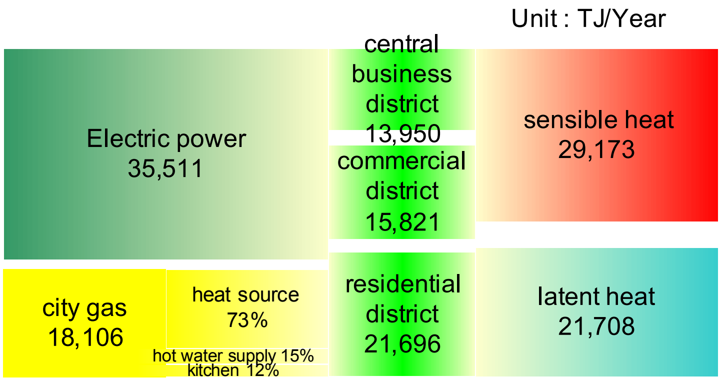

Figure 2 Energy flow in non-residential sector.

2.5 Total Energy Flow and Comparison with 1997 Energy Flow

Estimated energy flow in Osaka City is shown in figure 3. Total energy input to this area is 313,747TJ/year. As a composition of energy sources, both electricity and natural gas each occupy one-third of the total. Excluding the power generation sector, total energy consumption is 237,696 TJ. It means 1.5% of energy end-use in Japan concentrates only 0.06% of national land. The ratios of industrial, residential & non-residential and transportation sector are 28%, 39% and 23%, and the ratio of residential & non-residential sector is quite large compared to the ratio in Japan (28%).

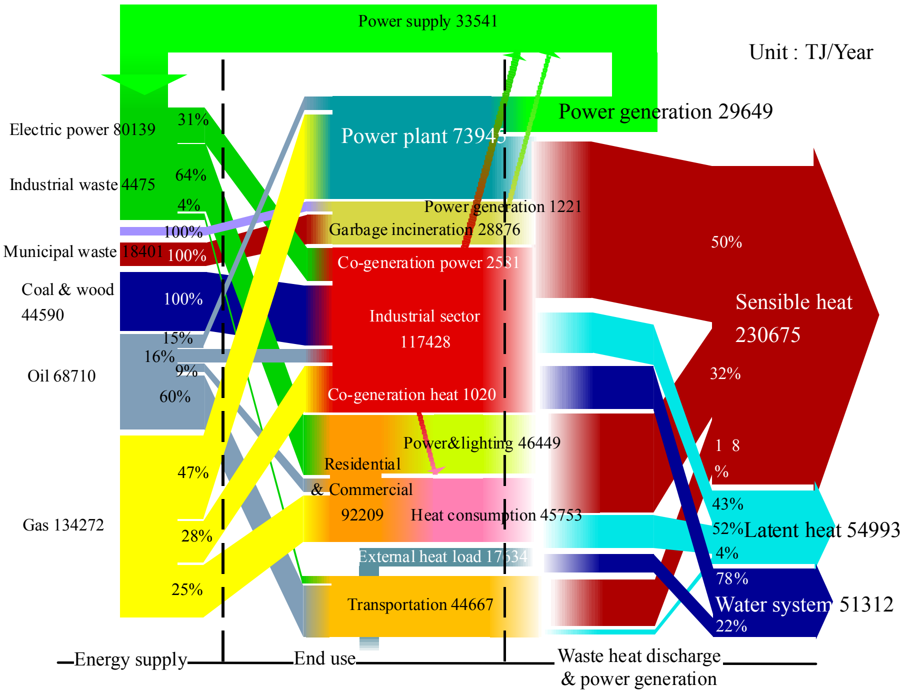

Figure 4 Energy flow in Osaka City (1997)

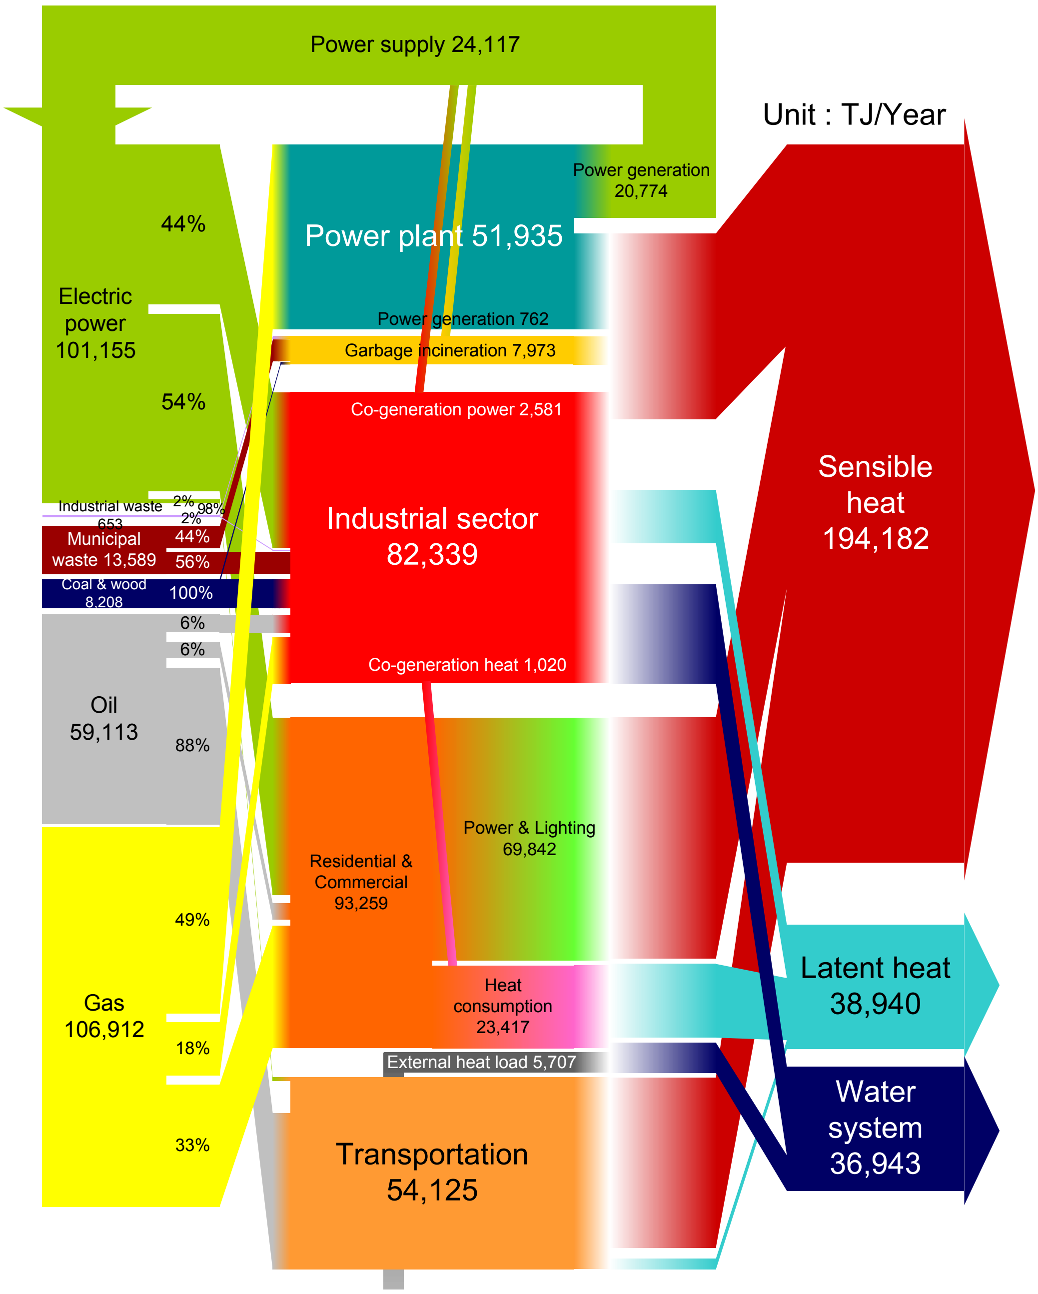

Figure 3 Energy flow in Osaka City (2005)

Figure 4 shows the energy flow in Osaka Prefecture in 1997. In total, energy consumption in Osaka City decreased from 1997 to 2005. The reduction of coal use is particularly large. Most of this reduction is due to the conversion of blast furnaces to electrical furnaces in the steel plant. On the other hand, energy use in the transportation sector has increased by 18%. No significant change occurred in the residential and non-residential sectors, while it should be noted that the method of estimating the energy flow for this sector is different between the result for 1997 and 2005.

3. Evaluation of Urban Energy Flow.

3.1 Sustainability Index of energy flows

Sustainability is a multidimensional problem. As an index of sustainability in urban energy flow, we propose three kinds of index as follows:

- Magnitude of environmental load on city/regional/global environment.
- Rate of non-renewable resource consumption.
- Efficiency in utilization of energy for required service.

Quantitative evaluation methods for these indexes are examined as follows:

3.1.1 Environmental Emission

The environmental load due to energy use in Urban Area can be classified into the following three categories: (1) air pollution; (2)greenhouse gas emission; and (3) thermal pollution (i.e. urban heat island).

(1) Air pollution: In air pollution, the magnitude of environmental impact depends on not only the amount of pollutant but also on the place where the emission occurs. Therefore, the authors developed a database which shows the link between the unit consumption of energy end-use (electricity, city gas and oil) and the amount and the place of air-pollutant emission, greenhouse gas emission and resource consumption. This database considers not only the direct emission but also indirect emission such as extraction of fossil fuel and marine transport. Table 1 shows the estimated atmospheric emission for unit electricity consumption. Figure 5 shows the total amount of air pollutant emission due to energy flows in Osaka City classified by the place of emission. Excluding the on-site emission, emission at the marine transport and extraction occupied large portion. The ratio of residential and non-residential sector in the total emission is much smaller than the ratio of energy consumption (39%). This is due to cleaner energy sources such as electricity and natural gas are mainly used in this sector.

Table 1. Estimated Environmental Emission for Electricity

	Extraction	Marine Transport	Domestic refinement	Power plant
kg-CO_2/MWh	16.6	3.9	8.4	354.0
g-NOx/MWh	20.8	42.5	15.3	41.4
g-SOx/MWh	12.9	12.0	6.8	21.8

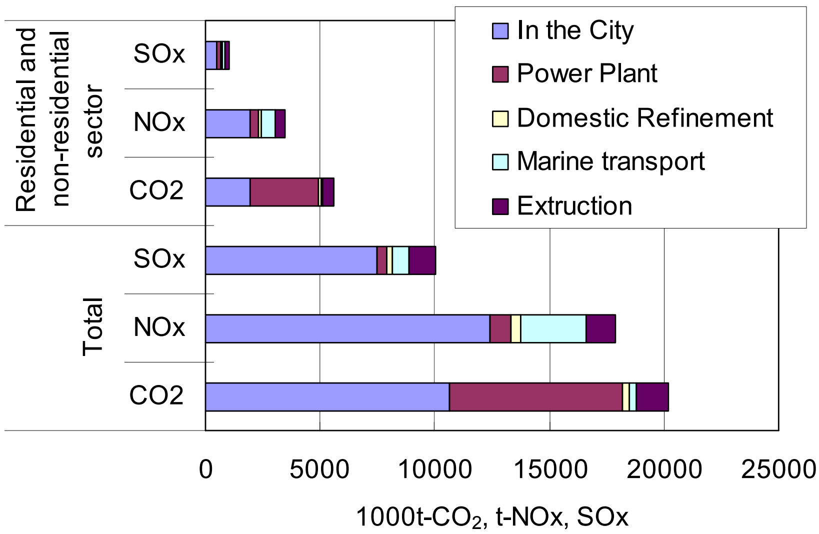

Figure 5 CO_2, NOx and SOx emission due to energy consumption in Osaka City classified by the site of emission.

(2) Greenhouse gas emission: In this paper, only CO_2 is considered as a greenhouse gas. As well as air pollutant, CO_2 emission due to the energy use in the city is estimated from the database which considers indirect emission as shown in table 1 and the result is shown also in figure 5. Large amounts of CO_2 are emitted at the power generation plant outside the Osaka City, especially in the residential and non-residential sector. 54% of the CO_2 emission occurs at the power generation plants. In the residential and non-residential sector, CO_2-emission per person is 2.12t-CO_2/person, which is smaller than the Japanese average (3.05t-CO_2/person).

(3) Thermal pollution (urban heat island): Usually, the urban heat island phenomenon is a serious problem only in the densely urbanized area. Since the impact of anthropogenic heat release on air temperature varies according to the phase (sensible heat to atmosphere, latent heat to atmosphere or hot water effluent to water system) of anthropogenic heat, the energy flow chart distinguishes the anthropogenic heat release by the phase. As shown in figure 3, Total anthropogenic heat release is 277,986TJ/year and it corresponds to 28% of total solar radiation in Osaka City. 73% of total anthropogenic heat is released as the sensible heat, which has direct impact on air temperature. As well as the phase, time variation and horizontal distribution of anthropogenic heat release affect the magnitude of urban heat island. Therefore, grid database of anthropogenic heat release is necessary for evaluating on heat island impact of urban energy flow. (Shimoda et. al., 2000b)

3.1.2 Rate of non-renewable resource consumption

As a sustainability indicator of non-renewable fossil fuels and uranium ore, normalized weighted resource consumption NWR is used. This is normalized value of resource consumption index of EDIP method (Wenzel et. al., 1997) and calculated by equation (1). This index means the rate of non-renewable resource consumption toward the depletion. Electricity consumption is transformed to non-renewable resource consumption using our database.

$$\mathrm{NWR} = \sum_j \frac{\text{Annual consumption of resource }(j)\text{ per capita}}{\text{Known reserves of resource}(j)} \tag{1}$$

Calculation results for total energy consumption in Osaka City and the residential and non-residential sector in Osaka City are shown in table 2. Resource consumption rate of uranium ore and natural gas have a large portion among all non-renewable resources. Rate of non-renewable resource consumption in the residential and non-residential sector is corresponds to 40% of the rate of all sectors. The residential and non-residential sector occupies 39% in energy end-use and 28% in CO_2 emission. This suggests that the residential and non-residential sector accelerate the non-renewable resource consumption rate by depending on low-carbon but more scarce energy sources such as nuclear power and natural gas.

Table 2. Rate of resource consumption

	Osaka City (All Sectors)		Residential & non-residential sector in Osaka City	
	Resource consumption per capita	NWR(j) ($\times10^{-12}$ /year)	Resource consumption per capita	NWR(j) ($\times10^{-12}$ /year)
Coal	227.6kg	0.25	114.1kg	0.13
Oil	760.0ℓ	3.98	101.6ℓ	0.53
Natural Gas	1296.6kg	9.57	204.0kg	1.51
Uranium Ore	49.4g	10.77	35.2g	7.67
Total		24.56		9.84

3.1.3 Efficiency in utilization of energy for required service

One way of quantitative evaluation on sustainability of energy consumption is ‘eco-efficiency’ (OECD 1998).

$$\text{eco-efficiency} = \frac{\text{value of products and services}}{\text{environmental pressures}} \tag{2}$$

If energy consumption or CO_2 emission is selected as an indicator of ‘environmental pressure’ and population or GDP is selected as ‘value of products and service’, calculation results of eco-efficiency are as shown in table 3.

Table 3 eco-efficiency indicators

Indicators	Osaka City All sectors	Osaka City Residential & non-residential sector	Japan All sectors	Japan Residential & non-residential sector
Energy/population(TJ/Person)	0.090	0.035	0.122	0.034
Energy/GDP(TJ/Mil. Yen)	0.011	0.004	0.029	0.008
CO_2/population(t-CO_2/Person)	7.675	2.118	9.158	3.054
CO_2/GDP(t-CO_2/Mil. Yen)	0.945	0.261	2.169	0.723

These results suggest that energy use and CO_2 emission per GDP in Osaka City is smaller than the Japanese average due to the composition of industries in Osaka City where tertiary industries are dominant. However, more discussion is needed to evaluate these values, for example, difference in primary energy and secondary energy, difference in daytime population and night time population, composition of GDP, and so on.

Another way of evaluation is thermodynamic efficiency of energy consumption. In this case, energy flow (enthalpy flow) is transferred to the exergy flow. Exergy E_x is calculated by equations (3) and (4).

$$E_x = Q \times \varepsilon \quad \text{(in case of fuel)} \qquad (3)$$

Where: Q : Amount of energy (enthalpy)

ε :Exergy ratio

$$E_x = \rho \cdot V \cdot C_p \times \left\{ (T - T_0) - T_0 \ln \frac{T}{T_0} \right\} \quad \text{(in case of fluid)} \qquad (4)$$

Where: ρ : Density of fluid.

V : Volume of fluid

C_p : Specific heat of fluid.

T : Temperature of fluid [K]

T_0 : Temperature of environment [K]

The exergy flow of the residential sector in Osaka City is shown in figure 6. This is distinctly different than the enthalpy flow shown in figure 1. Exergy loss from space heating and hot water supply is quite large. For example, exergy efficiency of city gas (12,169TJ/year) to hot water (397TJ/year) is only 3%, whereas enthalpy (energy) efficiency is 71%. It suggests that use of low-level heat energy such as waste heat from other sectors and use of heat pump are more appropriate for such purpose and these measures have a great potential of energy saving. Therefore, exergy flow evaluation is an important index to evaluate the efficiency of heat consumption.

4. Conclusion

Drawing urban energy flow diagram enables us to grasp the composition of energy source used in the city, the composition of energy end-use in each sector, the composition of energy use of each appliance and the composition of anthropogenic heat release classified by phase at a glance.

In addition, several kinds of sustainability index such as greenhouse gas emission, air pollutant emission classified by the place of emission, rate of non-renewable resource (fossil fuel) consumption can be calculated from the urban energy flow diagram. The results show Osaka City's energy use in the residential and non-residential sector accelerates the rate of non-renewable resource consumption by depending on low-carbon energy sources such as nuclear power and natural gas.

The flow of exergy, which shows the thermodynamic efficiency of energy use, is also investigated. It shows that exergy flow evaluation is an important index to evaluate the efficiency and to suggest the better way of heat consumption.

Further discussion is needed for the appropriate area size and time span of basic unit for urban energy flow, synthetic evaluation method for sustainability indexes.

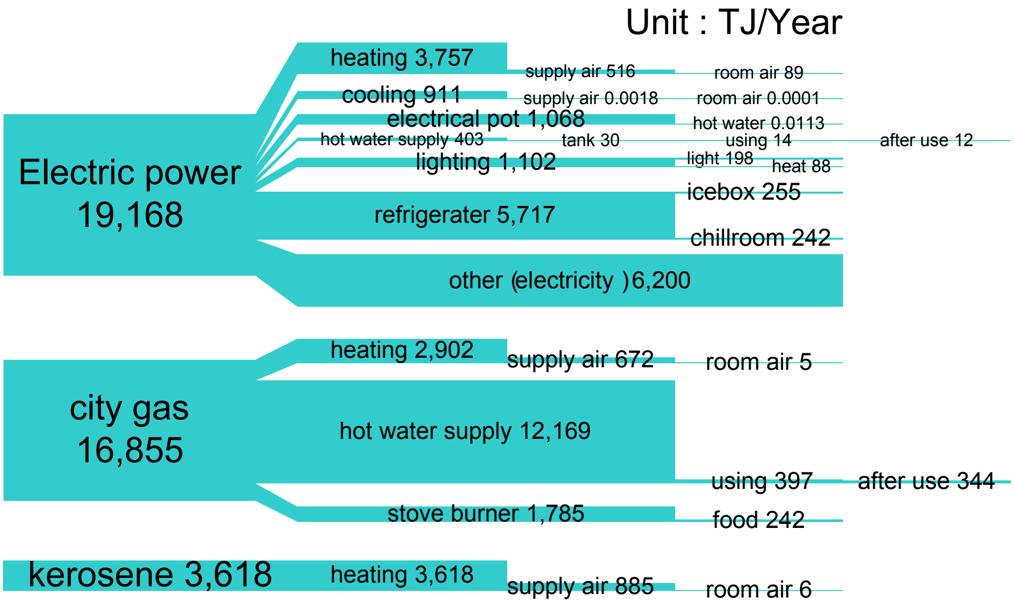

Figure 6 Exergy flow of residential sector in Osaka City.

Keywords: healthy living, sustainable community

Summary

Since 2004, Hong Kong Housing Authority initiated the comprehensive application of Micro-climate Studies in the planning and design of high density and high rise housing development using latest proven technologies, including computational fluid dynamics simulations and wind tunnel tests etc. These studies enable holistic consideration to optimize the development potential and enhance the built environment of the neighbourhood. They cover core topics of wind environment, natural ventilation, daylight and solar heat gain, as well as other special topics such as urban heat island effect, pollutant dispersion, etc. This Paper introduces the following key initiatives –

a) Passive design approach to enhance natural ventilation and pollutant dispersion of the domestic dwellings and public areas

b) Sun-shading and daylight studies to enhance the master layout and open space planning

c) Environmental façade design concept to mitigate solar heat gain and enhance human comfort

Up till March of 2008, over 30 public housing projects in Hong Kong have adopted the micro-climate studies, which provide greater human comfort for residents by enhancing sustainability with cleaner and greener environment for healthy communities.

1. Introduction

In the high-rise, high-density environment of Hong Kong, environmental performance of buildings has a significant impact on the public. High density living has the advantage of efficient land use, public transport and infrastructure, as well as the benefits of closer proximity to daily amenities. We have more than 7 million people living in 1,100 sq. km of which, only about 200 sq. km is developed and another 400 sq. km is devoted to country parks. There is a global trend in the shift from rural to urban populations and the corresponding increase in population densities and urban consumption patterns is reflected in every urban city.

About one-third of Hong Kong's population is residing in public housing. Among the stock of over 2,300,000 permanent residential flats, over 674,000 flats are public rental housing stock under the management of HKHA. It is always HKHA's prime objective to provide healthy living environment in sustainable housing developments. Environmental aspects of sustainable housing design comprises low energy consumption and high performance concept. In 2001, HKHA initiated the application of Micro-climate Studies, based on holistic approach, in the planning and design process of public housing developments to optimize the development potential and enhance the built environment of the neighbourhood. These Studies have recently won the Special Architectural Award 2006 organized by The Hong Kong Institute of Architects and the Annual Award 2007 organized by The Hong Kong Institute of Planners. The ensuing sections of this paper are to present some key features of the micro-climate studies in our planning and design process.

2. Wind Environment

We use the micro-climate studies as urban planning tool to optimize estate planning, disposition/orientation of blocks and building permeability to enhance wind environment for the housing development and as-built neighbourhood.

2.1 Site Wind Availability Data

Hong Kong lies in the tropical climate zone. With high rise and high density developments around the city, air ventilation condition with low wind speed, particular in urban areas, becomes common phenomenon. It is necessary to account for the characteristics of the natural wind availability of each housing development site. We make use of wind data from weather stations of local Observatory to qualitatively estimate the prevailing wind directions and magnitudes of the site for evaluation. For sites with weather stations nearby, wind rose with reduced set of prevailing directions covering most of the time in a typical reference year is vital for micro-climate studies whereas for those with specific site topography and being remote from weather stations, wind tunnel simulation test becomes more appropriate.

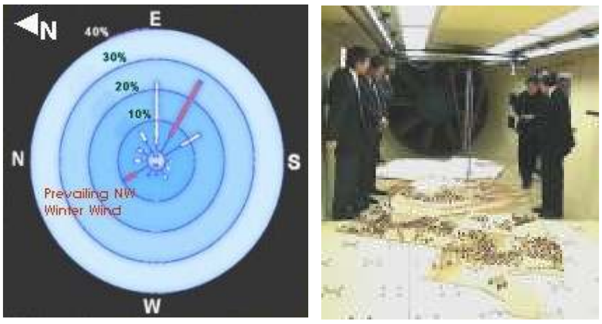

Figure 1 Wind Rose Diagram + Wind Tunnel Test

2.2 Air Ventilation Assessment (AVA)

Air ventilation assessment is an indicator to relate the wind availability of a city and the urban geometry, and to assess the built form's capability to optimize the available wind. This indicator addresses what minimum wind environment, and in what form, is needed to guide design and planning so as to achieve a better wind penetration into, and hence, air ventilation of the city, especially at the pedestrian level. It is represented by Wind Velocity Ratio –

$$VR_W = \frac{V_p}{V_\infty}$$

V_∞ is the wind velocity at the top of the wind boundary layer not affected by the ground roughness, buildings and local site features

V_p is the wind velocity at pedestrian level (2 metres from ground) after taking into account the effect of the housing development

VR_w indicates how much of the wind availability of a location could be experienced and enjoyed by pedestrians on ground taking into account of the as-built surroundings

With test points allocated at strategic site locations, wind velocity ratios at these points are identified to indicate the effects of different planning options of a housing development for comparison purpose. It is through comparison of different planning options in holistic approach that the optimal solution is derived.

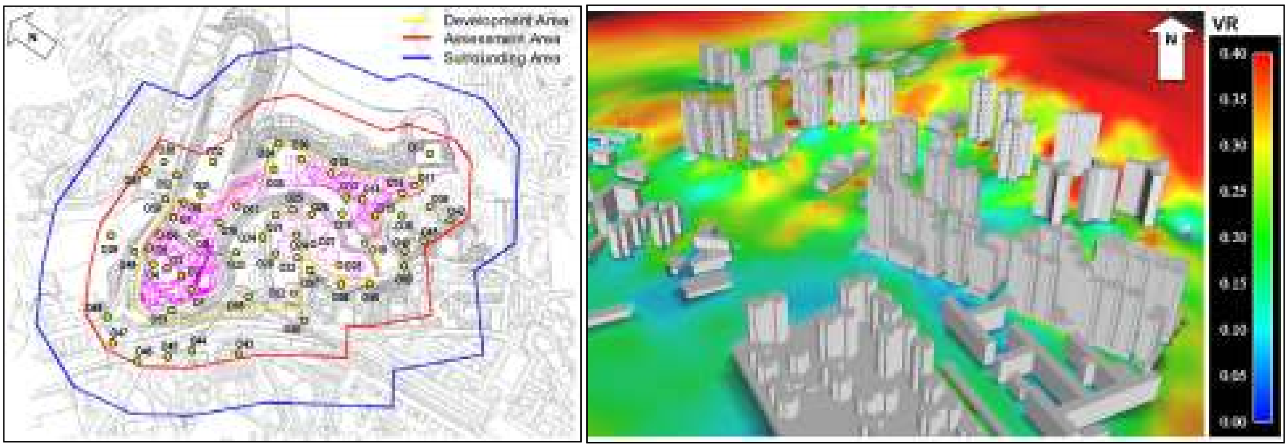

Figure 2 AVA Study for Choi Wan Road Housing Development

2.3 Wind Environmental Initiatives

In achieving the objectives to optimize estate planning, disposition/orientation of blocks and building permeability, we apply computer fluid dynamics (CFD) analysis to study the wind flow pattern and magnitude at low, mid, high zones of the high rise domestic towers (up to 40 storeys or above) for different enhancement measures in site planning and building design options, external circulation and open spaces, and impact on as-built surroundings. By comparing the micro-climate study results of various green initiatives, the most optimal planning and design option is worked out on both qualitative and quantitative basis in a scientific approach -

a) Effectiveness of “Wind Corridor” design, in quantitative terms, for enhancing site permeability for prevailing wind is identified by comparing simulation results of ‘Before’ and ‘After’ implementation of the development. The increase in air velocity with wind corridor under the prevailing “East” wind condition ranges from 18 to 250%.

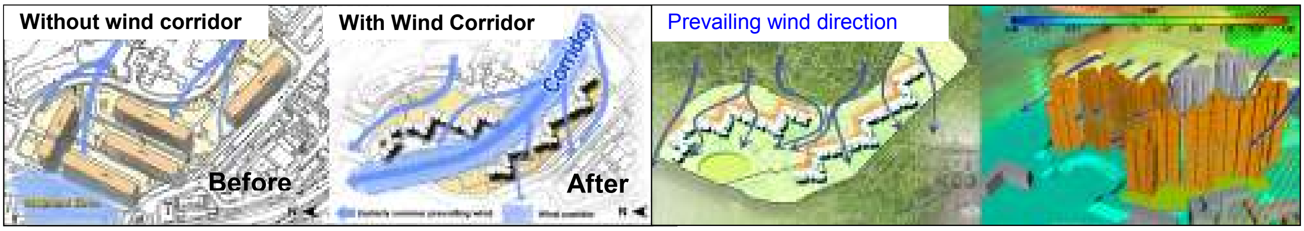

Figure 3 Environmental Performance “with and without” Wind Corridor

b) For constraint of narrow linear site configuration, design options for disposition and orientation (deviation up to 10 degrees) of domestic towers are compared to streamline the wind flow across the development and the as-built neighbourhood. In Figure 4, option 1 represents the wall effect in aligning the domestic towers along the frontage; in option 2, the domestic towers are inclined at 10 degrees with one another and truncated at the end wing to create the louver effect for enhancing wind penetration. The wind speed at open space between domestic towers increases substantially by 100 to 133% by adopting Option 2.

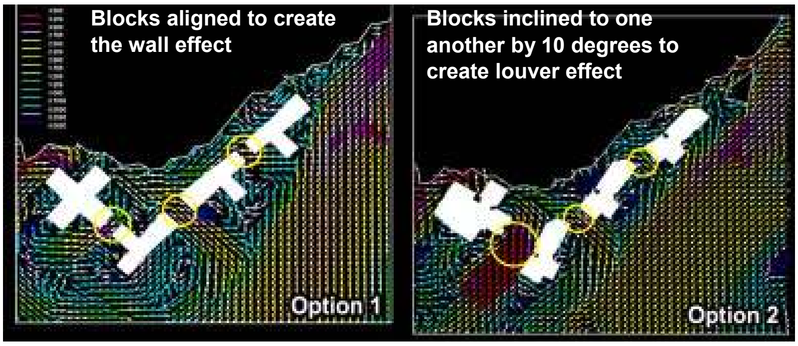

Figure 4 Environmental Performance with different orientation and configuration

c) CFD analysis is an effective tool for adjustment of variables in building separation and heights on site platforms at different levels to divert winds to lower levels. Site specific design options “with” and “without” full site coverage podium (based on same permeability condition) are compared for identification of the significant variance in building permeability for air ventilation at pedestrian level. The average wind speed and velocity ratio at street level (leeward side) increases by 13% and 14% respectively for the development without podium.

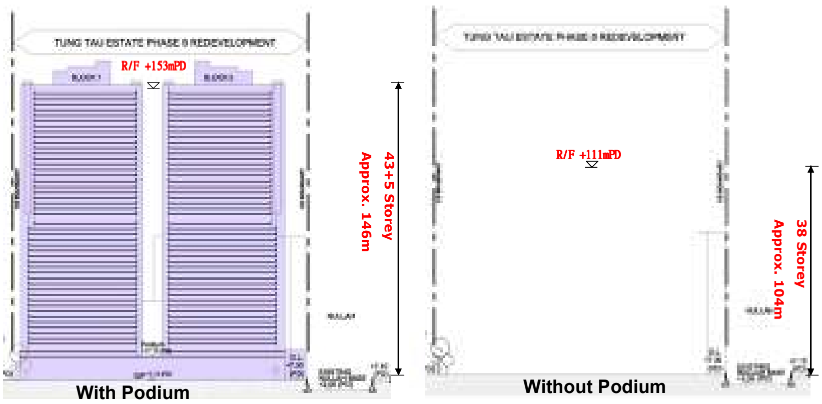

Figure 5 Environmental performance with and without podium

d) Urban greening filtrates the air flow and provides shade and cooling. To enhance the building permeability, a green deck garden is designed in one of the developments to link up the high rise domestic towers at 1/F level. It also extends the external garden into the habitable spaces.

Figure 6 First floor deck garden enhances building permeability with green filtration

3. Natural Ventilation and Pollutant Dispersion

We use the micro-climate studies as building design tool to optimize configuration of blocks, detailed architectural layout and window openings to enhance natural cross ventilation in habitable accommodations, public and circulation areas.

3.1 Natural Ventilation Initiatives

Functional and Cost-effective Design approach is developed to optimize the life cycle costing of public housing in Hong Kong, while meeting the crucial needs – comfort, safety, health and a quality living environment.

By simulating the wind flow pattern and magnitude of typical domestic units, lobby and public areas at low, mid and high zones of the high-rise domestic blocks, and ground floor entrance lobby etc., ventilation coefficients are determined to identify the ventilation performance of each design option at scheme design stage and fine tune the detailed design, in quantitative terms, to enhance natural ventilation with effective pollutant dispersion from toilet accommodations and refuse storerooms etc. -

a) Effectiveness of "Cross Ventilation Corridor" design for enhancing building permeability is reflected by quantitative results of 'With' and 'Without' the ventilation initiative. The increase in air velocity with cross ventilated corridor at selected points around the development ranges from 18 to 250%.

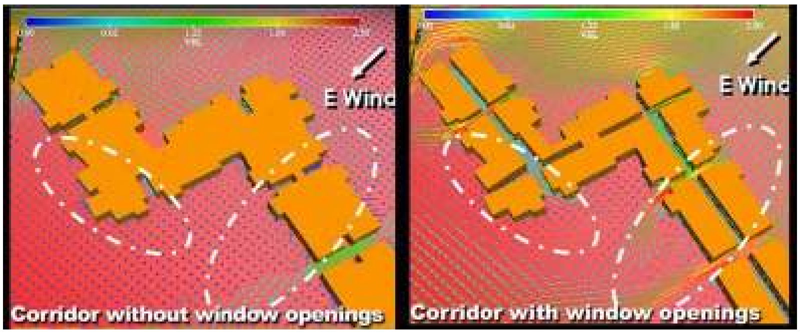

Figure 7 Environmental Performance with and without cross ventilated corridor

b) Effectiveness of "Wing Wall as Wind Deflector" for enhancing natural ventilation of domestic blocks at sites with low ventilation rate is reflected by quantitative results of 'With' and 'Without' of the ventilation initiative. In Figure 8, the wing wall increases the air velocity inside corridor under the prevailing wind condition by 2.5%.

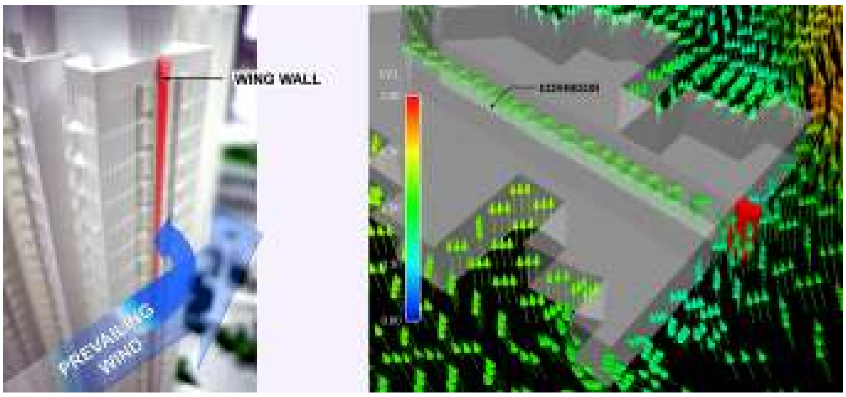

Figure 8 Environmental Performance enhanced by wing wall

c) Effectiveness of "Modular Design" for enhancing natural cross ventilation of domestic flats is reflected by quantitative results of the ventilation initiative.

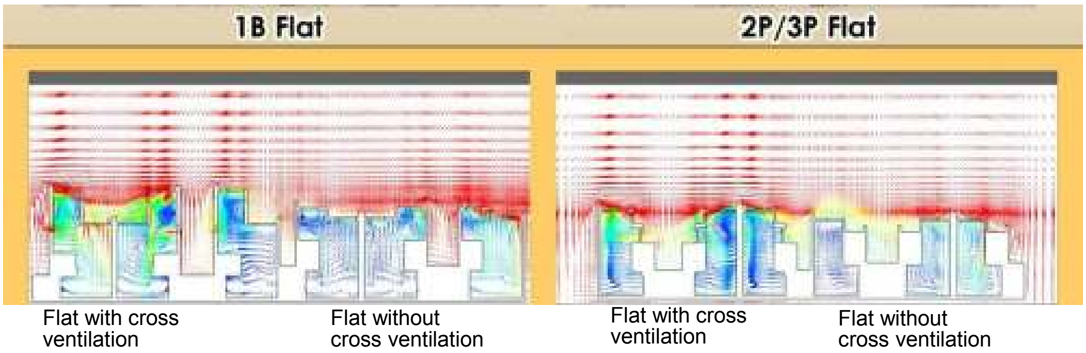

Figure 9 Comparison of ventilation performance for modular flats with and without cross ventilation

4. Daylight and Sunshading

We use the micro-climate studies as building design tool to optimize daylight penetration in domestic units and public areas of domestic blocks for energy efficiency, comfort and health, and optimize the passive and active open space layout planning within the development.

4.1 Natural Lighting Initiatives

Daylight has psychological effects and increases the comfort level of individual space. The amount of daylight on the surface of a building façade is related to the extent of its exposure to the natural environment. In high density and high rise developments, much of the daylight penetrating through window openings at lower floors come from the reflected light of the surrounding surfaces. We adopt the performance-based approach using "Vertical Daylight Factor (VDF)" (a ratio in percentage of the total amount of illuminance falling onto a vertical surface of a building to the instantaneous horizontal illuminance from an overcast sky) as a design tool for optimizing the natural lighting performance –

Figure 10 Natural lighting for modular flats and common corridor

a) Effectiveness of "Modular Design" for enhancing daylight penetration into domestic flats is reflected by performance based assessment.

b) Effectiveness of "Cross Ventilated Window Openings" for enhancing daylight penetration into the public areas of high rise domestic towers is reflected by performance based assessment. The windows at cross ventilated corridors bring about 13% saving in energy cost.

4.2 Sun shading Initiatives

High rise living renders it significant for environmental planning of the open spaces. Simulation of annual 3-D sun path diagram dedicated to Hong Kong context identifies the sunlight and shade pattern at external areas of the proposed housing development at different time of the day and different seasons of the year, taking into account of the site surroundings. It is an integrated design approach for optimizing the sunlight exposure to green areas, morning exercise and outdoor laundry space, sun-shading for leisure sitting, children play and ball courts, particularly for west facing open spaces –

a) Comprehensive performance-based open space planning for sustainable high density community: Activity areas that desire shading (e.g. children play area and foot massage trial) are planned at adequately shaded area. Areas exposed to sun heat most time of the day would be shaded by trees or shelters.

b) Detailed study of local landscaping layout by performance based assessment -

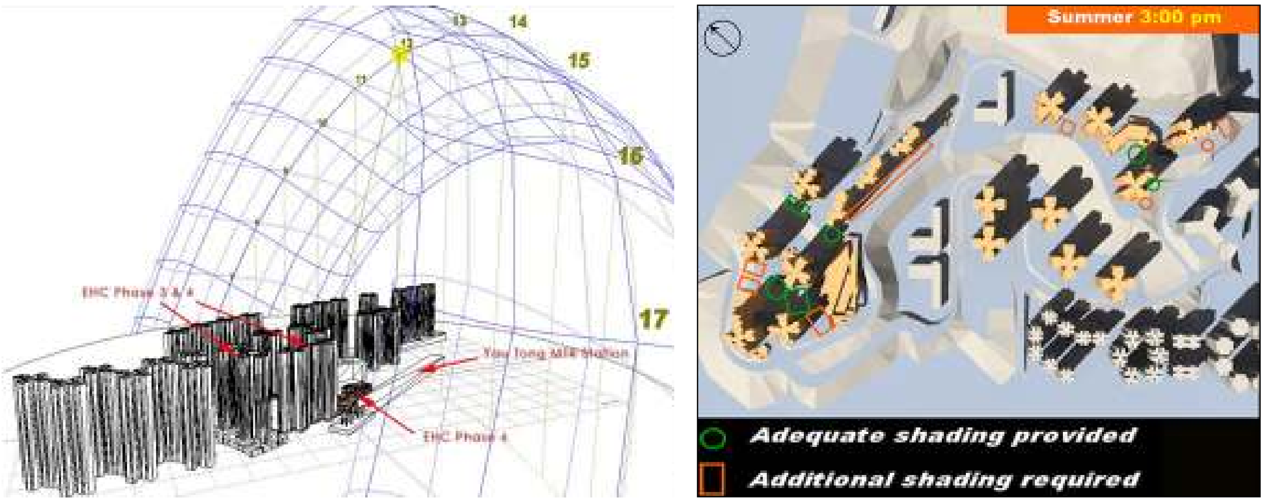

Figure 11 Using stereographic sun path diagram for open space planning

5. Solar Heat Gain

Hong Kong lies in the tropical climate zone. We use the micro-climate studies as building design tool to minimize solar heat gain in domestic units in order to have higher energy efficiency and better human comfort.

5.1 OTTV as an Indicator

The facade of a building is a complex system, comprising a range of components which coordinate to create a healthy living environment. Amount of energy saving resulting from a cost-effective and high performance facade design to maintain a thermally acceptable environment could be quantified through Overall Thermal Transfer Value (OTTV) which relates to fabric thermal mass, glazing, passive solar design, window design and shading devices. We have made use of the OTTV, as an effective indicator, for external wall colour scheme design.

