Proceedings of the 2008 World Sustainable Building Conference

Volume 2

ISBN 978-0-646-50372-1
9 780646 503721

World SB08 Melbourne
Melbourne Convention Centre
21–25 September 2008
www.sb08melbourne.com

Editors: Greg Foliente, Thomas Luetzkendorf, Peter Newton and Phillip Paevere

CSIRO Sustainability victoria Victoria The Place To Be UNEP iiSBE cib

First published 2008

These proceedings will initially be kept on the SB08 website:
http://www.sb08.org

These proceedings have been produced primarily as a web-based product. A limited number of CD-ROMs will be produced for those congress delegates who specifically requested a CD.

Any queries about these proceedings (or corrections of significant errors) should be directed to one of the editors listed below by 31 March 2009.

An Easy Guide to Navigating the Proceedings for SB08

The full Proceedings of SB08 have been made available as three multiple "PDF" documents.

• **Volume 1** includes conference welcome speeches, conference sponsors, special reports and SB07 papers, special forums and regional papers.

• **Volume 2** is approximately 168MB. Downloading of this file can take some time, however, once downloaded and saved to your hard drive, it is laid out in a manner that allows fast and simple navigation.
This file contains the full abstracts for both oral and poster presentations that form the scientific program of the conference. Abstracts can be searched by author or oral theme.

• **Volume 3** contains the power point presentations of plenary sessions and photo gallery.

Getting Started.

- Download the document from http://www.sb08.org/
  or, if supplied as a CD, open the document within the CD.
- This guide presumes the document was opened using Adobe Reader 6.0. Earlier versions of Adobe Reader may produce different results! To download the latest reader http://www.adobe.com/
- You may wish to use several Adobe "Tools". You should open at least the following "Toolbars":

– BASIC These toolbars are located in the "View" pull down menu at the top
– FILE of your screen under the heading "Toolbars". Left click (and hold)
– TASKS your mouse on "View", scroll down to "Toolbars" move across to the
– ZOOM tool bar you wish to open [if not already open - Open toolbars are "checked"] and release the mouse key.

Navigating around the document

At the bottom of most pages of the Proceedings you will see 'buttons'; clicking on a particular button will enable:

- BACK – takes you back one page
- HOME – takes you back to front page
- CONTENTS – direct link to the Contents page for these proceedings
- AUTHOR INDEX – direct link to the alphabetical "Index by Author "
- PROGRAM INDEX – direct link to the program "index by theme orals"
- FORWARD – proceeds to the next page

"Index by Author"

This section lists all 1500 word abstracts for oral and poster presentations from SB08 by author, alphabetically. Click on the box next to the author to be taken to the author's abstracts the reference number of which is listed next to the box. Note: some authors have several abstracts listed.

"Index by Theme Orals"

This section lists all 1500 word abstracts by presenters within each theme (as listed in the right hand column). Again, click on the box in the left hand column to be taken to that abstract.

Using the Adobe "Search" Function

Use the following steps to quickly search the document for words or phrases.

- Ensure that the "File" tool bar is open.
- Click on the 'Search' icon (looks like a pair of binoculars).
- Type the word or phrase in the box that appears on the right hand side of the screen and follow the written instructions provided. All listings of that word or phrase will appear and Adobe allows you to go straight to each one by clicking on it. For example, you may know the name of a delegate but not their country (the list of delegates is alphabetically by country); you can still search for the name throughout the proceedings.

Printing Information/Instruction

Please note, this is a long document. To avoid accidentally printing the whole document the default has been changed to a range of 1. Please set your printing range manually (use actual page numbers that you see at the bottom of the page to set beginning and ending pages) or to whatever setting you require in the print dialog box.

Contents

SB08 Conference Overview

SPONSORED BY

CONNECTED VIABLE LIVEABLE

Sunday 21 September

3.00 to 6.00	**Registration**
6.00 to 7.30	**Welcome Drinks**

Monday 22 September

8.30 to 10.00	**Plenary 1A:** **Sustainable Future and the Built Environment: Towards a Connected, Viable and Liveable Planet** **Speakers: • The Hon. Peter Garrett** AM MP – Minister for the Environment, Heritage and the Arts (Australia) • **The Hon. Gavin Jennings** MLC - Minister for the Environment and Climate Change (Victoria, Australia) • **Bill Rees** – Professor, University of British Columbia School of Community and Regional Planning									
10.00 to 10.20	Tea/coffee Break									
10.20 to 11.20	**Plenary 1B:** **Understanding the Global SB Landscape** **Speakers: •Dr Greg Foliente** - Leader, High Performance Built Environment, CSIRO Sustainable Ecosystems (Australia) •**Nils Larsson** – Executive Director, International Initiative for a Sustainable Built Environment (iiSBE) •**Thomas Luetzkendorf** – Professorial Chair, Sustainable Management of Housing and Real Estate, University of Karlsruhe (Germany)									
11.30 to 1.00	Special Forum 1: Climate Change Adaptation for Buildings & Cities	Special Forum 2: Whole-of-Life Sustainability Indicators & Benchmarks for Cities and Buildings	SB Regional Policy Reviews 1	Enhanced Sustainability Assessment Methods - Buildings & Components - 1	Sustainability Assessment Case Studies - Buildings & Components - 1	New Products, Technologies & Systems - Construction Products - 1	Innovative Management & Operation Principles - 1	Policy Making / Regulation / Standardisation - 1	Material Efficiency, Recycling & Durability - 1	Indoor Environment - 1
1.00 to 2.00	Lunch									
2.00 to 3.30	Special Forum 3: The Role of Government: Evaluating Policy Effectiveness	Special Forum 4: Achieving Sustainability Targets: Strategies and Case Studies	SB Regional Policy Reviews 2	Enhanced Sustainability Assessment Methods - Buildings & Components - 2	Sustainability Assessment Case Studies - Buildings & Components - 2	New Products, Technologies & Systems - Construction Products - 2	Innovative Management & Operation Principles - 2	Cultural Identity & Construction Traditions - 1	Material Efficiency, Recycling & Durability - 2	Indoor Environment - 2
3.30 to 4.00	Tea/coffee Break									
4.00 to 5.30	Special Forum 5: Social Transformation and Changing Community Behaviour	Special Forum 6: Pathways for Transitioning to More Sustainable Cities	SB Regional Policy Reviews 3	Enhanced Sustainability Assessment Methods - Buildings & Components - 3	Sustainability Assessment Case Studies - Buildings & Components - 3	New Products, Technologies & Systems - Construction Products - 3	New Concepts in Sustainability - 1	Policy Making / Regulation / Standardisation - 2	Material Efficiency, Recycling & Durability - 3	Health, Comfort & Well-Being - 1
5.30 to 7.00	**Exhibition Viewing and Accompanied Poster Session**									

Tuesday 23 September

8.45 to 10.30	**Plenary 2:** **Advancing Sustainability on All Fronts: Stakeholder Perspectives and Actions:** **Chair: Rick Fedrizzi** – President and CEO, US Green Building Council **Speakers: • Rosario Marin** – Chair, Green Action Team, California State Government; Secretary of the State and Consumer Services Agency • **Joe van Belleghem** – Partner, Windmill Developments, Canada; Co-developer, Dockside Green • **Douglas Durst** – President, Durst Organization, New York (via live video link) • **Bruce Fowle** - Senior Partner, FXFOWLE Architects									
10.30 to 11.00	Tea/coffee break									
11.00 to 12.30	Special Forum 7: Market Trends and Outlook for Sustainable Building	Special Forum 8: Building Environmental Assessment Methods and Market Transformation	SB Challenge 1	Advanced Design & Project Delivery Principles - 1	Sustainability Assessment Case Studies - Buildings & Components - 4	Energy Efficiency - Building Services - 1	New Concepts in Sustainability - 2	Policy Making / Regulation / Standardisation - 3	Material Efficiency, Recycling & Durability - 4	Health, Comfort & Well-Being - 2
12.30 to 2.00	Lunch									
2.00 to 3.30	Special Forum 9: Valuation of Sustainable Buildings	Special Forum 10: Transforming Materials & Technologies	SB Challenge 2	Advanced Design & Project Delivery Principles - 2	Sustainability Assessment Case Studies - Buildings & Components - 5	Enhanced Sustainability Assessment Methods - Subdivisions & Regions - 3	Sustainability Assessment Case Studies - Subdivisions & Regions - 1	Energy Efficiency - Building Services - 2	Material Efficiency, Recycling & Durability - 5	International Case Studies & Technologies
3.30 to 4.00	Tea/coffee break									
4.00 to 5.30	Special Forum 11: Financing Sustainable Property	Special Forum 12: The triple bottom line case for Green Building: Cost, CSR, and Workplace Productivity	SB Challenge 3	Enhanced Sustainability Assessment Methods - Buildings & Components - 4	Sustainability Assessment Case Studies - Buildings & Components - 6	Water Efficiency - 1	Adaptation to Changing Environments - 1	Energy Efficiency - Building Services - 3	Cultural Identity & Construction Traditions - 2	New Products, Technologies & Systems - Building Services & Equipment - 1

Wednesday 24 September

8.45 to 10.30	**Plenary 3:** **Climate Change and the Asia-Pacific Parnership (APP)** **Chair: Ms Harinder Sidhu**, Assistant Secretary, Global and Strategic Issues Branch, Department of Climate Change (Australia). **Speakers: Tony Arnel** - Chair, Green Building Council Of Australia • **Prof Wang Youwei** - Chair, China Green Building Council • **Kazuo Iwamura** - Musashi Institute of Technology, Yokohama									
10.30 to 11.00	Tea/coffee break									
11.00 to 12.30	Special Forum 13: The Challenges of Hyper-Urbanisation in Emerging Economies: Sustainable and Equitable Development	Special Forum 14: Developments in Sustainable Building Standards and Certification	Special Forum 15: Innovating & Integrating for Sustainability	Enhanced Sustainability Assessment Methods - Buildings & Components - 5	Sustainability Assessment Case Studies - Subdivisions & Regions - 2	Water Efficiency - 2	Economics - 1	Energy Efficiency - Building Services - 4	Energy Efficiency - Monitoring / Benchmarking / Demand Management - 1	Market Transformation - 1
12.30 to 2.00	Lunch									
2.00 to 3.30	Special Forum 16: Urban Renewal and Building Refurbishment	Special Forum 17: Global Building Regulation and Sustainability - Part 1	Special Forum 18: Education, Skills and Entrepreneurship for Sustainable Communities	Enhanced Sustainability Assessment Methods - Buildings & Components - 6	Enhanced Sustainability Assessment Methods - Subdivisions & Regions - 1	Advanced Design & Project Delivery Principles - 3	Economics - 2	Energy Efficiency - Building Services - 5	Energy Efficiency - Monitoring / Benchmarking / Demand Management - 2	Market Transformation - 2
3.30 to 4.00	Tea/coffee break									
4.00 to 5.30	Special Forum 19: The Future of Sustainable Building	Special Forum 20: Global Building Regulation and Sustainability - Part 2	Special Forum 21: The Passive House Concept: Worldwide Applications	Enhanced Sustainability Assessment Methods - Buildings & Components - 7	Enhanced Sustainability Assessment Methods - Subdivisions & Regions - 2	Advanced Design & Project Delivery Principles - 4	Economics - 3	Energy Efficiency - Building Services - 6	Energy Efficiency - Monitoring / Benchmarking / Demand Management - 3	Market Transformation - 3
6.30 to 10.30	**Conference Dinner**									

Thursday 25 September

8:45 to 10.40	Special Forum Summary (Brief presentation of key themes from all Special Forum sessions)			Enhanced Sustainability Assessment Methods - Buildings & Components - 8	Sustainability Assessment Case Studies - Subdivisions & Regions - 3	Education - 1	New Products, Technologies & Systems - Construction Products - 4	Energy Efficiency - Building Services - 7	New Products, Technologies & Systems - Building Services & Equipment - 2	Policy Making / Regulation / Standardisation - 4
10.40 to 11.00	Tea/coffee break									
11.00 to 1.00	**Closing Plenary: Sustainability Futures: where to from here?** **Facilitator & Interviewer: Kathy Bowlen, Journalist and ABC Stateline Presenter** **Interview Panel** • **Ms Kaarin Taipale** – UN Marrakech Task Force Chair, architect, urban researcher and former Chair of ICLEI – Local Governments for Sustainability • **Mr. John MacDonald** – Architect and Director of DesignInc, an award-winning design practice in Australia and Asia • **Ms Anita Roper** – CEO Sustainability Victoria, and former industry senior executive in Australia, Ottawa, London and New York • **Dr Harry Blutstein** – Director, Integrating Sustainability, and main organiser and primary facilitator of the UNEP *Melbourne Principles for Sustainable Cities* **Awards & Announcements Closing Remarks – Ms Anita Roper**									

Monday, 22 September 2008

Enhanced Sustainability Assessment Methods - Buildings & Components - 1

11:30 AM - 1:00 PM Room 1

Chair: Kazuo Iwamura

11:30am Harvey Bryan
Developing an operational and material CO2 calculation protocol for buildings abs#001

11:50am Gerd Hauser
From the energy evaluation to the assessment of the whole building performance abs#002

12:10pm Barbara Lippiatt
NIST BusiBEES METRICS AND TOOLS FOR GREEN BUILDINGS abs#003

12:30pm Barrie May
A Life Cycle Inventory for Australian forest products abs#004

Sustainability Assessment Case Studies - Buildings & Components - 1

11:30 AM - 1:00 PM Room 2

Chair: Frank Schultmann

11:30am Jane Toner
Applying rating tools to develop an Autonomous House abs#005

11:50am Paul Bannister
Business hotel utility consumption and saving opportunities abs#006

12:10pm Harvey Bryan
A comparison of two environmental rating systems using dual certified buildings abs#007

12:30pm Guri Krigsvoll
Life Cycle Costing as part of decision making-use of building information models abs#008

New Products, Technologies & Systems - Construction Products - 1

11:30 AM - 1:00 PM Room 3

Chair: Nigel Howard

11:30am Yasushi Nakata
Novel PCM microcapsules for residential house abs#009

11:50am Yasushi Nakata
Transparent insulation material for residential houses and buildings abs#010

12:10pm Jing Siong Cheah
Overview of a cement-stabilised, flax fibre reinforced rammed earth (uku) building system for New Zealand indigenouscommunities abs#011

12:30pm A Entrop
Field experiments on the use of phase changing materials, insulation materials and passive solar radiation in the built environment abs#012

Innovative Management & Operation Principles - 1

11:30 AM - 1:00 PM Room 4

Chair: Prem Jain

11:30am Steinar Nilsen
"Best Practice Cleaning" – Reducing costs, waste and use of chemicals by introducing a modern cleaning concept abs#013

11:50am Ian Kennedy
Connected, Viable, Liveable - The Facilities Managers role in delivering Built Environments. abs#014

12:10pm Karin Johansson
What encourage clients and contractors to take common action on sustainable issues? abs#015

12:30pm Lei Zhou
The economic benefits of sustainable private finance initiative: A case study of Newport southern distributor road abs#016

Policy Making / Regulation / Standardisation - 1

11:30 AM - 1:00 PM Room 5

Chair: Jeff Norton

11:30am Bram Entrop
Influence of past policies on today's energy saving objectives abs#017

11:50am Stephen Berry
Modelling the relationship between energy efficiency attributes and house price: The case of detached houses sold in the Australian Capital Territory in 2005 and 2006 abs#018

12:10pm Sonja Koeppel
Evaluating policy instruments for reducing greenhouse gas emissions from buildings – developed and developing countries abs#019

12:30pm Robert Foster
Estimating Electrical Peak Load Demand and Related Modelling of Policy Options abs#020

Material Efficiency, Recycling & Durability - 1

11:30 AM - 1:00 PM Room 6

Chair: Per Hovde

11:30am Mark Gorgolewski
Designing with reused building components abs#021

11:50am Nicole Sunke
Holistic approach to sustainable construction project management abs#022

12:10pm Han Seung Lee
Evaluation on the Environment Friendly Performance of Concrete From the View of CO2 Absorption abs#023

12:30pm Petr Hajek
Material effective structures - the way towards sustainable buildings abs#024

Indoor Environment - 1

11:30 AM - 1:00 PM Room 7

Chair: Hal Levin

11:30am Selwyn Tucker
CAD-integrated estimation of the quality of indoor air in enclosed spaces abs#025

11:50am Tomoyuki Chikamoto
Study on air-conditioning control which considers human comfort Corresponding to thermal environment change from outdoor to indoor abs#026

12:10pm Phillip Paevere
Indoor environment quality and occupant productivity in the CH2 building abs#027

12:30pm Usama Kadri
A Bio-Inspired Ventilating Envelope Optimized by Air-flow Simulations abs#028

Enhanced Sustainability Assessment Methods - Buildings & Components - 2

2:00 PM - 3:30 PM Room 1

Chair: George Baird

2:00pm Martin Erlandsson
Driving forces and barriers for implementation of a building environmental classification system – experiences from the swedish building/living dialogue project abs#029

2:20pm Nicolas Perez
The influence of construction materials on the life cycle energy use and carbon dioxide emissions of medium sized commercial buildings. abs#030

2:40pm Keisuke Shintani
Estimation of environmental efficiency related to CO2 reduction for office buildings up to 2050 abs#032

3:00pm Jonas Bengtsson
Climate change impacts in new zealand: a cross-disciplinary assessmentof the need to adapt buildings, with focus on housing abs#031

Sustainability Assessment Case Studies - Buildings & Components - 2

2:00 PM - 3:30 PM Room 2

Chair: Pekka Huovila

2:00pm Mark Lister
Retrofitting melbourne's office buildings abs#033

2:20pm Hulya Kus
Comparative environmental assessment of masonry wall units regarding manufacturing process abs#034

2:40pm Byron Stigge
A critical review of the energy savings and cost payback issues of double skin facades abs#035

3:00pm Ryoji Mizuno
Environmental considerations in construction in Japan, by Obayashi Corporation abs#036

New Products, Technologies & Systems - Construction Products - 2

2:00 PM - 3:30 PM Room 3

Chair: Holger Wallbaum

2:00pm Lidia Badarnah
Shading/ventilating skin inspired from natural systems abs#037

2:20pm Swee Mak
Sustainable housing using lightweight cellular concrete abs#038

2:40pm Neelam Manjunath
Future Of Bamboo??? - The Greenest Of The Green Building Materials abs#039

3:00pm Vincent Buhagiar
The Recycling of Used Tyres as an Insulation Material in Cavity Walls in a Mediterranean Climate. abs#040

Innovative Management & Operation Principles - 2

2:00 PM - 3:30 PM Room 4

Chair: Mike Syme

2:00pm Abbas Elmualim
Barriers For Implementing Sustainable Facilites Management abs#041

2:20pm Soonkam Lim
Developing an integrated decision model for the enhancement of sustainability deliverables for Australian road infrastructure projects abs#042

2:40pm Yasuhiro Imai
Environmental considerations in building life-cycle management of a general contractor in Japan: Obayashi Corporation abs#043

3:00pm Barbara Rubino
Competitive cooperation in Swedish projects for sustainable building abs#044

Cultural Identity & Construction Traditions - 1

2:00 PM - 3:30 PM Room 5

Chair: Chrisna du Plessis

2:00pm Phillipa Watson
Overcoming barriers to sustainable renovation of housing in Tasmania abs#045

2:20pm Karen Bayne
Life homes - moving beyond green design to enhance occupant lifestyle abs#046

2:40pm Juliana Cruz
A pattern language for a native indian village in Brazil abs#047

3:00pm Ceridwen Owen
Architecture in the wilderness: Reconceptualising place through interpretive environments abs#048

Material Efficiency, Recycling & Durability - 2

2:00 PM - 3:30 PM Room 6

Chair: Jean Luc Chevalier

2:00pm Maristela Silva
Use of steel-making co-products and ornamental stone-cutting waste in the production of low impact masonry components abs#049

2:20pm Jianguang Shi
The demand and recycling approach of construction material in China abs#050

2:40pm Cliff Abbott
Sustainable waste management in residential construction abs#051

3:00pm Rannveig Landet
National action plan for construction and demolition waste as formulated by the industry itself abs#052

Indoor Environment - 2

2:00 PM - 3:30 PM Room 7

Chair: Vyt Garnys

2:00pm Ming-Chin Ho
Taiwan green building material labeling system and its applications to sustainable building in subtropical zone abs#053

2:20pm Margaretha Borgström
Effects of Energy Saving Measures at Renovation abs#054

2:40pm Hal Levin
The big indoor air emissions threat -- secondary emissions abs#055

3:00pm Jin-Ho Kim
A study on the measurement of thermal environment in large enclosure abs#056

Enhanced Sustainability Assessment Methods - Buildings & Components -

4:00 PM - 5:30 PM Room 1

Chair: Deo Prassad

4:00pm Hanss-Dieter Hegner
From energy certificate to Sustainability report - Sustainable Building in Germany - Objectives, Results, Lessons Learned abs#057

4:20pm Janis Birkeland
Space frame walls: Facilitating positive development abs#058

4:40pm Usha Iyer-Raniga
A framework for understanding the environmental performance of buildings in Australia abs#059

5:00pm Antonio Frattari
Zero Energy House: an integrated design process for an intelligent sustainable building abs#060

Sustainability Assessment Case Studies - Buildings & Components - 3

4:00 PM - 5:30 PM Room 2

Chair: Karen Bayne

4:00pm Grace Ding
Environmental assessment of residential buildings in China abs#061

4:20pm Krystyna Pietrzyk
Quantification of building/environment system performance abs#062

4:40pm Zbyšek Pavlík
Semi-scale hygrothermal experiments and their role in sustainable design of building envelopes abs#063

5:00pm Ripudaman Singh
Energy efficient design & planning of small settlements as a sustainable building approach abs#064

New Products, Technologies & Systems - Construction Products - 3

4:00 PM - 5:30 PM Room 3

Chair: Ron Wakefield

4:00pm Robert Cerný
Application of alternative silicate binders in the production of high performance materials beneficial to the environment abs#065

4:20pm Ana-Maria Dabija
Sustainability in roof rehabilitation abs#066

4:40pm Waldo Bustamante
Avoiding overheating risk in timberframe dwelling in a mediterranean climate. The case of Santiago Chile abs#067

5:00pm Kentaro Yamaguchi
Frictional damping effect of walls connected by dry construction method which has potential to contribute toward the realization of structural design for disassembly abs#068

New Concepts in Sustainability - 1

4:00 PM - 5:30 PM Room 4

Chair: Manuel Macias

4:00pm Rob Roggema
Swarm planning: development of a new planning paradigm which improves the capacity to adapt to climate change of regional spatial systems abs#069

4:20pm Paula Femenias
Potentials and challenges for sustainable retrofitting of non-domestic buildings: A UK perspective abs#070

4:40pm Yuefeng Guo
The autonomous house: a demonstration of Buddhist economics abs#071

5:00pm Yeong Day
Associations of symbionts and standard survey methods of inventory system: An example on the Archilife Symbiosphere I Center abs#072

Policy Making / Regulation / Standardisation - 2

4:00 PM - 5:30 PM Room 5

Chair: Robert Enker

4:00pm Dominique Sellier
New economic incentives for sustainable building: density bonuses and domestic carbon project abs#073

4:20pm Hau-wai Cheung
Promotion of green and sustainable buildings in a high density built environment abs#074

4:40pm Peter Szental
Policies for Improving Energy Efficiency in the Built Environment abs#075

5:00pm Petar Johnson
Green Products for Green Buildings - The Ecolabel Solution abs#076

Material Efficiency, Recycling & Durability - 3

4:00 PM - 5:30 PM Room 6

Chair: Andrew Walker-Morison

4:00pm Paulien de Bruijn
Mechanical properties, water absorption and frost resistance of various lime-hemp concretes abs#077

4:20pm Lucija Hanzic
Water retention capability of mortars made of recycled aggregate abs#078

4:40pm Kazu Urano
Comparison of the amount of material and cost for both Canadian and Japanese office building construction abs#079

Health, Comfort & Well-Being - 1

4:00 PM - 5:30 PM Room 7

Chair: Gerd Hauser

4:00pm Joyce Tai
An empirical study on outdoor thermal environment of residential developments and street blocks in Hong Kong abs#081

4:20pm George Baird
User perceptions and feedback from the 'best' sustainable buildings in the world abs#082

4:40pm Ryozo Ooka
Study on the Effects of Various Mitigation Measures for Heat Island Reduction in the Different Existing City Blocks using Numerical Simulation abs#083

5:00pm Richard Hyde
Exploring a 'quality of life' approach for sustainable housing in southeast Queensland - Case study of the Currumbin Ecovillage abs#084

Exhibition Viewing and Accompanied Poster Session

5:30 PM - 7:00 PM Room 1

Tuesday, 23 September 2008

Advanced Design & Project Delivery Principles - 1

11:00 AM - 12:30 PM Room 1

Chair: Justo García Navarro

11:00am Annika Kruuse af Verchou
Urban vegetation as a tool for climate adaptation abs#086

11:20am Pekka Huovila
Building information models and innovative sustainable housing abs#087

11:40am Tarja Häkkinen
Sustainable building and BIM abs#088

Sustainability Assessment Case Studies - Buildings & Components - 4

11:00 AM - 12:30 PM Room 2

Chair: Usha Iyer-Raniga

11:00am Kok Wee Ng
An evaluation of the effectiveness of the green building performance tool in Singapore abs#089

11:20am Delwyn Jones
Piloting 4D Sustainability Assessment Software in The Netherlands abs#091

11:40am Alessandra Oppio
Energy-environmental retrofit of an existing building: from zero towards best practice environmental sustainability level abs#092

Energy Efficiency - Building Services - 1

11:00 AM - 12:30 PM Room 3

Chair: Roger Fay

11:00am Jan Tywoniak
Solar energy systems integrated in low-energy buildings. Motivation, strategies and built examples from Czech Republic abs#093

11:20am Dong-Hwan Ko
Fenestration Guidelines for Improving Energy Conservation in the office building with Daylight Control System abs#094

11:40am Matthias Haase
State-of-the-art of sustainable energy-efficient building envelopes in Norwegian office buildings abs#095

12:00pm Hiroyuki Akagawa
A large rooftop garden on a commercial building in Japan and its thermal environment during summer abs#096

New Concepts in Sustainability - 2

11:00 AM - 12:30 PM Room 4

Chair: Janis Birkeland

11:00am Chrisna du Plessis
Understanding cities as social-ecological systems abs#097

11:20am Yuefeng Guo
The ideas of progress and process in a sustainable society abs#098

11:40am Aleksander Panek
Possibilities of Green Building Design Process Optimization abs#099

12:00pm Maibritt Pedersen Zari
Bioinspired architectural design to adapt to climate change abs#100

Policy Making / Regulation / Standardisation - 3

11:00 AM - 12:30 PM Room 5

Chair: Jeremy Gibberd

11:00am Ari Ilomäki
Sustainability assessment of buildings in CEN/TC350 "Sustainability of construction works" abs#101

11:20am Sheridan Blunt
Sustainable business – greening hotels abs#102

11:40am Stéphane Pouffary
The building sector facing the climate change challenge: how to turn constraints and weaknesses into opportunities, the CDM example abs#103

12:00pm Holger Wallbaum
Sustainable land use: Approaches for an internal development of natural, semi-natural and urban landscapes abs#104

Material Efficiency, Recycling & Durability - 4

11:00 AM - 12:30 PM Room 6

Chair: Rajah Tharumarajah

11:00am Abdol Chini
Barriers to deconstruction and materials reuse abs#105

11:20am Junko Koga
Development of the life-cycle C&D wastes assessment method for buildings abs#106

11:40am Jenny Campbell
The waste component of "Sustainable Buildings" – Voluntary or Mandatory? abs#107

12:00pm Grace Pan
Adaptability potentials in hong kong public housing abs#108

Health, Comfort & Well-Being - 2

11:00 AM - 12:30 PM Room 7

Chair: Lu Aye

11:00am Feng Yang
Analysis of the microclimatic impact of greening in high rise urban built environment using site measurements and sky view image processing techniques abs#109

11:20am Jin Hui Woo
Effects of indoor environment quality on occupant comfort and performance in work environments abs#110

11:40am Briony Rogers
Results of a trial of urine-separation and dry composting toilets in a secondary school abs#111

12:00pm Andy van den Dobbelsteen
Smart and bioclimatic design: an effective approach to the sustainable use of resources and deployment of local qualities abs#112

Advanced Design & Project Delivery Principles - 2

2:00 PM - 3:30 PM Room 1

Chair: Chris Ryan

2:00pm Tarja Häkkinen
Significance of building performance, usability and serviceability in terms of sustainable building abs#113

2:20pm Thiemo Ebbert
Principles in façade refurbishment for sustainable office refurbishment abs#114

2:40pm Caitlin Mcgee
City limits: Pushing boundaries in urban infill development abs#115

3:00pm Hal Levin
Calculating buildings' greenhouse gas emissions abs#116

Sustainability Assessment Case Studies - Buildings & Components - 5

2:00 PM - 3:30 PM Room 2

Chair: Allan Rodger

2:00pm Luís Bragança
Accuracy of some EPBD implemented thermal performance calculation procedures abs#117

2:20pm Katrina Shum Miller
The A,B,C's of sustainable schools abs#118

2:40pm Giorgio Beccali

DEVELOPING AN OPERATIONAL AND MATERIAL CO_2 CALCULATION PROTOCOL FOR BUILDINGS

Harvey Bryan, Ph.D., FAIA[1]
Wayne B. Trusty, MA[2]

[1] College of Design, Arizona State University, Tempe, AZ. 85287, harvey.bryan@asu.edu
[2] The ATHENA™ Sustainable Materials Institute, 28 St. John Street, P.O. 189, Merrickville , Ontario, Canada, K06 1N0, wbtrusty@bellnet.ca

Keywords: CO_2 calculations, Life-Cycle Assessment (LCA), energy, materials, sustainable buildings, green buildings

Summary

The building sector is being called upon to help fight climate change by achieving ambitious reduction targets for greenhouse gas emissions while at the same time incorporating other "green" considerations. To resolve this dilemma, the Green Building Initiative (GBI) has embarked on converting Green Globes™ into an official national green building rating standard. At the heart of this proposed standard are an operational energy and materials sections that will use CO_2 as the basis for their respective calculations. This paper will review how both operational energy and materials CO_2 calculation protocol operate in this proposed standard. The authors of this paper are on the standards committee and were particularly active in developing the energy and materials sections. It will be argued that such a CO_2 calculation protocol will become an important new tool for promoting sustainable technologies and one that needs to be understood by the sustainable building community.

1. Introduction

With the launch of several recent carbon reduction initiatives, the U.S. is finally beginning to tackle the reduction of carbon emissions. These initiatives range from Kyoto Now, a movement to get corporations to address their carbon emissions similar to the Architecture 2030 initiative, which is asking the building community to design carbon-neutral buildings by 2030. Cities are also anxious to demonstrate their commitment to carbon reduction, as evidenced by the recent adoption of a resolution very similar to the Architecture 2030 goals by U.S. Council of Mayors. In addition, the U.S. Congress also has begun to discuss how best to introduce carbon emission reduction into national environmental policy. For example, carbon reduction strategies such as a carbon tax or a cap and trade type of system currently are being actively discussed in Washington, D.C.

Unfortunately, what these business people, designers, city administrators and politicians are quickly realizing is that there is a lack of proven tools to help them determine if they are on track to achieving such goals. To resolve this dilemma, the Green Building Initiative (GBI) has embarked on developing a national green building rating standard. At the heart of this proposed standard are operational energy and materials sections that will use CO_2 as the basis for their respective calculations. This standard has undergone one public review and is targeted for completion later this year. Significant changes could result from the public review process, thus this paper represents the thinking of the standard committee as of Spring 2008.

2. Green Globes™

Green Globes is a web-based environmental rating system which has been operating in Canada for a number of years. There it has been widely used by several federal agencies and is the basis for the Building Owners and Managers Association of Canada's "Go Green Plus" program for assessment of existing buildings. In 2004, the Green Building Initiative (GBI) acquired the rights to distribute Green Globes in the U.S. (www.thegbi.org). Since then it has been operating in the U.S. and a wide range of buildings have been certified. In the process of bringing this system to the U.S., GBI made a commitment to continually improve the system to ensure that it reflects changing opinions and ongoing advances in the field. In 2005, GBI applied for and became the first green building organization to be accredited as a standard developer by the American

National Standards Institute (ANSI), and began the process of establishing Green Globes as an official ANSI standard. The GBI ANSI technical committee and sub-committees feature a range of nearly 100 building science experts including representatives from federal agencies, states, municipalities, universities, leading AEC firms and building owners. Unlike other U.S. attempts at developing a green building standard, such as the ASHRAE 189 Standard, the proposed Green Globes Standard will be an environmental rating system which will allow a building to achieve several levels of environmental performance.

3. The Green Globes Operational Approach

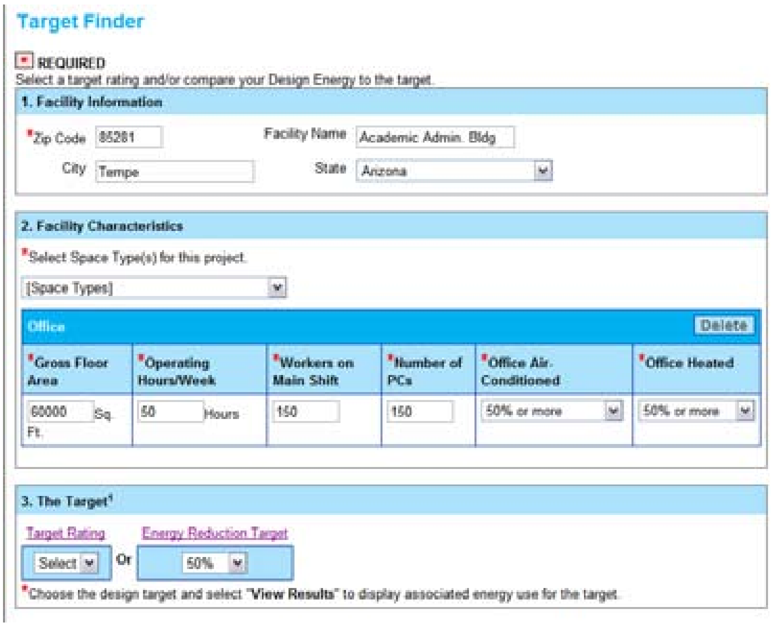
The energy or operational approach proposed by the GBI/ANSI committee is based on what has transpired in Europe in regards to CO_2 calculations procedures for buildings. Documents produced by the European Union provides a framework for all 27 EU countries to put into place CO_2 based calculation procedures for buildings by 2007 (EU 2003). The best application of this framework document is the United Kingdom's L2A Standard which became a requirement for all new U.K. buildings (ODPM 2006). The L2A Standard requires a new building to model its energy performance based on a set of prescriptive criteria, and then multiply the fuel mix of the building by the CO_2 emissions factor in order to determine a building's CO_2 target. This process is repeated for the proposed building and if the proposed building's CO_2 level is below the target, the building passes.

The proposed GBI/ANSI energy approach has some similarities to the ASHRAE Standard 90.1 (ASHRAE 2007), though it differs in several fundamental ways. For example, the Green Globes standard does not have any mandatory provisions except that minimum points have to be met in this category and that all buildings must meet local energy code, which would be most likely either ASHRAE Standard 90.1 or the International Energy Conservation Code. Points within the proposed standard are achieved only by going beyond code, which can be accomplished by either using the prescriptive or performance approach. The prescriptive approach gives points for meeting incrementally higher levels of component efficiencies, while the performance approach gives points as a function of how much better the proposed building performs vs. an industry agreed upon benchmark, which for the energy section is determined by the U.S. Department of Energy's Commercial Building Energy Consumption Survey (CBECS) database (DOE 2006). This is the most comprehensive source for building energy benchmarking currently available in the U.S. The CBECS database is also used by the U.S. Environmental Protection Agency's Energy Star Target Finder tool, which has been incorporated into Green Globes.

Unlike approaches such as ASHRAE Standard 90.1, which require designers to model a benchmark building as well as the building being proposed, the Green Globes standard is a much easier modeling exercise. Since CBECS is being used to determine the benchmark, only the building simulation for the proposed building needs to be completed. In order to determine a building's benchmark the EPA Energy Star Target Finder is used (www.energystar.gov/target_finder), which is a web based calculator that uses the CBECS database. This tool has the ability to normalize CBECS data to location, space type, occupancy density, internal load and hours of use (see Figure 1.). Target Finder generates an Energy Use Intensity (EUI) value and typical fuel mixes for a proposed 60,000 square foot Academic Administration building (see Figure 2.), which is then multiplied by the CO_2 equivalent (CO_2e) emission factor in order to determine the CO_2 target. Table 1 presents the CO_2e emission factors that are being proposed; a majority of these factors were generated by the National Renewable Energy Laboratory (NREL 2007). CO_2e has been used rather than CO_2, because CO_2e takes several other greenhouse trapping gases into consideration, particularly methane (CH_4) and nitrous oxide (N_2O). CO_2e also has a time horizon due to the atmospheric reactivity or stability of these contributing gases over time. The International Panel on Climate Change (IPCC 2001) 100-year time horizon figures have been used as the basis for establishing the CO_2e for both the operational energy and material calculations, that equivalence per unit mass is as follows:

$$CO_2 \text{ equivalent} = CO_2 + (CH_4 \times 23) + (N_2O \times 296) \quad (1)$$

The proposed building is then simulated; the resulting EUI and fuel mix is multiplied by the CO_2e emission factors in order to determine the proposed building's CO_2e level. This value is then divided into the CO_2e benchmark that was generated by Energy Star Target Finder to get percentage savings. The proposed Green Globes Standard currently awards 150 points to buildings that achieve a 50% CO_2e emission reduction from the average CBECS's building for that location. In addition, for every 1% CO_2e emission reduction beyond 50%, 2 points will be assigned to a maximum of 100 points (the Green Globes system has a total of 1000 points). Thus a CO_2e neutral building would score the maximum points allowable, 250 points which is one-quarter of all available points. As presently structured the GBI/ANSI energy approach dovetails very nicely with the Architecture 2030, only the time dimension (CO_2 neutral by 2030) would have to be included.



Target Finder

* REQUIRED
Select a target rating and/or compare your Design Energy to the target.

1. Facility Information
*Zip Code 85281 Facility Name Academic Admin. Bldg
City Tempe State Arizona

2. Facility Characteristics
*Select Space Type(s) for this project.
[Space Types]

Office Delete

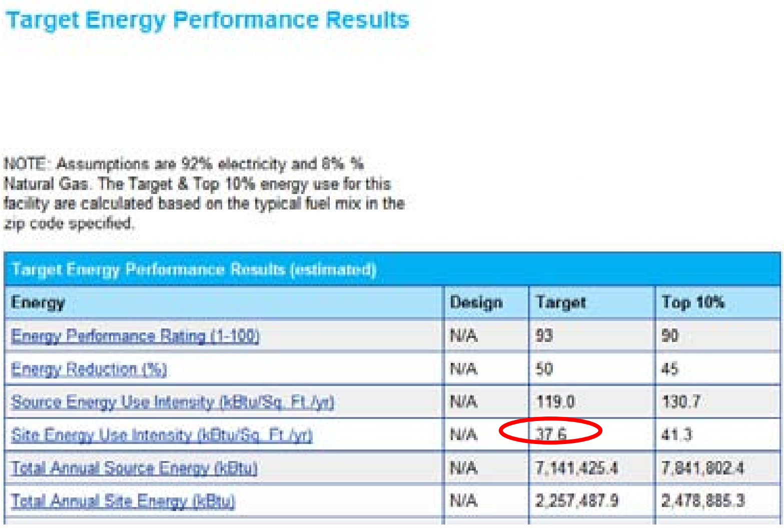
60000 Sq. Ft.	50 Hours	150	150	50% or more	50% or more

3. The Target[1]
Target Rating Or Energy Reduction Target
Select 50%
*Choose the design target and select "View Results" to display associated energy use for the target.

Figure 1. Target Finder's Input Screen for Example Building



Target Energy Performance Results

NOTE: Assumptions are 92% electricity and 8% % Natural Gas. The Target & Top 10% energy use for this facility are calculated based on the typical fuel mix in the zip code specified.

Target Energy Performance Results (estimated)

Energy	Design	Target	Top 10%
Energy Performance Rating (1-100)	N/A	93	90
Energy Reduction (%)	N/A	50	45
Source Energy Use Intensity (kBtu/Sq. Ft./yr)	N/A	119.0	130.7
Site Energy Use Intensity (kBtu/Sq. Ft./yr)	N/A	37.6	41.3
Total Annual Source Energy (kBtu)	N/A	7,141,425.4	7,841,802.4
Total Annual Site Energy (kBtu)	N/A	2,257,487.9	2,478,885.3

Figure 2. Target Finder's Output Screen for Example Building

Table 1. CO_2e Emission Factors

Fuel	kg-CO_2e/kWh(lb-CO_2e/kWh)
Natural gas	0.232 (0.510)
LPG	0.274 (0.602)
Fuel oil (residual)	0.311 (0.686)
Fuel oil (distillate)	0.299 (0.660)
Coal (bituminous)	0.373 (0.822)
Coal (lignite)	0.585 (1.289)
Gasoline	0.326 (0.719)
Biomass	0.026 (0.057)
Grid delivered electric	0.758 (1.670)
Grid displaced electric	-0.833 (-1.835)
Off-site renewable electric	-0.758 (-1.670)
Waste heat	0.019 (0.042)

3.1 The Operational CO_2e Benchmarking Calculation

From the Target Finder exercise we determine that the building's baseline EUI to be 37.6 kBtu/sf/yr. Target Finder also assumes fuel mix to be 92% for electricity and 8% for natural gas. Thus, the operational CO_2e benchmark that the proposed building will need to improve on is 17.39 lb/sf/yr.

Example of the benchmarking calculation:

For Electricity

$$\frac{0.92 \times 37.6 \text{ kBtu/sf/yr}}{3.412 \text{ kBtu/kWh}} = 10.14 \text{ kWh/sf/yr} \times 1.670 \text{ lb/kWh} = 16.94 \text{ lbs/sf/yr}$$

For Gas

$$\frac{0.08 \times 37.6 \text{ kBtu/sf/yr}}{3.412 \text{ kBtu/kWh}} = 0.88 \text{ kWh/sf/yr} \times 0.510 \text{ lb/kWh} = 0.45 \text{ lbs/sf/yr}$$

17.39 lbs/sf/yr

4. The Green Globes Material Approach

It is no longer enough to assume that individual material attributes, such as recycled content, the use of rapidly renewable materials, or local purchasing, automatically deliver the desired environmental benefits. Instead, those who design or build green buildings are increasingly being asked to look at a range of real environmental performance indicators or measures. This is done through a process called life cycle assessment (LCA), which takes into account the cradle to grave effects of manufacturing, transporting, using and ultimately disposing of products using a range of environmental impact indicators. Global warming potential (GWP in LCA parlance is the same as CO_2e) is one of the most important of those indicators. In the past, LCA's practical use was limited by the fact that it was perceived as too complex or time consuming for widespread use. That is no longer the case.

The Athena Institute recently introduced an online tool — the ATHENA® *EcoCalculator for Assemblies* —that provides instant LCA results for hundreds of common building assemblies. Developed by the Athena Institute in association with the University of Minnesota and Morrison Hershfield Consulting Engineers, the *EcoCalculator* provides LCA results generated using its parent software, the ATHENA® *Impact Estimator for Buildings*. The results take into account resource extraction and processing, product manufacturing, on-site construction of assemblies, all related transportation, maintenance and replacement cycles over an assumed building service life of 60 years, structural system demolition and transportation to landfill of those materials that are currently land filled as opposed to being recycled or reused. In addition, all energy use at every stage is factored up to account for the energy and other environmental effects of manufacturing and transporting different energy forms, termed pre-combustion effects in LCA.

The *EcoCalculator* was originally developed for use with the Green Globes and will be incorporated into the GBI/ANBSI version of the Green Globes. Because of its value as an indicator of climate change potential and other effects, the GBI also supported the team's creation of a generic version for use by the entire sustainable design community. This version is available free of charge from the Athena web site (www.athenasmi.ca), and is therefore available to other green building rating systems and programs that want to encourage greater use of LCA in material selection.

The *EcoCalculator* can be used for new construction projects, retrofits and major renovations on industrial, institutional, office or residential designs, either to compare specific assemblies or to assess all building assemblies. Building assemblies are evaluated in the following six categories, with the number of assemblies in each category varying widely depending on the possible combinations of layers and materials:

- Exterior Walls
- Interior Walls
- Roofs
- Windows
- Intermediate Floors
- Columns and Beams

Design results are available in spreadsheet form and show real time changes as the inputs are adjusted (see Figure 3.). This allows different assembly options to be considered in light of their environmental impacts and provides the information necessary to make informed, scientifically-based choices. Individual assembly impacts are then summed to determine whole building impacts for each of the following categories: primary energy, GWP (CO_2e), weighted resources, air and water pollution (see Figure 4).

In the development of specific assembly LCA results using the Impact Estimator, one must provide basic dimensional and other information, such as the length of an exterior wall or the live load on a beam. The results are presented on a per unit area basis (e.g., per square foot), but the base Estimator runs used large quantities, such as 1000 linear feet of wall. In other words, the assembly effects are estimated in a whole building context to take account of end conditions, such as the additional stud at the end of a wall or the perimeter columns in a beam and column assembly, window-to-wall ratios, and other realistic aspects of building design.

We assumed that all assemblies would be installed in either low- or high-rise buildings, using components and loadings typical for central areas of the United States (i.e., no unique seismic loadings were considered), but with a differentiation between northern and southern climates in order to properly define assemblies in terms of thermal performance.

Other specific assumptions and definitions are provided on the Athena Institute web site at www.athenasmi.ca.

4.1 The Material CO_2e Calculation

Figure 3 presents the LCA results for the same 60,000 square foot Academic Administration building that was benchmarked in Section 3.1. Figure 4 sums the whole building impacts for each of the six building component categories; here we see that the GWP (CO_2e) is 3306 tons or 110.2 lbs/sf. If we divide this value by the assumed 60 year service life for this building we get 1.84 lbs/sf/yr which is approximately 10% of the annual operational CO_2e for this same building. Correcting for the fact that this building is benchmarked to be 50% better then CBECS, a 1 to 10 ratio is very consistent with studies that found a similar ratio between embodied and operational energy (Cole and Kernan 1996).