5.2 Environmental Façade Design Initiatives

With the availability of latest proven simulation technology, we apply advanced computer programme which consists of modules of ventilation, thermal comfort and building energy analysis for computing the temperature profile for the internal environment of habitable rooms. Since the façade features that affect cooling load and achievable ventilation rates and daylight illuminance include (but not limited to) wall/roof construction, window/wall area ratio, glazing type, building orientation, configuration and separation, floor level, external wall finishes and colour, shading device etc., it demands an optimization study (e.g. Ant Colony Optimization (ACO) method etc.) taking optimization of the life cycle cost of the public housing blocks. We apply the study to design solar shading devices for reducing solar heat gain both on the building façade and in individual dwelling, to reduce the energy consumption on air conditioning and/or other mechanical ventilation means. In order to optimize the life cycle cost, the shading fins are integrated in the precast façade panels, taking into consideration of the transportation economy and loading for on-site installation.

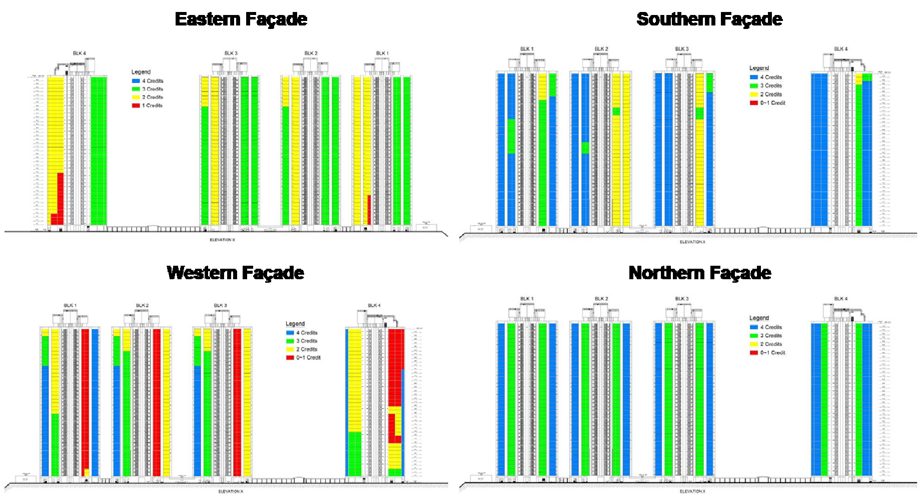

Figure 12 Climatic Colour Mapping in Environmental Façade Design

6. Miscellaneous

6.1 Holistic Environmental Planning and Design Approach

In terms of environmental planning and design, we adopt a holistic approach with balanced considerations on wind environment, natural ventilation and pollutant dispersion, daylight and solar heat gain etc. We apply a scoring system in working out the most optimal solution for the development. On-going researches are being conducted for establishment of local benchmarks. With a common goal and concerted effort by users, academia and researchers, regulators and practitioners, more healthy living environment will be created for now and the future.

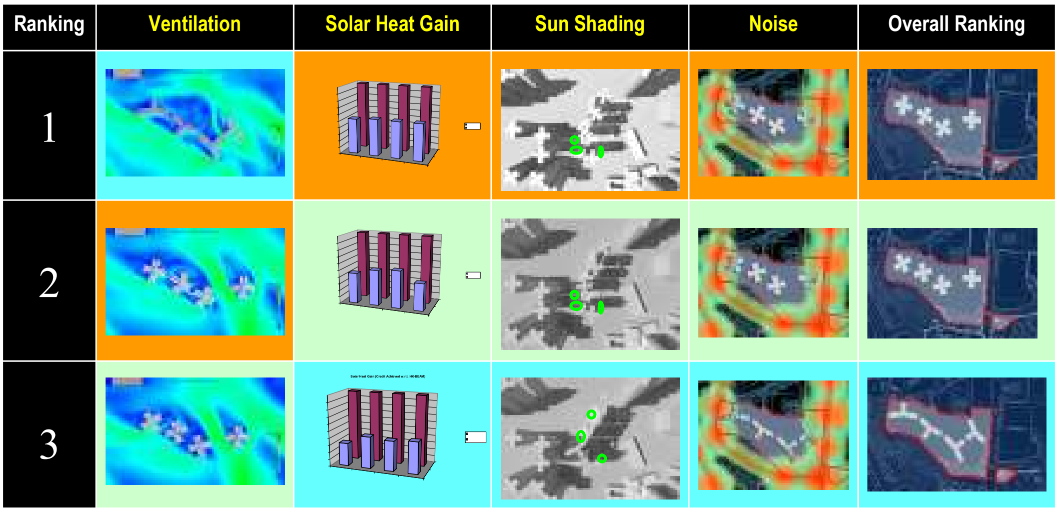

Figure 13 Comparison table on simulation results on different environmental aspects

6.2 Calibration of Simulation Tools at Planning and Design Stage

Apart from validating the simulation tools, we fine-tune the software by model calibration during the planning and design stages. Two completed high rise public housing developments with different micro-climatic conditions are selected for the model calibration. The process is composed of two parts, namely on-site measurement for actual field condition and model simulation for predicted field condition. The calibration exercise demonstrated the high accuracy of the simulation results with the software calibrated to local specific climatic conditions. The discrepancy is generally within 10%.

6.3 On-site measurements at Construction and Post Occupation Stages

Apart from fine calibrating the simulation tools, we conduct on-site measurements during the building construction and post occupation stages. The objectives of these on-site measurements are to -

a) test the effectiveness of current methodology adopted for the micro-climate study;

b) generate the data for the reference to benchmark the performance improvement of the projects as compared with the conventional design;

c) fine-tune the construction prior to building completion.

Initial results of on-site measurement for the projects on the pipeline indicated the actual wind environment, natural ventilation, daylight and thermal comfort conditions of the development under construction being comparable to the simulated ones at planning and design stage. Upon completion of the whole process, we shall generate field data for the statistical assessment of the study and establish benchmark for application in other projects.

Figure 14 On-site measurements for projects at construction and post-occupation stages

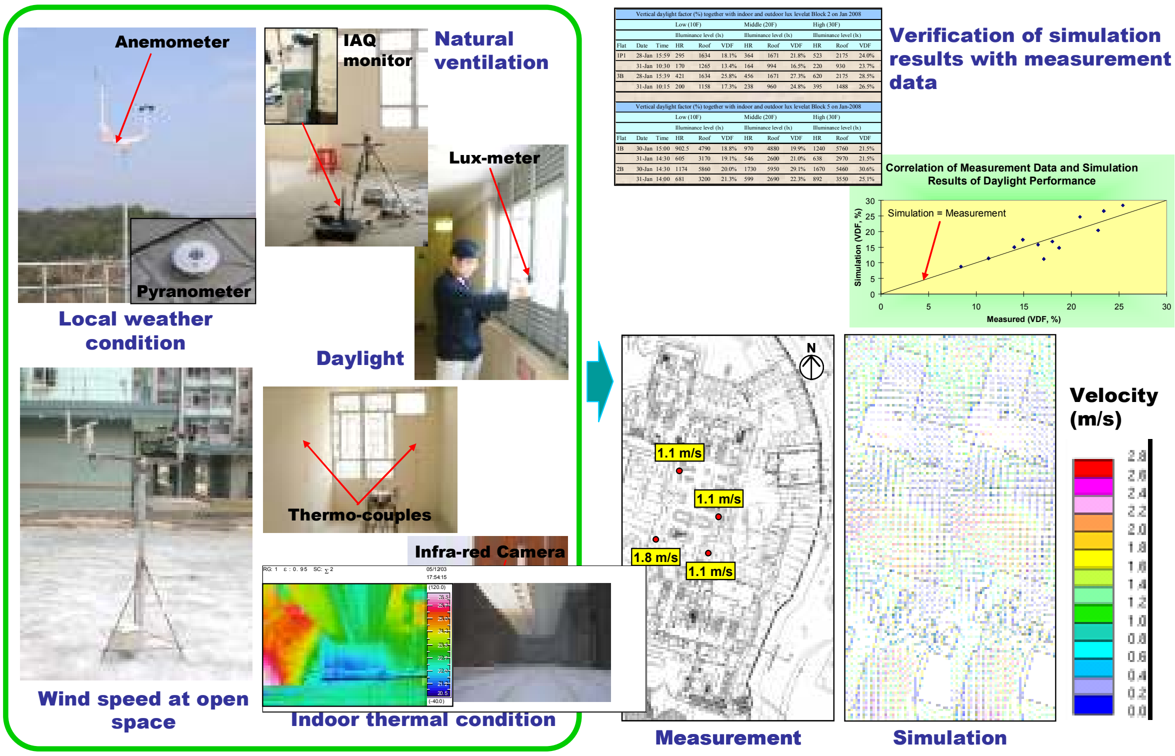

Figure 15 Process of on-site measurements

7. Conclusion

Public housing in Hong Kong has made an enormous contribution towards the well-being of the community. With the availability of the advanced simulation technology, the micro-climate studies are instrumental to improve the environmental performance for each new public housing development, which have long-term benefits to enhancing the built environment and quality of living of the society as a whole. Given a healthy living environment it helps to achieve a socially sustainable community. The application of the micro-climate studies in urban planning increases the practitioners' and public awareness of the importance of sustainable development in the society. This is a big challenge as well as an excellent opportunity to bridge the gap between policies and practice for the good of the coming generations. We need to continue to engage all stakeholders to gain their support as we articulate our strategies and lay out a road map in driving sustainability initiatives.

Summary

This study is an evaluation of a natural ventilation system in a large laboratory. The laboratory utilizes more than one hundred of the most current techniques for energy saving in order to reduce loads on the environment. The natural ventilation system is one of the techniques used in this laboratory. The ventilation system serves as a heat exchanger for a hygienic air supply by the stack effect through window openings and towards a large atrium with roof outlets. This system is controlled automatically by the metrological date of the BEMS system. In this project, energy consumption, air flow characteristics and thermal environment of the natural ventilation system were measured using 34 anemometers and 64 thermometers. This study was conducted in Nagano, Japan. Nagano is a cooler city than Tokyo. The study was performed from September to October 2006 and from June to September 2007. The measured data shows that the natural ventilation system can effectively create a comfortable indoor environment and reduce the loads on the environment. The comfort range was acceptable as shown by the -0.5 to 0.5 PMV. This mean was that indoor was neither warm nor cool. The reduction of environmental loads was approximately 100 [MJ/㎡] during one year.

1. Introduction

A natural ventilation system is a promising strategy to achieve energy-efficient laboratories and office buildings. It is expected to not only reduce air-conditioning loads but also to improve the level of comfort indoors. Therefore, such a system is being introduced with increasing frequency.

However, a natural ventilation system has problems such as an unstable amount of ventilation, deterioration of the thermal environment, external noise, and the inflow of smells and dust. Also, there have been very few studies documenting this system. Because of these problems, some buildings have actually discontinued the system[1)]. Therefore, more information about the operation and control of this system is needed.

The purpose of this paper is to estimate the amount of energy saving, clarify the indoor thermal environment and determine the air flow characteristics of natural ventilation.

2. Outline of test building

The laboratory is a large building located in Nagano, Japan. The climate this is cool compared with Tokyo. The mean air temperature is 5^0C lower than Tokyo in 2007. Therefore it was expected that it is opened long time in summer season. This laboratory total floor space is approximately 13,000 [m^2] and the maximum height is 37.9 [m]. Therefore, the internal load is large. In order to achieve 64% reduction of CO_2 emission in comparison to the 1990 benchmark, this laboratory utilizes many techniques to reduce its loads on the environment. Figure 1 shows the outside appearance of this building and Table 1 summarizes some building characteristics.

Figure 1. Appearance of test building

Table 1. Summary of Building Characteristics

Location	Nagano in Japan
Use	Laboratory
Number of floors	Seven floors and an attic room
Total area	29,525m^2
Total floor space	13,178m^2
Maximum height	37.9m
Date completed	February 2006

3. Outline of natural ventilation system

Windows for natural ventilation are positioned in every office room from the second through the sixth floor and in an attic room. There is no controlled natural ventilation on the fourth floor and the north side of the second floor because these spaces are laboratories and a dining room. Figure 2 (a) shows a photo and outline of a window for natural ventilation. The window size is 1.6 [m^2]. Figure 2 (b) shows the natural ventilation system. Air flow into the office rooms, into the atrium, then upward and out through roof outlets. This system utilizes the stack and venturi effects. A switching operation is controlled by the Building Energy Management System (BEMS) and manual systems. The BEMS is dependent on the outside temperature, humidity and velocity from April to October (Table 2). This system is operated not only in the daytime but also during the nighttime as a night purge system.

Table 2. Building Conditions

		Day time	Night time	Attic room
	Time	8:00-22:00	0:00-8:00	Day and Night Time

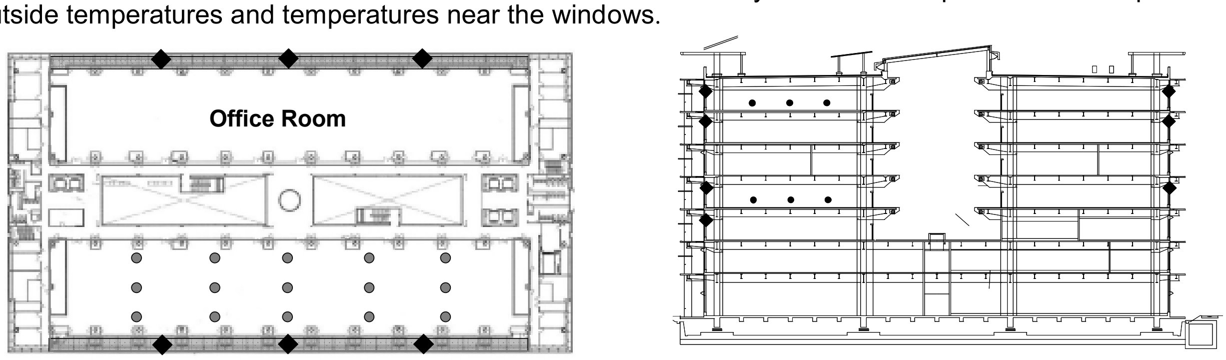
4. Method

The opening and closing conditions of the windows, the indoor thermal environment and the amount of energy saving were investigated in this study. Figure 3 shows the positions of the sensors. Confirmation of the opening and closing conditions was obtained after two year of accumulating BEMS system data. The data were recorded in 10-minute intervals. Estimation of the indoor thermal environment was obtained by using 15 thermometers and 1 anemometer on the south side of the third and sixth floors from June to September 2007. The amount of energy saving was evaluated using 32 thermometers and anemometers near the window. In the direction of the air flow was determined by the relationships of indoor temperatures, outside temperatures and temperatures near the windows.



(a) (b)

Figure 3. Position of sensors: (a) Floor view, (b) Outside view

5. Results and discussion

5.1 Outside air temperature and wind velocity

Figure 4 shows the monthly averages of the outside temperature and wind velocity. The mean air temperature was 12.1 [^{0}C]. The maximum temperature of the monthly averages was 25.9 [^{0}C] in August 2006 and the minimum was 0.6 [^{0}C] in January 2007. The wind velocity was less than 4 [m/s] during the entire measurement time.

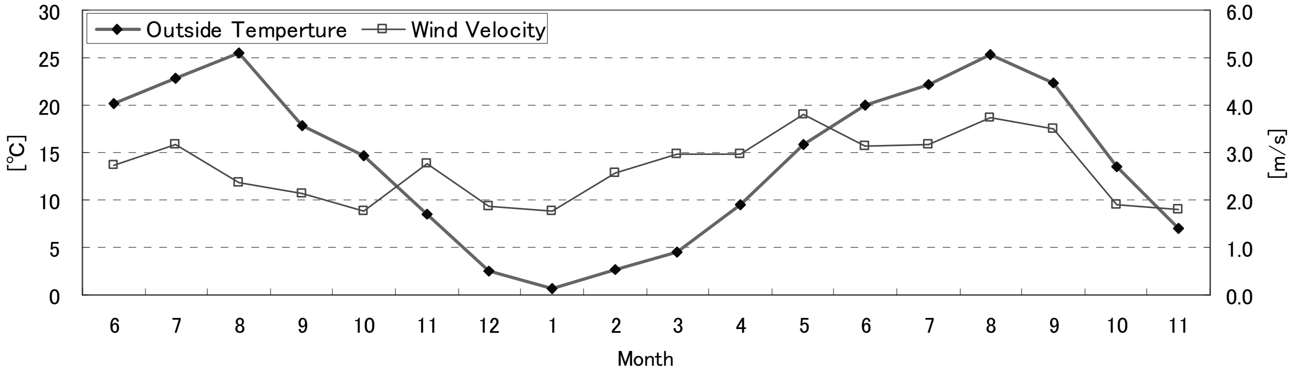


Figure 4. Monthly averages of outside temperature and wind velocity

5.2 Air flow characteristics by natural ventilation system

Figure 5 shows the air flow characteristics by natural ventilation when the velocity of the wind was 2 [m/s] and 10.1 [m/s]. As expected, the ventilation volume increased as the velocity of the wind increased. The air flow volume reached a maximum of 58,568 [m^3/h] when the wind velocity was 2 [m/s] and 245,444 [m^3/h] when the wind velocity was 10.1 [m/s]. For the 58,568 [m^3/h] volume, there were 11 air changes within one hour; for the 245,444 [m^3/h] volume, there were 45 air changes within one hour.

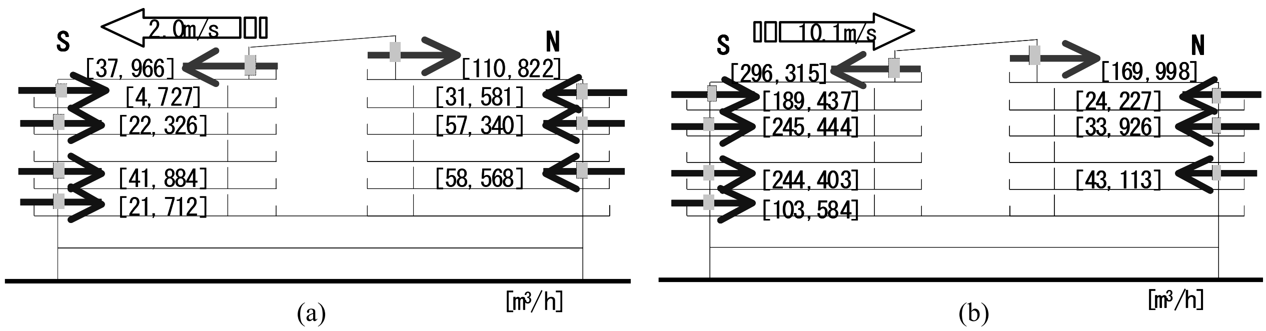

Figure 5. Air flow volume by natural ventilation: (a) Wind velocity 2 [m/s], (b) 10.1 [m/s]

5.3 Elapsed open time

Figure 6 shows the elapsed time for open windows from June 2006 to November 2007. The maximum elapsed time was 250 [h/month] in July 2007. This value of 250 hours is 34 [%] of that possible on July. The total amount of open window time was 1012 hours for one year. Even in the summer, the windows were opened, for example, 160 [h/month] in August. The reason is assumed to be that this laboratory is located in a cool climate. In the winter, the windows were a few opened though no control automatically. The reason assumed they were opened manually.

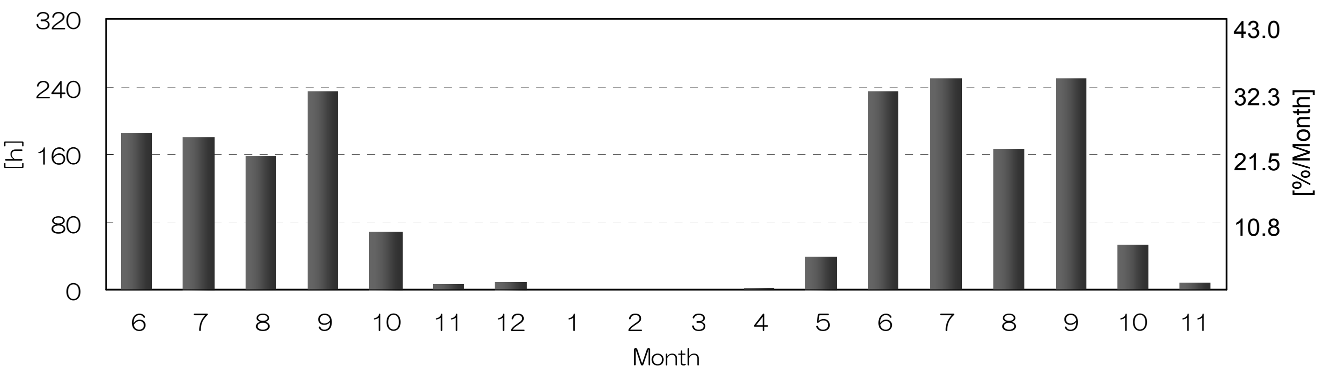

Figure 6. Elapsed time for open windows

5.4 Indoor environment

The indoor environment was compared for natural ventilation and air-conditioning. The maximum time at 26 [^{0}C] was 34 [%] for natural ventilation and the maximum time at 27 [^{0}C] was 58 [%] for air-conditioning (Figure 7(a)). In a comparison of the indoor wind velocity, the wind was less than 0.05 [m/s] for 62 [%] of the time for natural ventilation, and 91[%] for air-conditioning (Figure 7 (b)). Figure 7(c) shows the PMV evaluation for the natural ventilation. It was assumed that 0.50 was the [clo] value and 1.2 was the [met] value. The result from -0.5 to 0.5 is that indoor is neither warm nor cool. This result indicates that the indoor environment was comfortable.

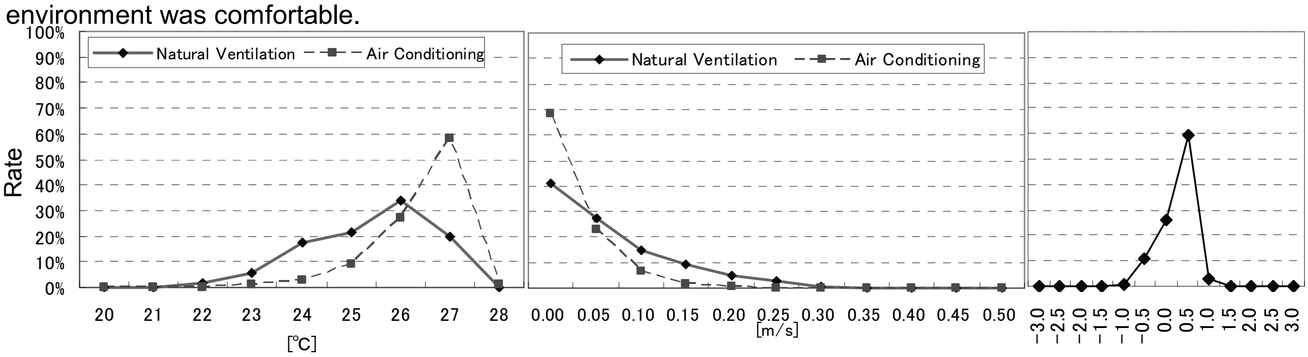

Figure 7. Indoor environment: (a) Indoor temperature rate, (b) Indoor wind velocity rate, (c) Evaluation of PMV

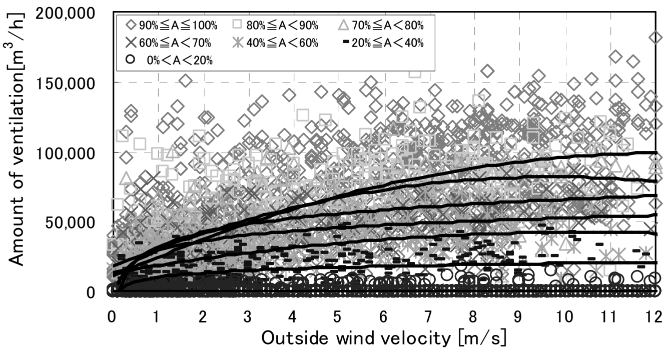
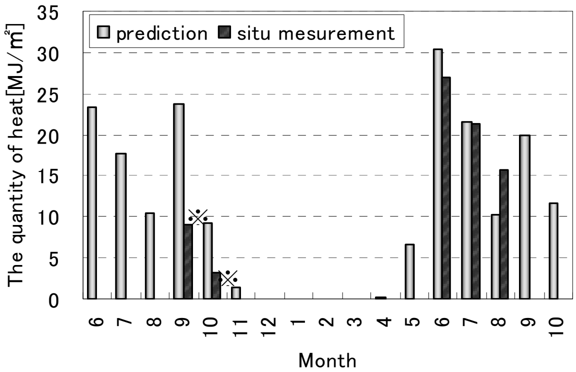
5.5 Amount of energy conserved

Figure 8 shows the relationship between inflow air and outside wind velocity. The line shows recentness carves by each rate of natural ventilation openings. This rate defined for all controlled ventilation windows is the ratio of opened ventilation windows to the total number of windows. Figure 9 shows the amount of energy saving by the natural ventilation system. The inflow air was assumed to be the relation of the outside wind velocity and the rate of natural ventilation openings. Therefore the amount of the inflow air during year was presumed from Figure 8. The situ measurements were smaller than the predicted measurements for September and October 2006 because the term was from shorter (17/09 to 13/10). The maximum energy saving (27 [MJ/m^2] heat saving) occurred in June 2007 for the situ measurement. The amount of energy saving was 103 [MJ/m^2] during one year.





※09/2006 situ measurement is 17/09/2006-30/09/2006
10/2006 situ measurement is 01/10/2006-13/10/2006

Figure 8. Relationship between outside wind velocity and inflow air   *Figure 9. Amount of energy saving*

6. Conclusion

This study estimated the reduction of loads on the environment and the influence on the indoor thermal environment by a natural ventilation system in a large laboratory building. This system was in operation 1012 hours during one year and the removed quantity of heat was 103 [MJ/m^2] during that one year. There was almost no difference in the operation time between the air-conditioning and natural ventilation system. For the natural ventilation system, the PMV evaluation was -0.5 to 0.5, which is that indoor is neither warm nor cool. This result indicates that the indoor environment was pleasant.

In summary, the natural ventilation system is efficient for energy conservation and can provide a pleasant indoor environment. It should also be noted that people can gain more pleasing effects from natural wind in comparison with air-conditioning. It is considered that this system has great potential for future applications.

Summary

This report shows a summary of the actual building project which adopted the air conditioning load reduction method integrated with the building environmental design. Generally, the thermal load of HVAC system is one of the major energy consumption sources of a building. Reduction of such load shall play a significant role on the environmental effect, but often in return causes the decrease of work-environment performance. This paper introduces a case of low story building (with floor area of 20,000 m^2), and the project's environmentally-conscious design and the evaluation of thermal performance based on the field measurement.

1. Project Outline

The building is a headquarter office in the suburbs of Tokyo. It is a four story building. Its typical floor plan consists of two wing zone with an atrium in between. Each wing is pillar-less, and length of wing is 33.6 m x 38.4 m which is approximately 1,500 m^2. South Façade, typical floor plan and outline of the building are shown in Figures 1, 2, 3, and Table 1, respectively.

2. Environmental Design Concepts

This building is placed upon a quake-absorbing structure. The main air conditioning system is "under floor air conditioning". A concept of the environment design in this project is the introduction of the environmental adjustment technology which can maintain the both of energy saving and comfortable indoor environment. In addition, and these technologies are integrated with the design of building at the same time.

As for the building, peculiar design is made with full-scale glass on north and south side. The adoption of seismic isolation structures, the big span PC slab and the furniture layout by "Universal unit patterns" to achieve a high functional work space. The air conditioning system unified with these design concepts was proposed. The outline of the various techniques is shown in the Figure 4.

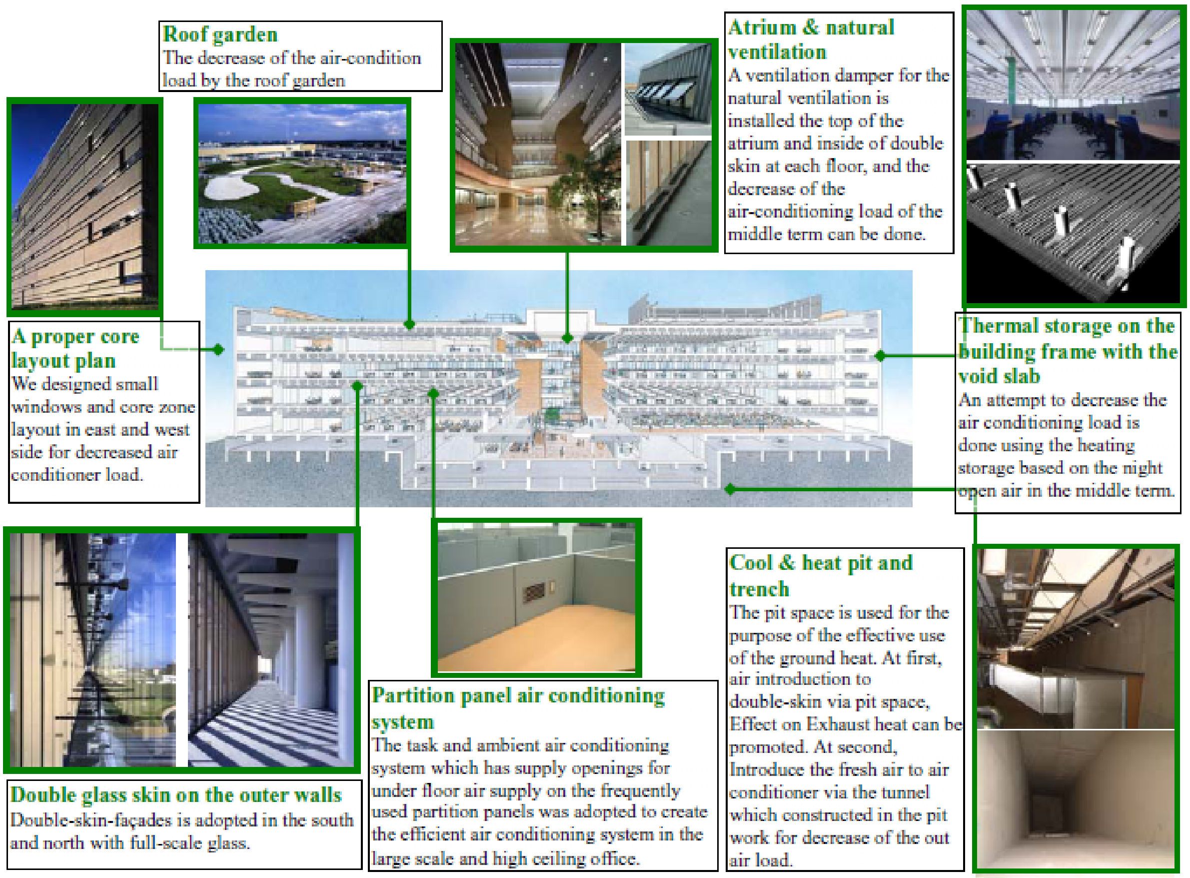

Figure 4. Main technologies of environmental design

2.1 System Outline of Double-Skin Façade (DS)

Double-skin façade (DS) covers the whole surface façade with glasses of full story height.

DS which has large scale opening will offer the comfortable work-environment from aspect of brightness and view. Under the climate of Japan, the double-skin glass is required to satisfy various functions such as the discharge of heated air between glasses in summer, the effective thermal insulation performance in winter and gaining the natural ventilation in spring and autumn.

These functions are achieved by the automatic control ventilation dampers in DS. DS has various ventilation dampers such as top ventilation dampers, bottom ventilation dampers, top ventilation dampers of atrium, and floor ventilation dampers of each floor. (Figure 5)

In the inside of DS during summer, top dampers and bottom dampers were opened, and heat in DS is exhausted by the natural ventilation. As a result, the thermal load of the building is decreased. The DS would be effective for the insulation performance if the top dampers and the bottom dampers are closed in winter. In middle season such as spring and autumn, natural ventilation can be useful by opening the bottom ventilation dampers, floor ventilation dampers, and top ventilation dampers of atrium. Patterns for controlling each ventilation dumpers are shown in Figure 6.

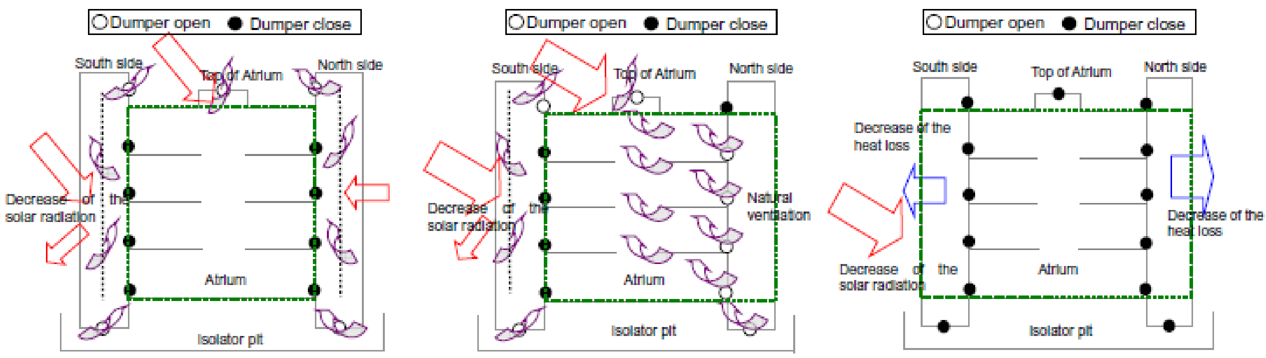

Figure 6. System outline of DS

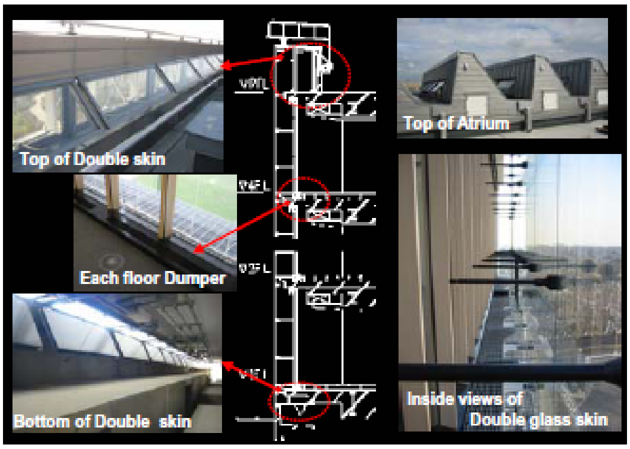

Figure 5.Ventilation dampers around DS

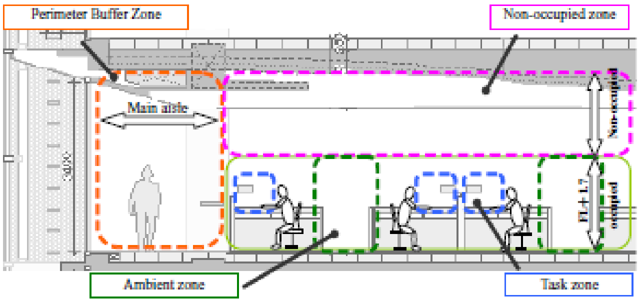

Figure 7. Outline of air-conditioning system

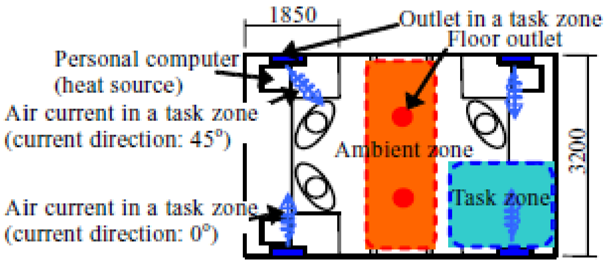

Figure 8. Booth layout

Figure 9. Partition-based outlet

2.2 System Outline of Task Air Conditioning (TAC)

The airflow is made to reach to the occupied zone (FL+1,700mm) by the under-floor air distribution system. The temperature makes stratification in higher zone than the occupied zone. The air-conditioning zone is divided into occupied zone and non-occupied zone in vertical direction. Moreover, it is divided into ambient zone and task zone that had been delimited by the partition in occupied zone. The air-conditioning system in task zone is the task/ambient air conditioning system (TAC) using the outlets installed in partitions (Figure 7)

Moreover, the main aisle is planned by the DS, so main aisle can state as perimeter buffer-zone. As a result, this building has no air-conditioning system for perimeter. In this building, the air-conditioning that adjusts to the characteristics of workspace - a high ceiling by a widespread space - is planned considering vertical zones an air-conditioning zone combined with a plan zoning. (Figure 8, 9)It is a combination system with under floor air-conditioning system of pressure type, process for design in the outlets installed in partition is as follows;

1) The air-conditioning capacity (the amount of air conditioner volume) in the task zone and ambient zone in total becomes less than planning capacity value (75CMH/person).

2) Using supply air volume control by differential pressure (pressure difference between under floor and upper floor, △P=15Pa) with under floor air-conditioning system.

3) Using supply temperature-set-point(19～20℃) of under floor air conditioning system.

2.3 System Outline of Thermal Storage on the Building Frame (TSS)

In this system, the void slab which forms the structure of the building is used as an air conditioning duct. At the usual air conditioning time(in daytime),the cooled air is supplied by under floor air conditioning system, and warmed return air passes through this void slab from the ceiling side. And the other way of the void slab is used for air supply route at night. (Figure 10)

The void slab is cooled with supply air from AHU (Air Handling Unit) at night, and this thermal storage (TSS) is filled with warmed return air from the room at the daytime. In summer, the peak load of electric power can be shifted by using both of the thermal storage and the ice storage system installed as a heat source. (Furthermore, in middle season, the cooling air conditioning load in daytime decreased with this thermal storage system using outdoor air cooling at night instead of using chilled water from heat source.)The void slab which used as air conditioning route has two kinds of forms. One is the form that circle ducts are installed in the slab which is close to perimeter zone. These circle ducts are used air conditioning supply and return route, and these are aimed for thermal storage and radiation mainly. This form is arranged on northern and southern four zones per each floor of the building (Figure 11). And the other form is the big mid-air layer in the slab installed in the interior zone. And the openings for an airflow connected with the mid-air layer are installed on the bottom side of a slab to face inside. (Figure 12)

When air conditioning at daytime, the air from AHU passes through this mid-air layer first, and then the air passes through the zone where circle ducts are installed. And finally it goes back to the AHU.

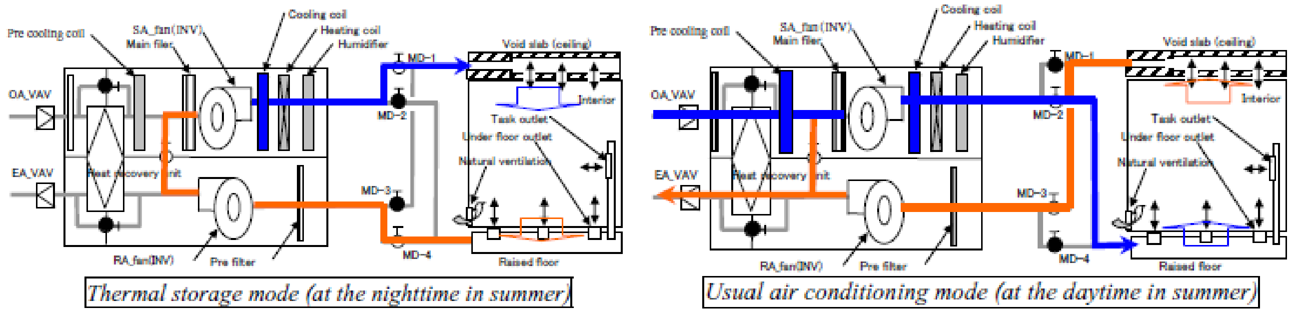

Figure10. Operation mode of air conditioning system

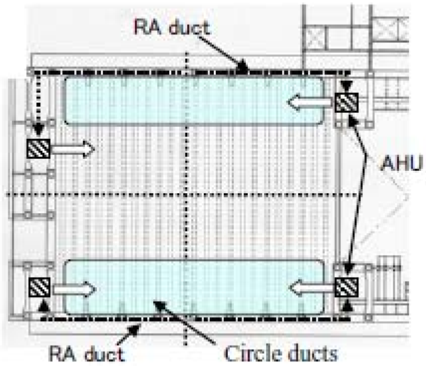

Figure.11 Layout of AHU

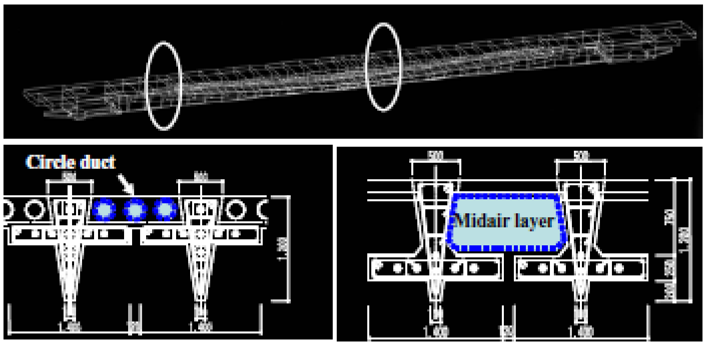

Figure 12. Outline of Void slab

3. Evaluation of Thermal Performance

3.1 Thermal Performance of DS

We carried out a performance prediction of DS by the simulation using the thermal ventilation network [2] at the design stage. In 2005, we confirmed the DS performance in operation at each season in summer, autumn, and winter. The measured items were temperature, the glass surface temperature, velocity in DS, and quantity of solar radiation etc.