5. Conclusion

This paper illustrates that both operational and materials CO_2e can be easily calculated, providing an opportunity for whole building CO_2e analysis. For our 60,000 square foot Academic Administration building example, the whole building CO_2e analysis amounted to 19.23 lbs/sf/yr. After the GBI/ANSI version becomes automated, like the current version of Green Globes is, this protocol will operate in a seamless manner. In addition, we envision that this protocol could be easily introduced into a Building Information Modeling (BIM) environment. Thus, as thermal properties and material assemblies are entered into a BIM program, the results of the whole building CO_2e calculation would automatically appear in a performance window.

We are sure that the protocol outlined here will move towards increased comprehensiveness; however, the trick will be to be comprehensive without becoming too complex or time consuming. As our knowledge increases, CO_2(e) calculation methods will undoubtedly improve. It is clear that the building industry is transitioning away from energy to CO_2(e) as a metric. This is an important transition in that it eliminates several issues that were problematic with energy as a metric. For example, the site vs. source energy issue that was current in the energy circles for so many years diminishes because site energy gets converted into source CO_2(e), thus, allowing the environmental impact of buildings to be accounted for more rigorously. However, new issues are beginning to emerge that may take some time to resolve, such as allowing fuel switching to take place between the benchmarked and proposed building or how on-site vs. off-site renewables are properly accounted for. While these are policy questions, they will have to be answered before we can develop a more definitive CO_2 calculation protocol, and they will undoubtedly get resolved. We believe the protocol outlined here will help us frame that discussion and become an important new tool for promoting sustainable buildings that move us toward carbon neutrality.

FROM THE ENERGY EVALUATION TO THE ASSESSMENT OF THE WHOLE BUILDING PERFORMANCE

Gerd HAUSER Prof. Dr. Ing.[1]

[1] Institute of Building Physics, University of Technology, Munich, Germany, hauser@tum.de
Fraunhofer Institute for Building Physics (IBP), Stuttgart, Germany, hauser@ibp.fraunhofer.de

Keywords: certification, assessment of building performance, energy performance certificate

Summary

Buildings are significant factors of all national economies. In order to label their quality and building performance, standardized evaluation methods are necessary. These methods should contain a high level of detail on one hand, and be as clear as possible and easy to understand for the user on the other hand, priorities differ according to the building type (housing, office, etc.). The following report will show the actual situation and the further development in Germany: the way from the energy evaluation (energy performance certificate) to the future assessment of the whole building performance (certification).

1. Functions of buildings

Buildings have numerous functions. Essentially, these are technical as well as social and cultural functions that are performed under the consumption of resources. The minimization of this resource consumption under consideration of the function and the location is named sustainable building.

The most important technical functions are:

Protection against:
- People and animals (safety need)
- Fire in the neighbourhood and on one's own premises
- Moisture in the form of precipitation, formation of surface condensation and mould, frost effects, swelling and shrinking processes
- Cold, when the outdoor temperature is low
- Heat, under mid-summer conditions and/or high internal heat loads
- Noise from the outside and from neighbouring other, or own, home or working areas
- Electric fields and radioactivity
- Glare problems due to direct or reflected solar radiation

Provision of:
- Light, preferably using a maximum share of daylight and high energy-efficiency artificial lighting
- Heat, to ensure thermal comfort when outdoor temperatures are low
- Cooling, to prevent overheating
- Humidity, in particular for use(r)-related requirements
- Fresh air, as available or conditioned
- Room acoustics, to ensure sufficient speech intelligibility and/or the requested auditory sensation of music

Removal of:
- Harmful substances (contained in building materials, released during use)
- Moisture (built-in moisture from the construction process, moisture generated during use)

These diverse tasks are fulfilled by numerous components and systems that are in general separately evaluated, labelled, and optimized. This scalar approach frequently leads to partial optima, but, however, not to an overall optimum. In part, it also produces contradictory statements. In many instances, only the investment costs for the insulation of the building or the heating system (and, for some time now, also the energy consumption during the use of the building) are used for the assessment. Other aspects, such as comfort, effects on performance, cleaning and maintenance costs and similar are not taken into account.

In addition, social and cultural functions must be fulfilled and aesthetic aspects must be considered. Quite often, these functions are not represented in a quantifiable assessment, although their importance may be dominant. This problematic situation makes the approach more difficult; consequently, it leads to a vectoral consideration with quantifiable “hard” and non quantifiable “soft” assessment quantities, with the inclusion of individual user wants and possibly the individual weighting of parameters.

2. Energy labelling of buildings

Now that the energy labelling of new buildings (and, in numerous cases, also of existing buildings) by means of an Energy Performance Certificate has been made obligatory by the Energy Saving Ordinance of 2007 (EnEV 2007) - almost two decades after the first presentation (Hauser and Hausladen 1990) - an important element in the description of a building's quality can finally be considered to have been worked out. Now, the approach of a holistic building assessment should be adopted, which is to include as many further criteria as possible.

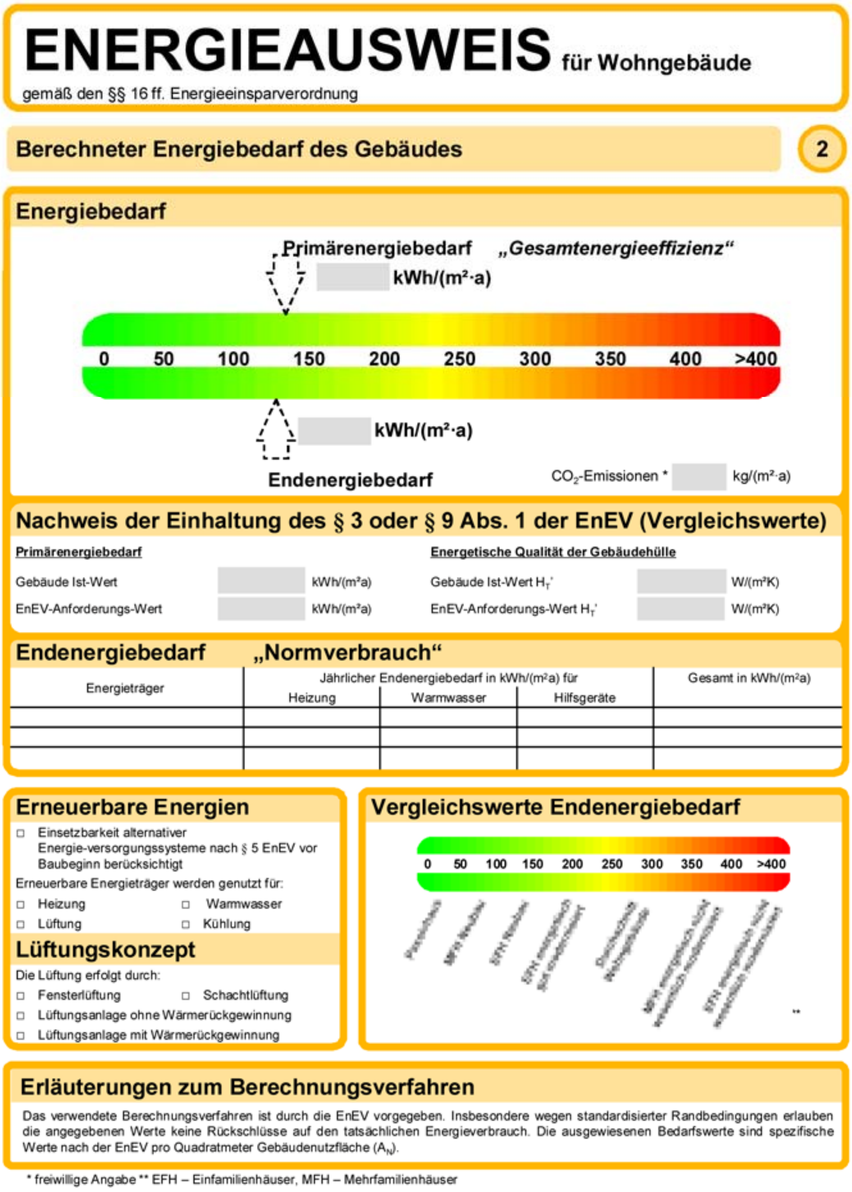

Figure 1: Reproduction of the second page of the Energy Peformance Certificate for residential buildings (EnEV 2007)

3. Holistic labelling of buildings

A room-conditioning assessment vector (RcA vector) is suggested in Hauser (2003) for at least the primary introduction of an overall holistic consideration of the “Room conditioning“ partial building function quantity. The principle structure of this vector is shown in Fig. 1.

From this and for each assessment criterion, the number of which can be very different according to the specific task, an objective assessment factor B will be introduced that can, however, be supplemented by an individual weighting factor W, so that the planner can better fulfill his particular wants and expectations in co-operation with the investor. The result is normalized to 1.

For the clear presentation of the complete vector, the form of a vectogram, as shown in Fig. 1, is suggested in Hauser (2003). This procedure enables any number of assessment criteria (which are if possible brought together in groups) to present the results obtained so that they are clearly and quickly recognizable, also allowing the comparison with alternatives. The definition and representation of reference curves from similar building projects simplifies the categorizing of the resulting solutions in respect to customary ones. Similarly, minimum standards can be pictured, as shown in Fig. 1.

The quality of a building can be clearly presented by the system described, which simplifies the processing of the flood of information. The task that is still to be done is therefore the definition of the criteria that are to be identified and the working out of methods for their objective assessment. For simpler implementation of the system, the designation "Sustainability Vector", or "Building assessment vector" is suggested.

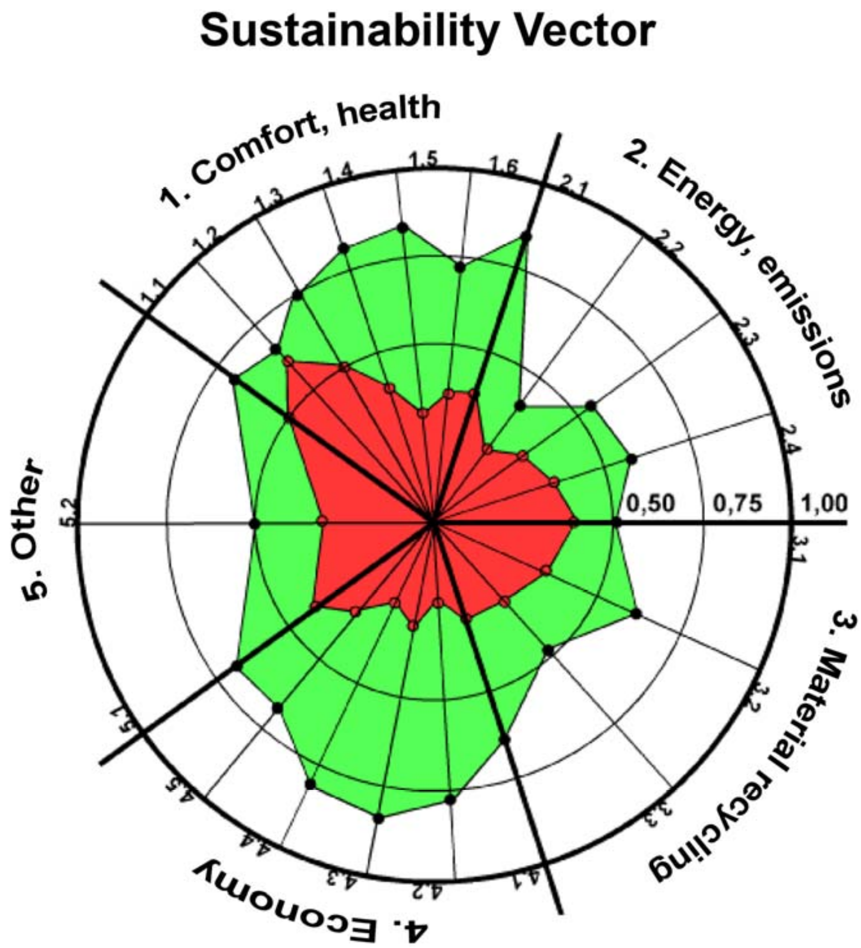

Figure 2: Reproduction of the room conditioning assessment vector (RcA vector) suggested in Hauser (2003), but named sustainability vector here.

There are already several international approaches to holistic building assessment methods, such as, for example, the assessment tools:

- BREEAM Building Research Establishment Environmental Assessment Method, GB
- SBTool Sustainable Building Tool (former GBTool), international
- LEED Leadership in Energy and Environmental Design, USA
- CASBEE Comprehensive Assessment System for Building Environment, JP
- EPIQR Energy Performance Indoor Environmental Quality Retrofit, GER, FhG-IBP
- ÖÖB Oekonomische und oekologische Bewertung (Economic and Ecological Assessment), GER
- EcoPRO Oekobilanzierungsprogramm (Life-cycle Analysis), GER, TH-Karlsruhe
- LEGEP Lebenszyklus Gebaeude Planung (Life-cycle Building Planning), GER

An illustrative labelling prepared with the methods described above has already been introduced in some countries, but the methods used have deficits. Programmes and evaluation schemes have also been developed at a national level in recent years. They have not yet been completely established in the planning process, however, and deal only with partial aspects of the overall assessment. For example, the EPIQUR and ÖÖB programmes (which were developed in Germany and Europe) are only for new buildings or for existing ones; programmes such as LEGOE and sirADOS are limited to the ecological life-cycle analysis or to the purely economic point of view.

Against this background, the development of a holistic assessment tool for buildings, which includes procedures used in Germany and Europe for the assessment of energy efficiency, user comfort and many more, and additionally takes methods that are already internationally used into consideration, is of great importance. A label that can be successful in the market - the Energy Performance Certificate (that has now at last been introduced) could serve as a good example here - and which is agreed upon in close co-operation between all building participants, is not only necessary but would also promote the aspects of sustainability in the construction sector (Hauser 1991, Hauser et al. 2007).

For this reason, the BMVBS (German Federal Ministry of Transport, Building and Urban Affairs) established the so-called “Round Table” several years ago. Here, experts first developed and then revised the “Guideline for Sustainable Building“ (Federal Ministry of Transport, Building and Urban Affairs 2001). In 2007, the “German Society for Sustainable Building” (German abbreviation DGNB) was founded. The focus was on the following five paramount protection targets for a certification system that is to be developed and is based on German environmental standards and environmental targets:
- Protection of resources
- Preservation of the natural environment
- Securing and preservation of worth
- Improvement in the surroundings and protection of public property
- Health and comfort of building users

With regard to the future German system, it is becoming apparent that the following areas will flow into the assessment of the whole building performance:
- Ecological Quality
- Economic Quality
- Social-cultural and functional Quality
- Technical Quality
- Process Quality
- Site Quality

These are presented in model shown in Fig. 4.

The individual areas on their part again comprise numerous criteria. Depending on the choice which criterion area is to be used 60 individual criteria are listed.

From the author's point of view, a 3-column model would make good sense as, for example, the “Acoustic comfort“ criterion is listed under “Social, cultural and functional quality“ and so already covers the “Noise control“ aspect subsumed under “Technical Quality“, which makes the “Technical Quality” column un-necessary. Fire protection, for example, could be categorized under “Functionality“, and so on.

Aspects	Criteria group	No.	Criteria
Ecological Quality	**Resource utilization and waste accumulation**	1.	Primary energy demand, non-renewables
		2.	Primary energy demand, renewables
		3.	Other use of non-renewable resources
		4.	Waste
		5.	Drinking-water consumption
		6.	Land consumption
	Effect on the local and global environment	7.	Greenhouse potential (GWP)
		8.	Ozone-layer destruction potential (ODP)
		9.	Ozone generation potential (POCP)
		10.	Acidification potential (AP)
		11.	Eutrophication potential (EP)
		12.	Risks for the local environment

Figure 3: Compilation of all individual criteria that are under discussion.

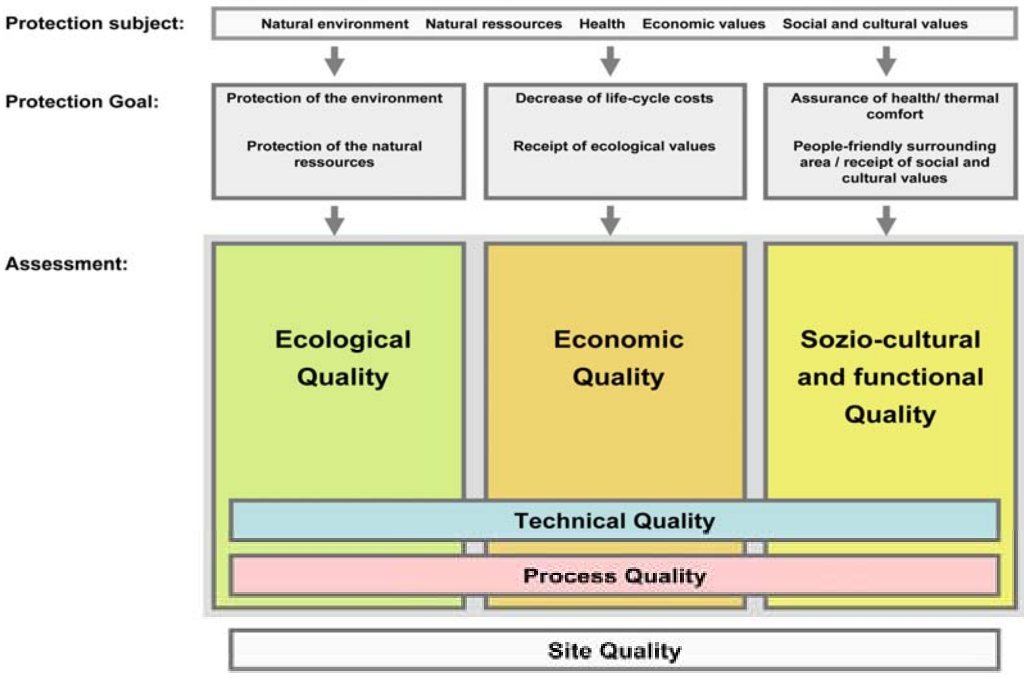

Figure 4: Presentation of the "Sustainability pillars" worked out by BMVBS and DGNB.

It must be possible to quantify all criteria comprehensibly (hard criteria) or to describe them qualitatively according to uniform points of view (soft criteria).

The form of a sustainability vector shown in Fig. 5 is suggested to enable a quick communication of the results to interested parties. The larger the particular area, the higher the sustainability of the building with respect to this criterion.

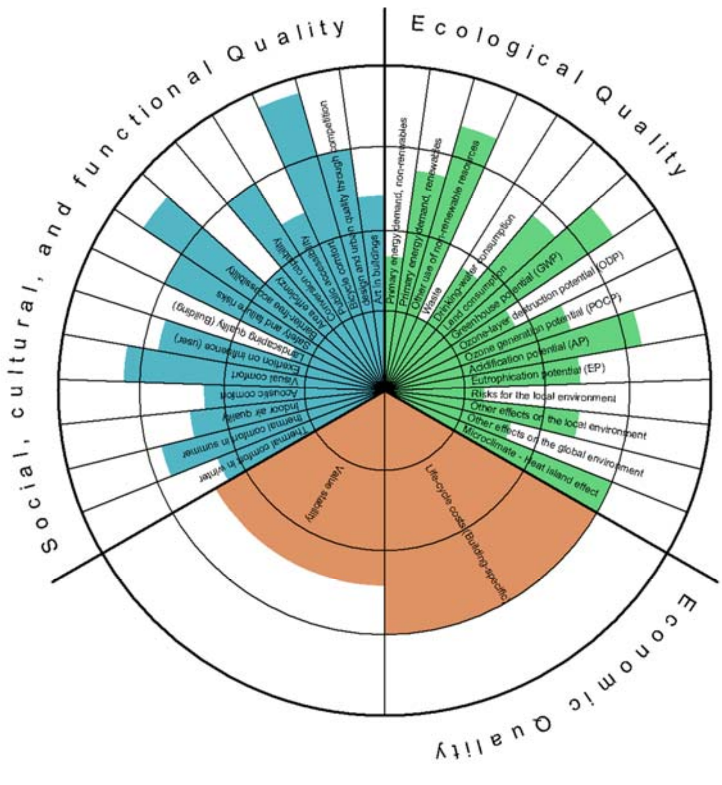

Figure 5: Suggestion for a sustainability vector for clear identification of the sustainability of buildings.

5. Added value and market chances of a holistic labelling

The Federal Ministry of Transport, Building and Urban Affairs (German abbreviation BMVBS) and the German Society for Sustainable Building, which was founded in 2007 in Stuttgart (German abbreviation DGNB), are working on a quality qualification for particularly environmentally friendly, healthy and resource-considerate buildings as the most important instrument for promoting sustained yield building. This new instrument for holistic building assessment takes up from agreements on international standardization and has as its motto, transparency and orientation to practice. Particularly important bases of information for the new system are quality and grade certificates for building products as well as environmental declarations on the basis of the ISO 14025 (EPD) international standard. The building assessment is based on an overview of the building and its life-cycle perspectives as basis for efficient sustained yield building.

The certificate that is being worked on proves the maintenance of the sustainability criteria both to the owner of the building and to the user of it. The demand for environmentally conscious ecological products is continuously increasing and is resulting in an enormous market shift. Up to now there is very little knowledge on the purchased real estate and it is limited to a general description of the building. Extensive information is provided for lower value products, but such information is lacking with long-lived real estate, although it is more and more frequently asked for.

Not only the owner and the user of the building can profit from this, however, but also predominantly the German and European building industry, whose environmental competence is rated very highly in international comparisons. This strength should be acknowledged in the international market with the new quality qualification.

Keywords: BEES, green building, hybrid life cycle assessment, life-cycle costing, buildings

Summary

Building stakeholders need compelling metrics, tools, data, and case studies supporting major investments in sustainable building technologies. Proponents of green building widely claim that these buildings are cost-effective, but often these claims are based on incomplete, anecdotal evidence that is difficult to reproduce and defend. The claims suffer from two main weaknesses: (1) buildings upon which claims are based are not necessarily "green" in a science-based, life-cycle assessment (LCA) sense and (2) their measures of cost-effectiveness often are not based on standard methods for measuring economic worth. Yet the building industry demands compelling metrics to justify sustainable building designs. The problem is hard to solve because, until now, neither methods nor robust data supporting defensible business cases were available. The U.S. National Institute of Standards and Technology (NIST) Building and Fire Research Laboratory is beginning to address these needs by developing rigorous metrics and tools for assessing the life-cycle economic and environmental performance of buildings. Economic performance is measured using standard life-cycle costing methods. Environmental performance is measured using LCA methods that assess the "carbon footprint" of tall buildings as well as 11 other sustainability metrics including fossil fuel depletion, smog, water use, habitat alteration, indoor air quality, and human health. Carbon-efficiency ratios and other eco-efficiency metrics are established to yield science-based measures of the relative worth, or "business case," for green buildings. The approach is illustrated through a realistic tall building case study. Finally, NIST activities and future plans in this area are described.

1. Introduction

A wave of interest in sustainability gathered momentum in 1992 with the Rio Earth Summit, during which *sustainability* was agreed to mean "meeting the needs of the present generation without compromising the ability of future generations to meet their own needs." In the context of sustainable development, needs can be thought to include the often-conflicting goals of environmental quality, economic well-being, and social justice. While the intent of the 1992 summit was to initiate environmental and social progress, by the 2002 Johannesburg Earth Summit, it seemed to have instead brought about greater debate over the inherent conflict between sustainability and economic development.

This conflict is particularly apparent within the construction industry's sustainable building efforts. Frequently, well-intentioned environmental improvement plans are not executed for economic reasons, and economic development plans fail to materialize over concerns for environmental protection. Thus, an integrated approach to sustainable building—one that simultaneously considers both environmental and economic performance—lies at the heart of reconciling the conflict.

This paper describes and illustrates, through a tall building case study, an approach that addresses the need to justify environmentally-friendly, or "green," building in economic terms. It suggests a framework for quantifying the "returns" on sustainable building using performance-based, science-informed thinking. The results refine and expand on preliminary results reported in early 2008 (Sunder, 2008).

1.1 Sustainable Building Metrics: A Review

A limited number of comprehensive, national-scale studies have been conducted to assess the benefits and costs associated with green building. A review of the U.S. literature finds that business cases for sustainable building typically evaluate commercial or residential buildings meeting benchmarks for green certification established by building industry stakeholders. A popular example of such a certification system is the Leadership in Energy and Environmental Design (LEED) rating system, developed by the U.S. Green Building Council (USGBC). LEED designates green buildings based on criteria including water, materials, and energy use, siting, and indoor environmental quality (USGBC, 2004). While other U.S. benchmarking systems have been established, LEED currently leads the way in defining guidance for green building attributes for the U.S. building sector.

Most published green building business cases are based on a certified green building's life-cycle costs, including: initial capital construction, operation and maintenance, repair, and replacement costs, which are typically collected through post-occupancy surveys. These cost data are used to determine the long-term economic merit of constructing a new building or retrofitting an existing one with green features, which usually requires higher initial construction costs. While the use of a life-cycle costing framework is common, different case studies often measure and collect these data in different ways.

The consensus among business cases is that building to environmentally-friendly guidelines is financially sound in the long run. Aside from the most commonly cited benefit—reduced energy costs—increased water efficiency and property values are among the other leading financial incentives for designers, builders, and owners to build green. When "soft" economic benefits, such as productivity increases, are monetized and included in life-cycle costs for office buildings, financial returns can increase significantly.

While approaches and conclusions in published business cases have been similar, their overall value is uncertain. These studies suffer from two major weaknesses: First, the buildings upon which these cases are based are not necessarily "green" in a science-based, life-cycle assessment (LCA) sense. Secondly, cost-effectiveness measures often are not based on standard methods of economic worth. A credible sustainable building metric first and foremost must be based on rigorous assessments of environmental and economic building performance.

1.2 Performance-Based Sustainable Building Metrics

1.2.1 Environmental Performance Measurement

Two quantitative, science-based approaches can help determine the environmental performance of a building: process-based life-cycle assessment (LCA) and input-output-based LCA. Both take a similar life-cycle approach, but each tackles the measurement challenge in a different way.

LCA is a holistic approach which considers the consequences of raw material, water, and energy inputs from, and releases to, the environment throughout the life-cycle of an "industrial" system. An industrial system is broadly defined: for the building sector, it can be limited to individual building products, components, or systems, or it can apply to an entire building or building sector. The term "life cycle" refers to the major stages in the life of the industrial system; these stages include raw material acquisition, manufacture, transportation, installation, use, and final disposal.

As standardized by the International Standardisation Organization (ISO), LCA clearly identifies and accounts for transfers of environmental impacts from one environmental medium (e.g., air, land, or water) to another and from one life-stage to the next. The ISO 14040 series of standards identify three steps in any LCA process: (1) *inventory compilation*, (2) *impact assessment*, and (3) *interpretation,* which lead to measures of environmental performance (ISO, 2006). During the first step, quantification of inputs, such as raw materials and energy, and outputs, in the form of environmental releases such as carbon dioxide and carcinogens, results in an *inventory* of environmental flows. During the *impact assessment step*, the environmental consequences of the identified inventory flows are assessed. In the third step, *interpretation*, impact assessment results may be synthesized to facilitate comparison of environmental performance across competing industrial systems.

A *Process-based LCA* begins by drawing *system boundaries* defining specific industrial processes to be included for the industrial system under study (e.g., ethylene production for input to the manufacture of the styrene-butadiene bonding agent for stucco walls). Since some of these "unit" processes involve additional, subsidiary unit processes, process-based LCAs follow system boundary-setting rules based on the magnitude of mass and energy contributions to the system from subsidiary unit processes. While compiling inventory flows for numerous industrial processes requires extensive, detailed data collection, the unit process-based compilation permits analysis of virtually any building product, component, or system imaginable. For this reason, the process-based LCA can be thought of as a “bottom-up” approach.

By contrast, the *Input-Output (IO)-based LCA* approach is a “top-down” approach which has its origins in macroeconomics. To assess the practical issues faced by governments and firms, economists have translated general equilibrium analysis for a competitive economy into a functional form. Economic IO Analysis recognizes and characterizes the interdependence of different economic sectors, and represents that interdependence by national IO tables quantifying, in monetary terms, inter-industry exchanges of goods and services throughout industrial supply chains. In other words, IO Analysis provides a macro-level view that includes secondary, and even tertiary-level, effects of consumer and producer spending decisions.

In the early 1990s, industrial ecologists began extending the IO Analysis approach. They developed physical IO tables corresponding to the existing monetary IO tables that tracked environmental inputs and releases among industrial sectors. By so doing, this tracking permits environmental inventory compilation following the “metabolic structure” of an economy. While IO-based LCA provides a straightforward and logical framework for inter-industry analysis of economic and environmental exchanges, its level of resolution is limited by the specificity of industrial categories in national IO tables. The North American Industry Classification System (NAICS) used by the U.S. Bureau of Economic Analysis to develop U.S. economic IO tables, for example, distinguishes fewer than 1,000 industries and commodities. Furthermore, IO tables are static in the sense that they represent current technology mixes and industrial practices. Thus, while IO-based LCA has a reasonable level of breadth, it is lacking in specificity and flexibility.

The respective strengths of the “bottom-up”, process-based LCA and “top-down” IO-based LCA complement one another’s weaknesses. While IO tables do not provide a level of resolution permitting analyses of new technologies, their breadth readily provides baseline inventory data representing complex industrial systems, such as buildings.

NIST has developed a new “hybrid” approach for analyzing the environmental performance of alternative building designs. By drawing on the specificity of the process-based approach and the comprehensive accounting framework of the IO approach, a meaningful comparison of traditional and alternative building designs can be made; one that systematically and scientifically compares life-cycle environmental performance at the building scale.

1.2.2 Economic Performance Measurement

Measuring the economic performance of buildings is more straightforward than measuring environmental performance. Published economic performance data are readily available, and there are well-established standard methods for conducting economic performance evaluations. The most appropriate method for measuring the economic performance of buildings is the life-cycle cost (LCC) method, standardized for building investment analyses by ASTM, International (ASTM, 2005a).

Economic performance is evaluated over a fixed period (known as the study period) that begins with the design of the building and ends at some point in the future. For a private investor, its length is set at the period of product or facility ownership. For society as a whole, the study period length is often set at about 25 years. While many buildings have much longer lives, a shorter study period is selected because technological obsolescence becomes an issue, future data become too uncertain, and the farther in the future, the less important the costs.

The LCC method sums over the study period all relevant costs associated with a building. Alternative designs for the same building can then be compared on the basis of their LCCs to determine which is the least cost means of fulfilling the building function over the study period. Categories of cost typically include costs for purchase, installation, operation, maintenance, repair, and replacement.

The LCC method accounts for the time value of money by using a discount rate to convert all future costs to their equivalent present value. Discounting accounts for the time value of money stemming from both inflation and the real earning power of money over time.

1.2.3 Business Case Measurement

By combining a building design’s life-cycle costs with its hybrid LCA performance measures, eco-efficiency metrics can be developed based on comparisons of alternate designs. The design alternatives will include both traditional and so-called “green” alternatives, resulting in eco-efficiency metrics that can be used to assess the “business case” for sustainable building.

2. Performance-Based Sustainable Building Metrics: A BusiBEES case study

The NIST technique is illustrated through a "BusiBEES" case study — a "Busi"ness case extension of the popular NIST process-based LCA/LCC tool known as Building for Environmental and Economic Sustainability (BEES) (Lippatt, 2005). The BusiBEES case study evaluates a tall commercial building with and without energy-saving technologies. Based on current U.S. industry practice, the following prototypical design is used to represent the baseline, "business as usual," tall building (RS Means, 2005):

- 20-story office building
- 3 m (10 ft) story height
- 43,000 m^2 (468,000 ft^2) of floor area
- 187 m (612 ft) perimeter
- steel frame
- double glazed, heat absorbing, tinted plate glass panel exterior walls
- heating, ventilation, air conditioning (HVAC) energy supply: oil fired hot water
- HVAC cooling generating system: chilled water, fan coil units
- HVAC energy intensity (EIA, 2003):
    - 290 MJ/m^2/y (25.6 kBtu/ft^2/yr)
    - 840 MJ/m^2/yr (74.4 kBtu/ft^2/yr)

The Missing Inventory Estimation Tool (MIET), version 3.0, is used to apply the IO LCA approach to develop inventory data for the baseline building (CML, 2004). Based on U.S. IO tables, MIET requires as input the dollar value of an industrial sector's economic activity, and reports as output an inventory of resulting environmental flows throughout the U.S. economy. Two industry sectors are of interest for the BusiBEES case study: (1) New office, industrial and commercial buildings construction (U.S. Bureau of Economic Analysis Input-Output Industry Code 110800) and (2) "Refrigeration and heating equipment" (BEA Input-Output Industry Code 520300).

The following published costs for construction of the baseline building, and for purchase and installation of its heating and cooling system, are applied respectively to the two industrial sectors (RS Means, 2005):

- Building Construction: $43,531,500
- HVAC Installation: $8,664,500

The IO-based life cycle inventory quantifies environmental flows from the materials production life-cycle stages (raw materials acquisition, manufacture, and transportation) and from the construction process. In other words, the IO inventory can be said to represent the baseline building's life-cycle flows from "cradle to site."

Next, the NIST Building for Environmental and Economic Sustainability (BEES) tool, which employs a process-based LCA approach, is used to compile inventories for the following four energy technology scenarios (Lippiatt, 2007):

- Conventional heating and cooling technology (represented by the baseline building)
- 30 % energy-saving HVAC technology, at a cost of $10.4 million ($10.4M)
- 50 % energy-saving HVAC technology, at a cost of $13.0M
- 100 % energy-saving HVAC technology (i.e. "net-zero energy" building), at a cost of $ 26.0M

For lack of reliable data, cost premiums for purchase and installation of the 30 %, 50 %, and 100 % energy-saving technologies—20 %, 50 %, and 200 %, respectively—are purely hypothetical. For the same reason, each energy-saving technology is assumed to be a higher-efficiency application of the same technology, installed in the baseline building with relatively minor changes to the overall design. While this assumption may be realistic, at least at the 30 % and 50 % energy savings levels, note that the BusiBEES approach permits refinement of these data. Indeed, NIST is in the process of developing additional data and case studies permitting development of these and other interesting scenarios. Otherwise, the BusiBEES case study uses current U.S. average data. Table 1 reports annual heating and cooling energy consumption and costs for the four case study energy technologies, based on U.S. average energy data for the baseline building design (EIA, 2003; Rushing et al. 2007).

The construction-to-site, IO-based life-cycle inventory is combined with each BEES inventory representing design-specific operational energy flows. Applying the BEES impact metrics to the hybrid inventory for each design in the second LCA step, impact assessment, permits calculation of life-cycle environmental performance for each building design.

Table 1 Annual energy consumption and costs for BusiBEES case study building design alternatives

Units	Base Case	30 % Energy Savings	50 % Energy Savings	100 % Energy Savings
MBtu/yr (MJ/yr)	4.68E+04 (4.94E+07)	3.27E+04 (3.45E+07)	2.34E+04 (2.47E+07)	0.00E+00 (0.00E+00)
$M/yr	1.22	0.86	0.61	0.00

Considering operational energy use over a 50-year study period, BEES life-cycle environmental performance results are summarized in figure 1. The figure displays weighted environmental impact category scores and their sum, the environmental performance score. The weights are based on those developed by a BEES stakeholder panel, and assign a relative importance weight of 29 % to global warming (Gloria et al., 2007). The results for each environmental impact—expressed in terms of the reference flow corresponding to the impact (e.g., carbon dioxide-equivalents for global warming)—have been placed on the same scale by dividing by total reference flows for that impact from all U.S. economic activity on an annual, per-capita basis.

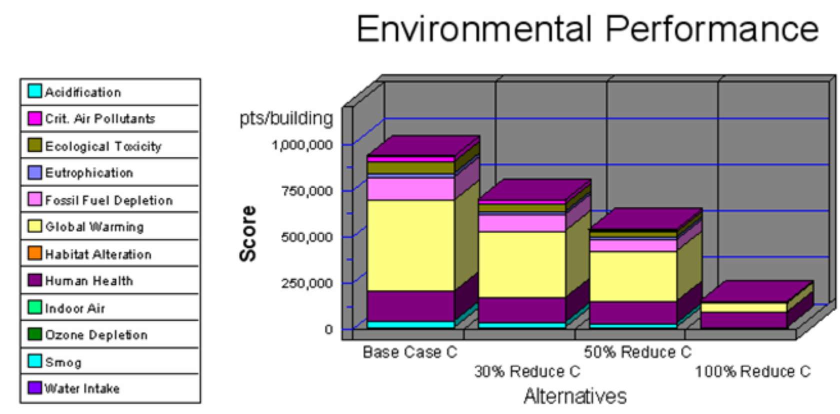

Figure 1 Life-cycle environmental performance for alternative tall building designs over 50 years

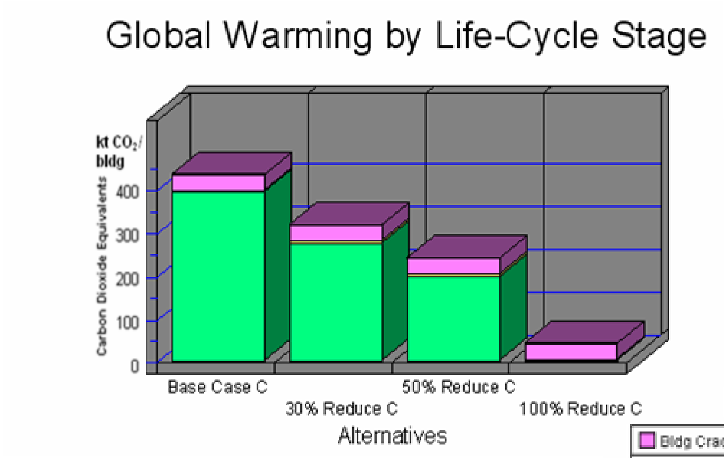
Buildings with lower BEES scores are greener. Over 50 years, the baseline design contributes about 900,000 times as much as each American contributes annually to U.S. environmental impacts, while the 50 % energy-saving design contributes about 500,000 times as much, yielding a reduction of 45 %.

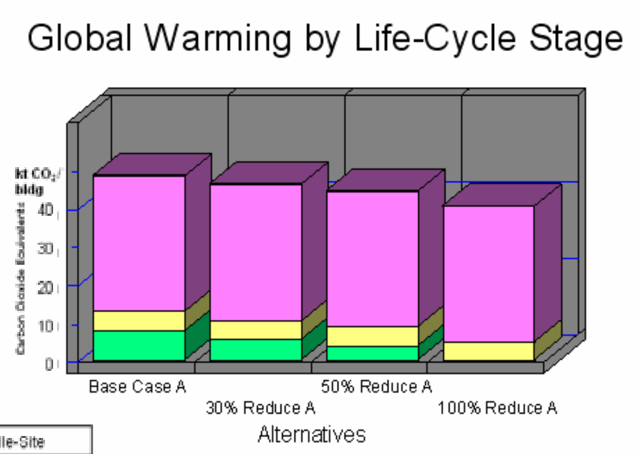
These BusiBEES case study results show a close relationship between environmental performance and operational energy savings. The explanation is straightforward: The cradle-to-site, IO-based LCA results for raw material acquisition, manufacturing, transportation, and construction of all four building designs—which are assumed similar in all respects except HVAC technology efficiency—drive a fixed amount of the BusiBEES Environmental Performance Score, leaving the rest for operational energy performance over 50 years. Given that each HVAC design uses the same fuel type, it stands to reason that environmental performance savings on a Btu-by-Btu basis (MJ-to-MJ basis) would not change, leading to building scale savings that are closely related to the efficiency improvement.

Figure 1 indicates that global warming constitutes the largest share of the BusiBEES Environmental Performance Score, which prompts further analysis in this case study. As shown in figure 2, the global warming impact from operational energy use over 50 years is a decreasing proportion of the life-cycle global warming impact as energy efficiency improves. The combined impact from building materials production and building construction (labeled “Bldg Cradle-Site”) constitutes the rest of the global warming impact. The global warming impact from *production* of the HVAC system alone is negligible.

By contrast, the relative global warming impacts for the four case study building designs, adjusted downward to reflect just *one year* of operational energy use, are quite different. Figure 3 clearly demonstrates the importance of the time horizon in the context of green building: the shorter the time period, the less important are future energy savings.

The same can be said for life-cycle economic performance, as shown in figures 4 and 5. While construction costs (i.e., First Costs) for the four case study buildings dominate life-cycle costs when considered over just 1 year of building operation, operational energy costs (i.e., Future Costs) become an important share of life-cycle costs over 50 years of operation. Based on a 3 % real discount rate, U.S. Department of Energy energy price projections, and LCC calculation methods prescribed by ASTM, International (ASTM, 2005a), 50-year operational energy costs range from $0M (net-zero building) to $97.8M in present value (PV) terms for the four building designs.





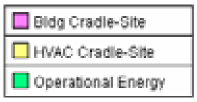


Figure 2 Global Warming impact over 50 years of building operation

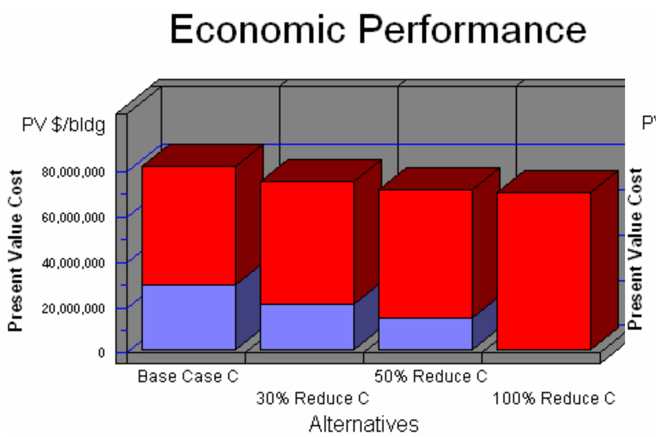
Figure 3 Global Warming impact over 1 year of building operation



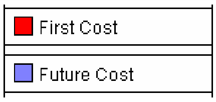


Figure 4 Life-Cycle Costs over 50 years of building operation.

Figure 5 Life-Cycle Costs over 1 year of building operation.

With estimates of life-cycle environmental and economic performance in hand, a rigorous metric quantifying business cases for the energy-saving designs may be developed. Since the global warming impact dominated all others in the BusiBEES case study, a carbon-based metric would be particularly meaningful. The metric, a "carbon efficiency ratio", indicates the change in life-cycle costs per metric ton of carbon saved.

As shown in Table 2, the carbon efficiency ratio ranges from a $1,580/t cost increase for the 100 % energy saving option, over just 1 year, to a $60/t cost savings for the 30 % option over a 50-year time horizon. Ratios for the two time horizons are shown to illustrate the importance of this parameter to investment decisions; when making actual investment decisions, the time horizon will be fixed. For a private investor, its length is set at the period of building ownership. For society as a whole, the time horizon is often set at the useful life of the longest-lived design alternative. However, when alternatives have very long lives, (e.g., more than 50 years), a shorter study period may be selected for three reasons: technological obsolescence becomes an issue, data become too uncertain, and the farther in the future, the less important the costs.

In accordance with ASTM, International E1185 (ASTM, 2005b) guidance, BusiBEES Carbon Efficiency Ratios are computed in a pairwise fashion. First the ratio for the lowest incremental cost alternative is evaluated with reference to the base case design alternative. If its Carbon Efficiency

Ratio is greater than 1.0, then the alternative is preferred on economic grounds and it becomes the base case design alternative against which the next-most expensive design alternative is evaluated. Based on this guidance, the ratio for the 100 % energy saving design alternative over 50 years is computed with reference to the 50 %, 50-year alternative.

Table 2 BusiBEES case study savings and carbon efficiency ratios, by time horizon

Time Horizon	Building Design Alternative	Incremental Life-Cycle Cost Savings ($PV)	Incremental Carbon Savings (t)	Incremental Carbon Efficiency Ratio (=$PV/t)
1 year	30 % energy savings	-1,380,000	2,300	-590
	50 % energy savings	-2,360,000	3,900	-600
	100 % energy savings	-12,410,000	7,800	-1,580
50 years	30 % energy savings	6,990,000	117,500	60
	50 % energy savings	3,220,000	78,300	40
	100 % energy savings	1,550,000	195,800	10

3. Carbon Footprint Metrics

The carbon efficiency ratio developed in the BusiBEES case study is a life-cycle carbon footprint metric. The carbon footprint of a building is the total amount of greenhouse gases produced directly and indirectly through its construction and operation, and is usually expressed in equivalent tons of carbon dioxide (CO_2). The carbon footprint of long-lived structures, such as tall buildings which require extensive operational energy use, can be significant as demonstrated in the case study.

The 2006 *Stern Review* on the Economics of Climate Change recognizes that while markets tend to deliver least-cost, carbon-inefficient short-term options, they may ignore technologies that could ultimately deliver huge carbon savings in the long term. As the BusiBEES case study demonstrated, there may be alternatives with positive BusiBEES Carbon Efficiency Ratios—those both financially superior *and* with reduced carbon footprints in comparison with conventional designs when considered over the long term. Furthermore, should carbon trading markets become widespread, even alternatives with negative ratios may become cost effective when the carbon market trades at prices above the alternative's incremental life cycle cost. Finally, designing buildings to low and even zero-carbon footprint standards on a large scale is likely to result in economies of scale that bring to competitive levels the investment costs for technologies and innovation which help to drive down existing levels of atmospheric carbon.

4. Conclusion

The carbon efficiency metric described in this paper is a meaningful business indicator for investments in reduced carbon-intensive building products, components, and systems. The value of the carbon efficiency ratio lies in its use as a metric for designing and sizing *cost-effective sustainable building investments*, particularly those for energy-saving technologies. While the most cost-effective choice is not necessarily the investment alternative saving the most life-cycle carbon, the ratio can be used to motivate investment toward measurable carbon reductions. The higher the ratio, the greater the financial gain per ton of carbon saved.