In summer, the inside temperature of DS on the fourth floor was 35.4℃ on the south side, and 36.5℃ on the north side. The north side and the south were similar temperatures though the strong solar radiation beats down on only south side. The maximum temperature on the inside glass surface of the third floor were almost equal to the outside temperature in summer both south and north side. The results show that the solar heat shielding has been effectively removed the heat in DS. Profiles of temperature in each season are shown in Figure 13, 14, 15.The room temperature near the inside glass was almost equal to the room temperature set-point (27.5℃), and the thermal environment in the perimeter zone was maintained. As for the temperature in autumn DS, the difference of the fourth floor and the first floor was large(△T = 9.6deg). As for the north side, natural ventilation was performed, and the temperature in DS became almost the same temperature in the fourth floor to the first floor. The indoor glass surface temperature was 30℃ on the south side and 24℃ on the north. In addition, the air temperature in DS was 24-25℃, and appropriate thermal environment was maintained. Figure16 shows the measurement result concerning the solar heat gain ratio of DS. The solar heat gain ratio at daytime was about 0.23, and the high solar shielding performance was confirmed. Moreover, the measurement result concerning the thermal insulation efficiency in winter is shown in Figure17. The over-all heat transfer coefficient of DS was about 2.7W/m^2・K.

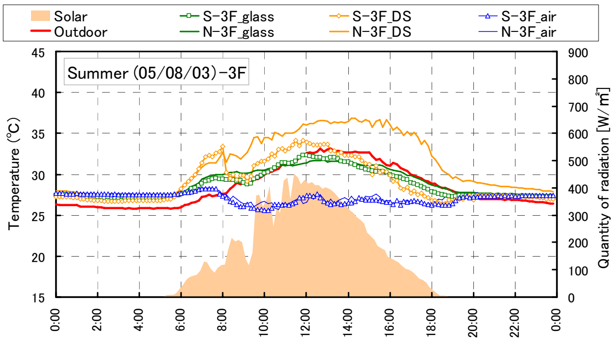

Figure 14. Result of field measurement at 3F in summer

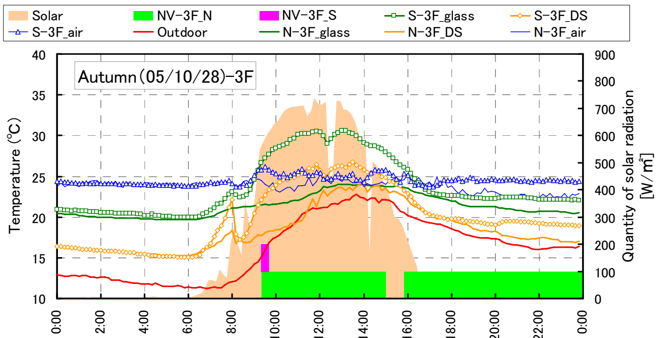

Figure 15. Result of field measurement at 3F in autumn

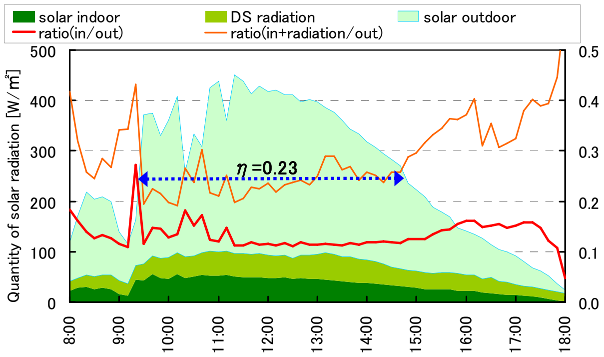

Figure 16 Solar heat gain ratio of DS

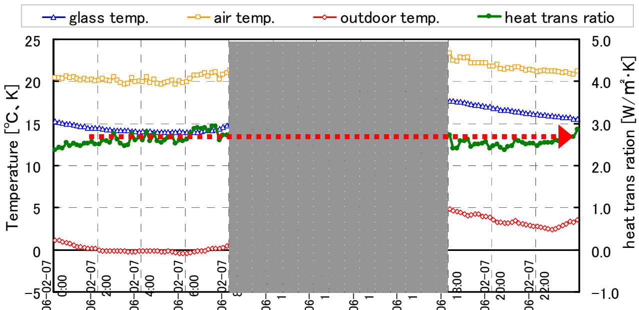

Figure 17. Over-all heat transfer coefficient of DS

3.2 Thermal Performance of TAC

One of the advantages using TAC is to provide fresh air to the occupants' breathing zone directly. Clean fresh air may increase work productivity of the occupants. The air change effectiveness was evaluated using SF6 tracer gas. Tracer gas concentration with or without supply air from partition-based outlet were monitored every second. So the effects of the both of partition-based outlet and the floor outlets were calculated, respectively. The experiment was conducted on 22nd (Saturday) and 23rd (Sunday) of October, 2005. [4]

Task air conditioning involved blowing out air from outlets on partitions. The efficiency of ventilation was monitored to understand the effects of the task air conditioning on its quality of the air in the respiration zones of people in task and ambient zones.

The monitoring conditions were set for different airflow rates at the task and floor outlets, different outlet angles, and different places of gas application.

In the conditions in which the gas was diffused through the task outlet, the air was blown at angles of 0deg, toward person, and 45deg. (Figure19)

Melikov et al. [5] conducted a laboratory experiment using a different air terminal device (ATD).

A comparison with the results of Melikov et al. is shown in Figure 20.

These were similar to the values calculated by Melikov et al. for a task air conditioning system that blew out air from the front, and the test was carried out in a laboratory.

Therefore, TAC in this project was effective in supplying fresh air to the occupant on the seat.

Figure 19-2 Location of gas generation and monitoring points (Section)

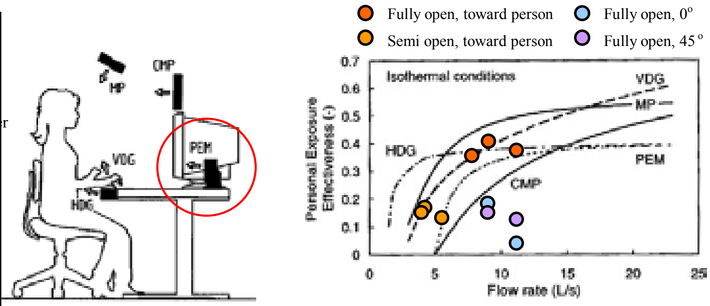

Figure 20 Comparison with the results of Melikov et al.

3.3 Thermal Performance of TSS

To grasp the performance of thermal storage system, we measured the temperature distribution, thermal load and energy consumption in an actual state of operation. The measurement elements were the air supply volume of AHU and the thermal storage driving time, and examined a characteristic of the system and the best operating method at the third floor south zone (366m^2) on 1st to 25th of August, 2006.

We prepared the total of four cases and a usual operating mode (CDN: Cooling Down) for the comparison and to a reference of three TSS modes. (Table 2)

Moreover, TSS driving mode was tried in the same air-conditioning zone with the number of patterning to reduce the deflection of the indoor thermal load in each case. It was assumed that the CDN and TSS （the comparison verifications） operation were usually done for the measurement period on the condition (verification day) which the thermal load situation was near.

In Figure21, the temperature of the mid-air is almost the same level at night time, between CDN and TSS at night time though the temperature of the mid-air slab in TSS had lowered at the air-conditioning time (daytime). So, we guessed for using up to descend, and to have been operated on that day by a proper amount of thermal storage.

Figure 22 shows the comparison of the peak loads.

The peak cut operation will be done from the result which could reduce both thermal and fan power peak load by CASE3 (air volume rate 50%, Operation time 2h).

Next, the primary energy (both cooling and fan power consumption) are shown in Figure23. CASE3 could be decreased the primary energy compared with CASE1. It is because the high effect of the reduction of fan power that accounts for about 30 percent of the total energy.

Table 2. Condition of verification for TSS

Case	CASE 1	CASE 2	CASE 3	CASE 4
mode	CDN	TSS	TSS	TSS
air supply Volume	–	50%	50%	100%
TSS operation time	–	1h	2h	2h
date	8/16-18 8/21-25	8/2	8/1 8/8-11	8/3

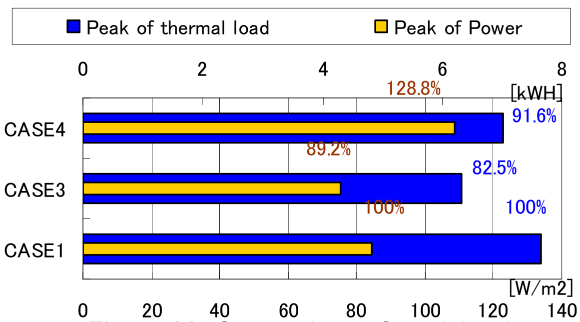

Figure 22. Comparison of peak load

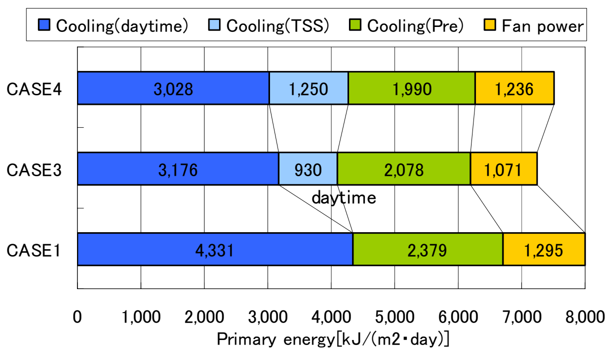

Figure 23. Comparison of total energy

3.4 Filed Measurement of Energy Performance

Figure 24 shows the annual heat source load. By effects such as reduction of thermal load by environmental technologies (DS, natural ventilation, etc), hot water load in winter, and both cold and hot water load in middle season were little. Figure 25 shows the primary energy consumed in this building from July, 2005 to June, 2006. The primary energy consumed value was 1,657 MJ/m^2 ･year.

It was estimated that 21.9% (comparison building value: 2,121MJ/m^2･year) of reduction in the primary consumed value could attain by the DS, TAC, and various technologies (ex: natural ventilation, cool and heat tubes, using sunlight, etc). And, it was 16.3% less in the primary consumed value that compared the standard office building in Japan (1,980MJ/m^2･year).Table 3 shows primary energy equivalent value by calculation.

Table 3. Primary energy equivalent value

Electirc power	Natural gas
9,760 MJ/kWh	45,000 kJ/Nm3

3.5 Environmental Assessment (CASBEE)

CASBEE (Comprehensive Assessment System for Building Environmental Efficiency) in Japan is an evaluation tool that is intended for implementation of the environmental assessments based on new concepts including BEE (Building Environmental Efficiency).

The concept of this project is “Improvement of environmental quality and performance” and “Reduction of environmental load” for global headquarters.

At the design stage, we evaluated with CASBEE, it was a classification of S-rank (Excellent BEE=3.7). [1]

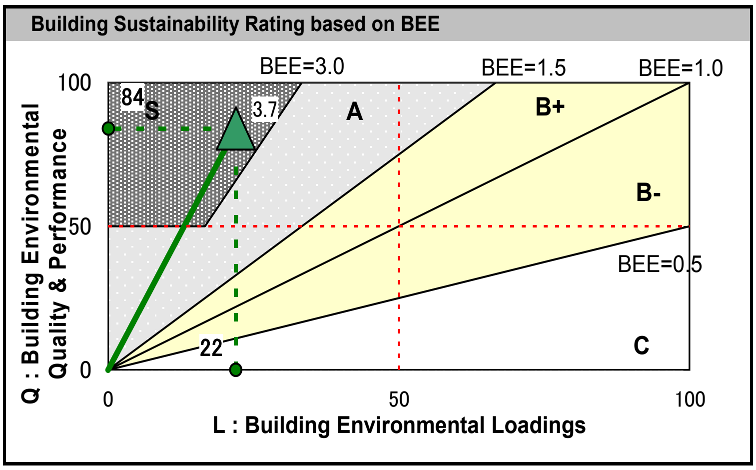

Figure 26. Result of CASBEE
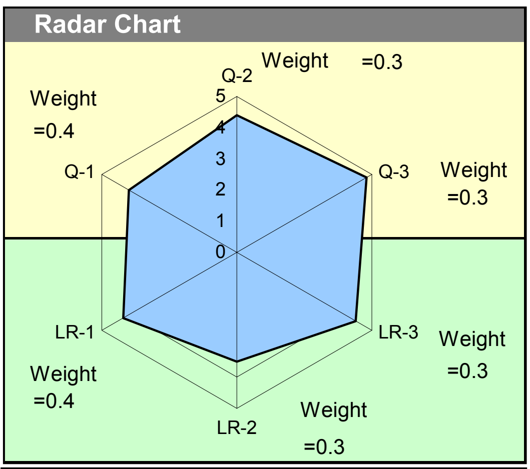
(Environmental assessment in Japan)



Q-1. Indoor Environment
Q-2. Quality of Service
Q-3. Outdoor Environment on Site
LR-1. Energy
LR-2. Resources and Materials
LR-3. Off-site Environment

4. Conclusion

The concept of this project is “Improvement of environmental quality and performance” and “Reduction of environmental load” for global headquarters. So, this building has integrated various environmental technologies.

We were able to obtain the following findings about both “Indoor Thermal Environment and “Reduction of Thermal Load” through the field measurement.

1) It was confirmed to be maintained within the range where the thermal environment at the perimeter zone was proper at each season. For the thermal performance evaluation about DS, the solar heat gain ratio shows about 0.23 and the U value shows about 2.7W/ m^2.Though DS is composed of the clear glasses, the performance of solar shading show the same as the high efficient heat reflection glass and the performance of U value shows the same as the pair glass.

2) We verified the performance of the air change effectiveness in an actual office with a thermal mannequin and tracer gas method too. The performance of TAC in this building shows the same tendency with Melikov’s laboratory experiment.It was shown that TAC was shown to be effective in supplying fresh air to the occupant on the seat.

3) We confirmed the peak cut performance about the energy consumption of the air conditioning system.TSS operation has the possibility which could be decreased both peak load and the primary energy compared with usual system based on the field measurement.

4) It was estimated that 21.9% reduction in the primary consumed value (comparison object value: 2,121MJ/m^2/year. this value is predicted by not installed various energy saving technologies in this building.) and, it was 16.3% less in the primary consumed value that compared the standard office building in Japan (1,980MJ/m^2・year).

5) From the aspect of the comprehensive environmental performance evaluation, it was a classification of S-rank (Excellent BEE=3.7) using Japanese evaluation tool called “CASBEE”.

Keywords: sustainable housing, energy efficiency, thermal performance, gated community

Summary

This paper will discuss the present integration of sustainable features in a self-contained residential development in the growing urban density in Malaysia - consisting of 36 units semi-detached and 4 units terrace houses – within the constraints of commercial viability of such a project. The projects features the layout planning for green-shared landscaped courtyard area, a rainwater harvesting system links all units for landscaping needs, double brick walls for energy efficiency, heat reclaim system for hot water and roof insulation for heat gain reduction. Each unit features a four-storey structure with a double frontage design, foyer space in the 1st level. Dining, kitchen and living on the 2nd level. Bedrooms and a family room on the 3rd and 4th level. The focus includes the outcome of an evaluation of the energy efficiency impact of the double cavity external wall and a heat reclaim system used in each unit in the development - where air conditioning heat is reclaimed at night for hot water use in the morning. A solar shadowing impact of two adjacent developments consisting of high-rise condominiums on the entire developments for different times of the day were also done to ascertain roof surfaces which can be used for grid connected solar panels. The paper presents an attempt by an ecological conscious developer to integrate green features – including rainwater harvesting and communal strategies such as shared green space within the commercial and resource constraints of a project.

1. Introduction

The paper presents a recent housing development in which the developer attempted to integrate a range of sustainable features, within the costs constraints of the project. It represents an initial model for upper middle class housing – a section of society, which typically consumed high energy within their lifestyle. This residential development consisting of 36 units of semi-detached and 4 units terrace houses in a gated community. Each unit's built-up area ranges from 3719 sq.ft. to 4333 sq.ft. The units are aligned in a courtyard arrangement with a central communal garden with communal facilities such as gym and multi-purpose hall located at opposite ends of the courtyard. Of particular interest is the impact of the use of double cavity brick as external wall material in the first three levels of the house – particularly in terms of reducing the heat gain into the internal space. The impact in terms of reduction in energy use and improved occupant comfort are also of interest. Ecological features implemented in the development but not tested in this study include a rain harvesting system, which collects rainwater for landscape maintenance in the development.

Due to the rapid rise of urbanization and development in urban areas in Malaysia, a rise of air-conditioning use has also been observed. This is related also to the widespread availability of technology and the rising income and lifestyle of city dwellers. The assumption of air conditioning usage reverses the prioritization of bioclimatic strategies from open-planning/lightweight construction towards more heavyweights, thermal mass, compact massing and planning. The following is a summary of a study of the impact of selected features in a residential development consisting of 36 units of semi-detached and 4 units terrace houses in a gated community.

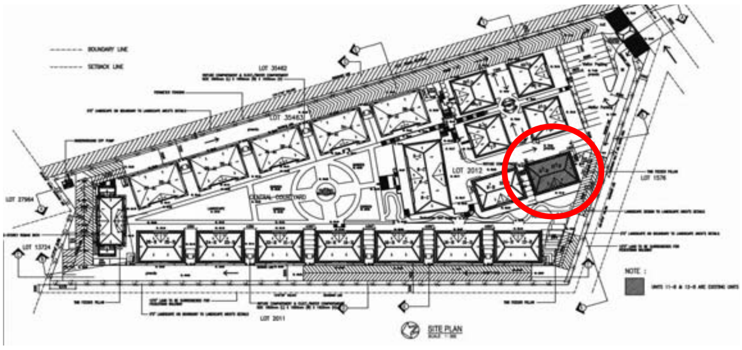

Figure 1 Site Plan - Whole development highlighting the location of unit modeled in study

1.1 Orientation of model (whole development)

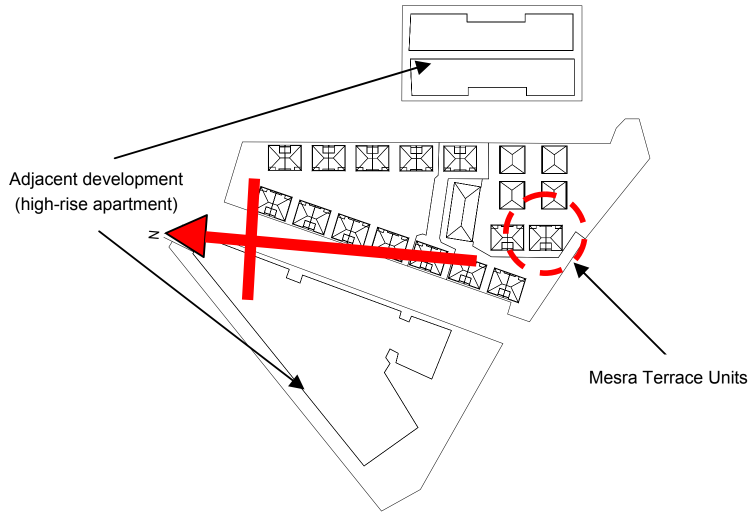

Figure 2 Orientation of model – Whole Development including all units and adjacent high-rise apartments (selected unit for study highlighted)

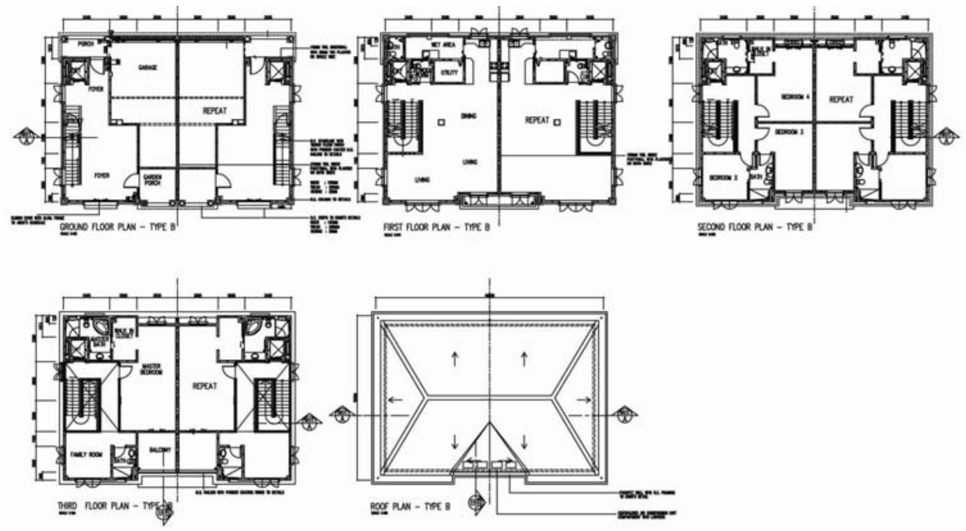

Figure 3 Typical floor plans (All floors - Selected unit – BEDFORD)

1.2 Layout and Planning

The layout of the development is aimed at a communal way of living, where units are arranged around a central courtyard that acts as communal space. In this way, green open spaces are utilised in an optimum manner, and maximised for the benefit of the community.

Figure 4 Overall layout and planning of the Mesra Terrace Development

1.3 Simulation Studies – Multi-Zonal Analysis

The MULTI-ZONAL ANALYSIS tool is used to analyze the impact of infiltration and natural ventilation in the building on the predicted temperatures within the internal spaces which are linked an assessment of the thermal comfort conditions of occupants. Under Malaysian conditions, comfort conditions for users and occupants can be enhanced through both mechanical means and enhancement of certain passive design features. Basically under the Malaysian conditions, comfort is difficult to achieve - particular in the daytime - but can be primarily enhanced through inducing cross ventilation and air movement and reducing solar gain and heat gain from all potential sources. The analysis uses a zonal-airflow model to calculate bulk air movement in and through the building, driven by wind and buoyancy induced pressures.

1.3.1 Internal Temperatures

The internal temperatures were analyzed using a multi-zonal tool. The following figures show the internal temperature patterns for one week in January for selected spaces in the house. The results also show trends for one representative day in January. The internal temperatures are compared with the external temperatures taken from the external weather data used in the program. The focus of the output is:

- The foyer, family and living, and selected bedrooms
- With and without cavity brick wall for selected areas

1.4 Assumptions (all models)

1.4.1 'All windows closed'

In almost all models and options, the windows are assumed to be closed. The aim here - and justification - is to attempt to highlight the impact of the double wall option on the internal temperatures. This serves to isolate the impact of heat gain through conduction gains through the external wall. Hence ventilation gains are not included in this calculation (except for infiltration gains - which is set at 0.5. ac/hr).

1.4.2 'With selected windows opened'

In the multi-zonal analysis, only the categories 'External glazing', 'Internal glazing' and 'Door' are important. Elements in these categories are called 'openings'. They may be assigned data allowing the tool to simulate the passage of air through them. An opening type is a type of building element which can be selected and consists of a specification of the element's air flow characteristics and the way they vary with time.

In the energy analysis, it is assumed that only the windows in one bedroom are opened for a total of two hours to 'air' the house.

In terms of internal temperatures, under naturally ventilated conditions i.e. the more windows are opened, the more the internal conditions will follow closely the external climatic conditions. Under such naturally ventilated conditions, improved comfort conditions depend on higher indoor air speeds. The flow of outdoor air through a building extends the upper limit of the comfort zone beyond the limit for still air conditions and this provide a direct physiological cooling effect. Hence when efficient cross ventilation is achieved during daytime, the temperature of indoor air and surfaces closely follow that of the ambient air temperature.

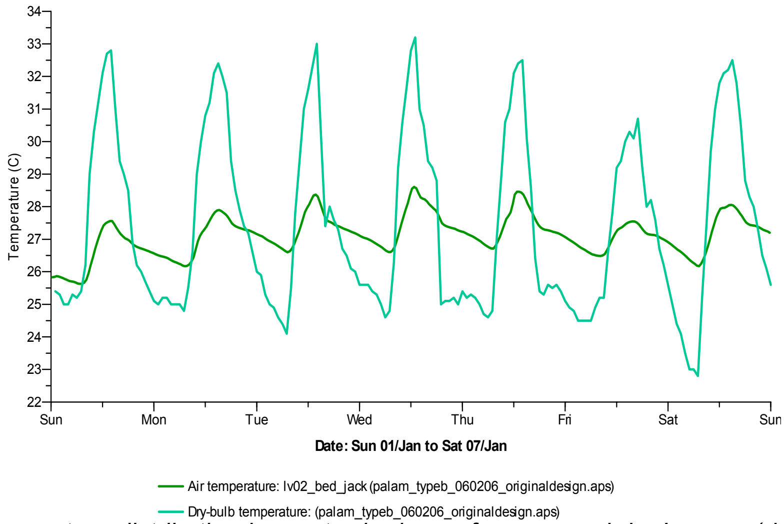

Figure 7 *Temperature distribution in master bedroom for one week in January (internal vs. external temperature) with cavity wall (windows closed, A/C OFF)*

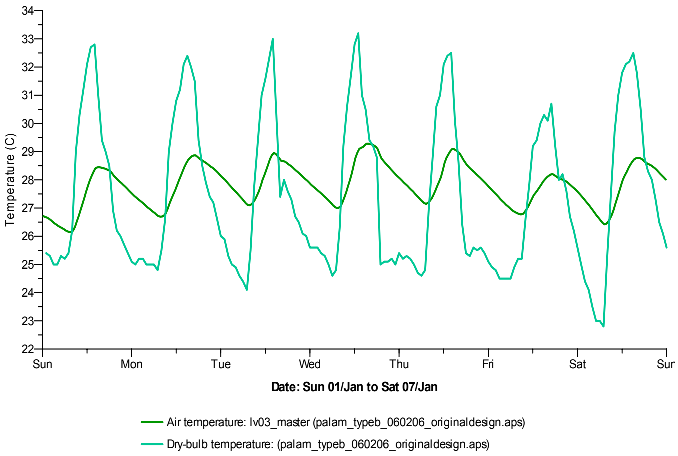

Figure 8 Temperature distribution in master bedroom for one week in January (internal vs. external temperature) without cavity wall (windows closed, A/C OFF)

2. Energy Saving Estimation of the Condenser Heat Reclaim System

An energy saving feature of the development is the heat reclaim system installed in selected rooms in all units. Typically there is an amount of energy required for the heating of the water - this is linked to all the bathrooms within the house. This heating requirement if supplied by conventional electrical heaters, the total cost of energy use per year would be considerable. Heat rejected from the air conditioning condensers represent energy that can be reclaimed at the supply water tank to save a considerable amount of the total cost of water heating.

2.1. Estimation and parameters in calculation

Assuming that the heat reclaimed from two cooling units of full capacity (2.93 kW operating according to the schedule), the coefficient of performance of the air-conditioning system (COP) is taken as 2.0 and the cooling set temperature is taken as 24°C.

Using the annual weather conditions data for Subang Jaya (1995), and according the operation schedule as shown above, the total electrical energy can be estimated for the cooling of the two of the bed rooms in the unit. This calculation takes into consideration the climatic variation throughout the year. The combined mechanical and electrical efficiency of the compressor can be considered in the range of 65%, and the heat exchanger efficiency at the water storage tank is taken as 80%. The following equations are used in this calculation;

$$COP = \frac{Q_L}{W} \quad (1)$$

$$Q_H = Q_L + W \quad (2)$$

Where COP is the coefficient of performance of the refrigerator, Q_L is the cooling load, Q_H is the heat rejected at the condenser and W is the compressor work. Table (1) shows the values of Q_L and the reclaimed heat for the whole year.

Table 1 The values of Q_L and the reclaimed heat for a whole representative year.

Date	Q_L(MWh)	Q_H(MWh)	$Q_{Reclaimed}$(MWh)
Jan 01-31	1.3	1.2	1.0
Feb 01-28	1.2	1.2	1.0
Mar 01-31	1.5	1.5	1.2
Apr 01-30	1.5	1.5	1.2
May 01-31	1.7	1.6	1.3
Jun 01-30	1.6	1.6	1.3
Jul 01-31	1.7	1.6	1.3
Aug 01-31	1.4	1.4	1.1
Sep 01-30	1.5	1.4	1.2
Oct 01-31	1.5	1.5	1.2
Nov 01-30	1.3	1.2	1.0
Dec 01-31	1.2	1.1	1.0
Summed total	**17.3**	**16.9**	**13.5**

From the results presented Table 1, it can be concluded that **a total of 13.5 MWh of heating energy can be saved which means a total reduction in the water heating cost of about RM 3800 per year**.

3. Rain Water Harvesting

The development is designed with a Rain Water Harvesting system to capture runoff from the roof. The system is designed to collect water that is captured at gutters into downpipes and store it into an underground tank placed at the center of the courtyard to for landscape maintenance purposes. As Malaysia receives an average of 1000mm of precipitation annually, the development capitalizes on this advantage to retain some amount rather than to let all the free water runoff to the public sewer.

The system focuses on reorienting the plumbing design so that water from gutters can be brought down using uPVC pipes directed it to a 2ft-deep sump. The water then goes into a filtration system to filter out debris and to make sure the stored water is clear of sediments. These waters will then be stored in a large tank underneath the central pond at the courtyard centre, and can be used by using a motorized pump to push the water back up and water the lush landscape.

The design also takes into advantage the natural slope condition of the site, placing the 4 x 20 x 1.5m rectangular tank in the dead centre on the site before re-distribution. The tank is connected by 5 main lines of water catch pipes from 2 main 150mm Ø uPVC feeding pipe lines.

With proper technology, these waters can also be used for day-to-day needs like drinking and cooking purposes. If the maximum collection is 90% efficient, the net amount of rainwater harvested annually amounts to approximately 1,200,000 litres that would benefit in saving water thus reducing water bills.

4. Roof ventilation design and insulation

To reduce internal temperature in areas below the roof, the roof was designed with heavy insulation. The roof design is a 20mm thick concrete roof tiles with light grey color finish. The use of light color was chosen to help repel heat. The roof tiles are made to rest on timber truss rather than a galvanized iron (G.I) truss. G.I. is commonly practiced in the Malaysian construction industry due to its low cost. The use of timber truss is because timber has a lower emissivity value which emits lower heat radiation. The insulation material used is a woven insulation foil, backed by fiber quilts and secured by a wire mesh to the soffit of the roof truss. As commonly practiced, these layers are then covered by a plastic sheet to make sure the fibres or dust will not fall and gets into the interior space. Not only that the layers repel heat, it also repels noise.

Figure 11 Roof construction layers

4.1 Roof ventilation system

To help trapped air escape from the roof area, the ridge is installed with ventilation holes using a ventilation product. The product is rubber based and is flexible. It is placed under the top most tiles before the ridge. As it is placed at the top, hot air raises and escapes through the deigned outlet. Figure 12 is showing the test session on the product. The system was testing for smoke escape as well as rain penetration at high horizontal winds. These studies were also crucial for fire departments approval for the building design's low party wall. The study shows a majority of smoke flow out from the roof area through these vent holes suggesting the performance of the product which makes the roof area to "breathe" which increases thermal comfort.

Figure 12 Roof construction mock up: to test the ventilation device effectiveness.

5. Discussions

Overall, the results demonstrate the thermal benefits of increasing thermal mass i.e. use of a more massive structure (such as a double cavity wall) - which amongst others, are the attenuation of the daily temperature swings and slight delay in reaching peak temperatures during the day. The difference in peak temperatures may range from 3°C to even 6°C during the day. The day night variation is also reduced from a range of 23-33°C to 26°C to 28°C. In this study, the indoor peak temperatures are found to occur at about the same time as the outdoor peak temperatures. The results thus demonstrate that the double wall has a positive impact on considerably decreasing surface temperatures and consequently, internal temperatures within the house.

The results reflect the general principle that the use of increased thermal mass in a building reduces and attenuates peak temperatures during the day. However because it stores some of the heat, it later releases some of these heat during the night –partially to the outside and partially to the inside of the building.

In colder climates with large diurnal swings, the re-radiated hear may be beneficial to offset heating requirements, however under the hot, humid climate, the increase in nighttime temperatures may lessen the impact in terms of energy savings – particularly when the A/C is used predominantly at night. Hence in such a case the use of ventilative cooling (cooling effect through air movement and ventilation) can be an effective strategy when employed at night.

The significant effect of the double wall can be particularly felt in space facing the full impact of the afternoon sun such as the master bedroom which shows a marked decrease in peak temperatures in the afternoon. (Refer *Figure 6 and 7*)

Similar results has been found in studies by Szokolay (1990) for example, which showed that in the tropical humid climate (in the case of Queensland), most comfortable conditions all year round was achieved by a 'heavy' construction (in this case slab-on-ground floor, reverse brick walls with insulation on the outside of the mass layer, a well-insulated roof and full shading of all windows) through the application of heavy construction. Cooling through passive means such as ventilation should be encouraged at night.

This has been supported by other studies such as Machado (1999) who tested a house design for the climate of Venezuela. The study found that the best performance was achieved by a heavy weight building with night ventilation. Soebarto (1999) also found that for the climate of Jakarta (Indonesia) for a heavyweight house, daytime closure of the windows kept the inside 3-4 deg K cooler than the outside. Hence in purely temperature terms, a building (with closed operation during the day) is slightly better as the heavier mass would also reduce the peak load and hence reduce energy use.

Conclusions

The project is an important attempt to incorporate a range of sustainable features which are in line with international rating systems and in line with the general definition of sustainability. In developing countries such as Malaysia, due to the drive for progress, sustainability is not a cultural-ideological movement - compared to the more developed countries. Many of the features in this project were initiated by the developer, while designers, researchers and suppliers provided the technical input in terms of design, specification, simulation and calculations. The developer is working within the constraints of not only, lack of institutional support within this context for sustainability, but also the press of fulfilling commercial and financial viability of the project. Though this project represents an urban gated community development targeted for the upper middle class homeowners, it can be argued that sustainability should be targeted to this group of people since they have the means of both ' spend' and 'save'. They are also a strata within society who are open to new forms of living, and whose level of education and lifestyle have given them exposure to sustainable ideas and ways of living. This is an important project which highlights that sustainability can be practised within the time constraints and financial limits of a commercial project.

Keywords: CHP, micro-turbines, national electricity market

Summary

Deploying gas micro-turbines as a source of combined heat and power (CHP) in residential complexes offers the potential for substantial reductions in overall energy use and greenhouse-gas emissions. Here we use mathematical modeling to predict the operational behavior of micro-turbine CHP in a hypothetical network of residential apartment buildings.

In our models the micro-turbines generate electricity for local needs and for participation in the national energy market, while delivering space heating and hot water to the residences in the network. The micro-turbines are operated using management strategies that optimize economic performance while satisfying the heat and power demands of the residential customers. The heat and power demand data has been synthesized using multiple information sources and is intended to represent a plausible demand pattern for residential apartment buildings in Victoria, Australia.

We demonstrate that deploying gas micro-turbines for CHP in residential apartment complexes promises substantial reductions in energy use and greenhouse-gas emissions. We also demonstrate that micro-turbine CHP can be an economically viable option for residential apartment complexes in Southern Australia, at least under certain market conditions. Our experiments uncover relationships between micro-turbine generation capacity, utilization of this capacity, energy demand and overall economic performance. The insight gained from the experiments has relevance in the specification and design of future sustainable buildings that incorporate micro-turbine CHP.

1. Introduction

Thermal generators for electric power only transform part of the chemical energy contained in their fuel into electrical power, most of the difference is transformed into heat. Data from the Combined Heat and Power Partnership, US Environmental Protection Agency [2002] indicates that a typical steam turbine used in a large coal fired plant has an electrical efficiency of between 15 and 38% while a micro turbine with combined heat and power (CHP) has a total efficiency (including heat) between 56 and 75%. Therefore, using micro turbines situated close to heat demand can reduce the emission of greenhouse gases compared to the currently dominant central generation model with large power plants far away from potential heat demand.

One example for using distributed generation in order to reduce CO_2 emissions is the TrigenAir technology project at the Hornsby Central Library where CSIRO Energy Technology installed a micro turbine driven system that not only provides electrical energy but also uses the waste heat of the turbine to provide air conditioning services [CSIRO Energy Technology, 2004].

Control strategies for single CHP plants have already received considerable attention in the literature. Kong et al. [2005] present a linear program for controlling a CHP plant with afterburner and integrated absorption chiller for cooling loads. A very similar setup is investigated by Cardona et al. [2006] for a plant at Malpensa airport in Italy. This paper also compares future investment options.

Lin and Yi [2000] investigate how a large scale CHP plant used in district heating can be used to reduce peak loads in the electricity network and present a dynamic programming approach to compute control solutions.

In this paper, we are concerned with micro turbines, used as decentralized CHP generators. Alanne and Saari [2004] present a general review of issues that can influence decisions when considering small-scale CHP (like micro turbines) as an alternative energy source for buildings, with a focus on the European market.

Another technology that can be used in small scale CHP are fuel cells. Aki et al. [2005] present strategies for controlling a set of four homes with CHP fuel cells that can exchange hydrogen, electric power and hot water. There is also a number of papers that propose algorithms for optimizing the dispatch of decentralized

CHP generators given a heat and power demand profile [Song et al., 1999, Rooijers and van Amerongen, 1994, Hernandez-Aramburo et al., 2005].

In contrast to these works, we do not assume a fixed demand that we are trying to match as cost-effective as possible. We assume that a company runs a set of micro turbine CHP generators that provide apartment complexes with heat and hot water. The electricity generated by the turbines is either sold for a fixed retail tariff to the occupants of the apartment complexes or sold in larger chunks on the national electricity market. Since the prices on the spot market can vary in orders of magnitude over one day, deciding when to sell how much electricity is critical for the profitability of the proposition.

2. The Business Model

A power company owns micro turbines connected to the hot water and space heating systems of apartment complexes. The company wants to offer the electric power to the national power market while keeping the temperature in the hot water and heating systems connected to the micro turbines in a given comfort range. The generated electric power that is not sold on the electricity market can be used to satisfy power demand in the apartment complex.

The company running the micro turbines obtains a fixed fee for the heating services it provides and wants to earn additional profit from selling the aggregated electric power of the turbines on the National Electricity Market in Australia. On this market, electricity generators submit bids one day ahead of dispatch. As described in the characterization of the Australian energy market [NEMMCO Ltd, 2005], the market operator then determines for each time slot the market price and the power will be dispatched if the market price is higher than the price requested in the bid. We further assume that the revenue from generated electric power that is used inside the apartment complex is equal to the retail price.

3. The Physical Model

The heating systems of the different apartment buildings are independent of each other. We assume that both the hot water service and the space heating service for each building use tanks containing hot water as energy storage. We assume that there is a constant loss of energy per time slot from the tanks even if no hot water is used due to imperfect insulation. Hot water use by the residents of the apartment complex draws additional energy from the tanks.

We assume a water based underfloor space heating system for the apartment complexes because it is well suited to CHP applications. These systems have a fairly large thermal inertia so that we can assume the energy demand for space heating to be almost constant over any given day. This means that the energy loss from the tank reserved for space heating is constant over time.

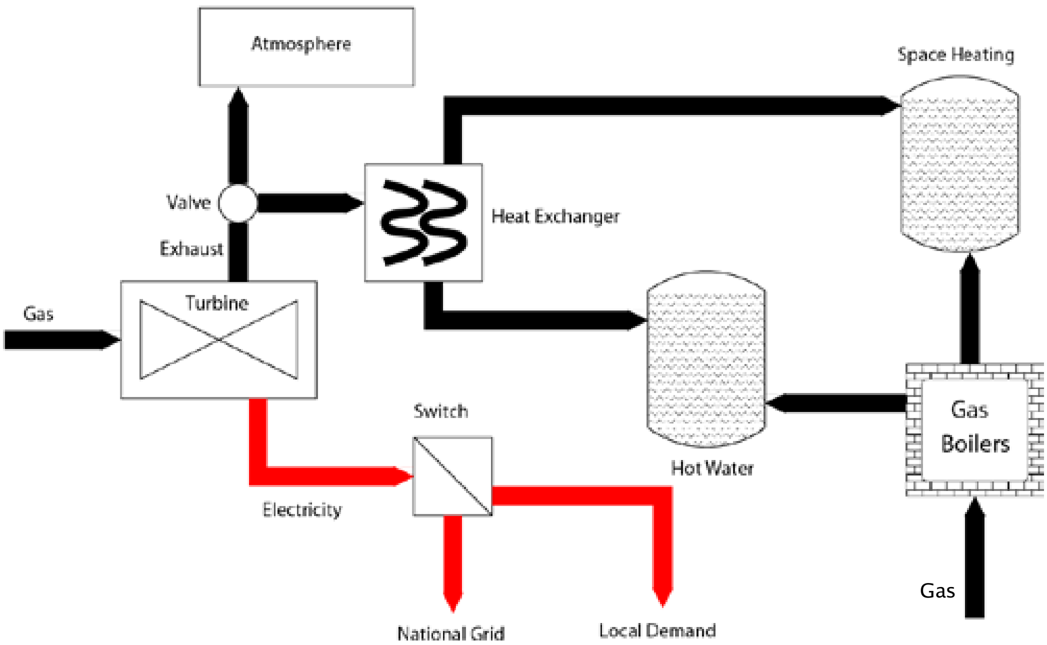

Figure 1: Energy flows in our micro-turbine model. Note that losses are not depicted but are part of our mathematical model

For each of the two tanks, there are two ways in which the temperature and thus the stored energy can be raised: Water can be heated in a heat exchanger using the hot exhaust of the micro turbine or the water can be heated using gas boilers. We assume that the connection between added energy and water temperature is linear. The linearity assumption can be justified since the water temperature in the tanks is always kept inside a narrow range. The turbines have minimum on- and off-times defined by the manufacturer.