For investments geared toward less obvious environmental improvements, such as from building material selection and other major design decisions, global warming will likely not dominate all other life-cycle environmental impacts. In these cases—when cradle-to-site processes are the primary drivers for environmental performance—an overall "eco-efficiency" metric should be used as the decision criterion. BEES Environmental Performance Scores may be readily substituted for carbon savings in the ratio denominator, resulting in a measure of dollars saved per unit improvement in life-cycle environmental performance.

NIST is currently applying the BusiBEES protocol to about a dozen additional prototypical building types in the commercial and residential building sectors, as well as refining and developing additional data and case studies permitting variation of BusiBEES parameters that were fixed in this case study. These parameters include important variables such as fuel types for technology alternatives and U.S.

climate region-specific energy loads and costs. An effort also is underway to better harmonize the MIET and BEES life cycle inventory databases.

The NIST BusiBEES approach combines a hybrid LCA performance metric with standard measures of economic worth. It enables calculation of carbon- and eco-efficiency ratios comparing the business value of alternative sustainable building investments. Building industry decision makers routinely make investment decisions with potentially significant impacts on the environment. By supporting their decisions with life-cycle, science based metrics, represented by a single value expressed in the monetary terms they are accustomed to using, they can better allocate scarce global and financial resources to investments having reduced long-term negative consequences on our environment.

Summary

CSIRO in collaboration with the FWPA (Forest and Wood Products Association) is developing a life cycle inventory (LCI) of Australian timber products. This LCI will be used to quantify inputs and emissions of alternative building materials and conduct life cycle analyses on their impacts on the environment, resources and human health.

The basis of the timber LCI is the forestry production process. Forestry covers the growing and management of forests, harvesting of trees and transportation of logs to processing facilities. Since this forms the basis of LCIs for all downstream timber products, it is important to ensure the appropriate methodology is used and that the data collected is representative and accurate. Forestry is a unique process in that a) the time periods between management inputs and wood product outputs are relatively long (eg. rotation lengths for sawlog production typically span 25-160 years), b) activities usually occur over large land areas, and c) it involves a variety of inputs and outputs which may impact other land uses not directly related to wood production (eg. water supply, biodiversity management, road construction, fire control etc.). Thus, there is a challenge to obtain robust, generalized LCI data for forest production systems.

The research focussed on seven forestry case studies Australia-wide – three native forest hardwood systems and four plantation softwood studies – to understand variations in stand management and productivity, harvesting methods and transport distances. Within each region, all inputs (fuel, consumables, machinery etc.) and outputs (emissions and wood products) across the entire forest estate were quantified and apportioned across the range of products produced, assuming that the forest was in a steady state.

The study has provided the first comprehensive dataset for inputs and emissions for key forest systems in Australia. This paper discusses the methodology applied in this project, some preliminary results and their implications for the LCIs for timber products.

1. Introduction

1.1 Background

Although there have been a number of studies accounting for GHG (greenhouse gas) emissions from forestry operations overseas (eg. Berg and Lindholm 2005; Schwaiger and Zimmer 2001; Seppala et al 1998; Sonne 2006), few have accounted for use of water, land, and materials used in forest growth and management. This is the first comprehensive LCI study undertaken in Australia on softwood plantations or hardwood native forests. The significance of this study is that all environmental impacts from growing, harvesting and transporting wood to sawmills and other processing facilities are addressed, providing an objective overview of log production in terms of their environmental profiles. It forms part of a larger study, funded by CSIRO and FWPA, which will produce a complete life cycle inventory of representative wood products produced from Australian forests and used in the construction industry. The forest production stages reported in this paper cover the growth, management, harvest and transport of forest products to processing facilities and include all direct and indirect energy, materials and emissions associated with these processes. This paper discusses the methodology applied in this project, some preliminary results and their implications for the LCIs for timber products.

1.2 Industry overview

The timber industry in Australia is primarily based on a mixture of native hardwood regrowth forests and softwood plantations. The primary areas of native forest that continue to be harvested are located in Tasmania, Victoria, NSW and south-west WA. These include a wide range of eucalypt species and cover 11.4 million ha; ABARE 2007), although only a small proportion of this is available for harvest. Softwood plantations have been established in all states and cover an area of just under 1 million ha (ABARE 2007). *Pinus radiata* (radiata pine) is the predominant species planted across southern Australia, while *P. caribaea*

(Caribbean pine), *P. elliottii* (slash pine) and their hybrids are planted in Queensland. Smaller areas of *P. pinaster* (maritime pine) in Western Australia, and native *Araucaria cunninghamii* (hoop pine) in Queensland, are also grown. Hardwood plantations have been established across all states in the past 10-15 years and now cover 740,000 ha (ABARE 2007). However, these are primarily being grown for woodchip production and thus are not included in this forestry and wood products LCI.

The average volume of logs (including sawlogs and pulplogs) harvested from 2001-07 was 26.2 million m^3 with 36% from native forests and 54% from softwood plantations (ABARE 2007). The average gross value of annual forest production was $1.6 billion including $599 million (38%) from hardwood native forest and $790 million (50%) from softwood plantations (ABARE 2007). On average, 35% of the production from native forests is saw and veneer logs, 63% is pulpwood and 2% other products. In contrast, 63% of the production from softwood plantations is saw and veneer logs, 34% is pulpwood and 3% other products.

1.3 Scope of this study

The focus of this study is the seed to sawmill LCI of wood production from native hardwood forests and softwood plantations. The primary information used in this report incorporated site-specific data collected from seven Australian case study regions (three hardwood and four softwood) primarily using surveys. Surveys were specifically targeted at forest growers, forest managers, harvesting and haulage contractors. The data have been collected using records spanning from 2002–2007. Secondary data for inputs and emissions associated with forest growth and management was obtained from relevant literature where this was not available from managers and contractors. Data for CO_2 and other emissions from upstream processes (eg. production and transport of energy, fuels and fertilisers) was sourced from LCI forestry and wood products SimaPro database.

A key component of all LCIs is the recording of the source of raw data and the processes used to derive final results. This study adheres to the ISO 14040 guidelines (ISO 2002) and the broader LCI Project's Quality Assurance (QA) requirements.

The benefits of this study include:

- Providing a benchmark average for forests to which will allow consistent comparisons of the environmental impacts of forestry and wood products with other land-uses and materials.
- Allowing foresters to provide verified environmental information. For example, assisting the forestry industry to better understand its processes from a life cycle perspective.

2. Methodology

2.1 Case studies

This study used a case study approach to cover the variation in stand management and productivity, harvesting methods and transport distances in Australian forestry. The studies included:

- Radiata pine plantations in the Tumut/Tumbarumba region of NSW;
- Radiata pine plantations in the Green Triangle border region of South Australia / Victoria;
- Radiata and maritime pine plantations in south-west WA
- Slash/Caribbean pine plantations in the Fraser Coast region of south-east Queensland;
- Regrowth native forests in the north coast of NSW;
- Regrowth native forests in the Central Highlands of Victoria;
- (Largely) regrowth native forests in south-west Tasmania.

2.2 Forest production processes

The production process for both softwood plantations and hardwood native forests include the following common operations:

- Seed or seedling production: collection and processing of seeds (native forests) or planting and growing seedlings and cuttings (plantations);
- Establishment: burning of harvest residues and or mechanical cultivation followed by planting (plantations) or aerial seeding (native forest under clearfell systems);
- Chemical application: application of fertiliser, herbicide or insecticide (plantations only);
- Fire protection and control: fuel reduction burning, fire surveillance and control;
- Road construction and maintenance;
- Harvest: thinning (plantations) and clearfelling or selective harvest (some native forests) of stands;
- Haulage: transport of different products from forest to processing facilities.

These operations and associated inputs and emissions during a forest rotation (period from planting to final harvest) are illustrated in Figure 1.

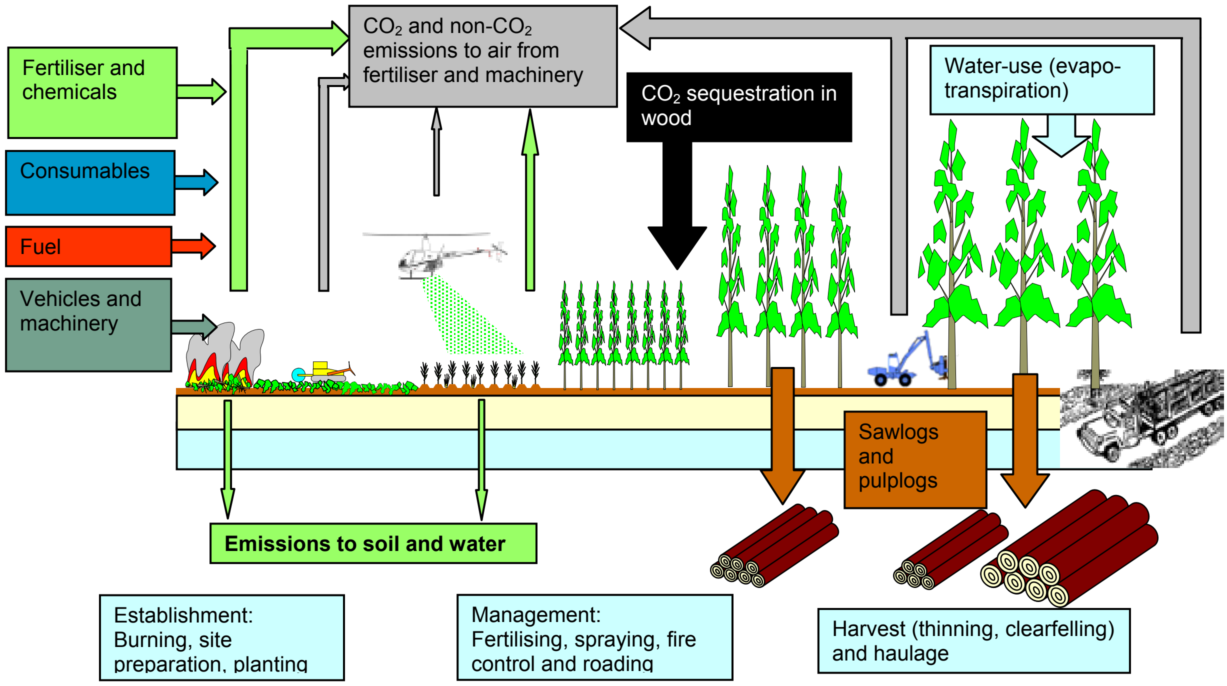

Figure 1: Example of a typical plantation softwood production system showing the inputs and emissions from the various processes. The production system for native forests is similar except there is generally no chemical application or thinning.

2.3 Reference unit

All inputs and emissions were expressed in terms of 1 m^3 of wood production to allow comparisons of the relative contributions of different processes to total inputs or emissions. Within individual operations, the reference unit was the relevant unit for the particular operation, e.g. for seedling production the reference unit was 1 million seedlings, and for forest management and fire control it was 1 ha of total forest area.

2.4 Forest products

The primary products from softwood plantations are sawlogs and pulplogs. However, native forests (and, to a lesser extent, softwood plantations) are managed for a wide range of products and services including wood production, water supply, biodiversity and recreation. This multiple use of native forests creates a problem for LCIs because most of these additional products are difficult to value in economic terms. For this study, it was assumed that wood was the primary product of both native forests and plantations, but that the results should be interpreted with regard to both wood and non-wood products.

Forest wood product classifications vary widely, both within and between different forest regions depending on the requirements of the local processing industry, as well as forest management objectives (James 2001). For this study, softwood product classes were based on those used in the Australian Pine Log Price Index (KPMG 2007), while hardwood products were classified according common categories across the different case study regions (Table 1).

Table 1 List of products covered in the softwood plantation and native forest hardwood case studies.

Softwood Plantation Products	Hardwood Native Forests Products
Large Sawlog/veneer log (< 44 cm)	Veneer log
Medium Sawlog (24-44 cm)	High quality sawlog
Small Sawlog (<24 cm)	Low quality sawlog
Pulplog	Pulplog
Other log	Other log

2.5 Assumptions

2.5.1 Allocation to products

Wood was assumed to be the only product of economic value from native forests and plantations. Other products including biodiversity, water, carbon storage, recreation and landscape value were noted as being important both in terms of the intrinsic value of forests as well as their influence on management operations especially for native forests but these were not included.

2.5.2 Steady state

A key assumption was that the forest system is in a steady state both with respect to carbon in pools of debris and to management operations (i.e. there is no change in land use or management systems over time). This avoided complications caused due to changes in soil carbon associated with conversion of previously unharvested forest or agricultural land to plantation or forest managed for wood production. It also avoided including inputs and emissions associated with expansion of the forest estate as the additional wood produced from this land would only be harvested some years in the future. Thus, where possible, only second rotation or regrowth forest was considered in the study. In some cases (eg. thinning or general management operations), it was not possible to separate activities on first rotation from later rotation stands, while for native forests in SW Tasmania a small proportion of old growth stands were included.

2.5.3 CO_2 emissions from burning and decomposition

A complex approach to CO_2 emissions would involve detailed accounting of decomposition and carbon turnover. However, existing data indicate that there is little change in soil carbon in forests that are at steady state. Thus, for this project, a conservative approach was been taken regarding soil carbon whereby any inputs from litterfall and root turnover were assumed to be converted back to CO_2 (i.e. have no effect on net CO_2 emissions). Further, because it is assumed that the forest carbon balance is in steady state, the CO_2 emissions from fuel reduction burns and post-harvest burning of slash can be ignored. Emissions from fire suppression efforts (e.g. tankers, aircraft, etc.) were included, but those from wildfire were not.

2.5.4 Non-CO_2 greenhouse gas emissions

Non-CO_2 GHGs, include nitrous oxide (N_2O), other nitrogen oxides (known as NO_x), carbon monoxide (CO) and methane (CH_4), can impact on global warming either directly (as in the case of CH_4 and N_2O) or indirectly (as in the case of NO_x). The impact of direct GHGs on global warming are indicated by emission factors which show their effective equivalent in terms of amount of CO_2 (IPCC 2006). Non-CO_2 GHGs from native forests and plantations include those arising from burning of slash and forest debris, application of fertiliser, burning of fossil fuels, tree growth and decomposition of forest debris. Emissions from burning were estimated from the amount of material burnt and emission factors published by the IPCC (IPCC 2006). Emissions of N_2O from fertiliser were based on rates of N_2O production per unit N fertiliser applied (IPCC 2006). Emissions from normal decomposition, growth and wildfires were assumed to be zero.

2.5.5 Emissions from herbicides, pesticides and fertiliser

As a result of the stringent controls placed on pesticide and herbicide use in forestry operations, emissions to air and water were assumed to be minimal (Jenkin and Tompkins 2006). However, amounts of herbicides, pesticides and fertilisers applied in nursery and plantation operations were included. Emissions from fertiliser to air covered in this study include NH_3 and N_2O. Emissions of NH_3 arise from urea volatilisation and amounts (in terms of N) are assumed to average 30% of the applied N in urea (May and Carlyle 2005). Emissions of N_2O are assumed to average 1% of applied N (IPCC 2006).

2.5.6 Water use

Water use by the total forest estate was estimated from a relationship between total rainfall and evaporation for forests developed by Zhang (2001) and allocated to harvested wood products. These estimates were validated with actual measurements of rainfall and catchment water yield for forested catchments (Benyon et al. 2006; Bubb and Croton 2002; Brown et al. 2005; Cornish and Vertessy 2001).

2.5.7 CO_2 sequestration in wood

Total CO_2 sequestration in this study was defined as the CO_2 sequestered by the tree to produce the biomass removed as wood products from the forest. This was estimated from average basic densities (sourced from Ilic et al. 2000) for the species (or species mix) relevant to each case study with an assumed carbon content of 50%. Net CO_2-e (CO_2 equivalent) sequestration was defined as the total CO_2 sequestration minus the total GHG emissions either directly or indirectly associated with forestry.

2.5.8 Wood price

For economic allocation of inputs and emissions to products and co-products it is necessary to know the relative prices as well as volumes of the various products from the system (in this case logs). Softwood log prices were based on average values published in the Australian pine log price index (KPMG 2007). For native forests, both mill door and stumpage values for logs were provided by forest growers.

2.6 Data collection

Most data were collected directly from forest owners and harvest contractors by means of surveys and interviews. It was important to define the scope of each case study spatially (the area that was covered), temporally (the time period included), as well as physically (the start and finish of the process). The spatial extent of the plantation study was based on the extent of the forest region as defined by the owner or manager. The temporal scope consisted of data collected from 2002-07. One difficulty was that data needed to be obtained from a sufficient sample of the numerous operators especially for softwood plantations. These are often small family owned businesses which lack the time and resources to provide the detailed information required by an LCI study. To reduce the time needed to compile the sometimes complex information a reference year of 2005-06 was selected for the data.

2.7 Calculations

In forestry, a large proportion of operations are undertaken by external contractors. Typically, for softwood plantations, roading, site establishment, planting, fertiliser and herbicide application, aerial surveillance and fire control, harvesting and haulage are all undertaken by individual contractors that may vary from single operator businesses to large companies. In native forests, harvesting and haulage are usually the main contracted operations.

A representative sample of contractors was selected from each case study region and information on machinery usage, production rates and fuel consumption was collected from each contractor. Average usage and fuel consumption rates were then calculated for each operation for each forest owner. Averages across the case studies for each operation were weighted on the basis of total production for each region.

2.8 Allocation method

Allocation was based on the economic value of each of the products. Thus, all forest inputs up to and including harvest were assumed to be for the combined production of all forest products, inputs associated with these activities were distributed across products according to their weighted average unit value ($ m^{-3}). Allocation of inputs and emissions excluding CO_2 sequestration was based on the total value of production of each product. Thus, high value products (such as veneer logs or large sawlogs) were allocated a larger proportion of inputs than low values products (such as pulplogs). CO_2 sequestration was allocated on a volume basis because the carbon sequestered is a physical part of the wood. Inputs and emissions associated with processes subsequent to harvest (i.e. chipping and haulage) were allocated to individual products with which they were associated. Thus, 100% of inputs and emissions associated with chip production were allocated to woodchips.

3. Preliminary Results

3.1 Survey coverage

The seven case studies covered approximately 50% of the average wood production from softwood plantations (2002-07) and 22% of the average wood production from hardwood native forests. Coverage of forest operations included 10 forest owners or managers, 18 harvesting contractors, 18 haulage contractors, five site preparation contractors, three aerial spraying companies two roading contractors, and two fire control agencies. Average coverage for these operations within the case studies varied from about 30% for native forests harvesting operations to 80% for seedling production for softwood plantations.

3.2 Inputs

3.2.1 Land

Land use efficiency as estimated from the total annual volume harvested divide by the total softwood plantation area varied from 10 to 20 m^3 ha^{-1} y^{-1} and averaged 17 m^3 ha^{-1} y^{-1}. .Land use efficiencies for hardwood native forests ranged from 1 to 9 m^3 ha^{-1} y^{-1}. The lower land-use efficiency, in terms of wood production, for native forests is a direct result of lower management intensity (eg. longer rotation lengths, no fertiliser or pesticide use) due to the multiple benefits for which native forests are managed (eg. biodiversity, water, recreation).

3.2.2 Water

Estimated total evapo-transpiration for forests relative to pasture (assumed to represent baseline water use) expressed in terms of total harvested product removal ranged from 0.07 to 0.23 ML m^{-3} (average 0.13 Ml m^{-3}) for softwood plantations and from 0.4 to 2.7 Ml m^{-3} (average 0.9 Ml m^{-3}) for hardwood native forests. The greater water use per unit of wood harvested from native forests is due to several factors: firstly, the lower management intensity in native forests results in lower growth rates and therefore lower production per unit water used compared with plantations; secondly, the native forests covered by the study were all located in high rainfall environments and water use generally increases with increasing availability of water (Zhang et al. 2001); and thirdly, the recovery of harvested product tends to be lower in native forests than in plantations as a result of a greater proportion of defective or unsuitable material, especially where there are limited markets for pulpwood. Importantly, because native forests are managed for multiple benefits, the impact of wood production on water yield (in terms of Ml ha^{-1} used by the forest) is lower than if they were managed to simply maximise wood production as with plantations.

These results should be viewed as indicative only, as the relationship on which they are based use data from forests in equilibrium (Zhang et al. 2001). In reality, evapo-transpiration varies with stand age (due to changes in leaf area) and management (thinning, time between harvesting and replanting etc.). Furthermore, while pasture may be an appropriate land-use with which to compare plantation water use, it is probably not so for native forest. However, data for a more appropriate comparison, unharvested native forest, is lacking.

3.2.3 Fuel and energy

Virtually all direct energy use was a result of diesel combustion in vehicles and machinery. Total fuel use in management, harvest and haulage of softwood plantations was 4.5 L m^{-3} (174 MJ m^{-3}) and for native hardwood forest was 8.7 L m^{-3} or 334 MJ m^{-3}. The greater fuel and energy use in the native hardwood forests per unit wood harvested was largely a result of differences in fuel use for haulage (3.3 L m^{-3} vs. 2.1 L m^{-3}) and harvest (4.4 L m^{-3} vs. 1.9 L m^{-3}). This was due to longer haulage distances, steeper terrain for harvesting machinery and lower harvestable volume per hectare in native forests compared with softwood plantations.

3.2.4 Chemicals

In softwood plantations a wide range of pesticides and fertiliser are applied either pre-or post planting or, for fertilisers only, near canopy closure or after thinning. The most commonly used herbicides included: atrazine (6.2 g m^{-3}), glyphosate (3.7 g m^{-3}), simazine (3.1 g m^{-3}) and hexazinone (2.2 g m^{-3}). Major fertilisers included triple superphosphate (0.83 kg m^{-3}), ammonium sulphate (0.54 kg m^{-3}), urea (0.36 kg m^{-3}) and potassium sulphate (0.11 kg m^{-3}). The amounts applied were equivalent to 0.29 kg N m^{-3}, 0.20 kg P m^{-3} and 0.06 kg K m^{-3}. Pesticides or fertilisers were not used in the native hardwood forest case studies.

3.3 CO_2 sequestration

Estimated CO_2 sequestered in softwood products ranged from 810 kg m^{-3} to 860 kg m^{-3}, depending on the average density for different species, and averaged 830 kg m^{-3}. For products from native hardwood forests, the amount of sequestered CO_2 ranged from 1,000 to 1,300 kg CO_2 m^{-3} and averaged 1030 kg CO_2 m^{-3}. Although basic density of wood varies with tree age and location up the stem (eg. butt versus top logs), it was assumed to be the same for different products due to lack of available data.

3.4 Emissions

Direct CO_2 emissions as a result of combustion of fossil fuel during vehicle and machine use in forest operations averaged 12 kg CO_2 m^{-3} for softwood plantations and 23 kg CO_2 m^{-3} for hardwood native forests. Direct non-CO_2 emissions including emissions of CH_4, N_2O and NO_x from slash or fuel reduction burning and N_2O and NH_3 emissions from nitrogen fertiliser application averaged 6 kg CO_2-e m^{-3} for softwood plantations and 36 kg CO_2-e m^{-3} for hardwood native forests. Thus, total direct CO_2-e emissions from softwood plantations averaged 18 kg m^{-3} compared with 59 kg m^{-3} for hardwood native forests. For softwood plantations, log haulage was the highest contributor to total CO_2-e emissions (32%), followed by harvest (29%), burning (23%) and nitrogen fertiliser (8%, Fig. 3a). For native hardwood forests, burning contributed 61%, harvest 20% and haulage 15% of the total CO_2-e emissions (Fig. 3b). The contribution of burning to total CO_2-e emissions varied considerably among case studies depending on the amount of slash left after harvest and whether fuel reduction burning was used as a fire management tool.