When a turbine is running during a time slot, it produces a fixed amount of electrical power and a fixed amount of heat power. An arbitrary part of this heat power can be vented into the atmosphere. The remaining heat power passes through a heat exchanger and is split between the hot water and the space heating storage tanks associated with the micro turbine. The ratio of the split can be freely chosen. Figure 1 gives an overview of the energy flows in our model, excluding the losses.

4. The Optimization Problem

We assume that the price development in the NEM is similar each day in the sense that the power demand and thus the price is always very low during the night. We also assume that the hot water demand in the apartment complexes is very low during the night. This justifies the assumption that the heating systems connected to the micro turbines are in a similar state early each morning before the hot water demand ramps up. We therefore treat each day as a separate optimization problem

We assume further that we want to offer at most one **block** of power to the NEM each day. A block is a fixed power output provided during a time interval without interruptions. Thus, the daily NEM bid is defined by three values:

- The start time of the bid block
- The duration of the bid block (defining the “width" of the block)
- The electrical power we want to offer (defining the “height" of the block)

The electrical power is bounded from above by the sum of the capacities of all micro turbines.

4.1 The Profit Maximizing Integer Program

We assume that the operator of the micro turbines has three revenue streams:

- The NEM bid submitted each day: This revenue depends on the characteristics of the offered block (power level, start time, duration) and the price development in the NEM on the given day.
- Electricity generated by the turbines used to satisfy the apartment's electricity demand: We assume that this electricity displaces electricity that the occupants would buy from their local retailer and the turbine operator obtains the same price as the retailer from the occupants.
- A fixed fee for providing hot water and heating services to the apartments: Since it is obligatory to meet this commitment and the fee is fixed, this revenue stream has no effect on the operation policy for the turbines and we ignore it in our optimization model.

The variable costs for the turbine operator are:

- Fuel costs: This includes the cost of the gas used by the turbines as well as by the gas boilers. We assume that at each point in time, a turbine is either running at full power or is off while the gas boilers can be run at any power level below their maximal output.
- Maintenance costs: We treat these costs exactly like fuel costs since a turbine has to be maintained after a fixed number of operating hours.

We do not include any fixed costs in our model since we concentrate on the question how an operator would run existing turbines and handle the NEM-bid rather than on the question if it is profitable to install the turbines in the first place.

We describe the optimization problem as an integer linear program. The constraints are also linear and can be grouped into the following groups:

- NEM block constraints: These constraints guarantee that exactly one block of power without gaps is offered on the day in question and that this block has at least a defined minimum duration (set to half an hour in our model). Another group of constraints guarantees that the power reserved at each turbine for the NEM-bid sums up to the required power level.
- The electricity distribution constraints: These constraints ensure that in each time slot and for each turbine, the amount of electric power output allocated does not exceed the amount of power produced by the turbine. The amount of power used consists of the following components:
    - The amount of power from the turbine reserved for the NEM-bid
    - The power used to satisfy power demand in the apartment building of the current turbine
- The heating constraints: The heating constraints make sure that for each turbine in each time slot, the water temperature in the hot water and space heating system remains inside the allowed ranges. The temperature is increased by one of the following mechanisms:
    - Using heat from the heat-exchanger of the turbine
    - Using the gas boilers

  There are also two mechanisms that lower the temperatures in the heating systems:
    - Insulation losses, that we assume to be constant over time
    - Heating demand: For the hot water system, this demand is caused by the use of domestic hot water. We model this demand with our hot water demand simulator, described in

Section 5. For the space heating system, we assume currently that the demand is constant over the day. This is not realistic but given that a hot water driven space heating system would have to be combined with under floor heating, which has a considerable thermal inertia, the demand differences over the course of the day should not be as large as for the hot water system.

- Turbine run constraints: Once a turbine has been switched on, it has to stay on for a certain minimum amount of time. When it is switched off, it has to stay off for a defined minimum of time. These constraints make sure that the turbines are not switched off and on frequently, which would shorten their lifetime.

5. Scenario Input Data

The amount of input for the model is considerable. For a one day problem instance with a time resolution of 30 minutes, 100 turbines, each associated with an apartment building of 25 apartments, the inputs amounts to 270 kilobytes of data. The solution data computed by the system is in the order of 500 kilobytes.

We assume that Capstone C65 micro turbines are used with 65 kW electrical output. According to the data sheet of this device the hot water heat recovery output of this device is 120 kW. In our model we will assume that the micro turbines can be in one of two states: either off or working at full capacity. Therefore, we will assume that the recoverable heat is 120 kW when the turbine is running. The amount of fuel needed to run the micro turbine is 230 kW at full capacity (data from the Capstone data sheet) and we assume variable maintenance costs of 0.534 AUD per hour (data taken from Firestone [2004]). The gas price (relevant for the turbines as well as the boilers) is assumed as 0.672 c/MJ (Origin Energy Melbourne CBD, excludes GST).

According to NEMMCO, generators with more than 30 MW dispatchable capacity have to submit bids to the National Electricity Market (NEM), while smaller capacity generators may also do so if they can show that they have the technical infrastructure (telemetry and remote control capabilities) to do so. If we wanted to set up a virtual power plant with 30 MW using the 65 kW Capstone turbines, we would need 462 of them, corresponding to the same number of apartment buildings. This does not seem realistic for a single operator in Victoria, so we assume a total power capacity of 6.5 MW, corresponding to 100 turbines.

We assume that each apartment complex has 25 apartments each with 100 m^2 floorspace. Note that the average floor space of new flats, units, semi-detached houses and townhouses was 134 square meters in 2003 according to the Australian Bureau of Statistics. But we assume a slightly smaller value which seems more realistic for apartment complexes.

The Nationwide House Energy Rating Scheme (NatHERS) established that houses built in Australia in 1990 averaged about 1 star on the NatHERS scale [Nationwide House Energy Rating Scheme, 2007]. If we are dealing with houses or apartments with a 2 star rating situated in Melbourne, the space heating demand is 462 MJ per square meter and year.

To simulate changes in the space heating energy need during the year, we modulate the space heating power needed using the average minimum temperature for Melbourne in each month such that the space heating power needed for a whole apartment building in February is 0 and 78 kW in July, which is consistent with the average heating power for a 2 star dwelling given by NatHERS.

Since water tanks are not completely insulated there will be heat loss associated with the tanks for space heating and hot water service. Harrington and Wilkenfeld [1997] provide in Table 5 information on heat loss: A tank of 400 liters loses 2.87 kWh/day. We assume that one such tank is used in each building for space heating and 25 for hot water service (because of the variable nature of the corresponding demand).

We set the temperature band over which the hot water is allowed to vary between 60 and 70 degrees. The reason for the 60 degree lower bound is that at lower temperatures (below 55 degrees) pathogenic microbes such as Legionella can grow. The upper bound of 70 degrees is chosen as a compromise between the ability to store energy in the tanks and the need for a consistent hot water temperature.

For the space heating system, we assume a temperature range from 45 to 55 degrees. Since this water is in a closed loop, bacteria are not an issue and 50 degrees is a typical temperature for underfloor heating. We use hot water demand data consisting of the total hot water demand for each apartment building and each 30 minutes time slot. We create this data using a simple demand simulator with the following assumptions (mostly computed from data contained in Energy Australia [2006] and Office of the Renewable Energy Regulator [2008]):

- The number of persons in each household is 3.
- 62% of people have one shower a day, 29% have two per day and 9% have three.
- Each shower uses 10.31 MJ of energy
- The first showers are normally distributed around 07:30, the second showers around 19:30 and the third showers around 21:30.
- Each household has an additional hot water use event 2.34 MJ that is uniformly distributed over the whole day. This simulates a dish washer or washing machine.

Since the hot water demand is very variable and we do not want to run the turbines constantly, we assume that we have additional gas boilers in each apartment complex with a combined power of 350 kW and an efficiency of 92%.

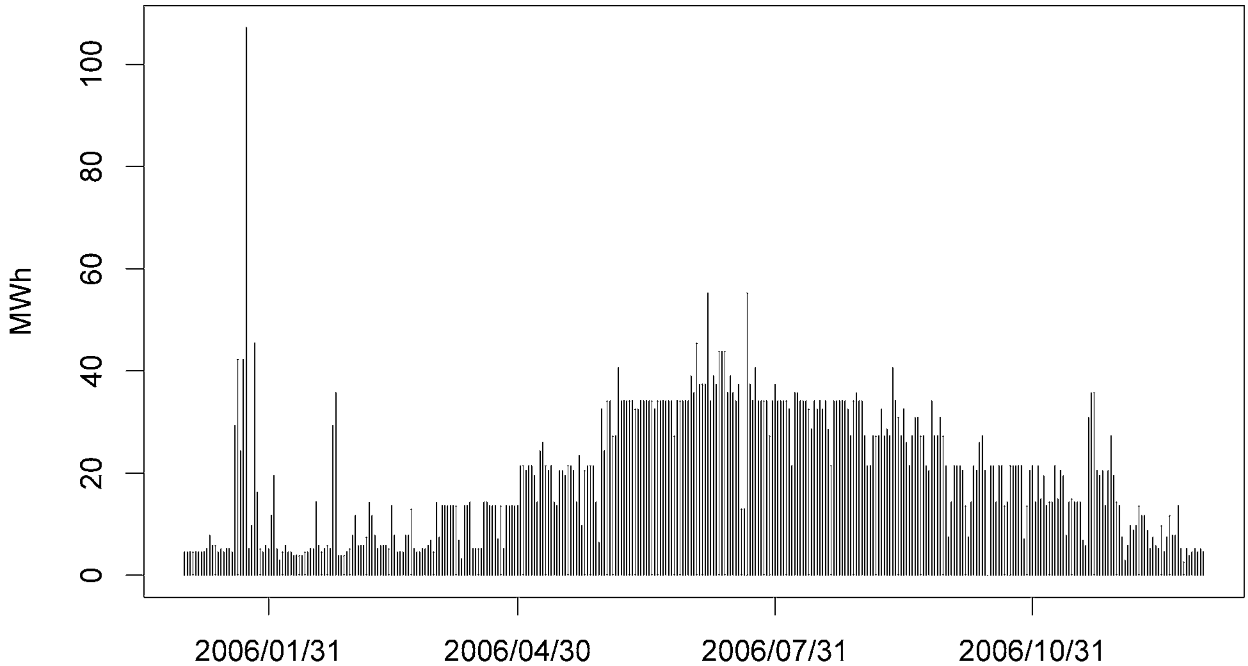

Figure 2: Amount of energy delivered to the NEM on each day in 2006

Our data for the local electricity demand in each apartment building is generated from half hourly winter and summer peak demand provided by EMET Consultants [2004]. We obtained our own winter and summer peak demand patterns by removing all space heating and hot water electricity demand from this data as well as pool pumps since our apartments are heated centrally and they do not have pools. To obtain demand pattern for all months, we generate linear combinations of these patterns depending on the average minimum temperature in the month. We obtain different demand data for each building by multiplying each type of demand (like dishwashers, freezers and TVs) with a uniformly distributed random number between 0.9 and 1.1. We assume a residential power price of 13.54 c/kWh (Origin Energy commercial residential tariff, Melbourne CBD)

6. Optimization Results

We want to use the optimization framework to predict how much power a rational operator with perfect knowledge about the power demands and prices on the next day would feed back into the grid as bids on the NEM. This will give us a benchmark for measuring the performance of optimization methods that use predictions for price and demand.

To see how much power the control strategy would provide to the NEM over a whole year, we used the half hourly resolution price data of NEMMCO for the Victorian part of the National Electricity Market in the year 2006. We compute a near optimal control solution for each day by running our integer linear programming model for each NEM-bid power level from 0.65 MW to 6.5 MW (the total turbine electricity output) in steps of 0.65 MW and choosing the solution where the objective function (maximizing the income from the bid and local power sale minus the fuel costs) is maximal.

Figure 2 shows for each day in 2006 the amount of electric power our strategy provides to the NEM. There is a pronounced spike in January at a day where wholesale price in the Victorian part of the NEM was exceptionally high for a number of hours. These extreme peaks mainly happen during summer when electricity demand is high due to air conditioning load and the interconnectors to other parts of the NEM are near capacity. The average amount of power delivered each day was 75.87 MWh while the total for 2006 was 27,693 MWh.

In general, the figure shows that more power is delivered to the NEM in winter when the CHP-system can take advantage of combining heating load with electricity production resulting in a low marginal price for electricity. The plot shows a concentration at certain values because the power levels of the NEM bid can only take 10 different values (from 0.65 MW to 6.5 MW) and each NEM bid block has a duration which is a multiple of 30 minutes in our model.

To evaluate the financial attractiveness of the CHP system, we compared it with a base case. In this base case, all electricity for local demand in the apartment buildings is bought at the standard electricity retail rate. All heating needs are met using gas boilers with an efficiency of 92%. For each day of the year 2006, we calculate the savings achieved with the CHP system compared to the base case as follows: Let l be the energy that was produced by the CHP system and used to satisfy local electricity demand in the apartment buildings (note that the CHP system does not meet all local electricity demand). Then the savings is the difference between the expenditure in the base case (gas for heating and buying l amount of energy from the retailer) and the expenditure of the CHP system (which is gas for the turbines and the boilers) plus the income generated by selling power to the NEM.

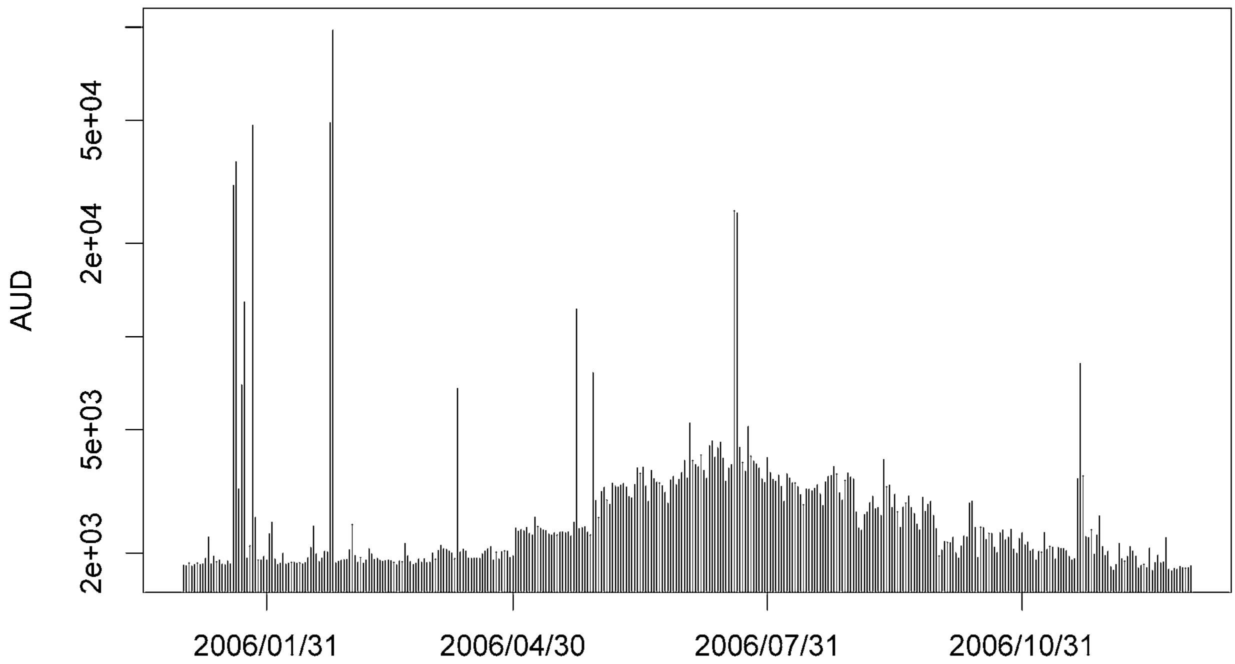

Figure 3: Savings achieved using the micro-turbine CHP scheme for each day in 2006. Note the logarithmic scale

Figure 3 shows the savings for each day in 2006 on a logarithmic scale. As expected, the savings are in general higher in winter when there is sufficient heat demand to lower the marginal price of electricity generation. However, the savings are huge on days where the wholesale price in the NEM is extraordinarily high. The average daily savings were 814.42 AUD while the total savings for the whole of 2006 were 297,262.68 AUD. Figure 4, where the profits are sorted in decreasing sequence, shows just how important the days with high wholesale price in the NEM are: the lion's share of the year's savings are obtained in just a few days with favorable market conditions. The CHP proposition would look much less attractive without access to the wholesale market. This result agrees with a recent paper by Toke and Fragaki where they stress the importance of aggregation in enabling distributed generators to profit from high prices on the wholesale market (D. Toke and A. Fragaki, 2008).

To compute the amount of CO_2 saved, we again compared with the base case where all electricity is bought and all the heating needs met using the gas boilers. According to the State Government of Victoria [2002], 1.444 kg CO_2 equivalent is produced for every kilowatt hour of electricity produced in Victoria. For each

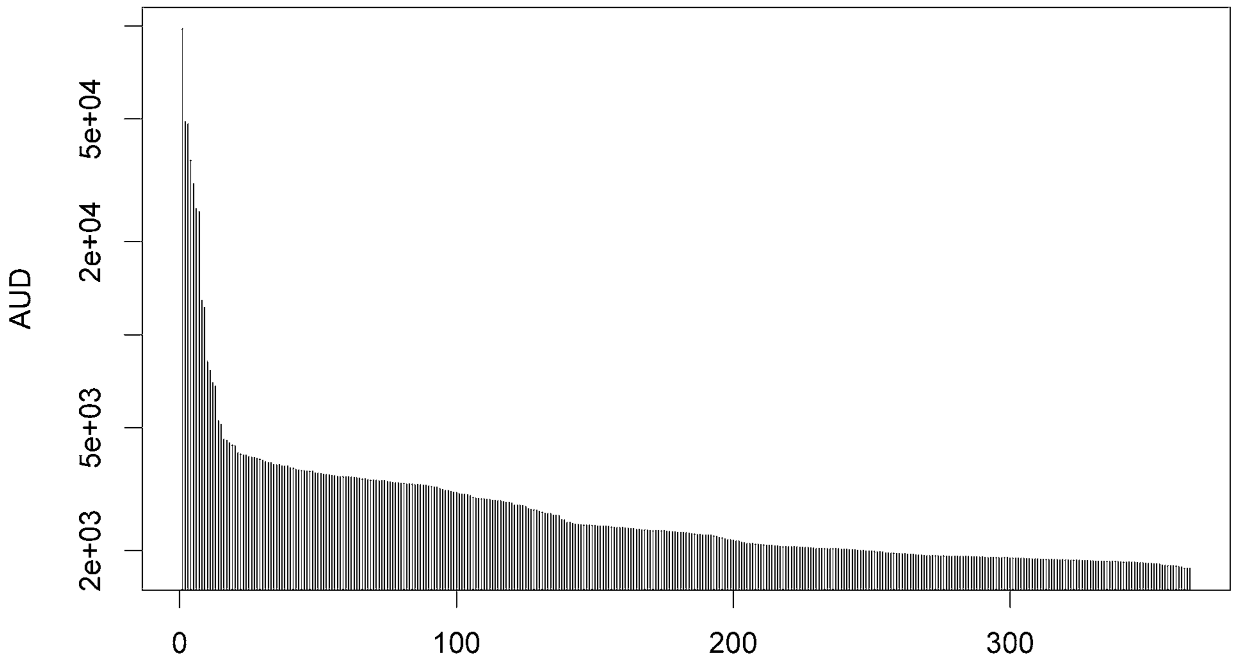

Figure 4: Daily savings achieved by the CHP scheme sorted in decreasing sequence. Note the logarithmic scale.

gigajoule of natural gas, the amount of CO_2 equivalent produced is 51.7 kg. These are the numbers we used to estimate the amount of CO_2 saved compared to the base case. As the base case CO_2 emissions, we added the emissions from the heating system to the emissions produced for generating the electricity that is produced by the turbines in the CHP solution (local use as well as export to NEM). From the resulting tonnage, we subtracted the CO_2 equivalent of the natural gas used by the turbines and boilers in the CHP solution.

The result of the comparison of CO_2 emissions is shown in Figure 5. The plot looks very similar to Figure 2, where the amount of energy exported to the NEM for each day is shown. This indicates that not only from a financial point of view, but also from an environmental point of view, access to the NEM is crucial for

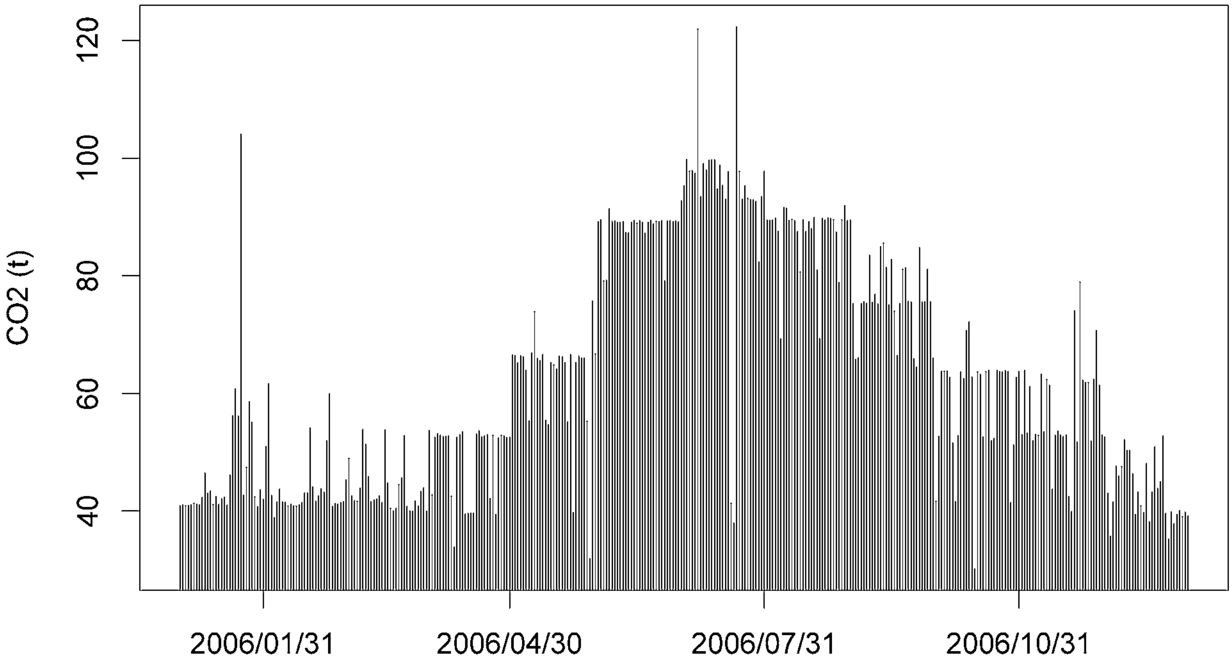

Figure 5: Savings in CO_2 emissions for each day in 2006

harvesting full benefits from the CHP scheme we suggest. The savings in emissions are around 40 t in summer and can go up to more than 120 t in summer. The mean daily savings were 63 t and the total savings for the year 2006 were 22,861 t. Assuming that an average car has CO_2 emissions of 226.1g per km (Federal Chamber of Automotive Industries, 2008) and drives 15,000 km per year, this is equal to the emissions of 6740 cars.

7 Conclusion

In this paper, we suggested scheme where an operator owns micro-turbines in apartment buildings that are not only used to provide heat and power to the residents but also act as a virtual power plant in the NEM. This allows the operator to benefit from extreme price events on the wholesale market in addition to benefiting from the combination of heat and power production. Our computational results have shown that the system can be run in such a way that savings can be achieved every day with substantial savings in winter and on days with high wholesale prices.
We have also shown that access to the wholesale market is crucial for the financial attractiveness of the scheme. The savings in CO_2 emissions are also substantial and benefit from access to the wholesale market. In the future, we want to develop strategies for controlling the micro-turbine CHP system as a virtual power plant that do not rely on perfect foresight of the local power demand and the wholesale price. Machine learning strategies may be well suited for this application as well as fuzzy logic or other rule based strategies.

ANALYSIS OF MATERIAL AND ENERGY EFFICIENCY OF MEXICAN, PERUVIAN AND DUTCH DWELLINGS USING THE THREE-STEP-STRATEGY

Olivia GUERRA SANTIN MSc

OTB Research Institute for Housing, Urban and Mobility Studies, TU Delft, The Netherlands

Keywords: sustainable building, energy, materials, method, international study

Summary

Buildings consume resources and produces emissions to the environment during their life cycle. They consume materials during their construction, maintenance and renovation activities, consume energy and water during their use, and produce waste at the end of their useful life. There are several sustainable building methods for environmental assessment; the results of these depend on the approach taken and therefore also on the objective or endpoint of the assessment. The most common strategies aim at reducing their impacts, but buildings will always have an environmental load. Therefore, to calculate the absolute damage of a building to the environment, as it is done in the Life Cycle Assessment may be considered inadequate for assessment when the objective is to improve the environmental performance of the building from design. The three step strategy is an option being a method that focuses on a different approach. This strategy establishes that for a sustainable use of resources, three steps are necessary: a) to reduce the need or use of resources, b) to use renewable sources to sustain the need and c) to be efficient with the remaining need. The method has advantages and disadvantages related to accuracy, data needed, output, and interpretation of results. In this research, the method is applied on case studies. Dwellings are analyzed to improve their environmental performance with the objective to point out at the limitation of the method in relation to its applicability and usability.

1. Introduction

Construction is considered one of the activities that contribute the most to the environmental burden. During its life cycle, a building consumes resources and releases emissions and waste into the environment having great responsibility for fossil fuel consumption and global warming (Edwards, 1996). The materials used in buildings also have a significant influence on the environment; concrete and steel having the greatest impact. In addition, these materials are the most intensively used on a global scale. Cement production emits greenhouse gases that contribute to global warming, while steel is one of the most energy-intensive materials (UNEP-IETC, 2002). The manufacture and final use of these materials is also water intensive.

The environmental burden and the quality of the building both depend on the interaction of the building with its surrounding environment. This interaction is defined from the design phase of the building. The type and quantity of resources used for the building, such as materials, energy and water are partly determined by design. In addition, the conditions of the indoor environment also depend on the design. Furthermore, the life cycle of the building is influenced by early decisions. The efficiency of maintenance, renovation and demolition activities will be defined by the potential of the building to allow such activities.

Design is an essential part of the construction process. If designed properly, dwellings can promote well-being of the occupants and ecological sustainability (Lawson, 1996). During this phase, environmental issues can be better incorporated. The design of the building determines the potential for good environmental performance during the entire life cycle (during maintenance, renovation and demolition activities).

An environmental assessment of the building is needed to determine the potential impact of the building on the environment. There is a great variety of environmental building assessment methods (Itard & Klunder, 2007), but these often have limitations that can cause uncertainty in the results or be ineffective in the assessment. These assessment methods, originally developed to calculate the environmental impact of buildings, are now used for design purposes (Ding, 2007). These methods can contribute to better understanding a building's impact on the environment, being most useful when the materials, construction processes and systems are chosen. Nevertheless, these methods may be unsuitable for a design analysis because they do not provide information on the choices made during the design of the building.

This study uses a method that allows analysis of the performance of the building in relation to design choices based on the Indicator Approach by Rovers (2005). This study was part of the Atlas Project (Rovers).

The impact of housing on the environment in three countries is assessed to point at the major environmental problems. Since this is a quantitative method, reference houses are needed. The reference houses were defined with the aid of demographic statistics and legislation. Reference houses were selected as representative of the average house. The reference dwellings provide examples of the most common building materials used. These examples are analysed focusing on materials and energy efficiency.

2. Methodology

2.1 The Approach

The approach followed for assessing the environmental performance is based on the Three Step Strategy. The strategy provides detailed information about building characteristics and has a direct relationship with design. The aim of the Three Step Strategy is to limit the inflow and outflow of resources and to retain for a longer time the incoming flows within the system (Hendriks, 2001). In order to decrease the environmental impact there are three steps that must be followed: reducing volume flows, using renewable sources, and being efficient with the remaining need. This is suitable for analysing the potential environmental impact of choices made during the design process because it provides detailed information about different aspects of the design of the building and point at the problems or areas for improvement. This study focuses on the resource efficiency of materials and energy.

2.2 Materials

An essential part of the design process is the selection of materials based on their sustainability (Jong-Jin & Rigdon, 2007). Materials possess characteristics that make them more or less sustainable in relation to the phases of the material's life cycle: pre-build, build, and post-build.

Hendriks (2001) and Jong-Jin and Rigdon (2007a) identified criteria for choosing construction materials according to their environmental sustainability. They group the criteria in the three phases of the life cycle of building materials: Pre-building, Building and the Post-building phase. The criteria for the Pre-building phase include the use of materials that produce a limited amount of waste and emissions during their manufacture, have low embodied energy, have a high content of recycled materials, and prevent depletion of natural stocks. The criteria for the Building phase are the use of non- or less toxic materials, with high durability, usability, reparability, safety, energy efficiency, and ability to withstand calamities. The criteria for selecting materials in relation to their performance in the Post-building phase are the use of materials with high potential for recycling and reuse, a low deterioration rate, and a long technical lifespan.

Most of the methods for determining the sustainability of materials (Hendriks, 2001) focus on the post-use or post-building phase of the life cycle of the building, Table 1 shows the methods and literature used. They are presented according to the steps of the Three-Step-Strategy.

Table 1 Summary of approaches to choose materials based on their sustainability

	Indicators		
	Material efficiency (2.2.1)	Renewability (2.2.2) and impact to environment (2.2.3)	Dismantling and reusability
Three Step Strategy	Step 1: Reduce need	Step 2: Use of renewables	Step 3: Increase efficiency
Hendriks	Avoid depletion of natural stock	Use materials with less emissions	Reuse materials Use materials with higher usability, reparability, and longer lifespan
Jong-Jin and Rigdon	Reduce waste	Reduce emissions Use materials with low embodied energy Higher recycled content Use of natural materials	Reuse materials Recycle material Use materials with longer lifetime
Design for recycling	Use fewer materials	Use of recycled materials	Design for dismantling Identification of materials

Sources: Hendriks (2001), Jong-Jin & Rigdon (2007)

Only the first two steps of the Three-Step-Strategy are considered in this paper. Therefore the objectives are to use fewer materials and to use renewable materials or materials with low embodied energy and emissions. In the present study, the following indicators are used:

2.2.1 Material efficiency: total embodied materials per useful living area. The quantity of embodied material consumption as a consequence of the design can reduce the demand on virgin resources and the production of waste, thereby reducing the environmental impact and energy and water consumption when needed for extraction and manufacturing (Jong-Jin & Rigdon, 2007a).

2.2.2 Renewability of materials: quantity of renewable materials. In a human perspective, a material is only considered renewable if it can be grown at a rate that meets or exceeds the rate of human consumption (Jong-Jin & Rigdon, 2007b). Non-renewable materials are materials that have a slow growth rate in relation to the consumption of the material for human activities.

2.2.3 High impact materials and low impact materials: embodied materials with high or low impact to the environment. Low impact materials have a low or no impact on the environment during their manufacture, requiring less processing and less embodied energy. High impact materials are those whose manufacture requires significant use of resources, high embodied energy and high production of emissions.

2.3 Energy

The design of the building plays an important role in energy consumption. The thermal properties of the building determine the energy use for heating and cooling. Another important characteristic of the building is the natural lighting of spaces; the better the natural illumination, the less energy is needed for artificial lighting.

According to the Three Step Strategy the steps needed are: reducing the use of energy, using renewable energy, and being efficient with the remaining need. This paper only focuses on step one. The energy indicators used are the following:

2.3.1Total energy consumption refers to the total consumption of energy per household. It includes energy used for artificial lighting, indoor climate, and for appliances, cooking and water heating. It is important to make a difference between primary energy and delivered energy. The efficiency of the generation of energy is given by the percentage of energy that is lost during the production and transport of energy. For this approach, only delivered energy is taken into account because the designer has little choice in the type of energy used, and therefore on the energy efficiency of the source (Rovers, 2005).

2.3.2 Energy used for heating or cooling: delivered energy used for heating or cooling per useful living area.

2.3.3 Energy use for artificial lighting: delivered energy used for artificial lighting per useful living area.

2.3.4 Energy used for appliances, cooking and heating water: delivered energy for appliances, cooking ans heating water per useful living area.

3. Reference dwellings

The goal of the international analysis is to place housing in a broader context for a better understanding of the situation. The dwellings used for the analysis are a Mexican reference house, a Peruvian reference house as defined in the Atlas Project (Wageningen University, http://www.iconwise.com/ue/), and a Dutch reference house.

The objective of the analysis is to determine the effects of different construction methods on resource consumption and sustainability. The institutional, cultural and social contexts are not deal with in the analysis. The goal of the analysis is to help to analyse housing design in relation to its context. Therefore the differences between the countries do not cloud the analysis but make it more useful. Nevertheless, the climate is an important factor affecting the performance of the dwelling therefore degree days are used to normalize the temperature in the three countries. The reference houses are introduced in next section. Table 2 summarizes the characteristics of the reference houses.

3.1 Mexican dwelling

In Mexico there is a great variety of climates due to its land extension, mountains and coasts. The climate in the selected area of study is semi-cold. Mexico City, Toluca, Tlaxcala, Puebla and Morelia are some of the cities with this climate. For the case study, the city of Toluca was chosen. The cold climate is due to its high altitude at 2,680m above sea level. During the night, temperatures can drop below 0^{o}C even in summer, and the maximum temperature rarely exceeds 27^{o}C.

Statistical data was used for the selection of the reference dwelling. The reference dwelling consists of a single-family row dwelling set over two floors. On the ground floor there is a living/dining room, separate kitchen, and toilet with sink. On the first floor there are three bedrooms and two bathrooms. The dwelling has continuous stone footing, confined masonry walls of fired clay units and reinforced concrete elements, reinforced concrete floor and roof, and a layer of gravel in roof as insulation.

Electricity produced in a thermoelectric plant is used for artificial lighting and appliances. For cooking and heating water the most common fuel used is gas. To calculate energy consumption in modern houses, a collection of data from a small sample of similar houses with different family composition was realized.

3.2 Peruvian dwelling

Most common type of construction in Peru is the self-build, carried out by the owners of the dwelling. The Peruvian case study and the data for the analysis was taken from Torres Mendez (2005), where a reference dwelling in the city of Lima was defined according to the typical construction processes, layout and construction procedures in the city. It is a three-level single-family dwelling with concrete with steel reinforcement footing, concrete with steel reinforcement beams and columns, walls of hollow clay and gypsum units. Energy consumption is based on a 5 person household.

3.3 Dutch dwelling

In the Netherlands, 70% of the housing stock consists of single-family dwellings. The Dutch case study was taken from the reference houses defined by the Agency for Sustainability and Innovation (Senternovem). In the Netherlands, reference dwellings have been defined and are widely used for comparative quantitative research. For this research, the “attached” house was chosen because it represents the average dwelling.

Data on energy consumption was obtained from the KWR survey (Ministry of VROM, Netherlands), and it represents the mean value for row houses with a four-person household. The dwelling consists of concrete and steel beams and poles footing, beams and columns made of concrete and steel, exterior walls made of double layer cavity gypsum walls with mineral wool or meranti insulation, interior walls made of gypsum walls filled with wool or fibre, wooden roof with concrete and ceramic tiles.

Table 2 Reference dwellings in Mexico, Peru and the Netherlands

	Mexican dwelling	Peruvian dwelling (*1)	Dutch dwelling (*2)
Useful Living Area	108m^2	214m^2	111m^2
Average outdoor temperature	10^{o}C–15^{o}C	18^{o}C	5^{o}C–18^{o}C
Layout	Row single-family dwelling over two floors	Two levels and service area on third floor	Row single-family dwelling
Electricity	Electricity generated in thermoelectric plants	Electricity generated in thermoelectric plants	Electricity generated in thermoelectric plants
Water boiler	Low efficiency boiler (turned on all day)	Electric boiler (turned on for 2 hours per day)	High efficiency boiler
Energy for heating water	LPG	Electricity	Natural gas

4. Analysis of material efficiency

4.1 Material efficiency and renewable, recovered and non-renewable materials

The Mexican reference dwelling is more material consuming than Peruvian and Dutch reference dwellings, the Dutch reference dwelling being the less material consuming. High impact materials are intensively used in all dwellings, due to concrete elements and ceramic bricks. All of the dwellings have a minimal percentage of renewable materials, which are mainly used in windows and doors. The Mexican reference house performs better than Peruvian or Dutch houses in terms of the origin of the material because of the higher percentage of low impact material from stone masonry footing used in Mexican dwellings (Figure 1).

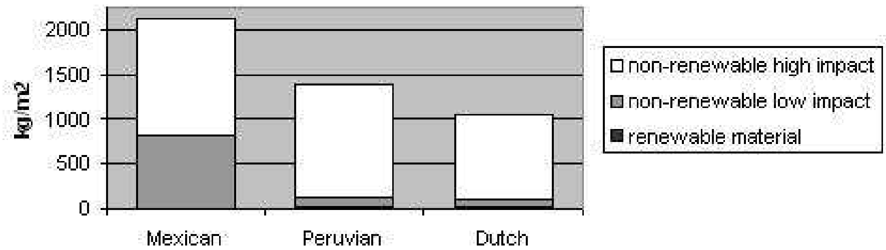

Figure 1 Percentage of renewable, non-renewable, high impact and low impact materials

4.2 Material efficiency of building elements

Figure 2 shows material use per useful living area per building element and the impact of the materials on the environment. Finishes are not shown in the graph.

Footing in Mexican housing is twice the weight of footing in Peruvian dwellings and more than triple that of Dutch houses because in Peruvian and Dutch dwellings, footing is made of concrete with iron reinforcement while footing in Mexican dwellings consists of continuous stone masonry along all walls, which increases the weight of the foundation.

Structural elements are more material consuming in the Mexican reference dwelling's walls than in the Peruvian and Dutch reference dwellings walls. Mexican vertical structural elements consist of confined masonry walls with horizontal and vertical reinforcement elements made from reinforced concrete. In addition, a higher percentage of walls in Mexican housing are structural walls. Materials used in structural walls in Mexican dwellings double the amount of materials used in walls in Dutch dwellings. The supporting elements in Peruvian housing consume half the quantity of material used in vertical structural elements of Dutch housing.

Non-structural elements in Mexican housing in comparison with Peruvian housing are lighter, given that a high percentage of walls in Mexican housing are structural. Nevertheless, non-structural walls are also made of solid brick with reinforced concrete confining elements. In Peruvian housing all the walls are non-structural; therefore consumption of materials for these elements is high. Non-structural walls in Dutch housing are very light in comparison to Peruvian non-structural walls. The weight of all vertical elements in Mexican housing is more than double that in Dutch housing and around 30% greater than in Peruvian housing. The large difference in weight between Mexican and Peruvian vertical elements and Dutch vertical elements shows that masonry structure accounts for a high percentage of material used in housing, while light walls, as in the Dutch case study, are more material efficient.

Materials in roof in the Mexican dwelling are lighter than in the Peruvian and Dutch dwellings because the roof tiles in Mexican housing do not need beams. Although Peruvian dwellings have concrete tiles like Mexican dwellings, roof tiles in Peruvian housing are hollow; therefore the use of beams increases the weight of roof tiles in Peruvian dwellings.

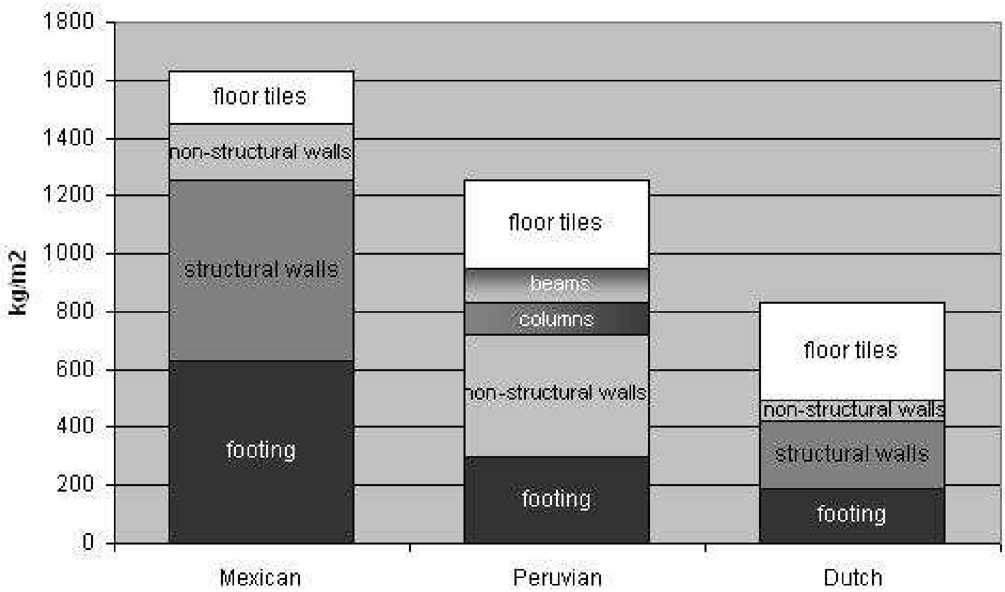

Figure 2 Material weights per useful living area per building element

4.3 Analysis of energy efficiency

Figure 3 shows the energy use for different purposes in the reference dwellings. Energy consumption in Peruvian and Mexican houses is visibly lower than for Dutch houses. Energy consumption for heating is high for Dutch housing, while in Peruvian and Mexican housing energy for heating or cooling is not used. This is because the weather in Lima is mild, and therefore, it is reasonable that energy is not used for heating or cooling. Nevertheless, Toluca is a city of cold nights, especially in winter, due to its altitude.

To test the relation between energy used for heating and the heating degree days per country, the energy consumed in Dutch houses is normalised with respect to the number of heating degree days in Mexico and Peru. Table 3 shows that in relation to the energy consumed in the Netherlands, energy in Peru is consumed according to its weather (real consumption is 0 while hypothetical consumption is 5.32 MJ), while in Mexico the energy consumed for heating is considerably lower than what is needed (real consumption is 0 while hypothetical consumption is 48.65 MJ). Nevertheless it is important to consider that the low temperature in Toluca is in the night when comfort is less needed.

Table 3 Energy consumption in the Netherlands according to degree days in different countries

	Netherlands	Peru	Mexico
Number of degree days	5328	566	3236
Hypothetical energy use in the Netherlands in relation to the degree days	80.11 MJ	5.32 MJ	48.65 MJ
Real energy use	80.11 MJ	0 MJ	0 MJ

Energy used for appliances, cooking, and for heating water in Mexican reference dwellings is higher than in Dutch and Peruvian reference houses. Energy used for cooking, heating water, and appliances in Peruvian houses equals about 80% of the total energy consumed. For Mexican houses this is about 75%. This shows a trend in Mexican houses of high consumption of energy for such activities.

Energy consumption for appliances, cooking and water heating in Mexican housing is higher than in Peruvian and Dutch housing, because of the large use of energy for heating water. The cause may be attributed to the type of boiler used in the majority of houses in the region, which is turned on all day.

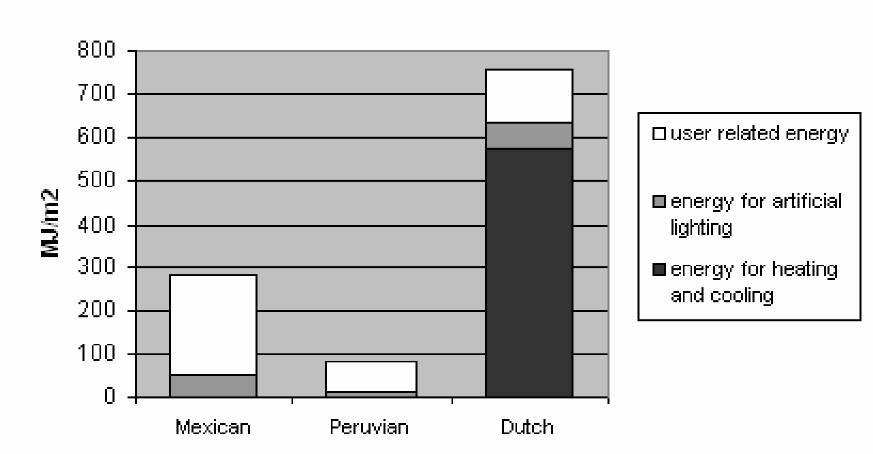

Figure 3 Energy use for different purposes

4.4. Conclusions

There is an intensive consumption of material in Mexico due to the use of continuous stone masonry footing along all the walls and due to the undifferentiated use of solid units in walls. Peruvian houses are lighter due to the use of hollow units. Dutch houses tend to have light interior walls, a factor that reduces the weight of the materials.

Non-renewable materials with high environmental impact seem to be intensively used in all dwellings due to the concrete elements and ceramic bricks. Renewable materials are almost not used with exception of the Dutch reference dwelling where wooden beams are used. The use of low impact materials makes the performance of the Mexican dwelling appear better in comparison to other countries but the amount of renewable materials is very low.

The performance of the Mexican and Peruvian reference dwellings could be improved by using more renewable materials in the structures such as in Dutch dwellings. The use of lighter walls in interiors and the use of hollow masonry units could reduce the material use in Mexican dwellings without compromising its thermal properties.

Diminishing the quantity of materials by means of using different processes in foundations would be a different solution for material consumption in Mexican housing without making structural or functional changes. Nevertheless, Mexican houses consume fewer high impact non-renewable materials than Dutch and Peruvian houses, this fact being attributable to the use of stone foundation.

Renewable energy is not used in any reference house, but in the Netherlands there is the possibility to choose sustainable sources. The energy consumption for artificial lighting is comparable in all dwellings, while energy for cooking and water heating seems higher in Mexican dwellings, followed by Dutch reference dwellings.

The high consumption of energy for heating water can be attributed to the use of low efficiency boilers in Mexico. Environmental performance in Mexican and Peruvian dwellings seems good in comparison to the Dutch reference house in relation to climate systems, because energy for air conditioning is not required. In Mexican housing there is no consumption of energy for heating in spite of the weather conditions in the region, where temperature in winter nights can drop below 0°C, and in summer nights to 5°C. This could be due to the use of massive materials in walls.

5. Discussion

Sustainable building is acquiring more importance worldwide. The current situation of sustainable construction and housing in developed and developing countries is clearly different. Developed countries have reached a high level of quality in housing but consume more energy. The main problem that these countries face is maintaining the current level of quality of life while minimising environmental interventions. On the other hand, housing in developing countries still lacks the quality reached in developed countries, but energy use is still low, which could be attributed to traditional massive materials and climate. Nevertheless, further research should be done about indoor temperatures in the region of study in Mexico. There is the indication that indoor temperatures, especially in winter nights, are cooler that in the Netherlands, which if true could lead to the conclusion that there are more factors influencing the low energy use than massive building materials alone.

The choice of indicators in the present study is based on the three step strategy and on needs identified from a designer perspective. From this perspective the use of Life Cycle Assessment is not recommended, because it is not directly related to building design. In the present study, the level of the indicators was determined by literature and estimates. However, to determine quantitatively, or to determine if a material has a low or high environmental impact, it would be better to use the Life Cycle Assessment method, or at least parts of it, because it is the only widely accepted quantitative method to determine these characteristics.

The method gives a general idea of the situation regarding material and energy use within countries. For example we saw that materials in Mexican dwellings are more intensive than in Peruvian and Dutch dwellings, that energy use for heating is higher in the Netherlands, and that energy use for heating water is higher in Mexico. Nevertheless, factors dependent on the background of the countries should be considered before trying to apply a different solution for problems in a determined country.

FROST FORMATION AND CONDENSATION IN STONE-WOOL INSULANTS – THE COURSE OF MOISTURE RESISTANCE FACTOR

Tomas VRANA Tecn.Lic.[1]
Folke BJÖRK Doc.[2]

[1] Department of Civil and Architectural Engineering, Division of Building Materials, KTH Royal Institute of Technology, Brinellvägen 34, 100 44 Stockholm, Sweden, tomas.vrana@byv.kth.se

Keywords: stone wool, material properties, frost formation, condensation, moisture resistance factor

Summary

Globally increasing prices of energy have result in raise of thermal qualities of building envelopes. Consequently, these heavy insulated constructions are facing undesirable phenomena – for instance a risk for occurrence of frost formation and condensation together with a changed thermal field in building constructions. Condensed moisture, as well as moisture trapped in thermal insulations during build-up, can also affect an increased dust contamination, algae or mould growth and structural damages.

This contribution reports on a laboratory experiment aimed at growth of frost formation and moisture condensation in stone wool opened to air for specific temperature fields – namely (+20; -20ºC), (+20; -15ºC), (+20; -10ºC), (+20; -5ºC) over fibrous specimens with varying density. Air on warm side of material samples was saturated with moisture. Frost accumulated with time in the part of specimens facing the cold air. In the part facing the warm humid air a condense formation occurred. The wider thermal field and higher density of material samples we used the more distinct border between frost and liquid condensate we observed. Also moisture resistance factor μ, as a basic moisture characteristic of an insulating material, had an upward trend for broader temperature intervals.

Next to the loss of insulating qualities, annual repetition of condensation and frost growth in stone wool can contribute to degradation of the material structure, thermal losses and, in consequence, higher energy consumption.

1. Introduction

Thermal insulation materials are very important to reduce energy load in both existing and newly built constructions. Especially demands on thermal protection of new buildings have become fundamental. Builders are using more and thicker thermal insulations for walls and roofs. A good thermal insulation should perform, among others, low thermal conductivity, durability, dimension stability, resistance to fire and as low negative impact on the environment and human health as possible. Stone wool - thermal insulation made from molten rocks, meets many of the listed features, though it has also negatives. This fibrous building material is one of the most common thermal insulation spread all over the world. Hand in hand with its great potential and expansion, there is a risk for heavy insulated structures. Thanks to insulation thicknesses a moisture capacity in a wall or roof construction is quite big. No doubt, these energy-saving trends in he building industry are right, but new findings and menace resulting from this design should not be omitted.

As we know from the building practice, thermal insulation materials are always exposed to temperature gradient through their thicknesses and to conditions for moistening and desiccation depending on ambient conditions around the layer of thermal insulation. Moisture can enter constructions via leakage in details of window sill, attics, etc. Constructions can also become wet in case of driven rain, heavy rain showers and snowfall during building processes. At the same time, the finished buildings are hardly permeable for inbuilt moisture even this tightness can worsen in time. As a result, moisture content can slightly grow depending upon actual temperature conditions, so condensation and frost formation are annually repeating in certain seasons (above all in late autumn, winter and early spring) of a year.

This contribution describes research project intent on finding possible changes of moisture properties in stone wool that could affect its future degradation. It also aims at better understanding of creation of frost formation and condensation in a limited time interval.

2. Moisture transport in porous materials

Moisture transport in porous materials is represented by vapour diffusion, surface diffusion and capillary conduction. The executed laboratory tests were based on a fundamental moisture transport theory by diffusion represented by Fick's law and its variations. Moisture flow rate *G* was obtained by laboratory measurement and then used for calculation of diffusive flux g. The point of this computational model is specification of moisture resistance factor μ as the key moisture characteristics.

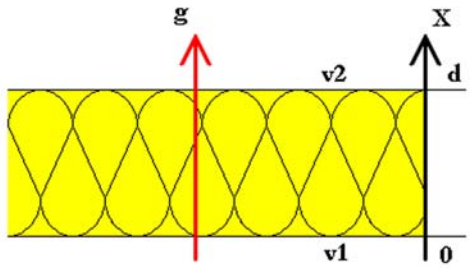

Figure 1 Diffusion of water vapour flux through a layer of stone wool where d is the width of material. Vapour permeability of material is termed δ_v (see Equation 1). Humidity by volume v is kept at v_1 at one side of the layer and at v_2 on the other side. The steady-state diffusive flux is defined as g.

According to Fick's empirical law the steady-state diffusive flux g is:

$$g = \delta_v \cdot \frac{v_1 - v_2}{d} \quad \left[\frac{kg}{m^2 s}\right] \tag{1}$$

Diffusive flux multiplied by cross-section area of the sample gives us moisture flow rate *G*:

$$G = A \cdot g \quad \left[\frac{kg}{s}\right] \tag{2}$$

The rate of diffusion, in the sample can be compared with the one obtained in stagnant air. Introducing the ratio between *D* and δ_v indicates moisture resistance factor μ:

$$\mu = \frac{D}{\delta_v} \quad [-] \tag{3}$$

3. Materials

All material specimens we used for our laboratory measurement were based on stone-wool. They all were commercial products widely used all around the world and taken from a product portfolio of a major producer. Materials with different densities and a varying sphere of use were chosen. Samples were dried and weighed prior to measurements and their dry densities ρ_d were calculated.

The heaviest material sample – SPECIMEN A is primarily used for flat-roof constructions. It is a stiff heavy board of stone wool with integrated double-layer characteristics, which is bonded by organic resin and fully hydrofobised throughout its capacity.

The second fibrous material – SPECIMEN B is a rigid stone-wool board, fully hydrofobised, especially used for flat roofs.

The lightest - SPECIMEN C is a semisoft batt, fully hydrofobised, used for insulating pitched roofs, ventilated facades and sandwich walls.

Table 1 Technical parameters of the used stone wool

Specimen	Declared thermal conductivity λ_D [$Wm^{-1}K^{-1}$]	Dry density ρ_d [kgm^{-3}]
A	0,040	145
B	0,039	112
C	0,035	44

4. Test equipment

At the Department of Civil and Architectural Engineering of the Royal Institute of Technology in Stockholm we designed and built up a special testing device to observe condensation and frost formation in fibrous insulations. The testing set-up consists of a plastic box with open roof, which was replaced by thermal insulation material – stone wool. All specimens were 100mm thick and with surface 300*300mm. Walls and the bottom of the box were insulated with 40 mm thick XPS boards on the outside and coated by an aluminous foil to prevent any weight-gain in surrounding walls caused by moisture uptake from ambient air.

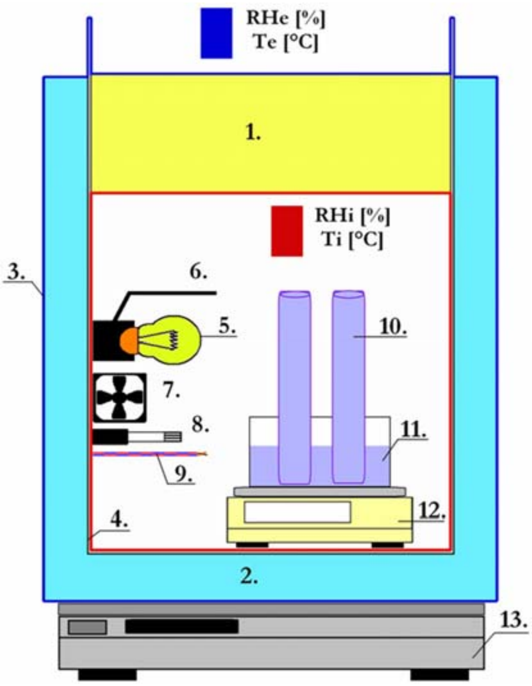

Figure 2 Composition of testing set-up including numbered list of components:

1.material sample (th. 100 mm), 2.XPS insulation of the box-walls (th. 40 mm), 3.aluminium-foil coating, 4.plastic wall of the box, 5.light bulb, 6.cover of the light bulb, 7.ventilation fan providing circulation of air in the testing box, 8.calibrated humidity sensor, 9.temperature sensor, 10.Wettex textile installed to increase evaporation of moisture in the box, 11.water reservoir circa 400 ml, 12.precision laboratory balance registering evaporation of water from the reservoir, 13.precision laboratory balance registering a change of weight of the entire system.

In the box was placed a vessel with water. Volume of water was 400ml. For faster spread of moisture in the box, the water reservoir was settled with two tubes of Wettex textile – a piece of non-woven material based on cellulose with high water retention and water sorption. Evaporating water from the inner reservoir was registered by a precision laboratory balance under the vessel. The box was also equipped with moisture and temperature sensors collecting data about inner conditions (Ti, Rhi). Stable indoor temperature in the box was provided by a light bulb connected to a voltage transformer. Bulb shielding protected specimens from heat radiation. To keep circulation of warm air in the inner space, we used a tiny ventilation fan.

Any weight change of the entire system was registered by another precision balance placed under the testing box. Thanks to both inner and outer balances, it was possible to observe the amount of moisture evaporating in the system and the amount that truly left the system. To control temperature gradient and relative humidity in material specimens, extra three moisture and temperature sensors were installed into outer sides and centre of each material sample, see Figure 3. That gave us a complex view of moisture processes in different altitudes. Moisture leakages in joint around the material sample were denied by sealing with non-absorbent polypropylene tube and silicon bonding agent.

Figure 3 Temperature and humidity sensors placed in material specimen.

The entire testing set-up was placed in a climate chamber with regulated temperature (Te). Conditions in the climate chamber were recorded by another couple of temperature and humidity sensors. Thanks to two pieces of Wettex (mentioned above) the inner volume of the plastic box (30 litres) became saturated by water flux within few minutes. After reaching the saturated state, relative humidity in the box (RHi) remained stable for the rest of the testing interval.

5. Results and discussion

Specimens were tested for four different outdoor temperatures (Te=-20°C, Te=-15°C, Te=-10°C, Te= -5°C), while the indoor temperature was always the same, Ti=+20°C. Each measurement lasted 100 hours. Material samples were cut into pieces in two altitudinal levels just after the testing period and each piece was weighed before drying. This helped us to map an extent of moisture throughout the material.

Water in the upper part of specimens was in form of frost (see Figure 4), while in the lower part it was in form of condensation. Both zones accumulated in time. The frost was equally spread over the depth of tested materials. Growth of frost formation in specimens was clearly visible in cross-sections of material samples A and B (materials with higher densities). There was no visible zone of frost formation and condensation for the specimen C (material with the lowest density) even it occurred.

The collected data were analyzed and charted into figures. Moisture characteristics like moisture flow rate *G* (kg/s), diffusive flux *g* (kg/m^2s) and, consequently, moisture resistance factor *μ* (-) were calculated.

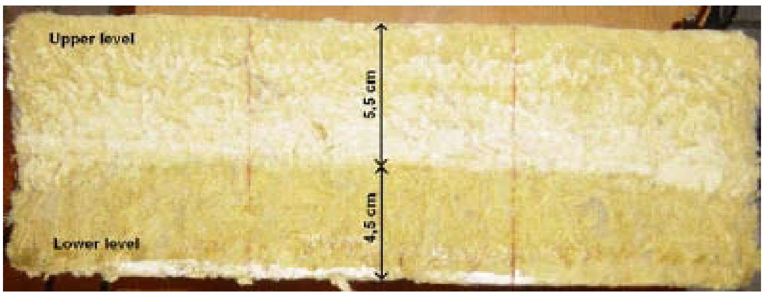

Figure 4 Specimen A - zones of frost formation (upper part) and condensation (lower part).

Measured and calculated data are summarized in Table 2 below. Moisture resistance factors *μ* for all tested materials were highest for outdoor temperature Te=– 20ºC and also the frost formation was most widespread in this case. The frost was stationary, as it is in practical cases, where it does not melt and evaporate until outdoor conditions turn.

Mi factors were compared with standards. They were found 2 times or 2,5 times higher than standard values, that are equal to 1 for both dry or wet mineral wool with density between 10-200 kg/m^3, for the highest temperature gradient through the material (Te=-20°C; Ti=+20°C). Consequently, EN 13162 says:" In the absence of measurements, the moisture resistance factor, *μ*, of mineral wool products, either unfaced or faced with a fabric with an open structure, may be assumed to be equal to 1." Remaining *μ* values for the temperature gradients (Te=-15°C; Ti=+20°C), (Te=-10°C; Ti=+20°C), (Te=-5°C; Ti=+20°C) had a downward trend (see Table 2) towards the tabulated values.

Our previous laboratory measurements for outdoor temperature Te within an interval (+20°C to +5°C) detected *μ* values in the interval <1,13-1,18> for the stone-wool specimen A. We used the same testing set-up, as well as, the same dimensions of material samples. In this case, results coincide with tabulated values introduced in EN standards mentioned above.

Table 2 Experimentally measured moisture resistance factors μ for the specified indoor and outdoor conditions within time interval 100 hours.

SPECIMEN A				
External conditions		Internal conditions		μ [-]

Taking into account results from others´ research, water vapour transport properties of stone wool are also influenced by fiber orientation and bulk densities of used specimens.

6. Conclusions

The constructed testing set-up, as well as, the chosen research approach was found effective in the studies of moisture processes in stone-wool based insulating materials. It also proved that the phenomenon of frost formation in the stone wool can exist for specific temperature gradient and moisture load - input conditions we often meet in practice.

Frost formation in the stone-wool samples opened to air was noted in all cases when the temperature field was between (+20 and –20ºC), (+20 and –15ºC), (+20 and –10ºC) and (+20 and -5°C). Air on the warm side was saturated with moisture. In the part of the specimen facing the warm humid air a condense formation occurred. Samples with higher densities (specimen A - ρ_d=145kg/m^3, specimen B - ρ_d=112kg/m^3) were visibly divided into the zone of frost formation and the zone of condensation in the cut. Also in the lightest stone-wool sample (C - ρ_d=44kg/m^3) the frost formation and condensation occurred, but no sharp borderline was observed.

Further studies are relevant in finding why moisture resistance factor (*μ*) in stone wool is comparatively high under circumstances of frost formation and if this can deteriorate in time. Last but not least, consequential degradation of the material structure together with loss of insulating qualities is paramount from the view of new trends in building industry, energy costs and sustainable development.

Keywords: life-cycle, LCA, environmental product declarations, PVC, plastics

Summary

The importance of life-cycle thinking is underlined in the European Commission's Communication on Integrated Product Policy. The Commission sponsored a review of the Life Cycle Assessments of PVC products by a group of independent consultants led by PE International. The objective was assessing the existing information and identifying gaps. The report covers all key B&C applications.

It concludes that comparing PVC with alternative materials does not make sense in general, but has to be considered application by application, usually with the conclusion that no material scores better on all criteria. The overall impacts of products depend not only on the production of the material itself, but also on its applications. The impact assessment must take into account all the life cycle stages. It shows that PVC is a material as any other, with both strong and weak points, depending on the application and use, and hence that there is no reason to treat PVC differently from any other material.

In parallel, the 'eco-profiles' (cradle-to-gate Life Cycle Inventory) of PVC resin were updated in 2005, as part of an on-going activity for all major thermoplastics. Results show that impact of PVC is comparable to competing materials. The environmental impacts have been aggregated into an Environmental Declaration.

1. The Importance of Life-Cycle Thinking and its Instruments

The Communication of the European Commission on Integrated Product Policy of June 2003 states "Up to now, product-related environmental policies have tended to focus on large point sources of pollution, such as industrial emissions or waste management issues. Often these have been successful. Now, however, it is becoming clear that they need to be complemented by a policy that looks at the whole of a product's lifecycle, including the use phase. This should ensure that environmental impacts throughout the life-cycle are addressed in an integrated way – and so are not just shifted from one part of the life-cycle to another".

The Integrated Product Policy approach is based on five key principles, the first being Life-Cycle Thinking, which "considers a product's life-cycle and aims for a reduction of its cumulative environmental impacts - from the "cradle to the grave". In so doing it also aims to prevent individual parts of the life-cycle from being addressed in a way that just results in the environmental burden being shifted to another part. By looking at the whole of a product's life-cycle in an integrated way, IPP also promotes policy coherence. It encourages measures to reduce environmental impacts at the point in the life-cycle where they are likely to be most effective in reducing environmental impact and saving costs for business and society"

The Communication goes on by stressing that "LCAs provide the best framework for assessing the potential environmental impacts of products currently available. They are therefore an important support tool for IPP." It mentions also Environmental Product Declarations (EPD) as a "a means of presenting quantified, life-cycle based information about a product in a standardised way" and as a "potentially important instrument"

2. Life Cycle Assessment of PVC and of Principal Competing Materials

2.1 Background

On 26 July 2000, the EU Commission adopted a Green Paper on the Environmental Issues of PVC. This Green Paper followed a commitment undertaken by the Commission in the proposal for a Directive on End of Life Vehicles, i.e. to assess the impact of PVC on the environment, including related human health issues, in an integrated approach.

In the debates before and after the publication of this Green Paper, including the April 2001 debate in the European Parliament, the question of a potential substitution of PVC in some specific applications was raised. In 2002, the Commission issued a tender for a study to provide, among others, information on the life-cycle impacts of PVC from production of chlorine to disposal, a comprehensive catalogue and critical analysis of all existing life cycle assessments of both PVC and products made from the principal competing materials, and an assessment of possible gaps in the information.

In its introductory considerations, the Commission stressed that “Substitution or phase-out of a certain material is the ultimate resort if all other measures to increase its sustainable use have failed or are insufficient. In the case of PVC, due to its versatility and wide range of different applications, there is not an individual other material that could be used as an alternative, but there is a whole range of different ones, depending on the product concerned. As always in the debates about replacement of one substance or material by another, a major concern is to establish that the use of the substitutes is indeed overall beneficial. A potential substitution would therefore need to be underpinned by a comprehensive and objective assessment of the main environmental, health, social and economic impacts both of PVC and of competing materials during their whole life cycle.”

2.2 Preparation of the Report

The tender was awarded to a consortium of consultants led by PE International GmbH. The key stakeholders were involved throughout the process of assembling and assessing the information. After a final review by the Commission, Baitz et al. (2004) published the final report.

2.3 Key Conclusions

2.3.1 Regarding the methodology

LCA comparisons should be undertaken at application level rather than at material level, particularly when used to support decisions. LCAs on applications are more comprehensive and draw a complete picture of the environmental impacts over the whole life cycle. This is not to say that LCAs at material level are without merit, but they appear to be an insufficient measure for decision-support.

Depending on the kind of product, the environmental impact during use or after end-of-life can be even more important than the environmental impact of material production. Even if a material has less environmental impact during production, it is not necessarily environmentally favourable. Moreover, advanced materials with a larger environmental impact in the production phase can have a much lower impact in the use phase due to a better system quality (e.g. less weight, longer durability, lower maintenance frequency, lower thermal conductivity)

LCA approaches can easily indicate the importance of material choices within a given life cycle and quantify the effects of possible alternatives. Therefore, material choices on case-to-case bases are often carried out and are accepted. However, if LCAs are intended to be used for the overall evaluation of preferable material alternatives of a certain product group, it would be necessary to clearly define a representative life cycle for this product This must represent all possible uses and application situations in an adequate and sufficient way. If not, then no useful or comprehensive overall comparison of the alternatives is possible and a decrease in the environmental impact due to chosen preference would be unlikely. The definition of such a representative life cycle is missing today, and it is doubtful that such a representative life cycle can be defined since the individual advantages and disadvantages of different material alternatives are most often a result of specific boundary conditions and application case.

2.3.2 Some key conclusions on PVC and its life cycle

- Approximately 100 LCAs related to PVC were identified, with only 30 making comparisons at the application level. Many of the reviewed LCAs did not fulfil all requirements outlined by the ISO 14040 ff norms.
- The most important applications of PVC are in the building and construction sector (windows/shutters, sheets, flooring and pipes), the electric and electronic equipment sector (predominantly cables), the transport sector and the packaging sector. A remarkable amount of LCA information is available for building materials and products.
- The production of intermediates, particularly the processes from the extraction of crude oil and salt up to VCM production, plays a major role for the environmental impacts.
- The production of stabilisers and plasticizers plays a significant role, whereas the production of pigments offers a comparatively low optimization potential, because of the small volumes used
- Some new technologies exist, e.g. mechanical recycling based on selective dissolution, for recycling PVC in an economically feasible way. Incineration, in conjunction with municipal waste disposal, is a simple option that allows for the partial recovery of energy and substances, if state-of-the-art technology is applied.

- Regarding the positive effects of increasing recycling rates, mechanical recycling (or material recycling), which loops the material back directly into new life cycles, substitutes, to a certain extent, the processes of resource extraction, intermediate production and granulation/polymerisation during the production of virgin material. Chemical recycling (feedstock recycling) is another option of recycling PVC into another life cycle.
- In contrast to some metals, the recycling market of plastics, and therefore the demand in secondary material, is not yet established in an adequate way. Nevertheless, today and in the near future, a mix of mechanical and chemical recycling pathways and state-of-the-art disposal routes appear as the most favourable way to optimise the environmental impacts of PVC and of competing materials.

2.3.3 Main findings regarding building sector- and application-specific LCAs

- For windows, one of the most important PVC applications, the available studies conclude that there is no “winner” in terms of a preferable material since most studies conclude that none of the materials has an overall advantage for the standard LCA impact categories. The most promising potential for lowering environmental impacts of windows is expected to be through the optimisation of the design and specific construction processes, which means increasing the quality of the windows with respect to their main function of saving heating energy in the use phase. Raising the amount of secondary material used, or lowering the amount of material required for the same function, may be another ground for optimization of the constructions. Therefore the choice of material is of rather minor importance, as long as the material can provide the required system quality of the window.
- Most flooring application studies conclude that linoleum has comparable or slightly lower environmental impacts compared to PVC flooring of equivalent quality in the production phase. One study states that wooden flooring tends to have lower impacts than PVC and linoleum, but is more demanding in the use and maintenance phase. All analysed studies claim the importance of the use phase due to detergent or chemical use in cleaning and maintenance. One study concentrates on the use phase and suggests that PVC might have advantages over linoleum in this phase and that the absolute demand seems to be strongly dependent on the context of the individual application (private use, professional use, industrial use). Therefore, the use phase should be analysed in more detail to obtain a representative judgment. Some studies are already considering this in adequate detail. There is little LCA information about carpeting, a main competitor for flooring applications.
- For roofing applications, available studies conclude that the quality of the systems (thermal conductivity per thickness of roofing sheet layers) as well as the accuracy of the laying and maintenance processes has the largest influence on the reduction of environmental impacts. Additionally, the studies conclude that ‘green roofing’ (e.g. planting on the roof) further decreases environmental impacts because of the subsequent longer lifetime of the roofing systems. Three polymer solutions (one PVC system and two competing polymer systems) have the potential to perform better, with similar environmental impacts on global warming, acidification and ozone formation over the life cycle. The studies report that polymer solutions tend to have lower environmental impacts than bitumen systems, due to the heavier construction of the latter.
- The results on pipes are very heterogeneous. Some studies see clear advantages for concrete and fibre cement pipes, some report clear advantages for polymer pipes such as PVC and PE, some conclude that the material plays no role as long as no cast iron is chosen. Two studies conclude that no material preferences for pipes can be stated, moreover, that no generalizations on ‘best materials’ are adequate, as the best choice is dependant on the local situation. Important technical parameters influencing the LCA of pipes are durability/maintenance, intended duration of use, the maintenance intensity and the weight/diameter of the pipes. Cast iron waste water pipes seem to be disadvantageous in comparison to PVC or concrete pipes. This is due to the fact that cast iron has relatively high impacts in production and weight makes laying pipes rather energy-intensive. Despite the heterogeneous results, some general conclusions on the environmental impacts of pipes can be drawn. Digging, laying, installation and use have to be included in the LCA studies of pipes. Reduction of the pipes’ weight will most likely lead to less environmental impact (less material needed, easier to lay). The use of recycled material would also lead to less environmental impact and is possibly easier than in other applications as no strict aesthetic requirements exist (especially for underground pipes). Leakage has a high impact, therefore the durability and mechanical properties of the pipes are of great importance.
- PVC does not seem to have significant competitors in many cable applications, therefore few PVC cable LCA studies exist. Recycling processes have been in place for some time, due to the high economic value of the recovered copper and aluminium. Economically feasible options exist for the recycling of recovered PVC.

2.3.4 Data gaps

No data gaps were identified in the building and construction applications.

3. Eco-Profiles and Environmental Declarations for PVC as a Material

3.1 Background – Link with Life Cycle Thinking

All LCA studies on PVC products have to rely on a quantification of the impacts of PVC resin production. Although the impacts during use phase are sometimes more important, production impacts have a major role, as mentioned in section 2.3.2, and hence are a key building block for LCA studies. In addition, impacts during production are often perceived as particularly detrimental, and hence need to be assessed carefully.

A LCA or LCI (Life Cycle Inventory, defined as the compilation and quantification of inputs and outputs for a product) covers the entire life-cycle of the product, starting with raw materials in the earth and covering all chronological processing and use operations until the materials are eventually returned back to nature. It is sometimes referred to as a 'cradle-to-grave' analysis.

The same type of information, applied to an intermediate product such as PVC resin is sometimes called an eco-profile. It is essentially a 'cradle-to-gate' analysis, .This means that the assessments start with raw materials in the earth and end with polymer resins ready for despatch to the converter.

3.2 The Eco-profiles of Plastics*Europe*

APME, the Association of Plastics Manufacturers in Europe (now Plastics*Europe*) decided as early as 1990 to develop LCI data sets for all major polymers. The initial methodology was published in 1992 and the first eco-profiles were published in 1993. They have been freely available via the Internet since 1999. PlasticsEurope eco-profiles are European industry average data-sets, compiled from individual company data by independent consultants. They cover the major proportion of European polymer production.

Even though only part of the life cycle is covered, some methodology issues have to be resolved. In some cases, several rational options are possible. A typical example is the allocation of impacts between several products and by-products. Choices have to be made, which is not a problem as long as they are clearly documented and transparent. For instance, chlorine production by electrolysis of sodium chloride is a multi-output process, yielding caustic soda and hydrogen as well as chlorine. Therefore all inputs and emissions have to be assigned to the different products. As this process is totally coupled it was decided to assign all inputs and emissions to the products on a mass basis. The detailed methodology of the Plastics*Europe* eco-profiles can be downloaded from http://lca.plasticseurope.org/methodol.htm

These eco-profiles are considered by specialists as the reference for environmental impacts of plastics until and including resin production. PlasticsEurope is a partner in the European Platform on Life Cycle Assessment, a project sponsored by the European Commission; PlasticsEurope provides the Life Cycle Data for plastics and intermediates of the European Reference Life Cycle Data System (ELCD). This EU project lead by the Joint Research Centre is intended to provide the technical and scientific basis for a life cycle approach in EU policy making.

3.3 PVC Eco-profiles

3.3.1 Scope and data sources

The first eco-profiles for suspension, emulsion and mass PVC resin were published in 1993. Several updates took place, but most were merely based on revised data for upstream manufacturing steps, for instance ethylene production. The only complete revision before the one reported here took place in 1999.

The eco-profiles for suspension-PVC, emulsion-PVC, vinyl chloride monomer (VCM) and chlorine production have now again been fully updated, based on plant data for the reference year 2004, collected in 2005 throughout the manufacturing chain,. The eco-profiles were prepared by the IFEU-Institut in Heidelberg and followed strictly the methodological guidelines of Plastics*Europe*. Minor issues were ironed out by close contact with the industry, through a dedicated industry task force and a review by manufacturing experts.

The results are very robust: Data obtained for VCM, S-PVC and E-PVC cover a total annual production of 5.6 million tonnes of PVC, representing 92% of Western European production. For one process type, bulk (or mass) polymerisation, information was obtained only from one plant and hence, for reasons of confidentiality, the eco-profile for bulk PVC could not be published this time.

The data relevant to chlorine production were obtained from PVC producers also producing chlorine, or from companies belonging to the same group. This yielded an eco-profile representative for the sub-set of Western European chlorine plants supplying vinyl chloride plants. The data cover nevertheless more than 50 % of the Western European chlorine production capacity.

3.3.2 Key results of the most recent update

Some key results for PVC are given in Table 1

Table 1 Some Key Results per kg of Suspension or Emulsion PVC

Emissions	Unit	Suspension PVC	Emulsion PVC
Carbon dioxide	kg	1.8	2.3
Methane	g	< 3.9	< 5.4
Sulphur dioxide	g	< 2.6	< 3.3
Nitrogen oxides	g	< 3.7	< 4.5
Mercury, to air and water	mg	< 0.24	< 0.41
Dioxin, to air and water	µg TEQ	$< 0.3 * 10^{-3}$	$< 0.3 * 10^{-3}$
Vinyl chloride, to air and water	mg	< 74.3	< 472
Total energy consumption	MJ	56.7	65.9

Energy consumption and related emissions (carbon dioxide, methane, sulphur dioxide and nitrogen oxides) are close to those of the main polyolefin polymers PE and PP. 90 % of the mercury is emitted to atmosphere, as a result of burning coal or oil in power plants.

The level of dioxin emissions during all the steps leading to PVC resin represents a yearly emission of less than 2 g per year for the whole European Union, i.e. far less than emitted by the metal extraction and processing in Germany alone (Federal Ministry for the Environment of Germany, 2005). The level of monomer emission is within the ranges quoted as “Emission levels associated to Beat Available Technology”, (European Commission (2006).

3.4 Further Work on the Eco-profiles of Plastics*Europe*

A project was initiated early 2007, in cooperation with the European Plastics Converters association EuPC, in order to take polymer eco-profiles one step further. Data are being gathered about the energy consumption and emissions of the key plastics conversion processes. PVC pipes and fittings, profiles and flooring will be covered. Completion is expected during the first half of 2008.

3.5 Environmental (Product) Declarations - EPD

ISO TR 14025 defines “Type III” labels, called “environmental declarations”, as the means of supplying environmental data based on Life Cycle Assessments on a business-to-business basis in the supply chain. A Type III EPD is a set of quantified environmental data consisting of pre-set categories of parameters based on LCA, but may also include additional environmental information provided within a Type III environmental declaration programme.

EPD schemes have been developed in order to provide credible information on the environmental impact of products. Their main function is providing input for sustainability solutions and for stakeholder dialogue. They are often used in business-to-business communication, but are also gaining importance in business-to-consumer communication. EPDs are a good example how key environmentally relevant product information can be provided in an easy-to-understand and condensed format.

An important advantage of using EPD is the possibility to add up LCI/LCA-based information along the supply chain. This feature makes EPDs specifically valuable for the building sector where the final building is based on a large number of materials, construction products and semi-manufactured products.

3.6 EPDs of PVC resin

In 2005, Plastics*Europe* developed Product Category Rules (PCR) for “Uncompounded Polymer Resins (or Reactive Polymer Precursors)”. The PCR document was published in September 2005 (Plastics*Europe*). The general programme rules were published in March 2007. The resulting EPD documents for polymer resins will be derived from the corresponding eco-profile data.

The EPDs for suspension PVC and emulsion PVC were the first published under this new Plastics*Europe* programme (September and October 2007 respectively, both updated in January 2008). Some key quantitative information given by these documents is included in Table 2.

Table 2 Input and output parameters as indicated in the Environmental Declarations for 1 kg of PVC

Parameter	Unit	Suspension PVC	Emulsion PVC
Non-renewable energy resources	MJ	55.4	64.4
Renewable energy resources	MJ	1.3	1.5
Water used for process (cooling excluded)	kg	10	11
Global Warming Potential	kg CO_2	1.9	2.5
Acidification Potential	g SO_2	5.3	7.0
Photochemical Ozone Creation Potential	g ethene	0.42	0.45
Nutrification potential	g PO_4	0.62	0.80
Dust/particulate matter	g PM10	0.43	0.75
Total particulate matter	g	0.49	0.83
Non-hazardous waste	kg	0.14	0.23
Hazardous waste	g	8	5

The Ozone Depletion Potential could not be calculated, as the entries in the eco-profiles were below quantification limits. Indicators such as Human Toxicity Potential and Fresh Water Aquatic Ecotoxicology Potential were not determined, because the methodology for assessing toxicity impacts on humans and the environment within LCA is still subject to scientific debate. Additionally, emissions potentially contributing to toxicity impacts originate essentially from the combustion of fuels for energy production and from oil refinery, not from specific PVC processes.

In addition to such input an output parameters, the PVC EPD documents provide a brief process description, information about the use phase and end-of-life management, as well as additional environmental, health, technical and economic information.

4. General Conclusions

All manufactured materials and products have an impact on environment during their entire life cycle. In order to be significant and comparable with other competing products having the same performances, the evaluation of the global environmental impact and of the sustainability of products has to be developed in a normalised way. The ISO 14040 series of standards issued as from 1998 are the reference method for evaluating the life cycle of a product or service.

Both sets of data described in this paper follow this standard. They show that PVC has both strong and weak points, depending on the application and on its use, and that there is no reason to treat PVC differently from any other material. Comparing a material such as PVC with alternatives does not make sense when made in general, but has to be considered application by application. Such comparisons usually conclude that no material scores better on all criteria.

MAINTAINING GREEN BUILDINGS - BEYOND THE DESIGN PROCESS

Stephen J. HENNESSY, B.Eng, MBA, C.Eng, CPEng, FCIBSE, FIEAust [1]

[1] Steensen Varming Australia Pty Ltd. 160 Sailors Bay Rd, Northbridge NSW 2063, Australia, stephen.hennessy@steensenvarming.com.au

Keywords: maintenance, performance, efficiency, compliance, commissioning, building services.

Summary

If there is one thing that most buildings services engineers can agree upon, it is that building services rarely perform as well as desired. The causes emanate from deficiencies in design, construction, commissioning, fit out changes and maintenance.

With the advent of greener buildings, considerable attention has been paid to preventing faulty design, construction, and commissioning. Poor maintenance, however, is much more universal, and its causes and remedies are not so widely understood.

This paper will focus attention on the objectives to be pursued by maintenance to help ensure that the building services are operated efficiently and effectively. Drawing from extensive experience gained in a number of buildings, it will highlight how small changes to maintenance procedures can deliver substantial energy savings, whilst improving occupant comfort. It will also demonstrate how good maintenance should begin at the design stage.

It is no longer appropriate for design professionals to believe that their sustainability obligations cease at the end of the design process. To be truly sustainable, we need to do much more than just deliver green buildings, we need to ensure that what we deliver continues to deliver, and that can only happen with proper maintenance.

1. Introduction

The performance of the building services installations in modern commercial, retail and industrial buildings, (and in particular air conditioning) rarely lives up to the owners' expectations. This is despite the fact that, in most cases, the services are installed to provide pleasant and efficient conditions for the occupants (and consequently to make the building more attractive to tenants).