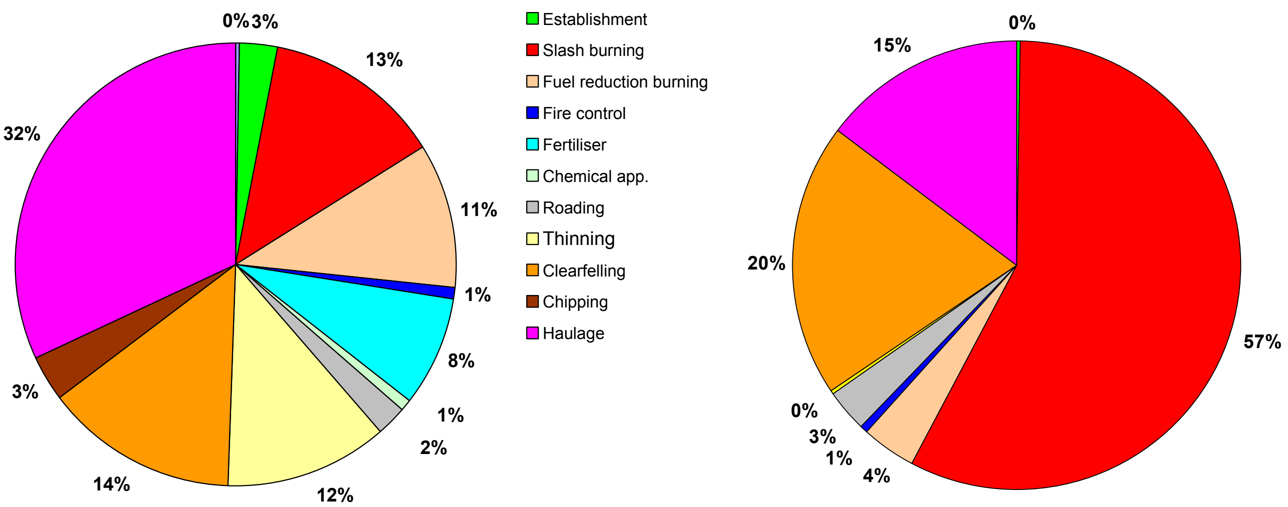

Figure 3: Contributions of different forest operations to total direct CO_2-e emissions for an average log from a) softwood plantations and b) hardwood native forests.

3.5 Direct plus indirect emissions

Indirect emissions include those from upstream processes used to obtain and process raw materials, produce and distribute fuel and energy, and manufacture machines and infrastructure. The SimaPro model was used to estimate total indirect plus direct emissions arising from wood production. This has LCIs for most upstream processes already developed for Australia and these were linked to our forestry LCI to provide a full forestry life cycle up to the point of delivery of products to downstream processing facilities.

Preliminary results for total direct plus indirect GHG emissions arising from growing, harvesting and hauling an average plantation softwood log were estimated to be about 23 kg CO_2-e m^{-3} (excluding the CO_2 sequestered from the atmosphere contained in the form of carbon in the log) compared with about 64 kg CO_2-e m^{-3} for an average native hardwood log.

In terms of allocation to individual softwood products, total emissions varied from 10 kg CO_2-e m^{-3} for pulplogs to 39 kg CO_2-e m^{-3} large sawlogs (Table 2). These represented between 1 and 5% of the total CO_2 sequestered in the logs. For hardwood products, there was wider variation in allocation of CO_2-e emissions as a result of the greater variation in product value. Emissions varied from 41 kg CO_2-e m^{-3} for pulplogs or 4% of the total CO_2-e sequestered to 330 kg CO_2-e m^{-3} for pulplogs or 25% of the total CO_2-e sequestered.

Thus, for both softwood and all but the highest value hardwood logs, total emissions of CO_2-e and other GHGs arising either directly or indirectly from production, harvest and transport of those logs represented only a small fraction (<12% for hardwood and <5% for softwood) of the amount of CO_2 sequestered and stored as carbon in the same logs (Table 2). If we convert these amounts to average rates per ha based on the land use efficiencies of the two forest types, these figures are equivalent to a net rate of CO_2 sequestration of 13.7 t ha^{-1} y^{-1} for products from softwood plantations and 5.5 t ha^{-1} y^{-1} for hardwood native forests. If we assume this is effectively permanently sequestered in wood products, then the total amount of emissions sequestered over 100 years would be equivalent to 1370 t CO_2-e ha^{-1} for softwood logs and 550 t CO_2-e ha^{-1} for hardwood logs in addition to the amount of CO_2-e sequestered in the standing forest biomass.

Table 2 Summary of SimaPro outputs for total (direct and indirect) CO_2-e emissions by product for softwood plantations and hardwood native forests. Values are averages across the three case studies.

Forest type and product		CO_2-e sequestered	Total CO_2-e emissions		Net CO_2-e sequestered	Growth rate	Net CO_2-e sequestration
		kg m^{-3}	kg m^{-3}	%	kg m^{-3}	m^3 ha^{-1} y^{-1}	t ha^{-1} y^{-1}
Softwood	Sawlog, large	812	39	4.8	773		
	Sawlog, medium	824	30	3.6	794		
	Sawlog, small	863	21	2.5	842		
	Pulplog	828	10	1.2	818		
	Woodchips	812	24	3.0	788		
	Other log	823	21	2.5	802		
	Average log	829	23	2.8	806	17.0	13.7
Hardwood	Veneer log	1227	170	13.8	1057		
	Sawlog, high quality	1050	123	11.7	927		
	Sawlog, low quality	1114	47	4.2	1067		
	Pulplog	1003	41	4.1	962		
	Other log	1301	330	25.3	971		
	Average log	1029	64	6.2	965	5.7	5.5

4. Knowledge gaps

This study revealed significant knowledge gaps in terms of the environmental loads and impacts of a variety of forestry-related activities in Australia. One of the most important of these is emissions of non-CO_2 GHGs from slash and fuel reduction burning. At present, data on the volume of residues left or burnt following harvest are not recorded, and non-CO_2 emissions from burning this material are based on international figures which have large uncertainties. Other major sources of GHG emissions which lack data include harvesting, haulage and fertiliser application. Additionally, further studies of CO_2 emissions from hardwood plantations, and harvest of old growth native forest, non-CO_2 emissions from burning, decomposition, fertiliser and pesticides, and impacts of plantations and native forest management on water availability are required.

5. Conclusions

This LCI study is the first of its kind for forestry in Australia. This work will allow consistent comparisons to be made between environmental impacts of forestry with those from other land uses. It also provides a means for identifying operations, such as slash burning, where relatively minor changes could lead to substantial reductions in these impacts. In terms of wood products, the study forms the basis for LCIs of wood product manufacturing processes, many of which have been developed as part of the overall project. These LCIs will be used to compare the potential impacts of wood products with those of other materials such as steel and concrete.

There is significant potential for forestry as a means of carbon sequestration, not just in the standing forest biomass, but also in the products removed. Net carbon sequestration potential of forest products ultimately depends on energy use, emissions and, product recovery in downstream processing, as well as their longevity and ultimate disposal. However, the results here show that CO_2-e emissions associated with the production and transport of saw and pulplogs represent only a small proportion of the total amount of sequestered CO_2 stored as carbon in those logs. If it is assumed that a large proportion of this carbon will remain in these products in the medium to long term, then sustainable harvest of wood products represents a means for substantial ongoing sequestration of CO_2 from forests. However, if, as is the current practice, this carbon is assumed to be lost after harvest, then much of the potential benefit of forestry as a potential carbon sink may remain unrealised.

6. Acknowledgements

The work outlined in this report was part of a research project conducted for, and substantially funded by, Forest and Wood Products Australia in collaboration with CSIRO and RMIT. Substantial assistance both in provision of data and review of results was provided by forest owners and managers including Auspine, Department of Conservation and Environment Victoria, Forest Plantations Queensland, Forests NSW, ForestrySA, Forestry Tasmania Green Triangle Forest Products, HVP and Vicforests,. In addition, a large number of contractors involved in harvesting, haulage, site preparation, spraying and fire control provided detailed data on their operations. From CSIRO Forest Biosciences, Nico Marcar and Randall Falkiner assisted with data collection and Richard Benyon for advice on forest water use. Maureen Puettmann of Oregon State University also provided valuable comments on the project.

Keywords: autonomous house, rating tools, measurement, design

Autonomous = not subject to control from outside; independent; self-governing; existing and functioning as an independent organism; free from external control and constraint

Summary

Increasing awareness of climate change has heightened understanding that human behaviours have contributed to the situation; this has influenced an increased desire by some members of the community to reduce their individual impacts.

In our consultancy work, Sustainable Built Environments (SBE) has noted a marked increase in the number of home owners seeking to go beyond the regulatory requirements of the 5 Star standards by minimising, or negating, their reliance on traditional infrastructure, that is, to become autonomous.

To inform strategies and assess various options for how this can be approached, and achieved, there are simple to use, freely available tools that can be employed by building designers.

SBE will discuss these tools and how they can be used in the design process to optimise environmental outcomes. Three case studies will be presented to illustrate how tools can be used through the design process with an analysis of a post construction assessment of one of the dwellings.

1. Introduction

An autonomous house operates independently of any inputs other than those from its immediate environment. The concept of the Autonomous House was developed and championed by Brenda and Robert Vale as part of a philosophical shift resulting from the oil crisis or “doom debate” of 1972 – 73. The Vales extended the idea to include: self-sufficiency in food, using on-site materials for building, and reducing building services and technology to a level where they can be operated and maintained by the home-owner.

The recent drought in Australia has once again sharpened community concerns about water security and further highlighted the effects that climate change may have. As concern has grown, SBE has noticed a marked increase in the number of our clients wishing to go beyond 5-Star energy rating compliance, with many seeking to become autonomous in terms of water and energy use. As we have seen with the “green bag” phenomena, if society is presented with achievable actions to improve the environment, people are happy to embrace them.

SBE believes that the ultimate environmental design aim for our built environment is to create comfortable buildings that use no energy, no water, produce no waste in operation or construction, and are made of materials that are derived from fully sustainable sources. Whilst this is very difficult to achieve in practice, this aim acts as a theoretical lighthouse for the opportunities that should be considered in any project.

2. Process

The process to develop an autonomous house is the same as for most design projects, with the main difference being an iterative process of assessing various design options in order to optimise overall environmental performance. Simple and publicly available tools, such as energy modelling, STEPS and STORM, can be used through the design process to predict energy and water demands for the site. These tools provide the means by which various reduction strategies can be assessed, so that the most effective ones can be integrated into the project.

2.1 Briefing

From the outset of the project it is essential to have an understanding of the climate and micro-climate of the site (including extreme events), in order for the design to utilise the free attributes available such as solar heat gains and prevailing winds.

In formulating the performance requirements of the site it is also important to again an idea of the client's motivation for sustainability and their willingness to be involved in operating systems for the house. The level of involvement that the client is prepared to have with building systems will help to define what systems should be used and their potential success.

Also important is gaining an understanding of the client's architectural objectives, such as priority values, function, aesthetics, special experiences, financial constraints, use of building and occupancy patterns. These objectives must balance sustainable design with the client's expectations in terms of comfort and commitment to operate active or passive control systems. The level of involvement that the client is prepared to have with building systems will help to define what systems should be used and their potential success.

2.2 Sketch Design Stage

The early design stages of a project are the ideal time to investigate the affect that various options will have on the potential operational performance. The architectural design should respond to the climate and site analysis by integrating best practice passive solar design concepts where possible; these include window sizing and orientation, and shading. Optimising passive design elements will reduce the need for active systems to provide heating, cooling and ventilation.

Energy rating tools can be used to assess some of the passive design attributes and optimise the building fabric so that it responds to its environment appropriately, and the heating and cooling energy requirements are reduced. Using energy rating data, Sustainable Tool for Environmental Performance Strategy (STEPS) can then provide a base case for reducing greenhouse gas emissions from the operation of the site based on the building services and systems selected.

From this exercise, design targets can be developed for the potential energy required for the operation of the house which will guide the sizing of renewable energy systems. Detailed steps and tools used for the main environmental impact areas are shown in Table 1 below.

Table 1 Early ESD Considerations

Energy	Water	Materials and Waste
Passive solar design principles – solar heating, shading, natural ventilation, daylighting	Demand management through specification of efficient fixtures and fittings	Use Ecospecifier to select environmentally preferable materials
Preliminary energy rating to optimise building fabric and reduce heating and cooling loads	Assess rainwater harvesting potential, most appropriate use, and storage requirements	Construction waste – consider pre-fabricated elements
Determine base case for overall energy requirements with STEPS	Grey and Blackwater harvesting potential and potential reuse strategies	Green waste
Optimise appliances using SBE Autonomous House Calculator	Develop water reuse hierarchy eg: rainwater for potable water and showers, recycled greywater for toilet flushing	Waste separation
Work out how much renewable energy is required	Assess site runoff through use of STORM to achieve best practice	
Establish costs to provide renewable energy systems		
Buy green power to meet the remaining energy needs		

2.3 Design Development

Through the development stage, system sizes are determined to match performance requirements. Life-cycle costings and maintenance considerations are weighed up at this stage so that the systems selected complement the intent of the design. Design decisions should continue to be re-evaluated as the design progresses to ensure that the project objectives developed in the briefing stage are met and to fine tune the performance targets. New servicing options may be explored.

For a standard project, building systems and services are generally selected on the basis of their capital costs and payback times. For an autonomous house project, the analysis of individual systems is based on criteria of environmental benefits (quantified where possible), capital costs (and possible rebates), maintenance costs, payback time, predicted savings and client priorities.

3. Rating Tools

3.1 ENERGY RATING - NatHERS

The Nationwide House Energy Rating Scheme (NatHERS) family of software includes: FirstRate, Accurate and BERS. The scheme is administered by the Federal Government and the tools engine was developed by the CSIRO. In Victoria, FirstRate is administered and owned by Sustainability Victoria.

NatHERS software is used to assess the energy performance of residential buildings by assessing the effect that building fabric will have in influencing potential heating and cooling loads.

In addition to providing formal building code compliance, energy rating tools can be used as a design tool to assess the impact of various building fabric options and inform a cost benefit analysis allowing more informed design decisions to be made. There is often a point at which the improvements to the building fabric outweigh the benefits to be achieved in terms of reducing energy use.

3.2 STEPS

Moreland STEPS was developed by Moreland City Council to assess the environmental impact of residential developments and to promote early integration of sustainable design initiatives at planning stage. The web-based tool is available for the public to use and assesses the key areas of their project including: energy, peak demand, water, stormwater and materials on a scale of percentage improvement above the average residential development. Targets are set for each of these aspects with innovation encouraged through credits awarded at council discretion.

SBE uses this tool at design stage to assess various strategies for their ability to reduce environmental impacts for greenhouse gas emissions, or to improve water run-off quality across the site to meet best practice, for example.

3.3 Ecological Footprint

According to EPA, Victoria: *the ecological footprint measures how much nature we have, how much we use and who it is used by*. In general, it measures the resources consumed by human activities across the lifecycle of a service, product or building, and interprets this information as the biologically productive land and water required to support that activity. It can be used to inform a residential project by measuring the quantity of the planet's resources required to construct and operate a residence. Typically, the Footprint is reported in "global hectares" (gha). Ecological Footprint calculations consider the following factors: biological value of land, materials, waste, water, greenhouse emission, transport, residents. The tool identifies areas where resources could be used more efficiently to ensure a sustainable future.

3.4 STORM

STORM has been developed by Melbourne Water to assess stormwater treatment levels on a site and determine whether stormwater treatment measures achieve best practice water quality objectives. It is a simple correlation tool based on the more complex tool, MUSIC, Model for Stormwater Improvement conceptualisation v3.

The tool can analyse seven treatment measures: rainwater tanks, ponds, wetlands, rain gardens, infiltration, buffer strips and swales and compares the treatment against best practice standards. A 100% STORM rating relates to a 45% reduction in typical annual total nitrogen loads. The tool is designed for general public to assess simple Water Sensitive Urban Design issues through the simple input of impervious area and selected treatment measures for runoff water from that surface.

3.5 Ecospecifier

Ecospecifier provides a knowledge base for building designers, specifiers and homeowners to source, assess and specify environmentally preferable and healthy products, materials and design processes. It is a subscription based service however, 10% of the data base is available in public domain to increase knowledge of sustainable materials choices. Ecospecifier identifies products with improved performance in the areas of greenhouse gas emissions, human health impacts and pollution impacts.

3.6 In-house water calculator

SBE has developed a water calculator to determine the potential water demand of a residential project and analyse the efficiency of various options for water recycling and re-use systems. The water calculator takes into consideration: local rainfall data, building type and occupancy rate, number of building users, efficiency of appliances and fittings, irrigation requirements and swimming pool top-up needs. Water demand data has been synthesised from a number of sources including the Yarra Valley Water, Residential End Use Study, 2004, Peter Roberts. SBE uses more recent rainfall patterns from the last two decades rather than long term historical data to inform tank sizing.

3.7 In-house autonomous house calculator

SBE's in-house autonomous house calculator analyses the proposed building services systems (e.g. heating and cooling, water heating, appliances, pool heating, lighting) and calculates CO2 emissions / energy demand of each system type. The tool assists in optimising the space heating, cooling, water heating, mechanical ventilation systems as well as proposed appliances by primarily focusing on reducing their energy use and CO2 emission during operation. The tool also calculates the energy generated by systems utilising renewable energy sources.

4. Case Studies

4.1 Broome Sustainable House

The Broome House was designed as a competition entry for the West Australian Office of Housing. The brief was to develop an sustainable, affordable detached social housing model dwelling that could be used as a template for future design of housing in tropical climate of Broome. The home was constructed in 2003.

4.1.1 Climatic response

The Broome climate is a tropical characterised by cooling winds from the coast to the west and blustery hot winds from the east. In the context of Broome's tropical climate, a design priority for cooling performance often took precedence solar heat gains over winter. This cooling objective led to the development of a low thermal mass building fabric, designed to shed heat quickly.

While the site places constraints on optimal orientation for the house, the design prioritises living areas and the main bedroom to receive direct solar access to the north with calculated solar eaves. The outdoor living areas are oriented to the north-west with full rain and shade cover provided to the deck by an insulated roof. To avoid this deep roof cover to the deck from cutting off solar access to the living room, filtered northern light is made available by north facing clerestory windows above it. Passive ventilation has been extensively used in the project's cooling strategy with thermal stack ventilation encouraged by the placement of high set vent clerestory windows in both pavilions. Fully openable louvre windows are positioned to maximise direct cross ventilation control from the full range of prevailing wind directions. The building is of lightweight composition so that it is able to respond quickly to changes in external temperature conditions. Any heat gained may be quickly purged via cross and chimney ventilation. The living and sleeping areas are heavily insulated to act as "cool cells"; they can be isolated from the outdoor environment and cooled or heated to maintain temperature as desired.

4.1.2 Air-conditioning and heating

Air-conditioning and heating represent about 26% of household energy use. To meet the competition briefing requirement of maintaining internal temperatures between 17 and 27 degrees Celsius, an efficient reverse cycle unit was specified to satisfy heating and cooling requirements of the living and sleeping areas only. Optimising the building fabric to these areas resulted in reduced heating and cooling loads which in turn reduced the size and energy consumption of the reverse cycle unit. Further efficiencies are gained by using the system to heat or cool one cell at a time with active occupant switching or automatic timed controls to service the preferred area.

4.1.3 Water supply

The major response to reducing water usage is the provision of tanks to catch rainwater for non-potable water demands and AAA rated fittings with aerators used in all tapware. The in-house water calculator was use to size three 23,700 litre poly-tanks are required to catch 100% of roof rainwater and maximise the mains water supply reduction. A constant pressure pump below the meter cupboard feeds rainwater into the house supply. First flush devices are fitted to divert initial salty run-off from the downpipe systems.

4.1.4 Solar hot water

Hot water uses approximately 31% of household energy. To reduce this, 3.5 m^2 of solar hot water collectors are mounted on north façade at the eastern end of the Living pavilion. Collectors are mounted at 18 degrees, which is the latitude of Broome, to give optimal performance. A standard domestic Solar Hot Water system with 300 litres storage tank, split panel system and gas boosting was used.

4.1.5 On-site electrical production from photovoltaic system

Eleven photovoltaic solar panels are mounted on the northern façade of the building, and are linked to a grid connected inverter that maintains grid availability, whilst also feeding excess supply back to grid. The regulator, inverter and reversing electronic meter are located in a ventilated meter cupboard.

4.1.6 Results based on on-site measurement of energy and water use

Data loggers were installed in the house post-occupancy to monitor energy and water use. A similar sized social housing dwelling was also monitored for comparison purposes. As a result it was found that in comparison to the documented average energy use of a residence in Broome in 2004 (6,154 kWh per annum), the Broome Sustainable House used 14% less electrical mains power (5,281 kWh per annum). Much larger savings were achieved in comparison to the Reference House, with the Broome Sustainable House residents using 60% less mains power.

Table 2 Broome House - energy use comparison between predicted and measured data

Broome average annual usage	Predicted average annual usage	Predicted saving	Metered usage for 12 months	Metered saving for 12 months
6154 kWh	1,500 kWh	76%	5,281 kWh	14%

Interestingly, the reference house used more than twice the amount of mains power (12,992 kWh per annum) than the average residence in Broome (6,154kWh per annum). We would expect a variation in the order of 30% due to the vagaries of occupant behaviour. If we assume that the reference house occupants are at the extreme of this range, you would expect the average household in Broome to consume ~9000kWh, 50% higher than the original figure provided in the competition brief. It is likely that the Broome average energy use figure supplied was either dated (as energy use has increased in recent years due to increased reliance on air-conditioners) or, based on the energy use of houses in milder climates. It is also noted that the demand based load calculations did not include heating and cooling, this is likely to have led to an underestimation in the predicted electricity load.

The energy generated by the PV's was only half of the amount anticipated. Reasons for this are likely to include: overestimation of the hours that 80W can be provided due to less sunny days or overshadowing; dust coverage and other maintenance problems; inefficiencies in the inverter.

The mains water use for the house was 54% less than the average daily use in Broome, which is extremely close to the predicted reduction of 51%. It is also interesting to note that the total water use in the house was higher than expected, but this was buffered by the fact that the rainwater tank provided 30% more water than predicted, possibly a result of higher water demand or higher rainfall. Aside from difference in behaviour, one known factor for the higher than expected demand is the change in the landscaping away from the originally intended indigenous planting.