The causes for this poor performance arise from a number of activities which include :

* design faults
* construction faults
* commissioning faults
* tenancy alterations
* poor maintenance

Perhaps the most universal of these problems is poor maintenance. Even if the design is excellent in all respects, the installation and commissioning faithfully carried out, and the tenancy alterations properly controlled, good maintenance is needed to keep the installation in that condition.

With the move towards greener buildings, and the proliferation of building energy performance rating systems such as the Australian 'NABERS Energy and Water', maintenance is taking on much a more important and urgent role. The effects or poor or inappropriate maintenance can significantly impact upon the building rating, which in turn may have leasing or performance guarantee implications.

2. Why Maintain?

It is somewhat ironic that many buildings owners and property managers understand the value of having their cars serviced regularly but consider the maintenance of their building services as more of an inconvenience. Ask property managers why they get a car serviced and they are likely to answer that a) it reduces the chance of a break down, b) it keeps the car running efficiently and c) it keeps the car safe. The same reasoning should be applied to building services. Proper maintenance should aim to -

- **P**RESERVE the asset
- Maintain its **E**FFECTIVE operation (eg, provide comfortable conditions)
- Maintain its **E**FFICIENT operation
- Maintain its **R**ELIABLE operation
- Maintain its **S**AFE operation.

Obviously, the weight to be given to each of these objectives will vary from one application to another. Reliability may be paramount in the air conditioning of a major computer installation, while efficient operation may be more important in an office building.

2.1 Preserving the asset.

Preserving the asset is an easily understood concept . Ensuring that an item of equipment is kept substantially in the same condition as when it was installed will of course prolong its life. Given the replacement of an asset is considered a "capital" item of expenditure and therefore not normally recoverable from tenants whereas maintenance is a legitimate "outgoing" that is recoverable you would expect all building owners to put "preserving the asset" high on their list of priorities.

In an industrial building complex north of Sydney the owners were faced with a potential $400,000 bill for the replacement of air conditioning units that had rusted away. The units were only 5 years old. Proper maintenance directed at preventing the corrosion would have cost less than $10,000 per annum.

2.2 Maintain its effective operation

Good maintenance is essential for effective operation. The equipment may appear to be in perfect condition, it may be very safe, it could even be efficient in operation, but if it fails to provide the desired end result it is not effective and therefore of limited value. In some cases the costs associated with ineffective operation can be clearly calculated (loss of production, high component failure rates etc) but in commercial buildings the costs are hard to quantify.

2.3 Maintain its efficient operation

The loss of system efficiency is the hidden cost of poor maintenance. A building does not generally become suddenly less efficient, it is a gradual change that makes it escape the notice of many property managers. Poorly maintained buildings systems often settle at a certain level of inefficiency so after a while the energy bills seem relatively reasonable (relative of course to the previous bill) and are accepted as a normal part of the building occupation costs. Proper maintenance could bring the building back to peak efficiency or even prevent it from degrading in the first place.

A study of nine commercial office buildings in and around Sydney yielded some interesting results. The mechanical services in each of the buildings were being maintained by a number of reputable contractors who carried out their maintenance tasks with little or no supervision. Prior to a proper maintenance specification and program of works being established, "Base Year" energy costs were calculated (the base year is calculated for each month of the year - based where possible, on the energy bills for the previous 3 years). Maintenance contracts were then let, and the work supervised by a third party. In every single case there was a substantial saving in energy.

The new maintenance contracts were let on a competitive basis and in most cases the cost was lower or equal to the price of the previously 'undefined' maintenance contract. After establishing the proper specification and program of works (a one off fee that varied depending on the complexity of the task), the only additional cost faced by the property manager was the cost of supervision.

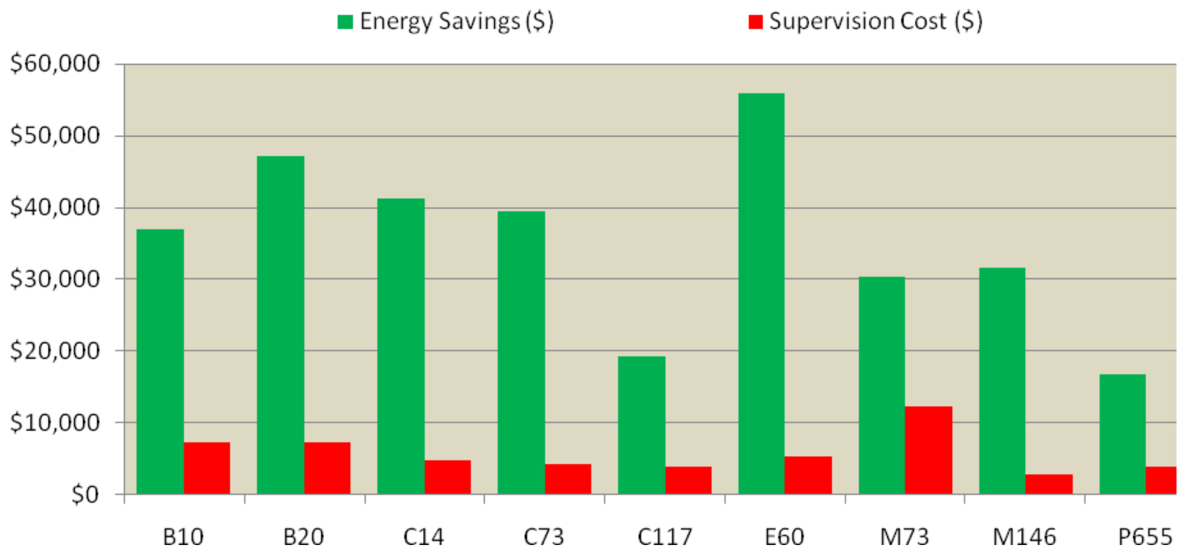

Figure 1 Supervision Costs Vs Energy Savings

The graph shows clearly that the savings in energy far outweigh the cost of supervision.

With the advent and proliferation of energy and water performance benchmarks, it is possible for tenants, investors and the like, to get a simple and comparative rating for a range of buildings. This is focusing attention on the energy and water efficiency of buildings in a way that we have not seen before.

2.4 Maintain its reliable operation

Maintenance to ensure reliability is a concept most owners and property managers can relate to. Making sure the bearings are lubricated, fans can turn, drains are clear etc are items we can all understand and it is not unusual to find maintenance programs that address this issue at the expense of all others.

2.5 Maintain its safe operation.

Maintaining safe operation should go without saying. Many would think that this is about checking guards etc and of course that is partly so. But it also includes the verification of safety device operations eg the ability of staircase pressurisation fans to sustain sufficient air flow velocity and pressure. Until quite recently it was common to find such safety checks were either not carried out, or tests were made and the results fabricated to cover up problems. In such cases the cost of poor maintenance could be measured in lives lost.

If all the above reasons were not enough to convince a property manager of the benefits of proper maintenance, there is always the law. There is an increasing amount of statutory work such as cleaning cooling towers, testing fire safety systems, etc, and often the legal responsibility for ensuring that these operations are carried out lies with the owner. Many building owners and managers are content to leave these matters to a contractor, but in our increasingly litigious society this is a dangerous road to follow, especially in the absence of proper contract documentation. Either way, tenants will be looking to the owner for damages and compensation of attributable losses, and building owners are perceived, rightly or wrongly, as having very deep pockets.

3. Ensuring Proper Building Services Maintenance

An owner or property manager who leaves a contractor to decide what equipment to include in the maintenance agreement, and how it should be treated, is taking a big risk - not least because the contractor's objectives may be quite different from his own.

Dealing specifically with the mechanical services, it is not uncommon for the building owner to place the maintenance of the plant in the hands of the installation contractor at the completion of the warranty period.

Some owners call for competitive prices to maintain the plant. Often such processes focus on cost, not value, so the contractor that quotes the lowest price will probably get the job, so there is a temptation to quote to provide the lowest standard of maintenance that they think will satisfy the client. To compound the problem, if there is a contract document, it will often be one that was written by the contractor (or his association) which would naturally tend to favour the contractor.

In the above case the owner is placing a great deal of trust in the contractor. Many owners do not have the technical knowledge to enable them to judge whether the contractor is doing what should be done, they simply hope that if they keep on paying, the end result will be satisfactory. Unfortunately, and the owner's hopes are not always realised.

The best way for the owner/property manager to get the desired results is to clearly define what is wanted in the form of a properly specified maintenance agreement. The agreement should include:

- a program of works
- concise instructions for the technician
- a requirement that the technician must report his results

The program of work should list what has to be done and when. It is not enough to say a certain job should be carried out annually or quarterly - the precise month and day the job is to be completed by should be nominated. The work should be schedule so that major services occur immediately before the equipment is expected to operate at its peak potential (eg service a chiller in September - immediately prior to the onset of the peak cooling season).

The instructions should be both item and job specific. A generic maintenance specification is an invitation for the service technicians to do what maintenance they see fit. Instructions such as 'set the damper as per the manufacturers instructions' is one of the best ways of ensuring the task is not done (technicians do not walk around sites carrying handfuls of manufacturer’s instructions, and they are unlikely to go looking for them).

Item specific instructions have their place, but maintenance specifications should also take into consideration that the building works as a system. Since almost no two buildings are the same it follows that the maintenance specifications should also differ from building to building. This is especially true when looking at controls - ensuring control strategies are properly maintained is the key to efficient operation.

With a properly prepared maintenance specification, the property owner/manager can call for competitive tenders secure in the knowledge that all parties are quoting to do the same level of work. Given that service company labour rates are fairly uniform throughout the various services disciplines, in theory the tenders should be fairly close. Obviously the owner should have a fair idea of the cost of the work before calling for tenders, and a company that has made a mistake during estimating should stand out when the prices are reviewed. Owners should avoid the temptation to award contracts solely based on the lowest price especially if it is obvious that the contractor has made an estimating mistake (any perceived saving will often be negated by the cost of extra supervision needed to ensure that the specified works are faithfully carried out).

Maintenance specifications can go too far. Some specifications list to the n^{th} degree all manner of maintenance tasks. Often the only useful function these will serve is as ammunition for the building owner to use against the contractor after some maintenance related disaster has occurred. It is essential that the specification is pragmatic (without being condescending), detailed (without being too detailed) and easy to administer and supervise.

Maintenance work by its very nature is difficult to supervise. Service technicians need to work throughout the plant, not primarily at work benches, and one often cannot tell by casual inspection whether the maintenance has been carried out or not.

Obviously it is necessary to keep the cost of supervision to a minimum, and the best way to do this is to have the servicemen report back to the owners supervisor on what they have done.

A specification should be based around service log sheets, and they can be made to function in a number of ways-

- As check lists to be sure that the contractor does not forget the obscure pump in a dark corner of the basement, or to treat rust before it is beyond repair;
- A reminder to the serviceman of special features of the installation such as an interlock to prevent a large chiller from running after hours, etc;
- A medium on which he is required to record all readings of pressures, temperatures and so on; and
- A communication tool between the serviceman in the field and his area supervisor, between the serviceman and the consultant supervisor, and between the contractor's area supervisor and the

consultant (this is also an excellent way for conveying recommendations, suggestions, prices for extras, etc).

An example of a service log sheets that satisfy these criteria appears in figure 2. The sheet is for the service technician to test and calibrate an air handling unit controller located in a commercial office building. The results give the supervisor a snapshot of the air conditioning performance, and when combined with readings taken at the same time (noted on other sheets), they become a valuable diagnostic tool.

Report for the Month of _______________, 19____		Equipment Numbers				
		AHU -8	AHU -9	AHU -11	AHU -12	AHU -14
AHU Controller						
- Using a recently calibrated thermometer measure temperature at room sensor (average out if TR4100 averaging sensors are used)	ºC					
- Note the corresponding temperature displayed at the controller	ºC					
- If the temperatures differ by more than 0.5ºC then re-calibrate controller.	OK/AR*					
- Adjust setpoint to equal display temperature.						
Check DA and RA outputs = 0 V	OK/AR*					
Check that both the hot and chilled water valves are fully closed	OK/AR*					
- Raise the set point and note temperature at which heating valve starts to open	ºC					
- Continue to raise the set point and note temperature at which heating valve is fully open	ºC					
- From the controller what is the DA voltage	V					
- From the controller what is the RA voltage	V					
- Lower setpoint until setpoint = sensor temperature. Is heating valve fully closed	OK/AR*					
- Lower the set point and note temperature at which cooling valve(s) starts to open	ºC					
- Continue to lower the set point and note temperature at which cooling valve(s) is fully open	ºC					
- From the controller what is the DA voltage	V					
- From the controller what is the RA voltage	V					
- Raise setpoint until setpoint = sensor temperature. Is cooling valve(s) fully closed	OK/AR*					
- Adjust set points as follows						
Set outside air thermostat at 20ºC (actual)	OK/AR*					
Set humidistat at 75%RH	OK/AR*					
Set controller to 22.5ºC	OK/AR*					
- Is the system operating properly	OK/AR*					

Figure 2 An example of an effective Service Sheet

The service sheet lists the check procedures, which are unique to this installation. The technician is taken through the tasks step by step with clear concise instructions. If the technician were told to 'check the controller and ensure it is operating correctly' it is very unlikely that any of the work would be done especially given that even the equipment supplier would not have some of the sequence information readily available.

Of course, with the advance in hand held computer technology, combined with bar coding or even more sophisticated identification means, it is no longer necessary to rely on paper based reporting systems, though the principals noted above remain the same

Whilst the specification can be designed to allow much of the supervision to be carried out from the supervisor's office, obviously it is necessary to visit the site often enough to ensure that the serviceman is diligent with his reports.

4. Statutory Requirements

As alluded to earlier, maintenance of building services is becoming more regulated. Fire and lift services have for some time been the subject of close government control, but it is only relatively recently that air conditioning maintenance has come under the spotlight.

An occupier, owner or his agent are liable to prosecution should they fail to comply with certain legislation. In addition, since mandatory maintenance requirements are to some extent better defined, so it is easier to determine negligence on the part of the building owner (no doubt we will see a growth in tenant initiated damages actions in the near future).

5. Better Building Maintenance

With all the apparent benefits associated with properly specified and supervised maintenance agreements it might be hard to understand why most buildings don't have them in place. To some extent the answer lies in a lack of awareness, both on behalf of the building owner/manager, and also the tenant/occupiers.

The preparation of proper specifications takes time, money, thought and experience. Owners do not normally have the engineering expertise to do this work themselves, and at the same time often lack the courage or conviction to employ a suitable consultant (ironically many owners understand the value of consultants during development and construction of a building, but not for maintenance).

An owner would assume that by appointing a property management company such matters as proper building services maintenance would be well addressed. Many property management companies make great issue of their 'in house' engineering expertise, but management fees are very competitive and sometimes the managers cannot afford to allocate the resources necessary to ensure proper maintenance. At the very least the owner should be prepared to pay a premium for better maintenance supervision. It is also desirable that an independent specialist check the maintenance procedures to ensure that the owners objectives are indeed being met.

It is usually the owner or property manager who makes the decision to implement properly specified maintenance, but it is the tenants who reap the benefits of energy savings. Because energy costs make up only a percentage of the total outgoings in a building, many tenants fail to comprehend the energy related benefits associated with proper maintenance (this in turn reduces the owner/managers incentive to try and achieve better energy efficiency). In the nine buildings used in the study above, the energy savings amounted to an average of \$3.60/m²/annum. Perhaps tenants need to take a more pro-active approach to such issues as proper maintenance.

6. Coping With Change

Putting in place proper and effective maintenance systems is not a ‘set and forget’ exercise. Buildings go through a number of changes throughout their life, including times of extensive refurbishment. It is essential therefore that the maintenance systems respond accordingly.

Good maintenance starts at the design stage. Systems and equipment must be inherently commissionable and maintainable. Involving maintenance personnel in the design review process can pay significant dividends further down the track.

With a move towards green retrofits of buildings, we are seeing an increase in the use of independent commissioning agents. Such agents are helping to ensure that buildings are handed over properly commissioned and fully operational. As part of this process there is a requirement to produce effective operation and maintenance manuals. This is the time to embed the principles expounded above.

Building professionals are also starting to embrace the concept of ‘soft landings’, whereby designers and commissioning agents continue to be actively involved in the building for a period of time after handover, primarily to ‘fine tune’ systems and ensure the building better meets the needs of the occupants. This soft landing period also presents a great opportunity to fine tune the maintenance systems, and to provide feedback to the design professionals such that they might improve the maintainability of future buildings.

7. Conclusions

There are many reasons why building services installations do not live up to expectations. These start with the initial design, and run through construction, commissioning, tenancy modifications and maintenance.

However, even if the design, construction, commissioning and tenancy work are all flawless; lack of proper maintenance will soon bring the quality of the building services down.

Maintenance contracts are usually not properly specified or supervised.

Good maintenance should achieve the owner's and the tenant's objectives (better conditions, longer plant life and more satisfied tenants), and the cost savings resulting from the energy savings alone usually amounts to more than the full cost of the maintenance itself.

Owners should be aware that property management companies with in house engineering expertise, may not necessarily be addressing the maintenance issues properly, and that at the very least their performance should be periodically checked by an independent specialist.

As tenants generally bear the costs and accrue the benefits associated with maintenance, it is in their interest to become better educated about the cost implications of proper maintenance, and to put pressure on the building owners and managers to perform better.

Owners and tenants should be aware that building services maintenance is becoming more regulated. In our increasingly litigious society it is more important than ever to stay abreast of the changes.

In short, maintenance can be much more satisfactory than is usually the case; it just needs careful thought and planning to deal with its intrinsic problems. The benefits to be gained are very substantial indeed.

Keywords: apartment complex, energy, Building Energy Efficiency Rating System, cost efficiency

Summary

The demand for sustainability capable of coping with worldwide climate changes has been increasing. Energy efficient buildings are essential for maintaining such sustainability. Buildings are responsible for over 25% of the energy consumption in Korea, and 68% of the total energy consumption in the building sector comes from residential use. This situation is not considered to be much different in almost every country. Improvement of energy efficiency may lead to the rise of construction cost. If each design element can be prioritized according to its cost efficiency, energy efficient buildings can be designed more cost efficiently. Thus, this study aims to analyze the cost efficiency of each item related to the energy efficiency of an apartment complex, which is the most common type of residential building in Korea. A baseline model apartment complex was set up, based on an actual apartment complex. Among all the assessment items in the Building Efficiency Rating System of Korea, items that were appropriate for cost efficiency analysis and applicable to the baseline model apartment complex were selected as target items. Then, alternatives for each target item were set up, and then construction and energy costs of each alternative were estimated through actual price data and the assessment method of the Building Energy Efficiency Rating System. Finally, the results presented four kinds of cost efficiency index-the LCC, the NPV, the IRR and the payback period-and the order of priority of each alternative in accordance with each index.

1. Introduction

With the effectuation of the Kyoto Protocol, many countries in the world have been endeavoring to reduce their emissions of greenhouse gases in various fields of industry. In particular, it is anticipated that Korea will be confronted with much more international pressure to lower its emissions of greenhouse gases after 2013 when the second commitment period of the Kyoto Protocol goes into effect because Korea has been ranked 9th in carbon dioxide (CO_2) emissions (IEA, CO_2 Emissions from Fuel Combustion, 2004) and 10th in energy consumption (BP, Statistical Review of World Energy, 2006) in the world. Greenhouse gases are usually generated from energy consumption. Buildings are responsible for over 25% of the energy consumption in Korea, and 68% of the total energy consumption in the building sector comes from residential use (Korea Energy Economics Institute, 2005). This situation is not considered to be much different from in almost every country. Consequently, energy efficient residential buildings can play a key role in reducing greenhouse gas emissions and further solving environmental problems caused by the use of fossil fuels.

The energy efficiency of residential buildings are being enhanced by numerous systems or projects such as the Home Energy Rating System (HERS) and the Energy Star New Homes of the USA, the MNECH1997 of Canada, the Code for Sustainable Homes of the UK, the Passive House of European countries and so on. In Korea, the Building Energy Efficiency Rating System has been in force since 2001 in an attempt to improve the energy efficiency of the apartment complex, which is the most common type of residential building.

Improvement of the energy efficiency may bring about a rise of construction cost. If each design element can be prioritized according to its cost efficiency, energy efficient apartment complexes can be designed more cost efficiently. Thus, this study aims to analyze the cost efficiency of each item related to energy efficiency of the apartment complex by using the assessment method of the Building Energy Efficiency Rating System. First, a baseline model apartment complex was set up, based on an actual apartment complex recently completed and regarded as the most common type. Among all the assessment items in the system, items which are suitable for analyzing the cost efficiencies were selected as target items. The lower and upper limit values of each target item were determined. Then more alternatives whose values vary stepwise between the lower and upper limits were set up. And construction and energy costs of each alternative were estimated through actual price data and the assessment method of the Building Energy Efficiency Rating System. Finally, the LCC, the NPV, the IRR and the payback period of each alternative were obtained as indexes of cost efficiency, and then an order of priority of each index was given to all the alternatives.

2. Building Energy Efficiency Rating System and Passive House

Substantial numbers of systems or projects in the world are being implemented to improve the energy efficiency of residential buildings. HERS is a standard measurement of the home's energy efficiency and Energy Star New Homes is a national mark given to the homes that meet guidelines for energy efficiency of USA. MNECH1997 and the Code for Sustainable Homes are national code of Canada and the UK, respectively, for energy efficient homes. The Passive House of the European countries, which is a voluntary project for very rigorous energy efficient buildings, is considered as a very strong project for energy efficient buildings in the world. And the Passive House, along with a domestic system, was selected for this study because it can provide criteria for a high performance energy efficient building.

2.1 Building Energy Efficiency Rating System

The System has been enforced by the Ministry of Commerce, Industry and Energy (MOCIE) and managed by Korea Energy Management Corporation (KEMCO). There are several regulations related to this system such as the Building Energy Efficiency Rating Regulation (MOCIE, Notification No.2005-10), Guidelines on the Funding of Energy Use Rationalization Work (MOCIE, Announcement No.2006-371) and the Building Energy Efficiency Rating System Management Regulation (also referred to as the Management Regulation hereinafter). An apartment complex with more than 18 units is qualified to apply for certification. Energy efficiency is determined by comparison of the energy demand reduction rate between the evaluated apartment complex and the standard apartment complex. The evaluated apartment complex is rated as 3 grades, as presented in Table 1. For the first or second grade, some incentives, such as loan at very cheap interest and so on, are given to the builder. The standard apartment complex, which is a hypothetical complex configured in accordance with the specifications mandated by the building codes currently in force, represents a complex with the minimum level of energy efficiency. The standard apartment complex is almost identical with the evaluated apartment complex except that each assessment item of the standard apartment complex has a value mandated by the building codes. Other physical conditions such as shape, size, structure, floor height, ceiling height, energy source, heating plant type and so on are the same as the evaluated apartment complex.

Table 1 Certification Grades of the Building Energy Efficiency Rating System[1]

Grade	Energy demand reduction rate against the standard apartment complex
1	33.5% or more
2	23.5% - 33.5%
3	13.5% - 23.5%

The energy demand reduction rate of the evaluated apartment complex is calculated by using eqs. (1), (2) and (3). In eq. (1), HED_{unit_std} and HED_{unit} are calculated in the same manner as HERS, by using the variable heating degree day method and the 2-zone model[2]. Assessment items of the System are divided into two types, the basic and the extra. Basic items are required to calculate the HED_{unit_std} and HED_{unit} in eq. (1), which include items mandated by the building codes. Extra items are optional items, not mandated but recommended by the building codes. These are composed of one that is related to the heating, domestic hot water, electric power, lighting and so on.

Energy demand and energy cost of the evaluated apartment complex can be obtained by extending the way of assessment in the system. HED_{apt_std} and HEC_{apt_std} can be obtained using eqs. (4) and (5), respectively. After calculating the RED_{apt} using eqs. (1), (2) and (3), ED_{apt} and EC_{apt} can be obtained using eqs. (6) and (7), respectively.

In eqs. (6) and (7), the terms ED_{apt} and EC_{apt} are used instead of HED_{apt} and HEC_{apt} because RED_{apt} includes the energy demand reduction rates for the extra items related to not only the heating but also to the domestic hot water, electric power, lighting and so on. In eqs. (1), (2) and (3), as well, both terms of heating energy and energy are used due to the same reason.

$$RED_{unit} = \frac{HED_{unit\_std} - HED_{unit}}{HED_{unit\_std}} \times 100 + \sum RED_{unit\_extra} \quad (1)$$

$$RED_{bldg} = \frac{\sum (RED_{unit} \times A_{unit})}{A_{bldg}} + \sum RED_{bldg\_extra} \quad (2)$$

$$RED_{apt} = \frac{\sum (RED_{bldg} \times A_{bldg})}{A_{apt}} \quad (3)$$

[1] Building Energy Efficiency Rating Regulation (MOCIE, Notification No. 2005-10), Appendix 1.

[2] Yu, K.H., 2006, A study on the energy efficiency rating and certification of apartment houses, Journal of AIK, Vol.22, No.12, pp. 322

HED_{unit}	Heating energy demand of the unit in the evaluated apartment complex (GJ/year)
HED_{unit_std}	Heating energy demand of the unit in the standard apartment complex (GJ/year)
RED_{unit}	Energy demand reduction rate of the unit in the evaluated apartment complex (%)
RED_{unit_extra}	Energy demand reduction rate by the extra item for unit, applied to the evaluated apartment complex (%)
RED_{bldg}	Energy demand reduction rate of the building in the evaluated apartment complex (%)
RED_{bldg_extra}	Energy demand reduction rate by the extra item for building, applied to the evaluated apartment complex (%)
RED_{apt}	Energy demand reduction rate of the evaluated apartment complex (%)
A_{unit}	Floor area for private use of the unit in the evaluated apartment complex (m^2)
A_{bldg}	Gross floor area for private use of the building in the evaluated apartment complex (m^2)
A_{apt}	Gross floor area for private use of the evaluated apartment complex (m^2)

$$HED_{apt\_std} = \Sigma HED_{unit\_std} \quad (4)$$

$$HEC_{apt\_std} = HED_{apt\_std} \times HER \quad (5)$$

$$ED_{apt} = HED_{apt\_std} \times \frac{100 - RED_{apt}}{100} \quad (6)$$

$$EC_{apt} = HEC_{apt\_std} \times \frac{100 - RED_{apt}}{100} \quad (7)$$

HED_{apt_std}	Heating energy demand of the standard apartment complex (GJ/year)
ED_{apt}	Energy demand of the evaluated apartment complex (GJ/year)
HEC_{apt_std}	Heating energy cost of the standard apartment complex (₩/year)
EC_{apt}	Energy cost of the evaluated apartment complex (₩/year)
HER	Heating energy rate per GJ (₩/GJ)

2.2 Passive House

The Passive House refers to the concept of highly insulated and air-tight residential buildings that can keep indoor environmental conditions comfortable. In the Passive House, the heating energy demand is minimized by means of passive ways such as super insulation, heat recovery, solar gain and so on. The Passive House has a limited energy demand of around 15kWH/m^2 for heating and around 120kWH/m^2 for heating, domestic hot water and all other electrical equipments combined and it is reported to have less than one fifth of the heating energy demand mandated by the building regulations currently in force in the participating countries.

Promotion of European Passive Houses (PEP) provides technical solutions[3] to achieve the Passive House level. It is a guideline about technologies applied in Passive Houses, and these technologies are composed of super insulation, heat recovery, passive solar gain, electric efficiency and on-site renewable. In addition, it provides the corresponding value range of each solution. Among the variable solutions, the one related to performance of the thermal envelope such as high insulation of walls, roofs, floors is selected for this study and the corresponding values are as follows: walls' U-value ≤ 0.15W/m^2K and roofs' U-value ≤ 0.15W/m^2K.

3. Baseline Model, Target Items and Alternatives for Cost Efficiency Analysis

3.1 Outline of the Studied Apartment Complex

In general, an apartment complex is divided into two types, the hall type and corridor type. Currently, the hall type is preferred because it offers privacy and more floor area for private use. The hall type "A" apartment complex, which was completed recently, has the unit of national housing size[4], so it was selected for this study. "A" apartment complex has fourteen buildings with eight types of units whose floor areas for private use range from 85m^2 to 273m^2. Considering that it may be appropriate to give precedence to national housing, it is assumed that the floor area for private use of every unit is 85m^2, while the gross floor area of the apartment complex is maintained. The analysis results of actual and reorganized apartment complexes are considered to show no difference because construction and energy costs of an apartment complex are mainly influenced by the gross floor area. Figure 1 and Table 2 show site plan and outline of the studied apartment complex, respectively.

3.2 Setting the Baseline Model

The baseline model is a unit building that has only 85m^2 units, nineteen floors and two cores. On every floor,

[3] Promotion of European Passive Houses (PEP), Passive House Solutions, 2006

[4] National housing defined in the Housing Act of Korea is originated from the housing policy to relieve the housing shortage. It can be regarded as the most common and normal housing for ordinary people. Its floor area for private use should be 85m^2 or below.

there are four units. The four units of the top floor have attics and there is a piloti at the right corner of the ground floor, so the baseline model has 75 units. The studied apartment complex was assumed to have only baseline model buildings. Figures 2 and 3 show a unit floor plan and a sectional plan of the baseline model, respectively, and Table 3 presents the outline of the baseline model.

Figure 1 Studied Apartment Complex Site Plan

Figure 2 Baseline Model Unit Floor Plan

Figure 3 Baseline Model Sectional Plan

Table 2 Outline of the Studied Apartment Complex

Location	Seoul
Gross floor area	192,451.98m^2 (Residence: 140,325.56m^2, Car park: 52,126.42m^2)
The number of units	Existing: 885 units → Converted: 1,263 units
Converted gross floor area for private use	107,384.40m^2
Heating plant	District heating

Table 3 Outline of the Baseline Model

Gross floor area	8,329.61m^2
Gross floor area for private use	6,374.25m^2
Floor area of the unit	111.16m^2 (floor area for private use: 84.99m^2)
Floor height	Top and ground floor: 3.0m, Base floor: 2.9m
Insulation	Wall:65mm, Side wall:90mm, Roof:110mm, Ground floor:50mm
Glass	16mm Pair glass(5CL+6Air+5CL)
Orientation	South

Table 4 Target Items

No.	Description	No.	Description
0	Balcony window U-value (W/m^{2}K)	16	Energy efficient control systems of ventilation fans of underground car park
1	Window U-value (W/m^{2}K)		
2	Window area (m^2)	17	Automatic control systems using computer, networking or internet
3	Door and others (facing the outside) U-value (W/ m^{2}K)	18	High efficiency induction motor (application rate, %)
4	Wall (facing the outside) U-value (W/ m^{2}K)	19	Voltage drop of main power line (%)
5	Wall (facing the outside) Area (m^2)	20	Bank configuration enables to control the number of current transformers in operation
6	Roof U-value (W/ m^{2}K)		
7	Ground floor U-value (W/ m^{2}K)	21	Peak demand control system of electric power
8	Wall and door (facing the unheated space) U-value (W/ m^{2}K)	22	Automatic control systems of equipments for receiving and transforming the electricity
9	Awning coefficient factor.	23	Application of high intensity discharge lamp and automatic on/off control system of the outside lightings
10	Thermostat per each room or zone		
11	Electric circuit configuration which enables to break the main power outlet of the living room conveniently or installation of certified energy efficient appliances	24	Energy efficient control systems of service water pumps such as inverter control, etc.
		25	Automatic adjustment equipment of power factor for power condenser installed in a group
12	Windbreak space at the building's entrance		
13	Average efficiency of pumps for heating water, service water, domestic hot water, etc. (%)	26	Decentralized control system with open protocol, which enables intensive control as well as data compatibility with each control system of mechanical and electrical equipments
14	Equipments, pipe and duct insulation		
15	Energy efficient control systems of heating water pumps such as inverter control, etc.		

※ 0~9: basic items for heated space, 10~11: extra items for unit, 12~26: extra items for building

3.3 Setting the Target Items and Alternatives

Among all the assessment items in the Building Energy Efficiency Rating System, the items which are suitable for analysis of cost efficiencies and whose performance values are changeable in the baseline model were selected as target items. The selected 27 target items are presented in Table 4. The overall performance range of each target item was determined. In the case of the basic item, a lower limit value was set to the value of the baseline model. The upper limit value was set to the value to reflect the Passive House level and the Management Regulation. Then, more alternatives of which values vary stepwise between the lower and upper limits were set up. Performance values of the alternatives were determined by dividing the overall performance range into 5 steps while consideration was given to practical matters such as the specifications or dimensions of the products on the market. In the case of extra items, the Building Energy Efficiency Rating System just assesses whether they are applied or not, or provides step-by-step performance values. The performance value of each alternative was set with consideration of these criteria. Table 5 shows the performance value of every alternative in the case of a typical.

Table 5 Alternatives for Each Target Item in the Case of Typical Floor

No.	Units	Low ◄ Performance range ► High						No.	Units	Low ◄ Performance range ► High

※ stands for the value of Baseline model apartment complex.

※ Actually, several extra items are applied to the studied apartment complex. However, this study assumes that extra items are not applied to the baseline model apartment complex because extra items themselves are the subject of cost efficiency analysis. In each case of No.13, No.18 and No.19, the value of RED_{extra_bldg} of the baseline apartment complex is zero.

※ No.2: The window area of the unit in baseline model is 23.14m², which is about 25.6% of total wall area. The window width is fixed for the day-lighting purpose, and the window heights of the living room and master bed room cannot be changed because they are entrance to the balcony. Window heights of the other 2 bed rooms are changed from 2.3m to 1.5m. Therefore, there are 3 alternatives for No.2: one is the baseline model, another is the case of only one bed room of 1.5m in height, and the other is 2 bedrooms of 1.5m in height.

※ No.3: According to the Management Regulation, only the two values can be approved as alternatives.

※ No.4: 4-1 the front wall, 4-2 the back wall, 4-3 the corner side wall, 4-4 the side wall except for corner side wall.

※ No.5, 9: There are 3 alternatives because No5 and No.9 are dependent on No.2.

※ No.7: 7-1 floors facing the outside directly, 7-2: floors facing the outside indirectly.
In the baseline model, there are 3 units in the ground floor because there is a piloti. These 3 units face the outside indirectly (there are underground car park) and one unit above the piloti faces the outside directly.

※ No.8: 8-1 wall, 8-2 entrance door. According to the Management Regulation, only the two values can be approved as alternatives for No.8-2.

※ No. 13, 18, 19: According to the Management Regulation, five values can be approved as alternatives.

4. Cost Efficiency Analysis

The spatial range for this analysis was set as the baseline model apartment complex, which means whole studied apartment complex composed of only the baseline model. Specific information on the cost efficiency analysis of each alternative of the target items is as follows.

4.1 Construction Cost and Annual Energy Cost

4.1.1 Construction Cost

Based on the construction project supplied by the government, the construction cost of a baseline model apartment complex and the construction cost difference between each alternative and the baseline model apartment complex were estimated, including both material and labor costs. Material cost reflects the price in Feb. 2008 and labor cost reflects the Standard Labor Work Estimation prescribed by the government in Jan.

2008. Estimated construction cost of the baseline model apartment complex is ₩ 15,276,753,777 (₩ 1,000 is about USD 1.00) and the construction cost difference between each alternative and the baseline model apartment complex is shown in Table 7.

4.1.2 Annual Energy Cost

HED_{apt_std} calculated by eq. (4) is 55,905.52 GJ/year. Energy rate of the Korea District Heating Corp. (KDHC) was applied to the value of HER in eq. (5). Monthly energy rate for the residential buildings of KDHC is presented in Table 6. HEC_{apt_std} calculated by eq. (5) is ₩813,843,820/year. The energy demand reduction rate of the baseline model apartment complex, calculated by eqs. (1), (2) and (3), is 23.74%. The energy cost of the baseline model apartment, calculated by eq. (7), is ₩ 620,637,297/year. The differences of both the energy demand reduction rate and energy cost between each alternative and the baseline model apartment complex are shown in Table 7.

Table 6 Monthly Energy Rate for Residential Buildings (KDHC, Mar. 2008, ₩ 1,000 is about USD 1.00)

Base Rate	Energy Rate
₩ 42.02/m^2 (exclusive residential floor area)	₩ 13,589/GJ

4.2 Cost Efficiency Index

4.2.1 Outline of the Cost Efficiency Index

There are various cost efficiency indexes such as NPV (Net Present Value), LCC (Life Cycle Cost) and IRR (Internal Rate of Return) which consider the time value of money, and the Payback Period which does not consider that. LCC is the sum of both the initial investment cost and operating costs during the lifetime. All operation costs are to be discounted to their present value prior to addition to the LCC total. LCC of both baseline model apartment complex and each alternative can be obtained by using eqs. (8) and (9). NPV is the sum of the present value of both investment and profits. NPV can be calculated by using eq. (10). The value of each alternative's NPV means the difference of LCC between the baseline model apartment complex and each alternative. Therefore, a negative NPV, which means an alternative is in the condition of discounted cash outflow, should be rejected. IRR is any discount rate that makes an investment's present value the same as the profits' present value, that is, specific discount rate that results in a NPV of zero. The greater an alternative's IRR, the better its rate of return. On the other hand, if an alternative's IRR is less than the standard rate of return (e.g., standard value can be real interest rate. see eq. (11)), that alternative should be rejected. NPV expresses cost efficiency of an alternative as a sum of money (i.e., the unit is ₩, see eq. (10)) and IRR does as a percentage (i.e., the unit is %). Therefore, the IRR can be a more effectual standard of decision-making under limited investments, because the size of the investment hardly influences the IRR. The payback period, which refers to the period of time needed to repay an investment amount, can be obtained by dividing the profits by the investment amount. It can be calculated by using eq. (12).

$$LCC = CC + PW \times EC \quad (8)$$

$$PW = \left(\frac{1+i}{1+R} \times \left(\left(\frac{1+i}{1+R}\right)^n - 1\right)\right) / \left(\frac{1+i}{1+R} - 1\right) \quad (9)$$

$$NPV = \Delta LCC = -\Delta CC + PW \times \Delta EC \quad (10)$$

$$r = \frac{1+R}{1+i} - 1 \quad (11)$$

$$PP = \frac{\Delta CC}{\Delta EC} \quad (12)$$

LCC	Life cycle cost (₩)	CC	Construction cost (₩)	PW	Present worth coefficient
EC	Energy cost (₩)	i	Price rise rate (%)	R	Interest rate (%)
n	Lifetime (year)	NPV	Net Present Value (₩)	r	Real interest rate (%)
PP	Payback period (year)				

ΔCC / ΔEC / ΔLCC Difference of Construction Cost / Energy Cost / LCC between Alternative and Baseline Model Apartment Complex

4.2.2 Calculation of the Cost Efficiency Index

LCC of the baseline model apartment complex and the difference of LCC between each alternative and the baseline model apartment complex are calculated using eqs. (8), (9) and (10). In eq. (9), i was set to 3.2%[5], which is the average consumer price index during the last ten years from 1998 to 2007. And R was set to 7.78%[4], which is the average loan interest rate of the Bank of Korea during the last ten years from 1998 to 2007. The age of an apartment complex used to determine the qualification of reconstruction is prescribed in the City and Residential Environment Maintenance Act as 20 years after the completion, which implies the minimum value of economic lifetime. However, n was set to 30 years, considering the fact that the body of research on the lifetime of a Korean apartment complex suggests 30 years or so, and knowing that the LCC

CC: Construction Cost (₩), ΔCC: Construction Cost Difference between Alternative and Baseline Model Apartment Complex (₩), RED: Energy Demand Reduction Rate (%),

ΔRED: Energy Demand Reduction Rate Difference between alternative and baseline model apartment complex (%), EC: Energy Cost (₩/year),

ΔEC: Energy Cost Difference between Alternative and Baseline Model Apartment Complex (₩/year), LCC: Life Cycle Cost (₩),

NPV: Net Present Value (₩) = ΔLCC(LCC Difference between Alternative and Baseline Model Apartment Complex), IRR: Internal Rate of Return (%), PP: Payback Period (year),

OP-1: Order of Priority of LCC and NPV, OP-2: Order of Priority of IRR and PP

(shaded)	this alternative is rejected (NPV < 0 and IRR < real interest rate)

of an apartment complex for more than 30 years hardly affects the entire cost.[6] As a result of the calculation, the LCC of the baseline model apartment complex is ₩ 25,460,421,604 and each alternative's LCC is shown in Table 7. And the calculation results of NPV, IRR and the payback period of each alternative are also presented in Table 7.

4.3 Cost Efficiency Analysis Results of Each Alternative of Target Items

Table 7 shows the cost efficiency analysis result. In the case of No.2 (window area), both construction and energy costs of Alt1 and Alt2 are smaller than those of the baseline model apartment complex. This is because the construction cost is directly proportional to the window area. With respect the energy cost, the decrement of heat loss is more than that of solar heat gain through the window with the decrease of window area. The IRR and payback periods of Alt1 and Alt2 for No.2 cannot be calculated, and Alt2 of No.2 is given the first priority because of its more decrease in construction and energy costs.