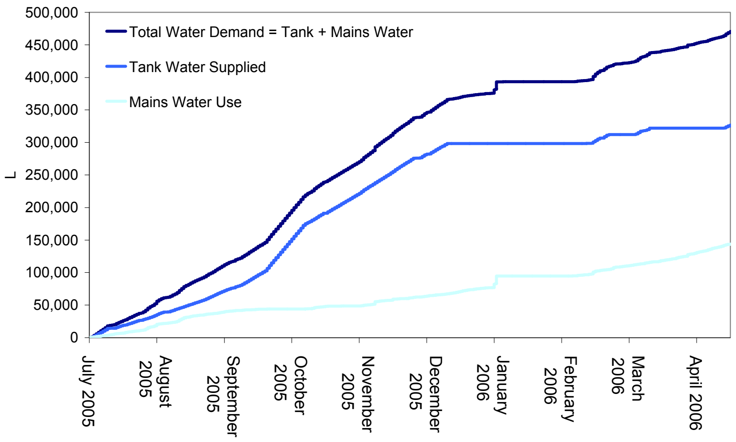

Figure 2: Measured total water demand, rainwater supply and potable water use

4.2 South Yarra House

The South Yarra House is a relatively large (553m^2), 5 bedroom dwelling located in Melbourne inner suburbs and is about to undergo construction. To optimise the potential performance of the residence, SBE used energy rating tools in conjunction with STEPS, STORM and SBE in-house calculators.

4.2.1 Climatic response

Melbourne is in a temperate climate with warm to hot summers, mild spring and summer and cool winters. The building design focused on ensuring the retention of heat over winter whilst eliminating the need for active cooling on Melbourne's numerous hot summer days. The building was designed to maximise exposure to the northern orientation by elongating the building on an east-west axis. This strategy allows for the most effective control of solar access throughout the year. FirstRate energy modeling was used to optimise heating and cooling loads. As a result, the building is to be heavily insulated with R3.0 total insulation to external walls and R5.4 total insulation to the roof. To reduce heat loss from a heavily glazed southern wall, glazing was replaced with 2 layers of multi-celled polycarbonate. Remaining windows are specified to be double glazed with a low-e coating to retain heat. To avoid overheating in summer, shading strategies include adjustable louvres to north facing windows and fixed shading to other windows. To add to the passive building performance, exposed concrete flooring and internal brick walls will provide thermal mass to temper indoor temperatures.

4.2.2 Air-conditioning and heating

As a result of the passive design principles employed in conjunction with optimised building fabric, zoned reverse cycle air-conditioning systems were installed to the up-stairs bedrooms only. Gas hydronic heating, using panel radiators with individual thermostats, has been specified to provide for greater efficiency in zoning areas to be heated. Hydronic heating has the ability to have individual room control, higher operating efficiency, low noise levels, reduced indoor air contaminants and other health benefits.

4.2.3 Water supply

High star rated efficient fittings and appliances were selected to minimise the potable water demand. To supplement the potable water supply, rainwater is to collected from roof and deck and conveyed to a 25kL storage tank plumbed to the cold water tap of the washing machine and to supply water for toilet flushing. Rainwater will also be used to water the vegetable and herb garden by hand. The benefits of rainwater collection for these uses is that no treatment required and no health concerns in case of direct human contact. In addition, greywater collected from showers is to be filtered through a greywater diversion system plumbed to sub-surface garden irrigation for the remainder of the garden. Sub surface irrigation has been specified to improve efficiency, minimise water required for landscaping and to mitigate health risks.

4.2.4 Solar hot water

Solar hot water is provided to both the domestic hot water supply and the pool water. The domestic system is gas boosted solar with high efficiency (a 315L SunPlus CPC solar hot water system). Pool water heating is provide by a separate low level heating system consisting of black piping equivalent to 200% of the pool surface area.

4.2.5 On-site electrical production from photovoltaic system

With the above initiatives and the use of compact fluorescent lighting a 3kW photovoltaic system would be required to negate the need for grid electricity (however, natural gas would still be used). In the first instance the client has decided to install a 1.0 kW photovoltaic system with 3.0kW inverter, allowing for increased capacity at a later stage.

4.2.6 Results

A combination of STEPS, STORM, energy rating tools and our own in-house calculators were used to make recommendations on this project and to predict demand. The predicted greenhouse gas savings are 71% and if the client purchases Green Power for the remaining mains gas and electricity supply, the house aims to be carbon neutral in operation.

Table 3 Annual energy use savings between preliminary and final design

	Baseline Annual Energy Use	Predicted Design Energy Usage	Predicted GHG saving	Annual GHG Saving	Annual Cost saving
Heating	9,900 kWh (gas)	800 kWh (gas)	11%	1,700 kg CO2	$1,600
Cooling	2,500 kWh	1,900 kWh	6%	900 kg CO2	$100
Hot Water	13,100 kWh (gas)	4,700 kWh (gas)	13%	2,000 kg CO2	$1,900
Other	18,300 kWh (mix)	8,900 kWh (mix)	32%	5,100 kg CO2	$2,300
Total Electricity	**6,400 kWh**	**5,300 kWh**			
Total Gas	**36,000 kWh**	**10,100 kWh**			
Renewable Supply	0 kWh	- 3,300 kWh	9%	3,300 kg CO2	$200
TOTAL	**42,400 kWh**	**12,100 kWh**	**71%**	**8,000 kgCO2**	**$6,100**

The potable water demand for the dwelling has been reduced by 36% through the use of alternative supplies.

Table 4 Water use savings from alternative water supplies

	Baseline Demand	Final Design Demand	Predicted saving	% Saving
Domestic	400 kL/yr	275 kL/yr	125 kL/yr	31%
Irrigation	30 kL/yr	0 kL/yr	30 kL/yr	100%
Total	430 kL/yr	275 kL/yr	155 kL/yr	36%

4.3 Upper Beaconsfield House

4.3.1 Climatic Response

The site is located 50 kilometres south east of Melbourne in the Dandenong Ranges in an urban residential area with large residential blocks, tree lined streets, varied eucalyptus forests, wet-lands, fern gullies and secluded creeks. Flora and fauna are protected. The climate is temperate to cool temperate with prevailing winds from the southeast in winter and temperatures varying from 22°C maximum in summer to 5°C minimum in winter. An existing house on the site did not meet the family requirements spatially or spiritually; it is to be demolished with the new residence built on the existing cleared area to minimise further site disturbance. Existing site infrastructure, such as rainwater tanks will be reused. The brief required the residence to respect the environment, open up to the bush (rather than the road) and consider views of Port Phillip Bay and Melbourne to the west, Westernport Bay to the SSE, and treed valleys to the NNE and SE. In conjunction with principles of passive solar design, the late David Oppenheim developed an axis mundi for the layout of the plan. The majority of the windows are located on the north side to maximise solar exposure and enable simple and effective shading solutions. The proposed residence is elongated from east to west. As a previous house on the site was destroyed by the 1883 bushfires, bushfire hazard management was another aspect of the detailed design.

4.3.2 Air-conditioning and heating

The building fabric has been optimised using FirstRate. To reduce energy used for heating and cooling, high levels of thermal mass are integrated in the internal spaces of the building. This includes R7.0 ceiling insulation and R3.5 wall insulation has been specified to ensure protection from outside temperatures. The area of thermal mass is approximately three times the area of north glazing. The need for cooling will be reduced through solar calculated shading to the north facing windows. Natural ventilation will be encouraged through operable facades and narrow floor plates. Cooling is aided by roof-overhangs or sun-shading above windows and natural ventilation through openable louvres above interior doors and at the centre breezeway. On hotter days, ceiling fans will be used. Air-conditioning will not be installed. The only heating is from the wood stove in the living room that will burn firewood from the site.

4.3.3 Water

The site is connected to mains water, however, the intention is for it to be self-sufficient in its water supply. There are 2 existing tanks that can collect a total of 30 kL of water and a designated fire fighting tank of 20 kL. The client's current experience of living on the site has proven that rain water is sufficient to meet all their potable water needs. Rain water will be collected from the large winged roof and stored to supply drinking and washing needs. A new black water treatment system (NOVA Clear Sewage System) will be installed to treat grey and black water from the site. The class A water obtain will then be used for flushing, irrigation and fire-fighting purposes.

4.3.4 Onsite energy production

Solar hot water will be used for with the default switching being with the gas boosting being turned off. The intention is for a PV system to be installed in future to supplement the electricity supply.

4.3.5 Results

The walls of the building were originally specified as double masonry to increase thermal mass. However, budgetary constraints have required walls to be brick veneer with increased levels of added insulation too provide similar performance. Thermal mass is, fortunately, still sufficient for passive heating & cooling. A 2kW photovoltaic system and Green Power for the gas use for hot water heating in winter will deem the house autonomous in operation.

Table 5 Energy use savings between preliminary and final design

	Baseline Annual Energy Use	Predicted Design Energy Usage	Predicted GHG saving	Annual GHG Saving	Annual Cost saving
Heating	9,900 kWh (gas)	200 kWh	12%	1,600 kg CO2	$1,600
Cooling	2,500 kWh	100 kWh	26%	3,500 kg CO2	$400
Hot Water	13,100 kWh (gas)	3,700 kWh (gas)	6%	900 kg CO2	$800
Other	5,200 kWh (mix)	3,200 kWh (mix)	23%	3,100 kg CO2	$300
Total Electricity	**6,400 kWh**	**3,300 kWh**			
Total Gas	**23,000 kWh**	**3,900 kWh**			
TOTAL	**29,400 kWh**	**12,900 kWh**	**67%**	**9,100 kgCO2**	**$3,100**

As the site will not be connected to mains water the site will be fully autonomous in water supply.

Table 6 Water use savings from alternative water supplies

	Baseline Demand	Final Design Potable Demand	Predicted saving	% Saving
Domestic	320 kL/yr	0 kL/yr	320 kL/yr	100%
Irrigation	700 kL/yr	0 kL/yr	700 kL/yr	100%
Total	1020 kL/yr	0 kL/yr	1020 kL/yr	100%

5. Conclusions

The path to achieving an autonomous home is relatively simple as described above. The process provides a quantitative understanding of sustainable performance against which the operations of the completed home can be assessed. Measuring the results is easy and low cost (energy meter and water meter for each residence).

By investing in the design process, clients are more motivated to engage with the building to maximise its operation. The impacts that it can have on lifestyle may outweigh the positive benefits of the building itself. Of course, the building also acts as a demonstration to the wider public of what it is possible to achieve. It is realistic for this approach to reach a critical mass in a relatively short timeframe with major benefits accruing to the environment.

The lessons from SBE's Autonomous House projects generally relate to the data used to calculate predictive performance. Predicted performance at the design stage will always differ from that in operation due to the necessity to make preliminary assumptions on usage patterns and behaviors. Resident behaviour and the appliances and systems used have a significant impact on overall environmental performance. Neither of these factors can be controlled by design, but can be influenced through effective communication during the design process. Further post occupancy studies are required so that baseline performance figures can be better correlated with actual performance to guide future projects.

The clients to whom we have provided Autonomous House advice are normal people with a concern for the future of the planet and with the moral responsibility to act to reduce their own footprints. The ESD initiatives included in their projects are aligned with architectural quality and aesthetics, they deliver the message of sustainability in a subtle and stylish manner.

It is more difficult to achieve autonomy for larger residences. While they may use the same amount of energy or water per m^2 as a reference home, due to their size they may still have a greater ecological footprint than a smaller home designed with less focus on optmising energy or water use.

Keywords: Hotels, energy, water, energy efficiency

Abstract

The utility consumption of business hotels is a key contributor to the overall environmental footprint of the commercial sector, but is less well explored than the office sector.

In this paper, the results of a preliminary energy and water use benchmarking study for business hotels in Australia are presented. The benchmarks demonstrate the feasibility of benchmarking as a means of indexing energy and water efficiency performance in this sector.

The results of 15 energy audits of business hotels conducted by the author's company are used to develop a characterisation of energy use and savings potential for this sector. The breakdown of energy and water consumption into end-use categories is identified and the key functional drivers for these end uses are identified, including space-conditioning, domestic hot water, laundry, meal preparation and swimming pools. Within each of these categories, common energy efficiency opportunities are identified and briefly discussed in terms of the scale of opportunity and the barriers that arise to implementation.

Introduction

The commercial sector is recognized as being one of the key areas for climate change action, owing to its significant impact on the international greenhouse budget. In areas such as office buildings, there is a long history of effort and a good deal of commercial activity towards the improvement of energy efficiency, but this activity is not uniform across the commercial sector as a whole. In this paper, the energy and water consumption of business hotels – one of the less thoroughly researched or commercially worked sub-sectors – is reviewed. For the purposes of this paper, business hotels are defined as typically multi-storey hotels, generally in city locations, with facilities geared towards business travelers and short-stay recreational travelers, i.e. without significant in-room cooking facilities and with only small recreational facilities (such as a small swimming pool and a gym). In the Australian context, this is particularly differentiated from the resort hotel and apartment hotel sector, which respectively have far larger recreational facilities and significant in-room kitchens.

The approach taken in this paper is firstly to examine some preliminary benchmarks developed in Australia for energy and water consumption, and then to examine savings opportunities as identified in a batch of 15 energy audits undertaken in Australia. The nature of the savings opportunities identified is then discussed in the context of the institutional and operational parameters of hotels.

1. Benchmarks for Energy and Water

Benchmarking is becoming recognised as a key methodology for the assessment of energy efficiency opportunity. This is evidenced by initiatives such as the European Building Performance Directive, Energy Star in the US [US EPA 2008] and the Australian Building Greenhouse Rating (ABGR) scheme in Australia [DECC 2008a]. The benchmarking study presented in this paper is derived from a preliminary benchmarking study conducted by the authors for the Department of Energy, Utilities and Sustainability of the New South Wales Government as part of the National Australian Built Environment Rating System (NABERS). NABERS is the broader environmental rating suite within which ABGR operates [DECC 2008b].

There are some international precedents for hotel energy and water benchmarks, including Energy Star for Hotels [US EPA 2008], UK Construction Industry and Research Association benchmarks (CIRIA) [Wagget and Arotsky 2006], World Wildlife Fund (WWF) benchmarks [WWF 2008]. Within Australia there has also been previous work conducted by the Department of Industry, Tourism and Resources (DITR)

[DITR 2002]. These benchmarks include a range of measures based on typically GJ per room per annum, MJ/m² and m³ per room, typically indexed by some form of basic categorisation of hotel type. While clearly useful in the context they were designed for, these benchmarks lack the detail and/or local specificity required for the NABERS scheme.

As a consequence, the preliminary benchmarking study reported in this paper was commissioned in 2007, with a view to establishing the feasibility of developing NABERS ratings for energy/greenhouse and water for the hotel sector. The pilot of this scheme, based on the full benchmarking study undertaken as a follow-on to that reported here, will be launched in mid-2008.

1.2 Benchmark Development

1.2.1 Compensation for Service Levels

The establishment of a hotel energy or water benchmark is considerably more complicated than for offices, because of the diversity in the sector even within notional categories of hotel. Most existing benchmarks have avoided this issue by retaining a highly simplified approach. However, this reduces the degree to which the resultant benchmarks can be used to assess efficiency, as an individual hotel that may be efficient but provides a greater range of guest services will be penalised relative to a potentially less efficient hotel with fewer guest services.

One well-known indicator for service level is the hotel quality star rating, which is an externally managed system with auditable standards. While there are some technical issues with the use of this, it noted the key purpose is to provide a means of ensuring that resultant benchmarks provide peer-to-peer comparisons.

In addition to the hotel star rating, the following factors are feasible as sources of additional corrections:

- **Number of rooms.** This is a preferred variable for benchmarking, as it is relatively well defined;
- **Number of beds.** This is a further size variable but with greater ambiguity due to the variable relationship between guest numbers and the number of beds actually provided.
- **Floor area.** This factor is strongly correlated to the number of rooms but is not measured to any consistent metric by the industry and as such is not a preferred index for hotel size.
- **Scale of meeting/conference facilities.** This varies independently of other factors and can be a significant contributor to the overall energy use of an individual site.
- **Scale of restaurant facilities**. While this is to some extent correlated to hotel quality, other independent factors also play a strong role.
- **Swimming pools.** The scale of swimming pools offered varies widely, again with a marginal correlation to the hotel star rating.
- **Laundries.** While most hotels have some form of house laundry, this may range from a small facility for washing a few select items (such as uniforms or a guest valet service) to a large facility washing sheets, towels and other linen for more than one hotel.
- **Retail operations.** Many hotels also house some limited independent retail operations. These are typically but not always sub-metered.
- **Level of occupancy.** In principle, the level of occupancy should have a large influence on hotel energy and water consumption, although in practice for energy at least this is not as significant as might otherwise be the case due to the propensity of hotels to provide service to empty rooms in preparation for unexpected arrivals.

Other factors that may be significant for individual hotels include: the provision of staff accommodation, water supply pumping and on-site power generation in more remote locations, the presence of a casino on site, and the provision of supplementary guest services such as health spas, valet cleaning services and executive club facilities.

1.2.2 Data review

The data for this study was assembled from commercial client information in the possession of the authors based on site studies and other works. As a result, the overall accuracy of source information is considered to be good. The data included: forty business hotels, typically of 4-5 star rating and located in major centres around the country; seven regional hotels of 3 star rating, all of which are located in regional Western Australia; and sixteen budget hotels, of 2 star rating, located around Australia.

The data sample is considered preliminary and is not adequate for use in generating a finalised benchmark due to the limitations of the data set with respect to the range of hotel groups and geographical diversity in the sample, as well as some limitations in the range of actual information gathered.,. Nonetheless, the data set is considered to have sufficient validity to be able to obtain a valid insight into the nature of the hotel sector energy and water consumption prior to a more complete survey.

1.2.3 Energy/Greenhouse benchmark

As hotels use both electricity and fuels, and there is some interchangeability between these, the energy benchmark was developed in the format of a greenhouse gas benchmark. This allows combination of the different fuel sources in a meaningful manner, and fits with the approach used in the ABGR and NABERS programs. For the purposes of this study, the total greenhouse gas emissions associated with the sites was calculated using 2005 New South Wales coefficients for all states (0.985 kg/kWh for electricity and 0.0713kg/MJ for natural gas; no other fuels were reported in any significant quantities).

A strong primary relationship was observed in the data between the hotel star rating and the emissions per room. This was used as the basis for the establishment of the benchmark. In addition, the following preliminary compensations were made to the data:

- Presence of laundry. This was determined by t-test (a statistical test to determine whether the difference in mean between two samples of data has significance) as being a significant correction at 6000MJ/room of gas.
- Presence of heated pool. This was determined by t-test as being a significant correction at 19,000MJ/room of gas. In application this was multiplied by the average number of rooms per site (171) and applied as a fixed figure to all sites as it is expected that pool size does not in practice correlate strongly with the hotel size.
- Food covers. A weak relationship between food covers (a hotel operational variable roughly proportional to meals served) and energy was determined. The equation of correlation was $\Delta=6708-14.7f$ where f is the number of food covers per room and Δ is the difference between the benchmark and the actual greenhouse emissions per room (after laundry and pool corrections).
- Conference facilities. No data were gathered on conference facilities in the original data sample so no compensation has been provided.

To determine the impact of star rating on the greenhouse per room, the median, seventy fifth percentile and twenty fifth percentile in greenhouse per room data (after pool and laundry corrections) were calculated for each of the star ratings, to give an aggregated view of the data. Only the median is used for the benchmark, as the benchmark is intended to provide an indication of the performance of the mid-point of the population. The results are shown in Figure 1.

Based on the data, the overall benchmark for median performance *M* (kg/room per annum) is:

$$M = 5772S + 14.7f + \frac{P}{r} + l - 14171 \qquad (1)$$

where *S* is the star rating, f is the number of food covers per room, *P* is the pool correction (=232,000kg if a heated pool is present) and *l* is the laundry correction (=463kg/room if a laundry is present) and *r* is the number of rooms.

The benchmark is a reasonable representation of the data, with an r^2 of 0.66 between the median benchmark and the data set. This relationship becomes stronger (r^2=0.81) when evaluated in terms of total greenhouse emissions. In either case a degree of spread is expected, as there is a range of efficiency levels. Indeed, in this context, as anecdotal but important confirmation of the benchmark approach is that a brief review of the position of hotels relative to the author's studies of the individual hotels indicates that the majority display the correct behaviour relative to the median, i.e. the energy audits indicate that sites with large potential energy savings tend to have above-benchmark emissions per room.

It is emphasised that the benchmark is preliminary only and that further data are needed. Further work is also required to allow climate effects to be included in the benchmark.

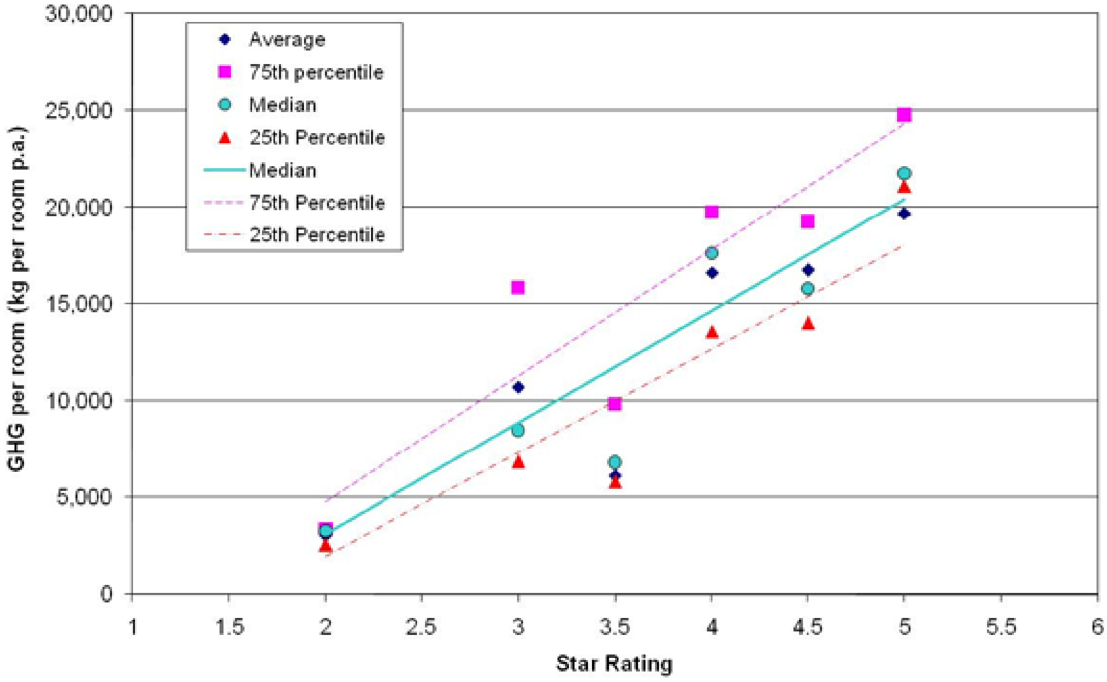

Figure 1 Relationship between laundry and pool corrected greenhouse emissions and star rating. The median relationship shown on the graph was determined using figures weighted for the sample size in each star rating. (noting for instance that the 3.5 star sample consisted of only three hotels).

1.3 Water Benchmark

A similar approach was used to generate water benchmarks, due to strong similarities in the data. Nominal correction factors were derived for laundries and swimming pools as follows:

- Large frontloading domestic washing machines use around 10 litres of water per kg of washing (as can be identified from www.waterrating.gov.au). The washing of a set of sheets and towels therefore would be expected to use around 30-40 litres of water per room night. This compares with the average water use of 590 litres per room night. As a result the approximation of 40 litres per room night has been used as an adjustment for sites with laundries. This is, however, not a significant adjustment.
- An approximate estimate of pool water consumption is around 60% of pool water volume [NAEEP 2004]. For the purpose of this analysis, a pool water correction factor has been allowed in the proposed rating equation and has been set to 120 kilolitres, based on an assumption of 60% loss from a 200m³ pool. Expressed against the range of actual water consumption for sites (2,200-109,000 kl) this is clearly only a minor adjustment.