Alternatives with negative NPV, No.0 (balcony window U-value), Alt3 of No.1 (window U-value), Alt4 and 5 of No.4-3 (corner side wall U-value), Alt 3, 4 and 5 of No.6 (roof U-value), Alt5 of No.7-1 (ground floor U-value facing the outside directly), No.10 (thermostat per each room or zone), No.11 (electric circuit configuration which enables to break the main power outlet of the living room conveniently or installation of certified energy efficient appliances), No.12(windbreak space at the building's entrance), No.14 (equipment, pipe and duct insulation), No.19 (voltage drop of main power line), No.22 (automatic control systems of equipments for receiving and transforming the electricity), No.23 (application of high intensity discharge lamp and automatic on/off control system of the outside lightings) and No.26 (decentralized control system with open protocol, which enables intensive control as well as data compatibility with each control system of mechanical and electrical equipment) should be rejected. In addition, with respect to the IRR, these alternatives also proved to be cost-inefficient due to their IRR value being lower than the real interest rate, 4.44%, which is calculated applying the price increase rate, 3.2% and interest rate, 7.78%.

All but the rejected alternatives are arranged according to their NPV values. In case that if there are several alternatives for one target item, only one alternative having the best NPV value among them is selected. As a result, Alt5 of No.8-1 (wall U-value facing the unheated space), Alt2 of No.2 (window area), Alt4 of No.4-2 (back wall U-value) and Alt5 of No.1 (window U-value) are proven to be superior from the point of NPV. In the same manner, Alt2 of No.2 (window area), Alt1 of No.13 (average efficiency of pumps for heating water, service water, domestic hot water, etc), Alt1 of No.8-1 (wall U-value facing the unheated space) and Alt1 of No.7-2 (floor U-value facing the outside indirectly) are proven to be excellent with respect to IRR. Alt2 of No.2 (window area) is proven to be quite good regarding both NPV and IRR. And the order of priority of NPV shows the same as that of LCC, and IRR appears also the same as payback period.

5. Conclusion

This study analyzed the cost efficiency of each item related to the energy efficiency of an apartment complex by using the assessment method of the Building Energy Efficiency Rating System of Korea. The baseline model apartment complex was set up, based on an actual apartment complex. Among all the assessment items in the system, items that are suitable for analyzing cost efficiencies were selected as target items, and alternatives for each target item were set up. Construction and energy costs of both each alternative were estimated by using actual price data and the assessment method of the system. As a result, the LCC, the NPV, the IRR and the payback period as indexes of cost efficiency and the order of priority in accordance with each index were presented. In addition, very cost efficient alternatives with respect to the NPV and the IRR were suggested. The results of this study are expected to be the guideline for developing energy and cost efficient design models of an apartment complex.

Summary

In 2005, a consortium comprising of thegreenroom, The University of Hong Kong, Davis Langdon & Seah Management Ltd., and the Business Environment Council completed a combined Life Cycle Assessment/Life Cycle Costing Study of a public rental New Harmony Block for the Hong Kong Housing Authority. The decision making tool measured the financial implications and ten environmental impacts of selecting 110 alternative building materials from the standard specification. The results showed that NHB block generated 1.54 HKE-points/CFA and cost HK$18040.46/CFA (US$2313.08/CFA) for the whole 55-year building life-cycle. If Ordinary Portland Cement block partition is changed to gypsum partition, the environmental impacts and the cost would increase by 0.26% and 0.07%, respectively. The decision-making tool assessed environmental and economic sustainability but did not assess the health advantages/disadvantages from alternative materials. To test the possibility of a health assessment, we identified three quantitative health indicators suitable for integration to the LCA and LCC tool: 1) risk-of-illness 2) burden of diseases in DALYs and 3) medical cost. This paper defines the health benchmark for existing residential building blocks in HK and it indicates the total cancer burden of residential building blocks with the three health indicators. The paper will demonstrate a three-tier decision-making process for health, environmental and cost performance with the three indicators and the health benchmark of a typical HK residential building. The final tool will assess the environmental, economic and health performance of housing developments.

1. Introduction – A Combined LCA and LCC Assessment Tool for HK Public Housing

In 2005, a combined Life Cycle Assessment (LCA) and Life Cycle Costing (LCC) building assessment tool for Hong Kong Housing Authority (HKHA) was completed by thegreenroom, The University of Hong Kong, Davis Landon & Seah Management Ltd., and the Business Environmental Council in collaboration with Building Research Establishment (BRE), UK. The building in assessment was the New Harmony Block (Option 2) (NHB), a 40-storey concrete-framed residential building for public-rental that accommodates a total of 3,196 individuals (fig. 1).

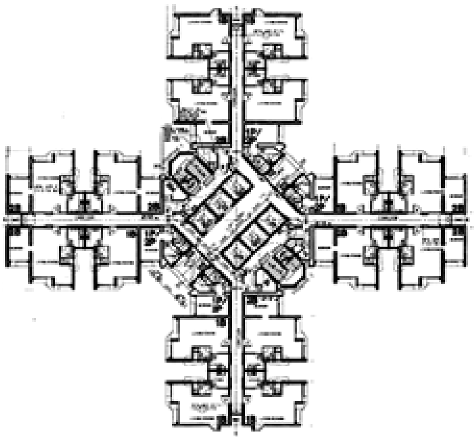

Figure 1 Typical floor plan (left) and the appearance (right) of the New Harmony Block (Option 2)

The goal of the combined tool was to measure the following ten environmental impacts and determine the financial implication of selecting 110 alternative building-materials under standard HKHA specification in the whole life cycle perspective, including (1) raw material extraction, (2) building material manufacturing, (3) transportation, (4) construction, (5) building operation, (6) repair and maintenance, and (7) disposal (Amato et al., 2006):

1. Energy (MJ)
2. Resource depletion (kg)
3. Water consumption (m^3)
4. Waste (kg)
5. Climate change (kg CO_2 eq.)
6. Acid Rain (kg SO_2 eq.)
7. Photochemical smog (kg C_2H_2 eq.)
8. Ozone depletion (kg CFC-11 eq.)
9. Toxicity to humans (kg toxic eq.)
10. Toxicity to ecosystems (kg toxic eq.)

a) Capital cost (initial cost)
b) Recurring cost (operational cost; repair and maintenance cost), and
c) Demolition cost

The tool characterised[1], normalised[2] and weighted[3] the ten environmental impacts into a notional HK Environ-pt (HK E-pts), which was equivalent to the ten environmental impacts generated by one HK citizen annually. By means of HK E-pts and the money spent, architects and other building management professionals can quantitatively judge the environmental-friendliness and cost-effectiveness of alternative building materials from the building life-cycle point of view. For example, the alternation of ordinary Portland cement block with gypsum partition can reduce life-cycle environmental impacts of NHB by 0.26% HK E-pts and increase the life cycle costs by 0.07% (Amato et al., 2006). The existing tool did not assess the social sustainability, which could include the aspect of health, skill, ability, education and social-connection (Hart, 1999).

1.1 Quantitative Health Impact Assessment and Indicators Combined with LCA and LCC

Existing LCA and LCC tool can potentially integrate with a Health Impact Assessment (HIA) module to measure improvement or decline in disease burden brought about through the use of alternative materials. To allow such an assessment, the selection of health indicators sensitive to modification of building materials would be important in the whole process. Wong et al. (2006) tested the sensitivity of various health indicators and found three that can be used to measure the disease burden from building materials (see table 1).

Table 1 Three types of quantitative health indicators appropriate for measuring burden of diseases related to building materials (Wong et al., 2006)

	Types of health indicators	Example of measurement
1	Risk of illness or dying	Probability of have specified illness or incidence rate per 1,000 or 100,000 population
2	Positive and negative burden of disease	Disability Adjusted Life Years (DALY) which measures both Years of Life Lost (YLL) and Years Lived with Disability (YLD)
3	Externality cost	Medical or treatment cost for illness

This paper provides a measurement of the potential disease burden of a typical 40-storey high-rise residential building in Hong Kong. The result can act as a comparison benchmark for the combined LCA,

[1] Howard *et al.*, (1999) described characterization as: *"The purpose of this is to translate different inventory inputs (emissions) into directly comparable impact indicators. The characterization process follows international practices in the characterization of inventory data for their potency with the different impact categories."*

[2] Howard *et al.*, (1999) described normalisation as: *"The purpose is to express impact indicator data in a way that can be compared among impact categories. The procedures normalized the characterized results by dividing by selected reference values, which can be:*

- *The total emissions or resource use for region that may be local, regional or global*
- *The total emissions or resource use for an area on a per capita basis"*

[3] The ten environmental impacts were weighted for their local, regional and global importance as set up according to a series of HKHA workshops organised in 2002.

LCC and HIA tool for public housing. This paper will use (1) the selected health indicators, (2) the health benchmark of typical HK residential building, and (3) the combined LCA and LCC decision-making tool to measure the health implications, environmental impacts and economic implications from applying different alternative partition materials on NHB housing block and discuss the benefits and the drawbacks.

2. Object of Study – A Typical Residential Premise

A typical HK residential building built in the 1990s is a 40-sorey high concrete-framed building. It accommodates 320 residential flats including 240 three-bedroom units and 80 two-bedroom units. The building can lodge as many as 1100-1200 individuals, which is one-third the population of NHB.

Figure 2 Typical floor plan (left) and appearance (right) of a residential building

Table 2 summaries the local indoor contaminant concentration level of a typical HK residential building and provides comparison to the mean Volatile Organic Compounds (VOC) concentrations of non-industrial indoors in Japan, the Level 1 and Level 2 Indoor Air Quality (IAQ) objective of HK Environmental Protection Department (HKEPD), and the carcinogen classification of those indoor air contaminants by the standards of the International Agency for Research on Cancer (IARC) (Ho 1996; Lee et al. 2002; Azuma et al., 2006; Indoor Air Quality Group Management Group 1999). Under IARC classification, Group 1 agents are carcinogenic to humans, Group 2A agents are probably carcinogenic to humans, Group 2B are possibly carcinogenic to humans, and Group 3 agents are not classifiable as to their carcinogenity to humans (IARC, 2007). Most of the indoor contaminants found in HK residential indoors have been classified as probably/possibly carcinogenic to humans, while radon, benzene and formaldehyde are definitely known for their carcinogenicity to humans (IARC, 2007). Note that carcinogenicity is defined by the concentration level and the occupants' exposure time to the carcinogen. This study assesses the potential cancer risk of these contaminants.

To benchmark the burden of cancer from radon and VOC concentrations of residential indoors, we applied the most updated epidemiological data from USEPA. Particularly, the data on radon was based on the cohort study based on the latest epidemiological follow-up of 68,000 underground miners (National Research Council, 1999). WHO (2000) considerers the epidemiological study on miners adjusted to residential context as the most reliable data for application to public health concerns.

We considered the hours of exposure data from different age groups to calculate the burden of disease Figure 3 shows the total hours of stay for HK dwellings (Chau et al., 2002) with the longest number of hours spent in bedrooms in HK residential buildings (7.9 to 9.8 hrs per day). Youth and elderly tended to stay longer in residential premises than other adults. Individuals of less than 18 years age and those above 60 years spend 57% and 68% of their time during weekdays at home, respectively. During weekends, the >60 age group could spend as long as 74% of their time indoors. Thus, the youth and elderly age occupants could have higher cancer potential from indoor contaminants than the adult group. According to our survey undertaken in a new town in HK, 12.4% of the population were smokers; 14% of the population was less than 15 ago old 30% was in the age group of 15-34; 44.3% was 35-64; and, 11.8% was higher than 64 age old living in a residential building.

Table 2 Radon and VOC concentration levels of HK residential dwellings, non-industrial indoors in Japan compared with the EPD Level 1 and Level 2 IAQ objective and International Agency for Research on Cancer classification of carcinogenicity to humans (Ho 1996; Lee et al. 2002; Azuma et al., 2006; HKEPD 1999; IARC, 2007)

3. Results of a Health Benchmark Study on a Typical HK Residential Premise

According to the time activity pattern, the indoor and VOC concentrations found in a typical residential premise, the surveyed population mix, and the smoking prevalence of occupants, we calculate the health performance of a typical concrete-framed residential building if all occupants live for 30 years in the dwelling. The indicators were in terms of cancer risk, cancer DALYs and cancer treatment cost. Table 4 shows the health benchmark result. Nearly 96% of the cancer risk arises from lung cancer associated with the radon concentration of the concrete-framed building and smoking habits of occupants. The 2nd and 3rd hotspots were leukaemia risk caused by benzene and nasopharynx cancer caused by formaldehyde, respectively. These contaminants were associated with 2nd-hand smoking, outdoor air pollution, cooking combustion and off-gassing of building materials (Niu et al., 2001).

Table 4 The potential cancer risk of a typical HK residential building built in the 1990s if all occupants live for 30 years in the dwelling

Health Indicators	Cancer Risk
Risk of cancer per 1,000 people	2.6-2.7
Cancer DALYS per 1,000 people	78.56-79.85
Cancer treatment cost per 1,000 people (US$)	278,514-282,968

4. Result of Health Performance of New Harmony Block (Option 2)

After setting up the benchmark, we utilised the combined LCA and LCC decision-making tool, the health indicators and the health benchmark to assess the health performances from different partition materials for a typical public housing block. The assessment of a public housing block was based on real ventilation measurements, and the results of studies on the actual population mix, window operation patterns and real exposure survey. These data will be explained in more detail in future publications.

Figures 3 – 5 show the difference of cancer risk, DALYS and treatment cost per 1000 people between a typical public housing block and the health benchmark of a typical HK residential building. The public housing block has 5-6% lower cancer risk, less cancer DALYs and lower cancer treatment costs than the benchmark for a typical residential building in HK of all occupants live for 30 years in the dwellings. This is because public housing block has better cross-ventilation than a typical residential block which lack corridor windows and whose main doors are always closed due to security demands from occupants, resulting in reduced potential air circulation.

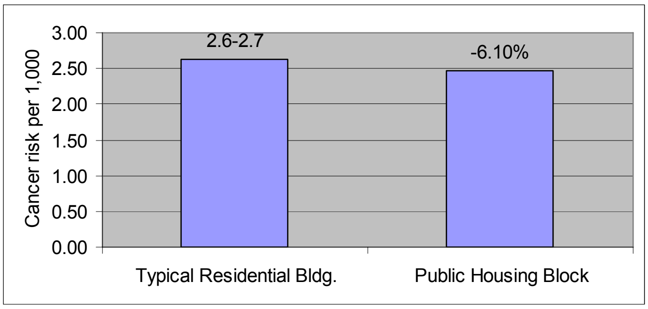

Figure 3 Cancer Risk per 1,000 people for a Public Housing Block and Health Benchmark

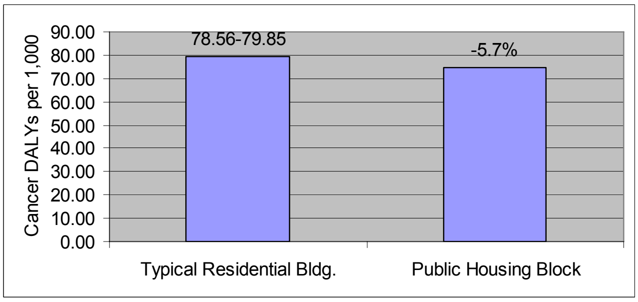

Figure 4 Cancer DALYs per 1,000 people for a Public Housing Block and Health Benchmark

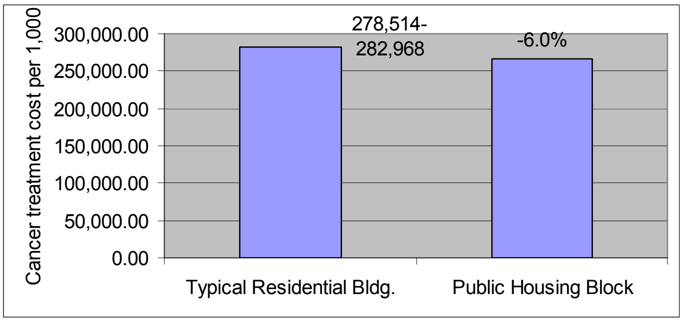

Figure 5 Cancer Treatment Cost (US$) per 1,000 people for a Public Housing Block and Health Benchmark

5. Alternative Study to Reduce Radon Cancer Risk from Partition Materials

Five alternative partition materials were tested by Mui (2005): PFA concrete block, lightweight concrete partition, gypsum partition, red brick partition and autoclave aerated concrete (AAC) block partition. These partition materials are made of soil or rock and they emit radon at different emanation rates as shown in Figure 6 (gathered from local literature by Mui 2005).

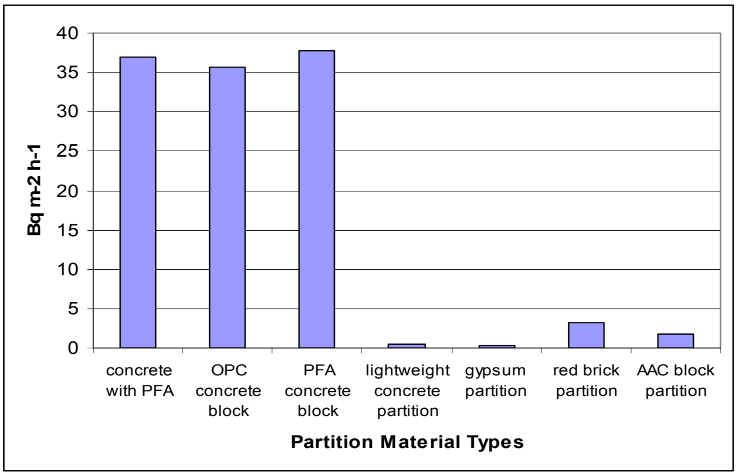

Figure 6 Radon Emanation Rate (Bq. m-2h-1) of different partition materials from local literature (Mui, 2005)

Some partition materials for example, gypsum partition, emit small amounts of carcinogenic VOCs. By applying the mass balance model and the VOC time decay pattern of building materials, the life-cycle environmental performance in terms of HK E-pts, life-cycle cost and the operational health improvement in terms of the three health indicators for a public housing block with gypsum partition are shown in Table 5. Gypsum partition increases the life-cycle environmental impacts by 0.26% and increases the life-cycle cost by 0.07%. Figures 6-8 show the cancer risk, cancer DALYs and cancer treatment cost per 1,000 people between health benchmark, the public housing block without any alternative materials and with gypsum partitions.

Table 5 Comparison of the life-cycle environmental impact and life-cycle cost between a public housing block without any alternative materials and a public housing block with gypsum partition

Case	Life Cycle Env. Impact (HK E-point per CFA)	Whole Life Cost (HK$ per CFA)
Base case with hollow concrete block	1.540	18040.5
Alternation from hollow-concrete block to gypsum partition	1.544 (+0.26%)	18053.1 (+0.07%)

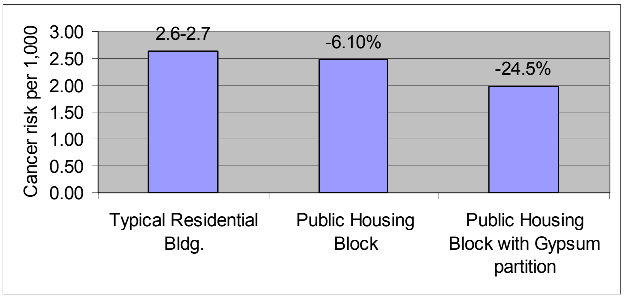

Figure 6 Cancer Risk per 1,000 people for a Public Housing Block and Health Benchmark and a Public Housing Block with Gypsum Partition

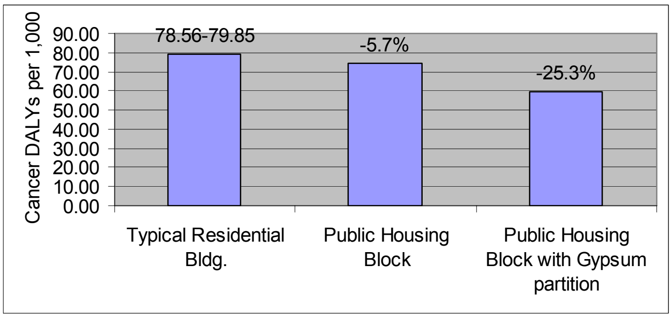

Figure 7 Cancer DALYs per 1,000 people for a Public Housing Block and Health Benchmark and a Public Housing Block with Gypsum Partition

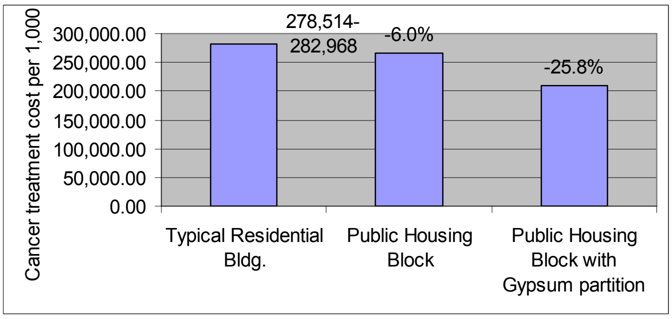

Figure 8 Cancer Treatment Cost (US$) per 1,000 people for a Public Housing Block and Health Benchmark and a Public Housing Block with Gypsum Partition

Compared to the benchmark for a typical HK residential building, a public housing block with gypsum partition can improve the health performance of the building during operation stage with 24.5% less cancer risk, 25.3% less cancer DALYs and 25.8% less cancer treatment cost. Although the gypsum partition increases the life-cycle environmental impacts and the life-cycle cost by about 0.3%, these costs are considered to be negligible in comparison to the greatly improved health performance by over 25% and reduced potential cancer treatment cost by 25.8%. In the long term, these can greatly reduce the burden on the society's health investment.

5. Conclusion

This paper demonstrates an example of the combined LCA, LCC and HIA decision making process. The combined LCA, LCC and HIA tools can potentially help decision makers to justify the environmental, economic and health performance of any building. This paper also measured the health, environmental and cost benefits from source control approach with gypsum partition.

Future publications will investigate the health, environmental and cost benefits from improvement on ventilation approaches and other alternative material applications. The future focus of our research will address the health burden of other life-cycle stages other that the 55-year building operation period included in this analysis. The final tool will assess environmental, economic and social sustainability of the whole building life-cycle and facilitate holistic decision-making for public housing.

Summary

During the last decades, the main focus of research in Building Services was on reduction of energy consumption of buildings. But no longer it is sufficient to look only at the building itself the occupant and the energy infrastructure need also be considered too. The strong focus on the energy reduction led to situations in which health and comfort are endangered. Integration between end-user and building is the ultimate in the intelligent building concept. "Connecting" the end-user to a building is complex. User-connectivity, the combination of usability and user interface together, is studied and developed further.A further challenge for future sustainable developments is a renewable energy infrastructure to reach an acceptable price level and a minimized environmental impact.

Design tools for renewable energy installations are available on the level of individual installations. There is a need for an Integral Design approach which describes at the conceptual level the process as a chain of activities, which starts with an abstract problem and which results in a solution. The paper will discuss the approach to reach the goal of integration of end-user and energy infrastructure.

1. Introduction

In today's modern buildings people expect a comfortable working environment. This is achieved by good integration of advanced technology for ventilation, heating and cooling in our buildings. Over the years energy efficiency of buildings has increased. At first by better ways of constructing followed by applying better insulation and better glazing. Also the introduction of more efficient building equipment has lead to further reduction of the energy use of buildings. Still there is a persistent discrepancy between increasing demands for comfort in buildings and the need to decrease the use of energy. Global warming, caused largely by CO2 emissions as a result of energy consumption, shows an increasing effect. Climate change is becoming a major problem. As results of Global Warming (Alley 2007) become more and more prominent, it is necessary to look for new possibilities to save energy and to generate sustainable energy to be used for comfort in the built environment. Preservation of energy resources, occupant comfort and environmental impact limitation are the key issues of modern and sustainable architecture. A major portion of primary energy consumption, about 40 %, is due to create thermal comfort in buildings by heating, cooling, ventilating and lighting. At each level in the design process different decisions have to be taken. One of those decisions is the application of sustainable energy systems and components. However this is rather complex to integrate in the early stages of building design as many aspects have to be taken into account. During the last decades, the main focus of research in Building Services was on reduction of energy consumption of buildings. The strong focus on energy reduction led to situations in which health and comfort are endangered.

Instead these sustainable energy systems are added during the final design stages. This results in sub optimal solutions and often leads to complete rejection of proposals to use sustainable energy systems at all. At the early design stages, usually only conceptual sketches and schematics are available, often rough and incomplete. Architects tend to develop their designs in a drawing-based, graphical way (prototypes are used to investigate the design concepts). As the design proceeds, more information and detail will be developed.

In office buildings most of the energy is needed for thermal comfort especially cooling. Present energy efficient technology is not sufficient to further reduce the energy use of buildings. New comfort control technology, such as individual control, offers new possibilities to further reduce energy consumption of office buildings. Dynamic online steering of individual comfort management and building management could save up to 20% of current energy consumption. Misunderstandings and wrong conceptions about indoor comfort and energy use are common. Most office users are not even aware of the fact that they can affect the energy use. The behaviour of building occupants needs to be taken into account as it is responsible for almost half the outcome of planned energy reduction (Claeson-Jonsson 2005). When the comfort control system is not working adequately, a lot of energy is wasted by too much heating or cooling. As a result of this overshoot indoor temperature is the most common issue in occupants' complaints about thermal comfort.

As until now the user has not been part of the building comfort system control strategy in offices, the energy consequences of the user behaviour are not accounted for. New technological development is needed to incorporate the behaviour of occupants of buildings. We did some development in this field. The first experiment was part of the European EBOB-project (Energy efficient Behaviour in Office Buildings). In EBOB so called *Forgiving* Technology was developed, with this technology each user in the building was given control of his or her personal comfort (Claeson-Jonsson 2005). The goal of the project was, by giving the user a choice in combination with feedback on the energy consumption/cost efficient operation was enhanced. In the SMART/IIGO project the agent technology was developed. SMART stands for *Smart Multi Agent Technology* (Jelsma et al. 2002) and IIGO (Kamphuis et al.2005) is a Dutch acronym for *Intelligent Internet mediated control in the built Environment*. The in SMART developed technology was tested in an extended field test in the IIGO-project. The lessons learned in these projects are used in the Flexergy project. In this project SMART control of the building is combined with agent technology for energy purchase on an open market. This technology was developed by ECN in the POWERMATCHER-project (PM). The PM-technology combines local demand and supply of electricity and efficiently incorporates distributed generation into the network (CRISP 2002).

The energy supply on a system level should be dominated by trends in demands by the occupants of the buildings (Fig.1).

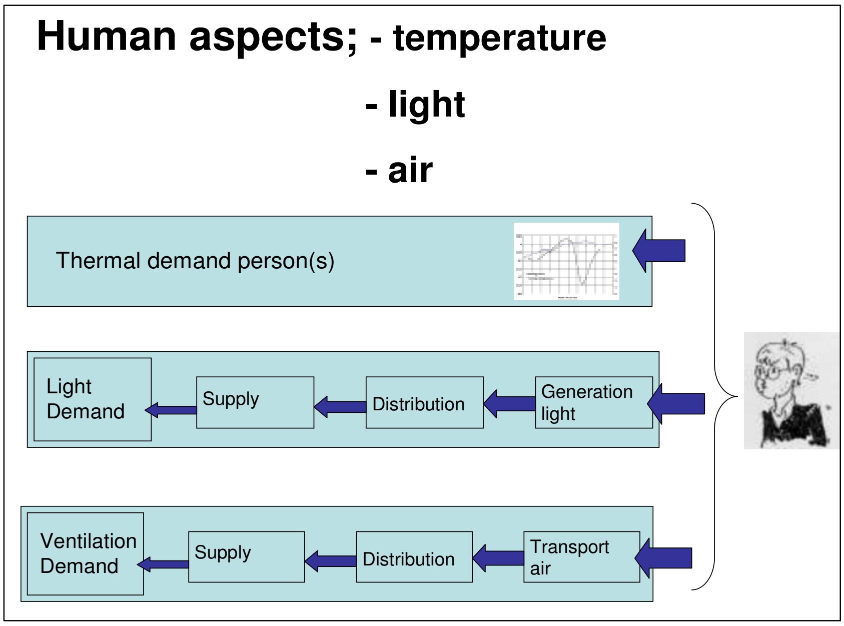

Figure 1 Human demands and needs

Until now the user has not been part of the building comfort system control strategy in offices and the energy consequences of the user behaviour were not accounted for. Integration between end-user and building is the ultimate in the intelligent building concept. "Connecting" the end-user to a building is complex. User-connectivity, the combination of usability and user interface together, is studied and developed further. Information and communication technology connects people and helps them to communicate with the building. New technological development is needed to incorporate the behaviour of occupants of buildings.

The energy supply on a system level should be dominated by trends in demands by the occupants of the buildings (Fig.2).

+

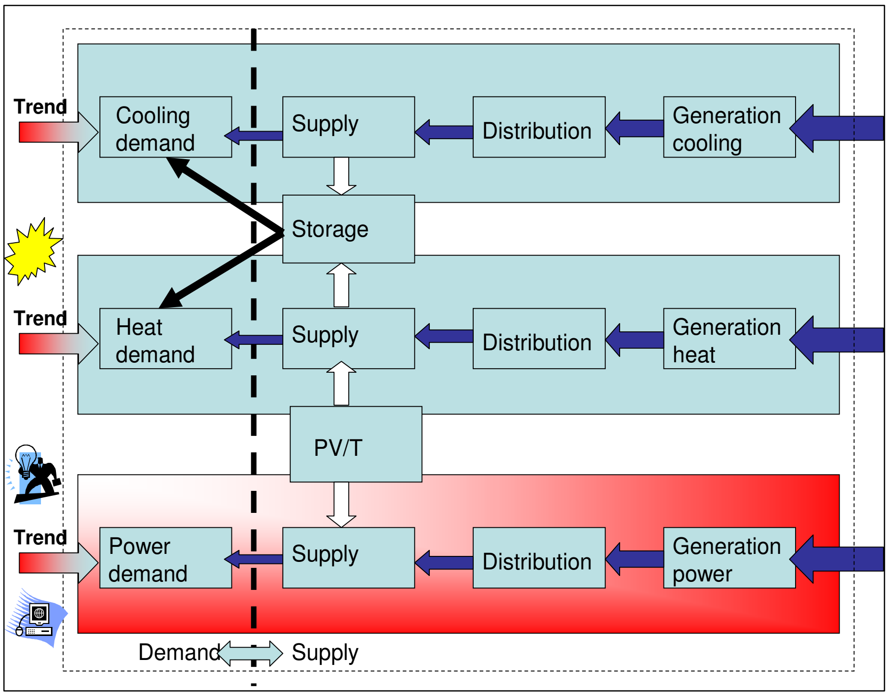

Figure 2 Demands and supply on system level

Such novel control systems should not only improve the energy performance of the building, but should also offer benefits to users (i.e. building operators as well as workers). Comfort management should be linked with improving energy efficiency. Individual comfort management makes it possible to optimize comfort, energy efficiency and costs. This combination would be beneficial for building operators as well as occupants. Therefore in commercial buildings, the inclusion of options for individual comfort management is an important feature to make such systems attractive to end users.

The making of the built environment has become more and more complex. In the conceptual design phase, in order to create conditions to assure a better built environment, the ingenuity of the whole design team existing of different disciplines should be used, not only architecture.

2. Methodology

2.1 Open building principle

Open building developed by N.J. Habraken (Habraken 1961) attempted to integrate industrial building and user participation in housing, but the concept can also used for office buildings. It approached the built environment as a constantly changing product engendered by human activity, with the central features of the environment resulting from decisions made at various levels. During the design process participants and their decisions were structured at several levels of decision-making; the infill-level, the support-level and tissue-level. On each level there has to be made a balance between the performance of supply and demand for the building during the life-cycle.The levels of city structure, urban tissue, support, space and infill were usually distinguished. Open building entailed the idea that the need for change at a lower level such as the dwelling, emerged faster than at upper levels, such as the support. The “thinking in levels” approach of Open building was introduced to improve the design and decision process by structuring them at different levels of abstraction. At each level in the design process different decisions have to be taken. One of those decisions is the application of sustainable energy systems and components. However this is rather complex to integrate in the early stages of building design as many aspects have to be taken into account. During the design process participants and their decisions are structured at several levels of decision-making; the infill-level, the support-level and tissue-level. On each level there has to be made a balance between the performances of supply and demand for the building during the life-cycle. Instead these sustainable energy systems and elements are often added during the final design stages. This results in sub optimal solutions and often leads to complete rejection of proposals to use sustainable energy systems and components at all.

Central idea of Open Building was to respond to the various needs of individual users through the phasing of the design and implementation process. In order to provide prospective occupants with the opportunity to influence their building, the elements decided by the occupants must be easy to change. Thus adaptability is not merely a means for modifying the dwelling during use; it is first and foremost a strategy for enabling the fulfilment of individual wishes without compromising. Thinking in levels is the basic Open Building principle.

To apply the principles of Open Building design to the optimization of the energy infrastructure of a building and the surrounding build environment, a methodology was developed by us. Not only the building to design but also the design process itself became a topic of study. The results of this new approach are called "Duurzaam Flexibele Proces Integration" – sustainable flexible process innovation. This makes it possible to integrate in a flexible way the energy flows connected to heating, cooling, ventilation, lighting and power demand, within a building and between buildings and the built environment. This leads to flexibility of energy exchange between different energy demands and sustainable energy supply on the different levels of abstraction in the built environment.

2.2 Design methodology

Our integral approach encompasses the built environment from initiative to design, construction and real estate management as a seamless whole. This seems to contradict with the subdivision of the construction industry in phases, in which parties operate with opposing interests, resulting in disintegration and waste. The coordination of these independent phases, scales, decision-makings and disciplines are crucial to the creation of a sustainable built environment in which the people concerned feel comfortable.

When attempting to integrate sustainable energy aspects into design decision-making, the process must identify opportunities of sustainable energy. Instead of developing new design methods, this research study attempts to utilize existing architectural design characteristics and decision making for the introduction of sustainable energy – resulting in good building designs. This implies defining a methodology that acts as a bridge between architectural elements, such as shapes and materials on the one hand, and sustainable energy use together with the aspects of indoor climate issues such as overheating and ventilation on the other.

To develop our required model of design support, an existing model from the mechanical engineering domain was extended: Methodical Design. This design model by van den Kroonenberg, it was based on the combination of the German (Kesselring, Hansen, Roth, Rodenacker , Pahl and Beitz) and the Anglo-American design schools (Asimov, Matousek, Krick) (Blessing 1994). This design model was chosen as a basis because; " it is one of the few models that explicitly distinguishes between stages and activities, and the the only model that emphasis the recurrent execution of the process on every level of complexity (Blessing 1993, p.1398)". Especially the horizontal dimension is not strongly represented in other familiar design models and thus tend to be forgotten (Roozenburg and Cross 1991, p. 216); "not so much by its authors but by its users and, above all, its critics, leading to faulty arguments and misinterpretations of the model." This design model was extended into an integral design model by us, by adding an evaluation step.

Our Integral Design process can be described at the conceptual level as a chain of activities which starts with an abstract problem and which results in a solution. The original design process is extended from three to four main phases, in which eight levels of functional hierarchical abstraction, stages can be distinguished. A feature of our extended model of design, Integral Design, is the occurrence of a four-step pattern of activities in each stage, see figure 3.

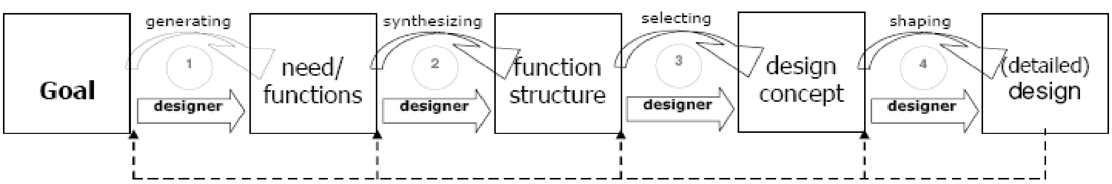

Figure 3 The four-step pattern of Integral Design

In order to survey solutions, engineers classify them according to various features. This classification provides the means for decomposing complex design tasks into problems of manageable size. Decomposition is based on building component functions. This functional decomposition is carried out hierarchically so that the structure is partitioned into sets of functional subsystems. Decomposition is carried out until simple building components remain whose design is a relatively easy task. This like the decomposition which is described in the guidelines 2221 and 2222 of the "Association of German Engineers", VDI (Beitz 1985). It possible to compare this highly abstract approach with the hierarchical abstraction of Open Building which is more commonly known in the building industry, see figure 4.

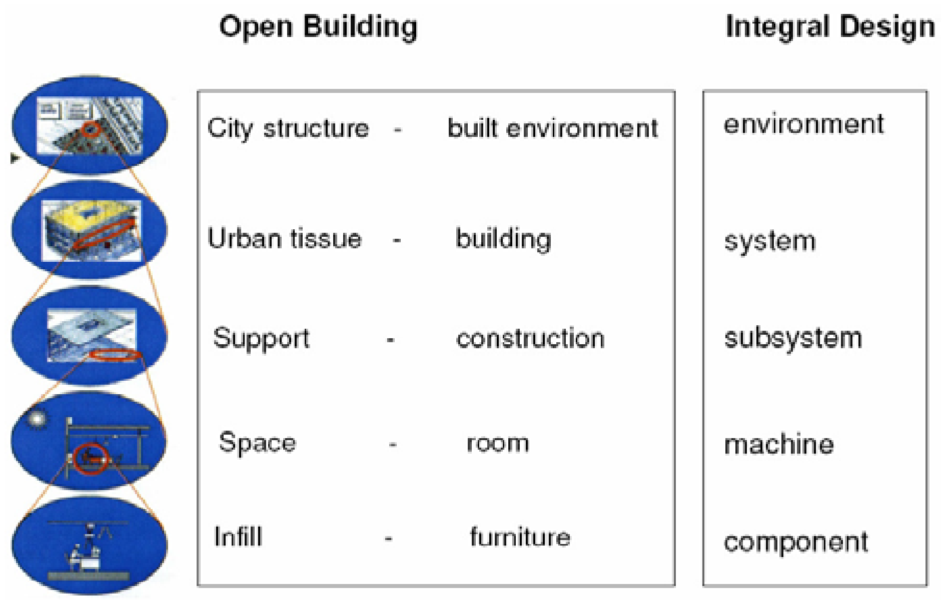

Figure 4 Comparison hierarchical abstraction Open Building and Integral Design approach

2.3 Morphological Overviews

For the synthesize activities of the Integral Design process morphological overviews can be used to generate alternatives in a very transparent and systematic way. General Morphological analysis was developed by Fritz Zwicky (Zwicky&Wilson 1967) as a method for investigating the totality of relationships contained in multi-dimensional, usually non-quantifiable problem complexes (Ritchey 2002). The Morphological overview is a key methodology that can improve the effectiveness of the concept generation phase of the design process (Weber and Condoor 1998). It is this aspect which we focus on in our research.

Based on definition of functions, morphological overviews make it possible to assess client's needs on higher abstraction levels than what a program of requirements (which is often too detailed) provides. The morphological approach has several advantages over less structured methods. We think it may help to discover new configurations, which thus far may not be so evident and could have been overlooked. The morphological chart gives a complete overview of aspect elements or sub-solutions that can be combined together to form a solution. The purpose of the vertical list is to try to establish those essential aspects and functions that must be incorporated in the product, or that the design has to fulfil. These are often expressed in rather abstract terms of product requirements or functions. Also the morphological approach is an excellent way to record information about the solutions for the relevant functions and aspects. It aids in the cognitive process of generating the system-level design solutions (Weber and Condoor 1998). The morphological approach has several advantages over less structured methods, it may help to discover new configurations, which may not be so evident and could have been overlooked. It also has definite advantages for scientific communication and for group work (Ritchey 2002). We think like Ritchey (2002) that the morphological approach has definite advantages for communication and for group work.

2.4 Technology layers

Design takes place in an environment that influences the process and as such it is contextually situated (Drost & Hendriks 2000, de Vries 1994). The context of a model of design is composed of a "world view". One of the major problems in modeling design knowledge is in finding an appropriate set of concepts to refer to the knowledge, or -in more fashionable terms- finding an ontology. Our model consists of 4 worlds (the real world , the symbolic world , the conceptual world and the specification world). These worlds are coupled to specific abstraction levels. The contents of the different abstraction levels are based on the technical vocabularies in use, technology-based layers (Alberts 1993):

1. Information Level: knowledge-oriented, representing the "conceptual world".

This level deals with the experts' knowledge of the systems. One of the essential ideas behind this is that human intelligence has the capacity to search and to redirect search. This information processing capacity is based on prior design knowledge.

2. Process Level: process oriented, representing the "symbolic world".

This level deals with physical variables, parameters and processes. The set of processes collectively determines the functionality of the variables that represent the properties of a device. Modelling at the functional level involves the derivation of an abstract description of a product purely in terms of its functionality. This abstraction reduces the complexity of engineering design to the specification of the product's desired functionality.

3. Component Level: device orientation, representing the "real world".

This level describes the hierarchical decomposition of the model in terms of functional components and is domain dependent. Generic components represent behaviors that are known to be physically realizable. They are generic in the sense that each component stands for a range of alternative realizations. This also implies that the generic components have yet to be given their actual shape.

4. Part Level; parametric orientation, representing the" specification world".

This level describes the actual shape and specific parameters of the parts in the form of which the components exist. Relevant technical or physical limitations manifest themselves in the values of a specific set of parameters belonging to the generic components. These parameters are used to get a rough impression, at the current level of abstraction, of the consequences of certain design choices for the final result.

The technology-based layers can be combined with the abstraction levels from the Integral Design methodology. The method/contents matrix, represents the recursion of the design steps of a design process from high abstraction level to lower abstraction levels and is now combined with the principles of Open Building and the technology-based layers of building services, see fig.5, which shows the relation between the technology layers of building represented in relation to the conceptual world view model.

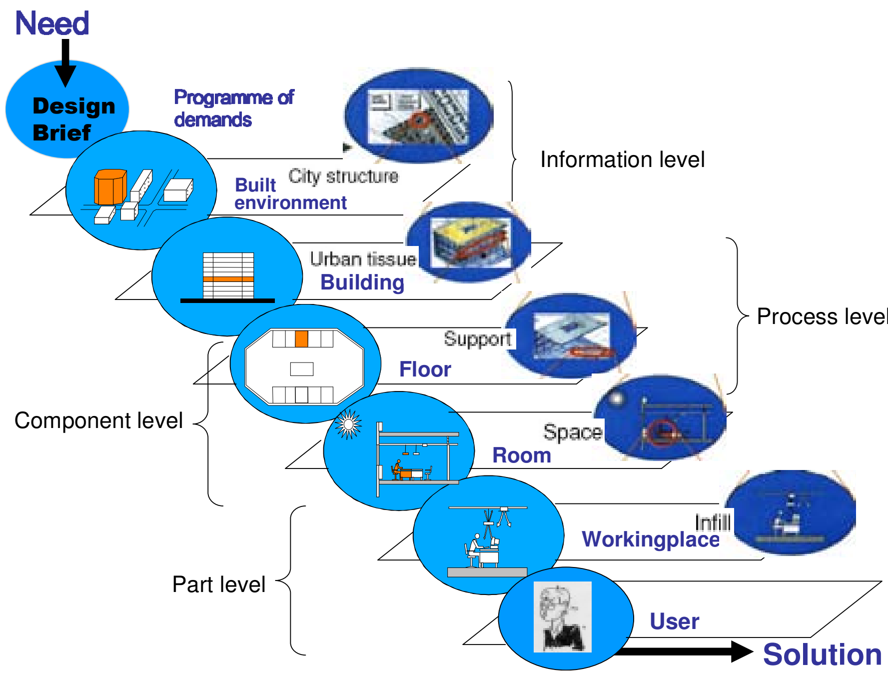

Figure 5 Hierarchical abstraction levels by functional decomposition and the different aspect levels

3. Results

The function-oriented strategy allows various design complexity levels to be separately discussed and, subsequently, generated (sub) solutions to be transparently presented. This way the interaction with the other participants of the design process is aided, and at the same time design process information exchange is structured, see fig. 6. Combining the concept of morphological overviews with hierarchical functional abstraction levels leads to a structure of different sets of morphological overviews for cooling, heating, lighting, power supply and ventilation.

In fig. 5 an example of the different abstraction level morphological overviews are presented. In these overviews the alternative solutions for generation, central distribution, central storage, local distribution, local storage and supply are presented to fulfill the need on the specific abstraction level of built environment, building, floor, room, workplace and person. The overviews are used to generate new possibilities for a flexible energy infrastructure in and between buildings to optimize the combination of decentralized power generation, use of sustainable energy source on building level and traditional centralized energy supply.

The overviews are used to generate new possibilities for a flexible energy infrastructure in and between buildings to optimize the combination of decentralized power generation, use of sustainable energy source on building level and traditional centralized energy supply. The energy flows of heat, cold and electricity have to be optimized together. For this a new design and control strategy based on Integral design and the use of agent technology is developed. The work on these subjects within the project will continue till 2010.

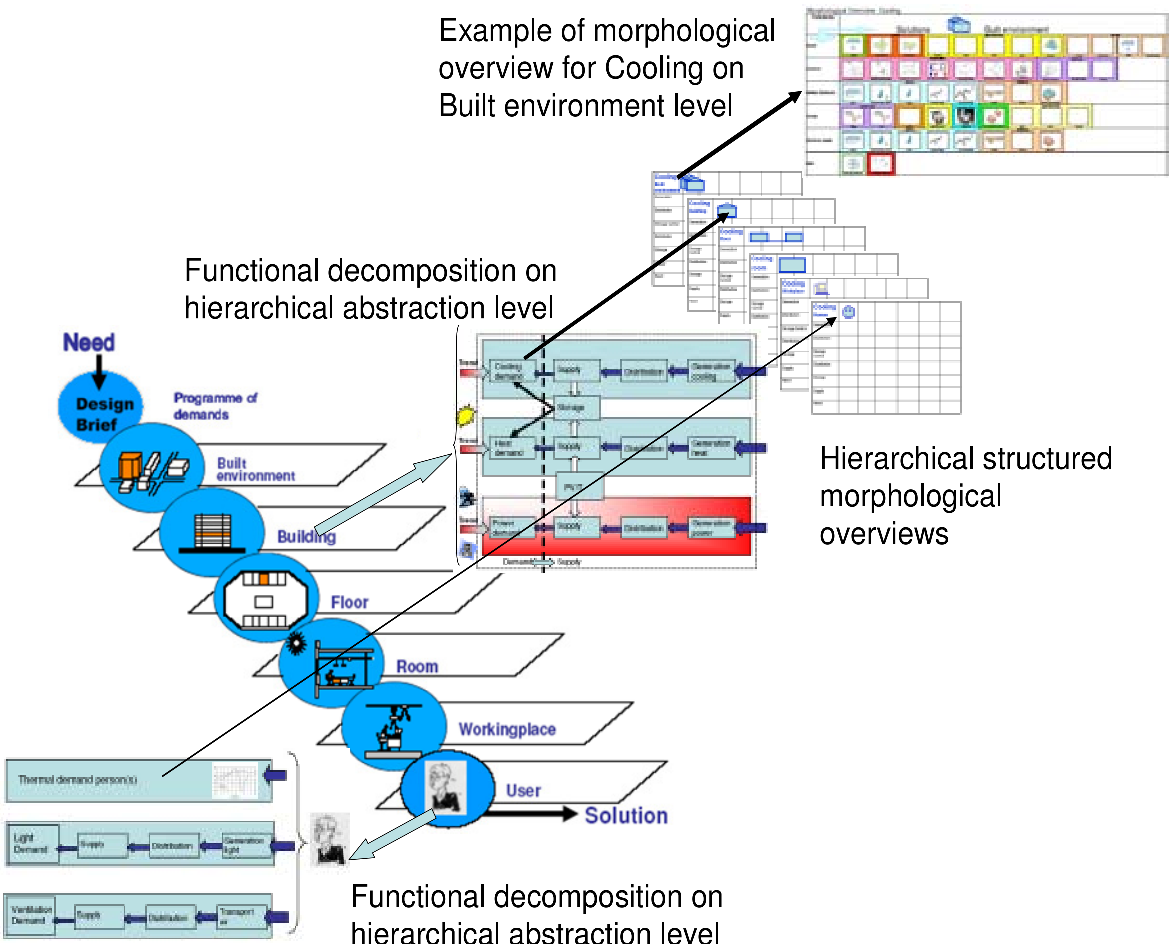

Figure 6 Set of connected morphological overviews about cooling on the different hierarchical abstraction and the infill on the built environment level

4. Conclusion

Taking the principles of Open Building as starting point, a new design methodology is defined for the energy infrastructure within and between buildings. The possibility to combine and exchange different energy flows within the building and between buildings results in an flexible energy infrastructure called Flexergy.

We think that the proposed design methodology is a possible solution to the direct design process support, it will be possible to supply information about sustainable energy applications at a much earlier stage in the design process.

In order to allow a stepwise approach in which each design decision has well defined implications, four different ontological levels are distinguished for designing energetic process: Information level, Process level, Component level and Part level. These levels provide a structured framework for morphological schemes.

Synergy between environment, its sustainable energy sources and the comfort needs of the building's occupants is the ultimate in a sustainable building strategy. The participants work on research for new energy infrastructural concepts to implement and combine the different energy flows on the level of building and built environment. Central in this approach is the abstract approach to the building design process which makes it possible to generate new solutions for a sustainable energy infrastructure to make buildings comfortable .

Keywords: embodied carbon, embodied energy, life cycle assessment, carbon-rating, buildings

Summary

Embodied carbon (CO_2) emissions need to be considered alongside other, more readily measured sources of carbon emissions related to the operation and use of buildings, to help establish a full picture of the carbon impacts of building and development. A new embodied carbon assessment scheme, developed by Davis Langdon during 2007, is intended to help construction clients and their professional advisors understand the carbon footprint of their buildings and developments and, if appropriate, to make informed decisions about how to reduce it in a cost-effective way.

This paper identifies key methodological issues associated with the development of a new scheme for assessing the embodied carbon of buildings and construction at an early stage in design development. It comments on the availability of data on the embodied energy and carbon associated with key building materials, products and components, and discusses key data shortcomings and how they may be addressed. It presents and discusses initial results from the new carbon assessment scheme developed by Davis Langdon, which suggest that embodied carbon in buildings is highly significant, potentially representing over 50% of operational carbon emissions and concludes with key questions for research and for the practitioner community in developing a common, shared understanding of embodied carbon assessments for buildings.

1. Introduction

The energy consumed in the production of a building's constituent materials and components is often referred to as 'embodied energy'. Similarly, the carbon (CO_2) emissions associated with this energy – and, additionally, arising from chemical processes involved in the production of materials and components (for example, in the production of cement) – are referred to as 'embodied carbon'. In this paper we use the term 'carbon' as shorthand for carbon dioxide (CO_2). Furthermore, the paper focuses principally on CO_2 and does not generally consider other greenhouse gases (GHGs) nor their CO_2–equivalent impacts.

The assessment of embodied energy in building materials is not new. Over 25 years ago Stein et al (1981) for example, assessed the embodied energy for a range of building materials and components in the USA using an Input/Output approach, and developed models of a range of building 'assemblies' to aid calculation. One of the current paper's authors (Connaughton, 1987) drew attention to the significance of embodied energy in UK construction vis-a-vis the energy used to operate and maintain buildings over their typical life cycles. However, more recent concerns about the impact of greenhouse gases on the global climate and, in particular, the significance of buildings in generating a considerable proportion of the anthropomorphic carbon dioxide in the atmosphere - due mainly to the consumption of fossil fuel for operational purposes (heating, lighting, cooling; and for equipment and appliances) – has brought with it a strong focus on carbon reduction in the building design strategies of government and businesses alike (see, for example, in the UK, Department for Communities and Local Government, 2006). Hand-in-hand with that is a realization of the significance of the embodied carbon in building materials and components to a building's overall carbon 'cost' (ie embodied carbon plus carbon emitted during building operation, hereinafter referred to as 'operational carbon'), especially when regulatory changes are increasingly targeting reductions in this operational carbon but not yet, to the authors' knowledge, focusing on embodied carbon.

Until relatively recently, construction clients and their advisers have had no readily available, accessible means of knowing how significant embodied carbon might be in the buildings they are commissioning/designing. Nor have they had the means of assessing the embodied carbon of a range of commonly used building materials and components, and their alternatives, so as to help reduce the overall carbon impact of buildings. Furthermore, designers have had to cope with frequently inaccurate and inconsistent data on embodied energy from a variety of sources that lack a coherent underlying assessment methodology (Pullen, 2000, for example, identifies a wide range of values for the embodied energy of timber from the literature, and suggests that differences are due to a number of factors, including methodological and estimating practices). In seeking to develop a usable and accessible embodied carbon assessment tool for buildings, the authors have had to address some of these challenges.

This paper reports on the development of the Davis Langdon embodied carbon assessment scheme and, in so doing, sets out to:

- Propose a workable, simplified scheme to assess the embodied carbon in buildings, focusing on the early stages of design and providing a complementary assessment to design cost estimating
- Present some initial results from the scheme in use, and discuss some of their implications
- Identify some key methodological challenges
- Conclude with some important questions for both the academic/research and practitioner communities in developing and adopting such a new scheme.

2. The Davis Langdon embodied carbon assessment scheme

2.1 Origins

As noted above, one of the authors of the current paper has had an interest in embodied energy in construction for some time. In the past 10 years or so Davis Langdon has undertaken ad hoc embodied energy assessments of important building projects, both in the UK (for example, a new headquarters building for Wessex Water in Bath – CABE 2007) as well as a headquarters building for the National Trust in Swindon (Koralek, 2005) and elsewhere (see for example, the report of work carried out in 2002 for the Hong Kong Housing Authority, one of the largest social housing providers in South East Asia - Amato & Humphrey, 2003). However, such opportunities have been relatively rare and, in the main, restricted to those clients and/or designers with a particularly strong interest in improving all aspects of building environmental performance.

More recently, however, the authors have witnessed a growing interest from both clients and designers in understanding the embodied carbon impact of buildings, and its relative significance over the building life cycle. This may be motivated by an increasing awareness of the importance of embodied impacts more generally (see for example, CNW Marketing Research [2006], examining the embodied and operational carbon emissions of a wide range of motor cars available in the USA. This analysis received some prominence in the UK via publication in the popular *What Car?* Magazine), or of the potential of Life Cycle Assessment in construction to provide a through-life picture of the environmental impacts of building products/components (for example, see Rankine at at, 2006). Regardless, the authors detected sufficient interest to prompt them to revisit their earlier work on embodied energy and consider developing a more formal scheme for estimating embodied carbon.

2.2 Key principles and estimation methods

2.2.1 Key principles

The authors were conscious of the complexities involved in undertaking assessments of embodied carbon based on Life Cycle Assessment methodology, compounded in the construction sphere by a lack of reliable, consistent and readily available data (this is discussed further in section 2.2.2 below). In particular, they wanted a framework that could provide estimates of embodied carbon at an early stage in design development (when the broad parameters of the proposed building project are known, together with some indications of material choices – for example, steel structural frame, aluminium-framed glazed wall cladding – but without full design and specification details). An analogy may be made here with the early design estimates typically undertaken by construction cost estimators/quantity surveyors, which can be used to guide subsequent design development (for an overview of cost estimating in construction, see Kirkham, 2007). Such a framework would not, of course, produce precise results, but the authors felt it should:

- Be transparent and open to enquiry and challenge
- Be robust, providing sufficiently reliable results to help guide design development, particularly as to the potential for *reduction/mitigation* of embodied carbon impacts through the selection of alternative design approaches/specifications
- Relate to the potentially more significant materials/products in terms of embodied carbon impact – our working hypothesis was that, in general, these tended to be materials/products with a *significantly high mass* relative to the overall mass of the building.

Of course, our criteria for robustness and significance can only really be tested following a thorough analysis, so the development of the scheme is somewhat iterative, with confirmation (or revision) of working assumptions following examination of initial results. Experience of the scheme in use, together with early results (discussed further in section 3 below) suggest that these criteria were justified.

2.2.2 Estimating methods and data sources

The core assessment methodology is based on Life Cycle Assessment (LCA). LCA was originally developed for the assessment of energy consumption associated with food production (Franklin Associates, 1991). It is a relatively recent development and an international standard for LCA has only been available since 1997 (International Standards Organisation, 1997). LCA aims to be an objective process that assesses the energy, materials and waste impacts of products or activities at each stage of the life cycle – from 'cradle to grave'. While there is a growing literature on LCA – and its appreciateness for different forms of environmental assessment – there are, in practice, a variety of interpretations of how the methodology in best applied, particularly in respect of the boundary conditions (see for example, Hunkler and Rebitzer, 2005) and data sources.

A critique of LCA is beyond the scope of the current paper; however, it may be noted here that while one of the more commonly used boundary conditions in LCA is 'cradle to grave' (which seeks to assess impacts to the end of the material/product lifetime, and can sometimes – though not always – include disposal and end-of-life impacts), another boundary condition more commonly used in construction is 'cradle to site' (which includes, in this case, carbon emissions from the extraction of raw materials to the delivery and fixing in place of the product at its point of use). **The 'cradle to site' boundary condition was adopted for the development of the Davis Langdon embodied carbon assessment scheme.**

The approach taken to embodied carbon data was, in so far as possible, to rely on secondary sources. The authors were aware of a growing body of literature on embodied energy (and carbon) and, primarily for practical reasons, did not wish to replicate research already undertaken. A number of publicly available embodied energy/carbon inventories were identified (for example, International Aluminium Institute, 2003, and European Copper Institute, 2005, Athena Institute, Various). However, an initial appraisal suggested that the Inventory of Carbon and Energy (ICE) produced by Bath University Department of Mechanical Engineering (Hammond and Jones, 2006) provided a potentially consistent and usable dataset for construction. The authors decided to adopt this as the core energy/carbon database for the Davis Langdon embodied carbon assessment scheme. The Bath ICE offered a number of important features:

- A 'cradle to site' boundary condition – although this is not universally maintained throughout the ICE database
- A degree of transparency in the sources used, enabling checking and comparison of apparently inconsistent and/or erroneous data; and a breakdown (where appropriate) of energy/carbon associated with primary materials, recycled content and feedstock energy (the latter can be important as feedstock input – oil, for example, is used as a material rather than fuel input to some manufactured products – may have lower carbon emissions than fuel inputs)
- Relevance to the UK construction sector (and growing recognition and adoption by practitioners and others in this sector).

Other sources were used to supplement this data, principally:

- The author's own estimates, using an LCA methodology with a 'cradle to site' boundary
- The Ecoinvent 2 database provided with the SimaPro LCA analysis package (for more information on Ecoinvent see links to http://www.ecoinvent.org/en/we-about-us/bodies-of-the-ecoinvent-centre/ for more information on SemaPro see links to http://www.pre.nl/simapro/)

2.3 The scheme in outline

2.3.1 Overview

Davis Langdon provides construction cost management (and quantity surveying) services on a great variety of construction projects worldwide. Because of this the firm has developed a good understanding (backed by comprehensive data) on material inputs to construction and buildings of all types. Building cost estimating models developed by the firm for early stage design cost estimating embody this understanding, and contain routines that generate key quantity data on the basis of simple building parameters (and based on historic records of similar building types). While the precise details are commercially confidential, it is sufficient for the purposes of this paper to note that similar routines are used to generate material quantities for the purposes of estimating embodied carbon.

2.3.2 Using existing cost model data and formats

For costing purposes, and in line with established convention in the UK and similar markets, such quantities are usually measured in terms of surface areas or a count derived from the extent of product used, or alternatively based on building floor area. They are typically aggregated into composite work items (for example, an upper floor quantity will be an amalgam of floor deck, concrete and applied finishes). To convert this data into data that can be used to assess embodied carbon, a degree of manipulation is therefore necessary to:

- Disaggregate the individual material inputs from composite work items (for example, cement, aggregate, steel reinforcement, and timber for formwork from a square metre of 150mm thick reinforced concrete upper floor slab)
- Express them in terms of material mass (usually kg) and, if appropriate
- Sum the embodied carbon amounts and re-combine them to express an overall carbon estimate for the composite item as CO_2 per element/floor area.

Figure 1 below outlines a simplified process of disaggregation/conversion, resulting in an embodied carbon estimate expressed per square metre of curtain wall area.

This form of analysis and presentation has a number of benefits:

- It utilizes existing data and early design cost estimating models with which clients and practitioners (including designers) are already familiar

- It is directly comparable with typically-used construction cost breakdowns – this is particularly important when seeking to reduce/mitigate carbon impact, when both clients and designers are very interested in consequential cost implications
- It is intuitive and easy to understand.

An important feature of the Davis Langdon scheme is its focus on composite construction items, as described above, rather than individual material inputs . This approach has the benefits of being compatible with design and estimating practice, and helps to highlight specific items of work where mitigation might be practical.

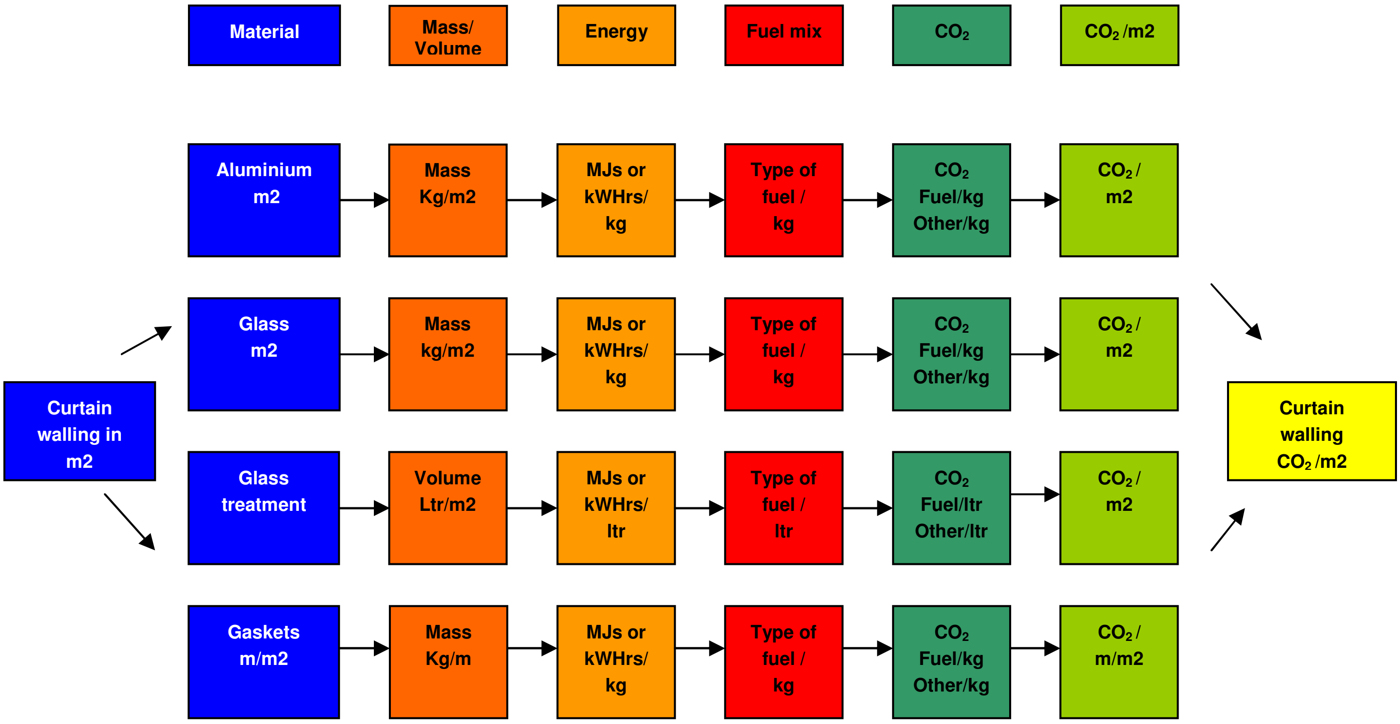

Figure 1 Disaggregating composite cost items into material masses for embodied carbon assessment

The scheme allows for changes in the fuel mix for energy inputs to individual materials – this is especially important for imported materials/products, where the electricity fuel mix can be quite different in the country of origin compared to the country of use (see further discussions under section 4 below). It also allows CO_2 emissions other than from energy inputs (shown as 'other' in Figure 1) to be included.

3. Initial results and case studies

3.1 Overall findings

The authors have undertaken assessments of the embodied carbon of two sample buildings – a distribution warehouse and a low-energy office building – using the methodology, data and the new scheme outlined in section 2 above.

Initial findings indicate that embodied carbon equates to about 23 years of operational carbon for the distribution warehouse building (ie the CO_2 emissions associated with the use of the building, fuel use for heating, lighting and cooling, equipment and appliances) and some 30 years of life for the low-energy office building. See Figure 2 below. Operational carbon was assessed on the basis of benchmark data taken from CIBSE, 2004. Recall also that the method of assessing embodied carbon does not (yet) account for all material inputs to the building, only the more significant ones in terms of mass. The authors' current best assessment is that the Davis Langdon scheme (as outlined) currently accounts for in the region of 85-90% of embodied carbon impacts.

These initial findings appear significant (and in line with recent, albeit partly anecdotal, emerging evidence from the UK – see Lane, 2007). For the distribution warehouse (with a floor area [net lettable] of some 46,000 square meters), there are relatively high lighting and heating requirements, as this particular building is operated on a 24 hour basis. For more traditional warehouse buildings with, say 12 hour operation, embodied carbon would represent a far more significant proportion of total carbon emissions over its design lifetime (assumed here to be 30 years) Whether of course the building as constructed will remain without major alteration for a full 30 years is an interesting point. Even casual observation of the distribution sector would suggest that this is highly unlikely, with a range of highly dynamic drivers (fuel prices, increasingly stringent transport emissions legislation, spatial planning requirements and changing demographic and consumer patterns) all exerting a strong influence on the nature and extent of the distribution infrastructure required.

For the office building, the authors selected a relatively low-energy naturally-ventilated office building of some 11,200 square metres net lettable area. The initial assessment of embodied carbon, at some 12,800 tonnes for the building is just over 1.1 tonnes per square metre of floor area. This is equivalent to about 30 years of operational carbon emissions, or about one third of total lifetime carbon emissions, assuming a design life of 60 years. Once more, it is highly unlikely that contemporary commercial buildings will remain for a full 60 years without major alternation and/or demolition and re-construction, and so the estimated proportion of embodied to operational in this case may be somewhat conservative. Of course, for an analysis of a fully air conditioned office building, the proportion of embodied carbon to total lifetime carbon emissions would be less than this, although the embodied carbon of the additional plant and distribution pipework/ductwork would need to be taken into account.

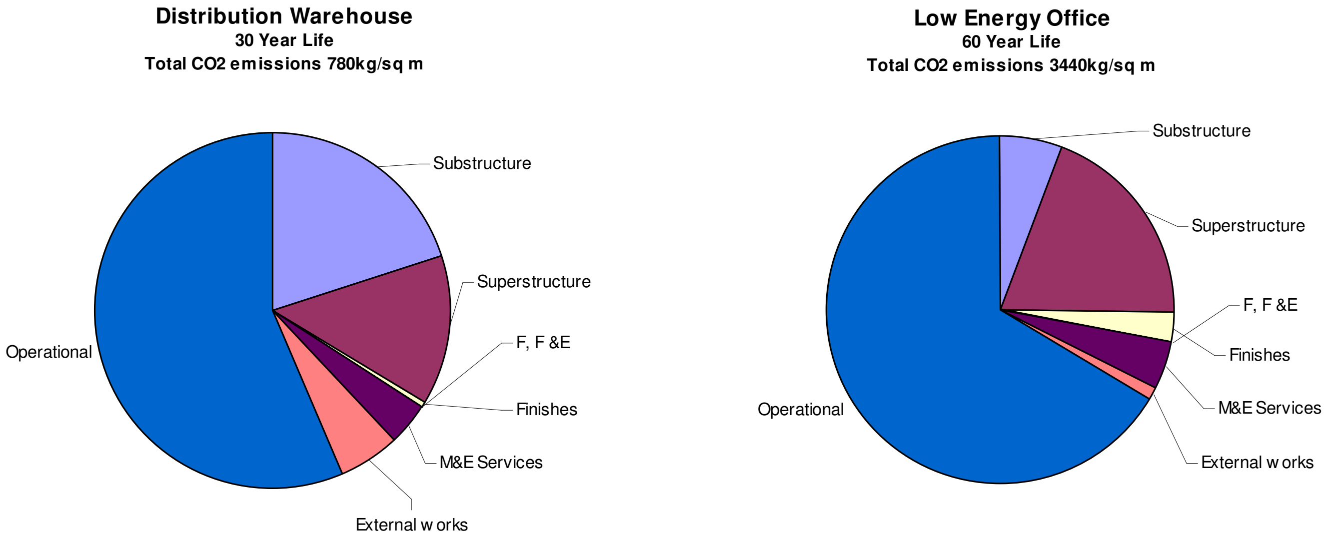

Figure 2. Proportion of embodied carbon to operational carbon for two sample building types.

3.2 Detailed analysis and potential for mitigation of carbon impact: office building

From the breakdown of embodied carbon for the office building (more detail is provided in Figure 3 below) it would appear that the more significant opportunities for carbon mitigation are likely to lie in the following elements:

- Substructure
- Structural frame and upper floors
- Windows and external doors, and
- Environmental (M&E) services

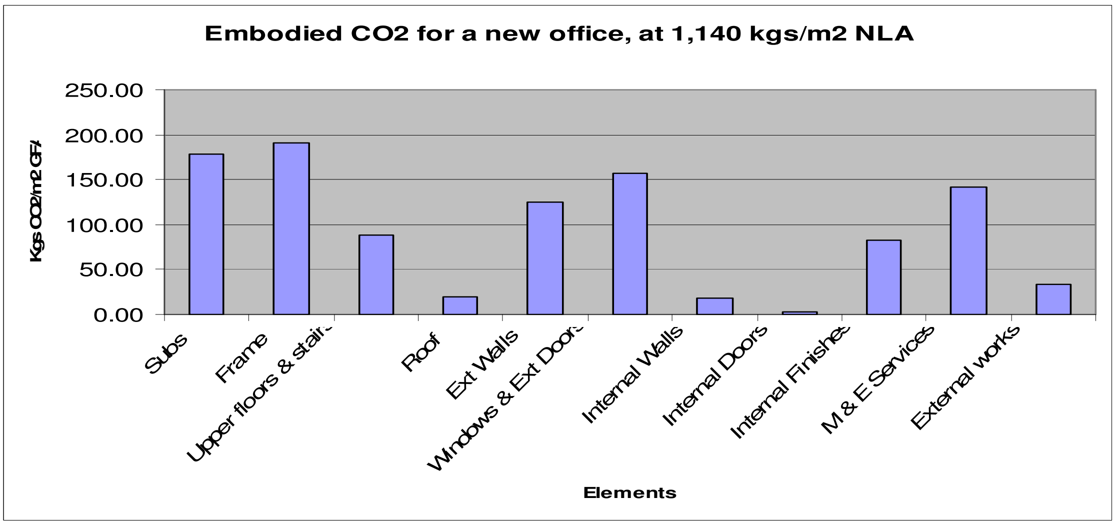

Figure 3: Elemental breakdown of embodied carbon for sample office building

Closer examination of the likely materials specifications for these elements suggests that the following material substitutions may provide significant carbon mitigation potential:

- Masonry and aluminium-clad timber framed windows instead of aluminium-framed curtain walling, and
- Ground Granulated Blast Furnace Slag (GGBS) instead of 40% Ordinary Portland Cement in the concrete mix for the substructure (ground floor slab), structural frame and upper floors and external works elements.

These relatively simple material substitutions realize savings of some 220 tonnes of CO_2, equivalent to over 20% of the building's total embodied carbon (see Figure 4). Further, this is equivalent to about 5 years of operational carbon for this building.

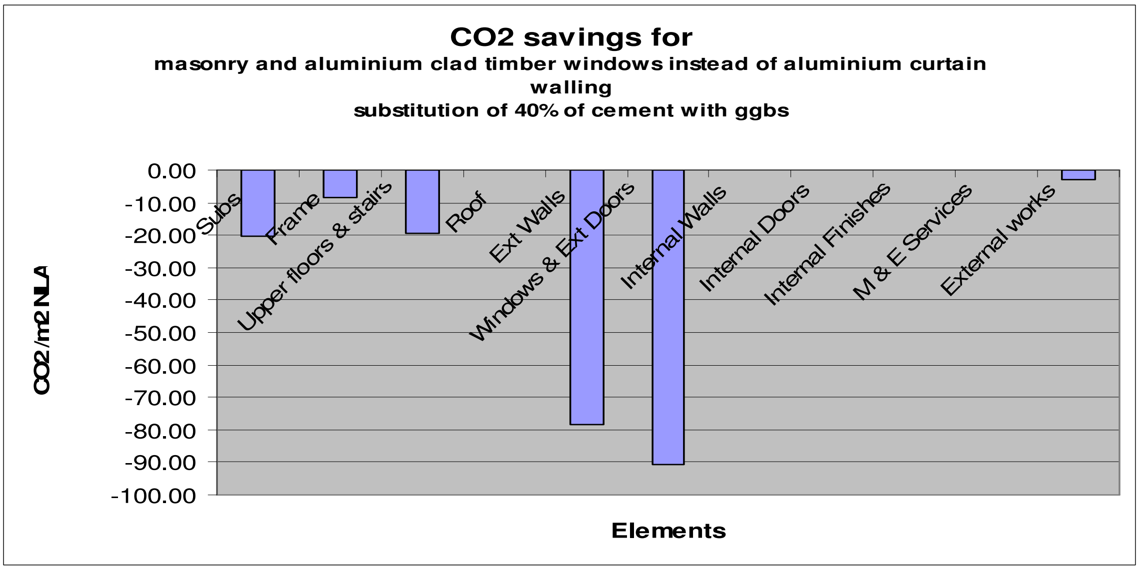

Figure 4: Embodied CO_2 savings resulting from key material substitutions: sample office building

3.3 Further mitigation potential

Further material substitutions are, of course, possible. Our initial analysis suggests that mitigation needs to focus on the energy/carbon intensive elements/work items to have any practical affect. For the distribution warehouse and office buildings examined, the following offer considerable potential (broadly in order of reducing significance):

- Cement substitutes. The most popular is GGBS, which is a by-product of steel manufacture. In the UK, most of this is utilized but that is not always the case in other countries. China, for example, has a large steel production industry but does not fully utilize GGBS. Pulverised Fuel Ash (PFA) can also be used but with a lower level of substitution is pemissible, and it affects curing times and appearance. Views vary on the appropriateness of PFA as a cement substitute; however, supply is plentiful in many countries as it is a by-product of coal-fired power generation. In the UK about 7M tonnes are produced each year.
- Re-use of recovered materials, such as steel beams or bricks.
- Recycled materials, or materials with a high recycled content, especially metals. Using recycled materials or recycled content does not always save money, but it nearly always saves energy/carbon (see, for example, Amato and Raven, 2000)
- Greater use or organic material such as timber, bamboo, hemp etc. However, like bio-fuels, problems may emerge if production of some organic material is scaled up too much, since land transferred for the growth of organic construction materials may be lost from other uses, such as food production or nature reserves.

While our analysis for the purpose of this paper focuses on material substitution, it is noted that carbon reducing potential may also be exploited via other design approaches.

3.4 The particular challenge of building/environmental services elements

In section 2.2.2 above, we provided an overview of the data inventory used for the Davis Langdon carbon assessment scheme. In general this – and other similar inventories that are publicly available – concentrate in the main on basic materials or part-processed construction items/products (such as timber particle board) only. Composite and/or highly manufactured items are more difficult to assess, and there is very limited data available for highly engineered components such as those found in building environmental services elements.

While it is possible to assess the embodied carbon of some of these components from first principles based on LCA methodology and data on basic materials inputs, for sophisticated plant and controls items the calculation process is lengthy and laborious. The authors are currently investigating a number of simplified approaches. One, for example, is based on regression analysis of key items of mechanical and electrical plant to discover the relationship between key output criteria (such as kW for a boiler) and weight This might enable reasonable predictions of plant weight to be estimated, from which broad 'first order estimates of embodied carbon could be calculated.

4. Some methodological challenges

The methodological issues associated with LCA in general and the assessment of embodied energy/carbon in construction in particular are well covered in the literature. The particular challenges faced by the authors in developing a simplified scheme for early design stage estimation of embodied carbon can be characterized principally as follows:

- The estimation of energy/carbon for manufacturing and fabrication
- The problem of international data
- Unknown and ambiguous boundary conditions.

For materials/components having little or no published data on embodied energy/carbon, we initially approached the larger manufacturers (such as those producing boilers and chillers) to see what data they could let us have. In general little useful data was forthcoming, as the supply involved chains were often very long and complex, involving overseas sourcing of key components. We are currently investigating whether smaller companies specializing in key manufacturing activities (such as casting) might provide more useful data on their energy/carbon intensity per unit/mass of output. Initial findings suggest that this may be a more useful approach to help develop initial estimates for composite and highly manufactured products.

The basic manufacturing processes for construction materials, requiring heat and other energy, tend to change little from one country to another in the developed world. However, the fuel mix for electricity used for manufacturing varies considerably between countries. The UK, for example, emits relatively high kgCO2/kWhr for mains electricity (as only about 3% of electricity generation is from renewable source and a good deal is from fossil fuel including coal). Norway, by contrast, generates over 90% from renewable sources, mainly hydro; France relies heavily on nuclear generation.

We noted in section 2.2.2 that we adopted a 'cradle to site' boundary in the development of the Davis Landon scheme. The available data tends to adopt a either a 'cradle to factory gate' or a 'cradle to site' basis, and in general we have not found the difference between them to be great. However, for some key construction materials there are significant differences in their embodied energy/carbon values depending on assumptions about boundary conditions. These materials include:

- Steel – a key consideration is the extent to which it may come a recycled source or from primary materials. For a discussion see Amato et al, 1996.
- Concrete – again, a key consideration is the extent to which concrete can be recycled (as agrgregate) and the re-carbonation of cement that can occur in the crushing/recycling process or at the end-of-life. For a discussion, see Clear & De Saulles. 2007,
- Organic materials, such as timber, especially end-of-life assumptions – a key issue is the release of CO_2 (and Methane) from decomposing organic material sent to landfill.

The authors do not have ready answers to these challenges. From the perspective of practitioners and, through the medium of this paper, they would like to appeal to the LCA community and those involved in assessing the embodied carbon of construction to develop workable protocols to address them.

4. Conclusions and recommendations for further work

Initial results from the Davis Langdon embodied carbon assessment scheme suggest that embodied carbon in buildings is highly significant – potentially representing over 50% of operational carbon emissions, and perhaps more if embodied energy in through-life repair and refurbishment is taken into account. With legislation in many countries now focusing on reducing operational carbon, it is likely that the significance of embodied carbon will increase in future. While some significant methodological problems remain and pose a challenge to those wishing to develop consistency and comparability in embodied carbon assessment, the authors believe that these can be resolved by a collaborative effort on behalf of the LCA community and those involved in embodied carbon assessments in construction.

The authors believe that the focus of policy making in the arena of carbon reduction in building and construction needs to shift more towards the life cycle carbon emissions associated with buildings, rather than only operational emissions. This requires careful consideration of embodied carbon and, in particular, the development of methods and tools for the estimation and mitigation of embodied carbon early in the building design stage. It also requires the development of a life cycle carbon index or rating scheme for buildings that, in time, would allow buildings of a similar function and performance to be benchmarked on the basis of embodied carbon as well as capital cost.

Acknowledgements

The authors acknowledge the invaluable assistance provided by Dr Alex Amato of Davis Langdon on LCA methodological issues, and Ellen Salazar on the analysis of operational carbon respectively.

Summary

Recently, the construction of super tall buildings utilized by high strength-concrete in the whole world is tending to be on the rise. The application of high-strength concrete in buildings results in the excellent cut-down effect in construction materials due to section reduction and long-life in view of durability. Therefore, in order to investigate the $LCCO_2$ reduction effect and economical evaluation for the reinforced concrete(RC) structures with high-strength concrete, comparisons of $LCCO_2$ in life cycle of building structures between high-strength concrete and normal-strength concrete have been performed.

As a result, it is concluded that RC structures with high-strength concrete showed the $LCCO_2$ reduction effect by 4.12% in construction step and by 1.12% in whole progress of 60 years, compared to RC structures with normal-strength concrete and had also the economical benefits of 2,760 thousand dollars during 60 year-life cycle.

1. Introduction

With serious environmental problems like global warming, resources depletion and pollution, there have been great attention to international conventions for environment conversion, and the conventions are increasingly asking the world for compulsory observance. The existing policies of many countries, which were centered on their development, are consequently under the situation of prompt changes into environment-friendly ones. According to the report of Environmental Protection Agency (EPA), the energy consumption and the carbon dioxide emission of the buildings in the United States are 70% and 38% of the entire energy consumption and the entire carbon dioxide emission of the country. That means the field of construction can be called an anti-environment industry featuring mass consumption and disposal, so there are demands for technology development to be an environment-friendly field: Architectural production activities thus should be changed to a new paradigm centered on sustainable development for the purpose of reducing environmental load and improving residential environment functions through the life cycle of buildings ranging from design, construction work and maintenance to demolition, rejecting fragmentary and anti-environmental development policies. Under the system of WTO, international organizations such as UN, OECD and ISO have made positive research into techniques of architectural production with the subjects of prevention of global warming by CO_2 reduction, environmentally sound and sustainable development and life cycle assessment (LCA) and have set up compulsory regulations including goals and practice terms of environmental load reduction(Damtoft, J.S. 2007, Sjostrom, C. 2001).
In addition, super tall buildings have been increasingly constructed since the early 2000s because of the intensive use of land for economical efficiency and developed construction techniques, and much attention has recently been given to environmentally sound and sustainable green buildings which can conserve the global environment and coexist with the ecosystem. Those high buildings are advantageous for supplying broad greens and open space, reducing the building-to-land ratio, and yet have weak points from the point of sustainability such as lack of social contact and ground connection, and difficulty of natural ventilation indoor. Consequently, there have been demands for research into sustainability assessment of super tall buildings for environment-friendly construction and city development which considers our environment, being harmonious with surroundings, under the principle of Environmentally Sound and Sustainable Development (ESSD), which is now firmly established as an international paradigm(Urushizaki, N. 2003).
As a part of the environmental performance evaluation for super tall buildings, this study examined the energy and life cycle CO_2 ($LCCO_2$) by the application of high-strength concrete used in tall buildings. Using SUSB-LCA ver.1.0, an environmental load assessment program developed by the researchers of this study, the previous design of a tall building (30-storied) and the re-design by applying high-strength concrete were compared and reviewed, and then based on the comparison, the effects of $LCCO_2$ reduction and economical benefits were evaluated.