As with the greenhouse benchmark, it was found that a significant level of variability in the data could be accounted for by assuming that different hotel star ratings have different water consumption characteristics. No significant correlation could be determined from the balance of the data with respect to food covers or climate, and so no correction was developed for these factors.

The overall equation for the median annual water use per room in kilolitres based on the current analysis is as follows:

$$M = 45.5S + \frac{P}{r} + L\rho \qquad (2)$$

- where S is the star rating of the hotel, P is the pool correction (120 kl), r the number of rooms, L the laundry correction (40 litres per room night) and ρ the annual occupied room nights.

The fit of the data to this median (expressed in terms of water use per room) is moderately poor, with an r^2 of only 0.41. This improves to 0.54 if the 3 star regional hotels – which have high irrigation requirements relative to the balance of the data set because of the nature of the individual sites involved - are removed from the analysis. The relationship on a total water consumption basis is somewhat better, with an r^2 of 0.85 being achieved across the full data set.

As with the greenhouse benchmark, this is a provisional benchmark only and is not suitable as a means of directly proceeding towards the development of the rating without further data collection.

2. Energy Use and Savings Opportunities

The author's organisation has been involved in a significant number of energy audits of hotels. In this section, the results of the 15 Australian sites within this group are summarised, comprising 3.5-5 star hotels in major centres (mainly state capitals) with a total energy consumption of 370 TJ of electricity and gas.

2.1 Energy End-Use Breakdown

As part of the audit process, detailed energy end-use breakdowns were generated. These breakdowns comprised a build up of all energy-using equipment on an hourly basis, reconciled against known usage patterns and, if available, half-hourly utility consumption data. The aggregate of these figures across the 15 hotels is shown in Figure 2 below. It can be seen from the figure that HVAC is a dominating factor; lighting and food-related equipment are also important (the latter supplemented somewhat by the presence of in-room fridges at typically 30-70W continuous load per room). Domestic hot water is also a significant load. Laundries and other loads (including pools) are minor overall although on an individual site the laundry may be more significant.

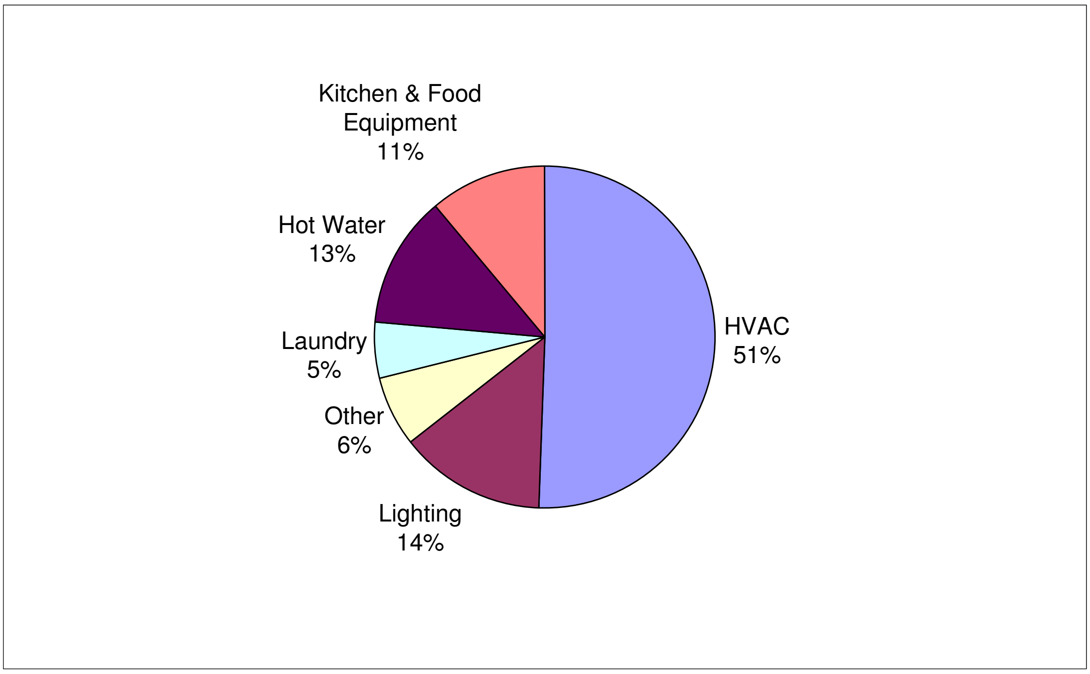

Figure 2 Energy end-use breakdown, aggregated across 15 audited hotels. All fuel sources are included within this figure

2.2 Energy Savings Opportunities

The focus of the energy audits was on the generation of energy savings within relatively short term pay backs (typically under 3 years aggregate across a whole site), reflecting the commercial parameters of the clients involved. While this ruled out the use of more innovative measures, such as renewable energy or more deep-seated modification of existing systems, it does provide a useful review for commercially acceptable measures. Savings measures from these audits have been categorised as follows:

- **Lighting (power density).** Upgrade of lights comprising mainly simple lamp replacements and fitting refurbishments. There is a general perception that halogen and incandescent lamps provide a certain "ambience", resulting in the liberal application of these lamp types throughout hotels for area lighting, particularly in meeting rooms and foyers. Replacement of these lamps with fluorescent alternatives or through the use of the more efficient IRC halogen lamps and electronic transformers was found to be a significant measure at many sites. Other measures included the refurbishment of fluorescent light fittings using delamping, reflectors and/or autotransformers.
- **Lighting (time of use).** Upgrade of lighting control systems to achieve turn-off out of hours. Typical measures included the installation of occupancy sensors in toilets, car parks and back of house areas and the use of timer controls in some locations.
- **HVAC (control).** Upgrade of air-conditioning systems through improvement of control. Hotel HVAC control was found to be poor at all levels, and in particular: building management and control systems were uncommon and where implemented were often very old and poorly programmed; unitary controls were often poorly configured and subject to ad-hoc modifications by the hotel maintenance staff; and time of use control was generally very poor, with an underlying assumption of 24/7 operation being prevalent even in areas that have little or no overnight use. Furthermore, the presence of significant levels of control failure due to lack of maintenance led to the availability of significant savings through the rectification of items such as broken valve and damper actuators and valves failing to provide full shut-off of flow upon closure. In some cases, equipment failure was so prevalent that upgrade to normal operational levels could not be justified on the basis of energy savings alone. In such cases, measures were limited to "work-around" solutions that were economically viable but far from optimal in terms of total savings. Other measures included: modification of chilled water and condenser water control to optimise chiller efficiency, changes to air-handler control algorithms to reduce simultaneous heating and cooling and to improve economy cycle utilisation, changes to chiller staging algorithms and the introduction and control of variable speed drives to pump circuits.
- **HVAC (plant).** Upgrade of air-conditioning plant. Savings in this area were dominated by the replacement of life-expired chillers with new high efficiency (typically magnetic bearing) chillers. The cost of such measures could only be justified because the replacement of the chiller was imminent, and thus the economics could be assessed on the basis of incremental capital cost for high efficiency chillers rather than the full cost. The presence of significant amounts of life-expired equipment was fairly typical of most hotels visited. Other measures in this category included revisions to or deletion of steam generation and distribution systems and modification of boiler systems.
- **Domestic hot water.** Upgrade of domestic hot water generation, distribution and end-use. The most common measure in this area was the reduction of shower flows to below 10l/minute. One of the 5 star hotels in the sample has had 10l/minute showers in place for several years without problem, indicating that the significant numbers of sites with 12-15l/minute shower heads could be upgraded without compromising service levels.
- **Pool.** Upgrade of pool efficiency. This was a minor category as most pools were unheated. However where pools were heated, measures included pool covers and upgrades to the pool heating system (typically through the replacement of gas heating by heat pump or waste heat heating).
- **Laundry.** Upgrade of laundry efficiency. Where sufficiently large laundries were present, laundry heat recovery was considered, primarily as an option to be adopted upon replacement of existing equipment rather than as a retrofit to existing equipment.

Energy savings were calculated for the energy audits through the calculation of the energy end-use breakdown, application of savings estimates to the individual components and aggregation of estimates. Where multiple savings measures affected a single end-use, the savings were estimated by applying the most strongly recommended (typically lowest payback) measure first, followed by remaining measures in order of priority. This approach avoided double-counting of savings. The overall savings identified constituted 22% of electricity consumption and 7% of gas consumption, equating to approximately 13,000 tonnes per annum of CO_2. These savings figures are estimates only and are not based on post-implementation measurements.

The breakdown of savings for electricity and gas can be seen in Figure 3 and Figure 4 below. It can be seen that HVAC control measures and lighting power density measures strongly dominate the available savings. This reflects the poor maintenance and capital upgrade practices in the hotels, plus the widespread use of inefficient light sources.

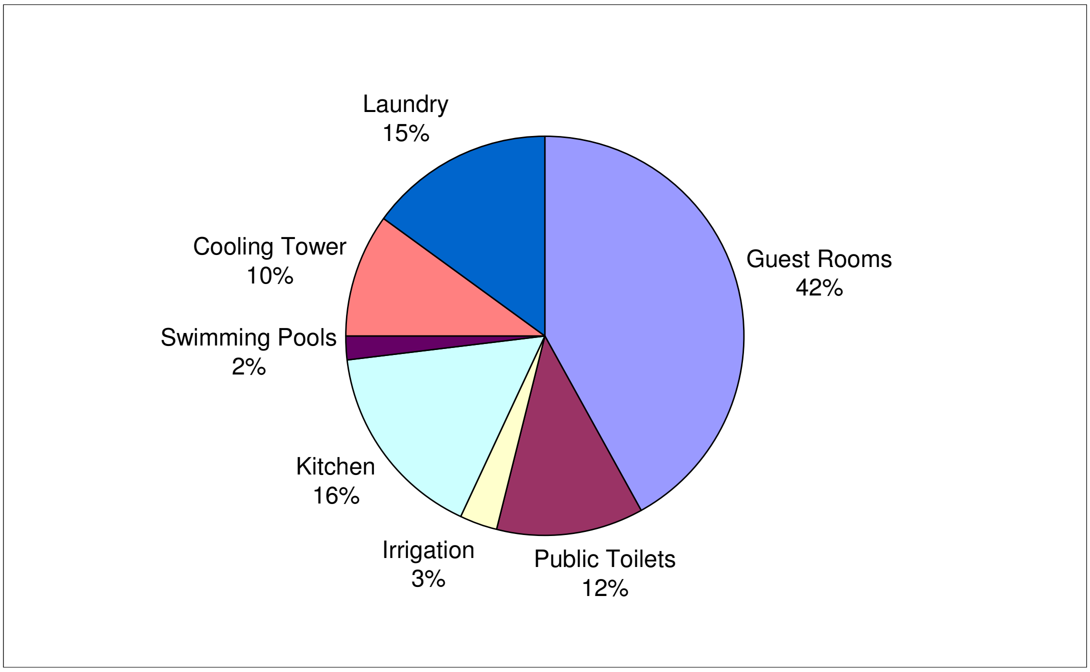

Figure 3. Electricity savings across the audited hotel sample

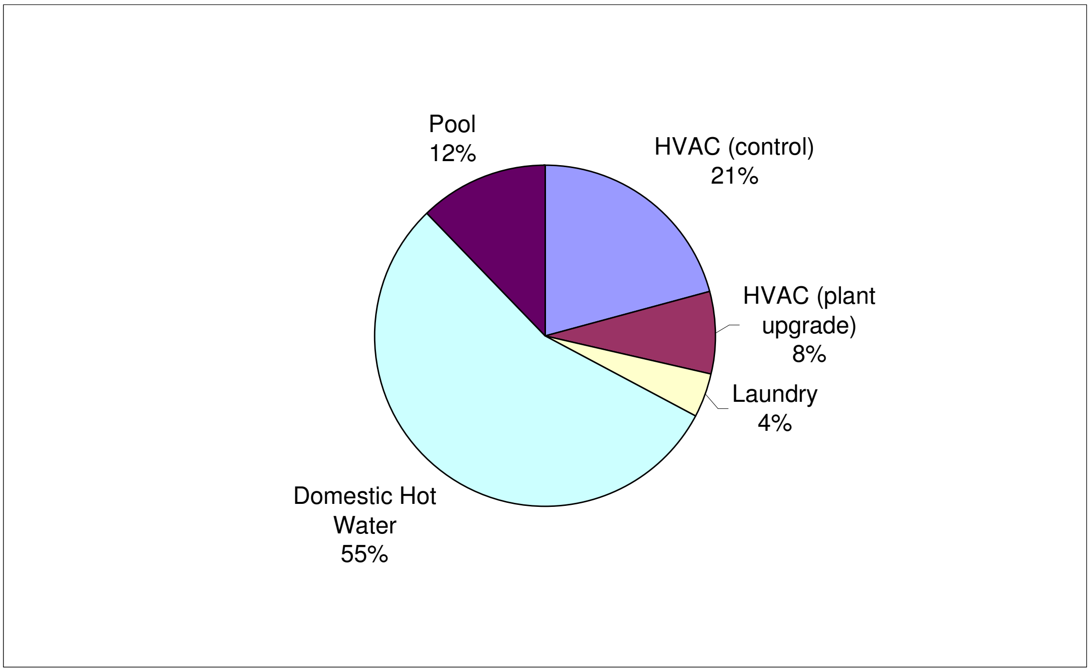

Figure 4. Gas savings across the audited hotel sample.

3.0 Conclusions

In this paper draft benchmarks have been presented for water and energy consumption in Australian business hotels. It has been shown that the hotel quality star rating has a significant impact on utility consumption. Results from 15 energy audits of Australian hotels have been summarised, demonstrating the availability of significant savings within relatively short payback periods.

Overall, it is concluded that the hotels sector is a unique sub-sector of the commercial buildings sector and that it has significant opportunity for improved energy efficiency.

3.1 Acknowledgements

The benchmarking study was conducted for, and fully funded by the NABERS program, which is currently operated by the NSW Department of Environment and Climate Change. The ongoing input of Matthew Clark from this department is gratefully acknowledged. With respect to the audits, the work conducted by Chris Bloomfield and Erica Kenna in completing many of these audits is gratefully acknowledged, as is the assistance of Erin Davies and Lawrence McIntosh in compiling the audit data for this paper.

Keywords: rating systems, building comparison, sustainable buildings, green buildings

Summary

The environmental rating system tools presently available to the design community in North America are limited in numbers. Before green buildings can become mainstream more systems need to emerge, however equivalency between these rating systems must be determined. Thus this paper will attempt to compare the environmental attributes of the two most popular environmental rating systems in use today in North America. The comparison will be performed by means of seven dual certified buildings and use the official submission summaries from each system to determine their relative robustness to various individual environmental criteria as well as to the overall rating systems performance.

1. Introduction

Architects, builders and developers have many tools at their disposal to improve the environmental performance of buildings. Two such environmental rating systems that are being widely promoted in the North America are the LEED (Leadership in Energy and Environmental Design) Green Building Rating System® developed by the U.S. Green Building Council (USGBC) (www.usgbc.org/leed) and Green Globes,™ a web-based tool being advanced by the Green Building Initiative (GBI) (www.thegbi.org). Green Globes has been operating in Canada for several years and has been widely used by several of their federal agencies. Green Globes is the basis for the Building Owners and Managers Association of Canada's "Go Green Plus" program for assessment of existing buildings. Adopted by BOMA Canada in 2005, it has been used to assess more than 500 buildings, over 300 of which were from Canada's Department of Public Works and Government Services national portfolio of buildings.

However the GBI did not introduce Green Globes into the U.S. until 2005. The first year of its introduction was spent in a pilot phase to ascertain if Green Globes was appropriate for the U.S. market. During this pilot phase a number of buildings were evaluated, of these seven had or were in the process of also undergoing LEED certification. Thus the Green Globes pilot also offered an opportunity to undertake a comparison of these two environmental rating systems using dual certified buildings. While both of these systems offer a range of rating products for new and existing buildings, for this comparison only Green Globes for New Construction and LEED-NC (New Construction) will be used. The aim of this paper is to use the official submission summaries for each system that was generated by the rating authority to compare their relative robustness to various environmental criteria (see Figures 1 and 2). Although these two systems address slightly different levels of detail (for example Green Globes includes an integrated design process, life-cycle assessment and noise criteria which are not addressed in LEED), the general comparison between the two systems indicates a similar rating nomenclature. Table 1 compares the rating nomenclature use by these two systems.

Table 1. A comparison of the four levels of ratings that are used by Green Globes and LEED

Green Globes	LEED
One Globe (>35%)	Certified -- 26 to 32 points (>37%)
Two Globes (>55%)	Silver -- 33 to 38 points (>47%)
Three Globes (>70%)	Gold -- 39 to 51 points (>56%)
Four Globes (>85%)	Platinum --52 to 69 points (>75%)

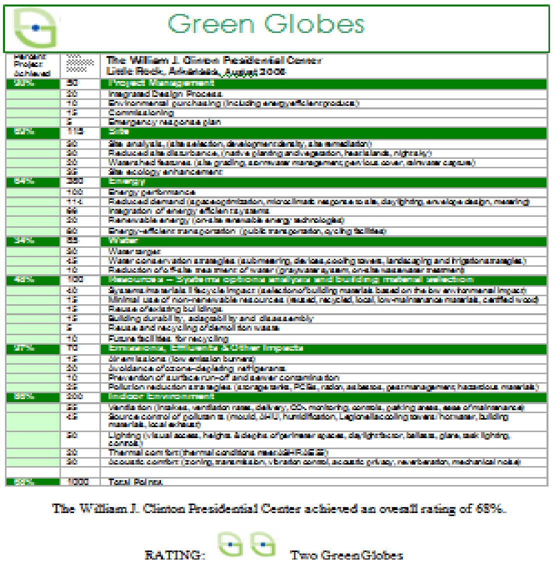

Figure 1. Typical Green Globes Summary Sheet

Figure 2. Typical LEED Summary Sheet

Beyond the issue of nomenclature, both systems are similar in regards to the number of credits and point assignments to each of the categories. While LEED has six categories and Green Globes has seven categories, it is possible to reassign the Green Globes credits from categories that do not exist in LEED. For example, the Emission & Effluents category in Green Globes has a credit for the prevention of site run-off, a similar credit appears in LEED within the Site category making reassignment a relative easy task. There is only one relatively minor category that does not line up well, which is the Innovative and Design Process category. The closest category that Green Globes has to this is their Project Management category. Table 2 shows the percentage of points assigned to each of the categories. While the percentage of points assigned to categories vary somewhat, the relative importance, as shown by the ranking of the categories based in the point assignment are identical.

We did not need to undertake a comparison of individual performance criteria for each system because of the excellent study that the University of Minnesota did on this subject. Their study, “Green Building Rating Systems: A Comparison of the LEED and Green Globes Systems in the U.S.,” report nearly 80 percent of the points in the Green Globes system were also addressed in the LEED system, and more that 85 percent of the points in LEED were addressed in Green Globes (Smith, et. al., 2006).

2. The Pilot Project

In 2006, eight buildings were selected to undergo certification under GBI’s U.S. pilot of Green Globes. All eight were also planning to undergo LEED certification, however one project dropped out of the LEED process. The remaining seven buildings included: the William J. Clinton Presidential Center, Little Rock, AR., which achieved Two Green Globes and LEED Silver, the Alberici Headquarters, Overland, MO., which achieved Four Green Globes and LEED Platinum; the Pfizer Clinical Research Unit, New Haven, CT., which achieved Three Green Globes and LEED Silver, Blakely Hall, Issaquah, WA., which achieved Two Green Globes and LEED Silver, the Wisconsin Electrical Employees Benefit Fund Office, Madison, WI., which achieved Two Green Globes and finally the Home Savings Bank, Madison, WI., which achieved Two Green Globes and LEED Silver. The green features for all seven of these buildings have been verified by third-party agents. LEED requires systems commissioning to be undertaken by a third party. While Green Globes requires that all their certified building undergo a comprehensive on-site verification by a third-party verifier.

2.1 The William J. Clinton Presidential Center

This 150,000-square foot building, located in Little Rock, Arkansas, is constructed on an old underutilized industrial site and has become a stimulus for adjacent development. This Center incorporates the use of

Table 2. Percentage of points assigned to system categories

LEED	Points	% of Total	Green Globes	Points	% of Total
Energy & Atmosphere	17	25	Energy	325	33
Indoor Environmental Quality	15	22	Indoor Environment	220	22
Sustainable Site	14	20	Site	220	22
Materials & Resources	13	19	Resources	100	10
Water Efficiency	5	7	Water	85	9
Innovative & Design Process	5	7	Project Management	50	5
Total	69	100	Total	1000	100

environmentally sensitive systems, uses low impact materials, renewable energy and the purchase of green power. This building achieved the same rating level in both systems, Two Green Globes and LEED Silver. However, within that second rating level, Green Globes rated this building slightly higher than did LEED. This was due to the fact that the Center scored well in Green Globes' Project Management and Emissions categories; LEED does not have such categories.

2.2 Alberici Headquarters

This two story, 110,000-square foot Class-A office building, located near St. Louis, Missouri, is constructed on a previous industrial site. This building reused much of the previous structure, it remediates previously contaminated land, has exceptional energy performance, an on-site wind generator, significant reuse and recycling of construction waste, uses low impact materials and exceptional attention was paid to IEQ issues. Both systems gave this building their highest rating, Four Green Globes and LEED Platinum. It achieved 93% and 87% of all possible points within the Green Globes and LEED systems, respectively.

2.3 Pfizer Clinical Research Unit

This 62,500-square foot clinical research building, located in New Haven, Connecticut, is constructed on an existing Brownfield site. This building remediates previously contaminated land, significant reuse and recycling of construction waste, uses low impact materials, and significant attention was paid to IEQ issues both during construction and operations. This building received a one level rating difference between the two systems, Three Green Globes and LEED Silver. This difference was due to the fact that the Clinic scored very well in the Green Globes' Project Management and IEQ categories. The integrated project team that Pfizer formed for this project was highly valued within Green Globes; LEED has no equivalent category. In addition, the level of IEQ quality that exists in a clinical building such as this one seems to have scored much better under Green Globes (scored 80% in their IEQ section) than it did under LEED (scored 60% in their IEQ section).

2.4 Blakely Hall

This 7,000-square foot mixed use building, located in Issaquah, Washington. Blakely Hall is part of the 2,200 acre Issaquah Highlands Community, a community noted for making a strong commitment to environmental stewardship. This building incorporates the use of daylighting, natural ventilation, uses low impact materials and significant reuse and recycling of construction waste. Blakely Hall achieved the same rating level in both systems, Two Green Globes and LEED Silver. However, within that second rating level, Green Globes rated this building slightly higher than did LEED. This was due to the fact that Blakely Hall did not have the resources to perform energy modeling, thus they did not achieve any energy points. Green Globes requires a much easier energy performance exercise, which is why there was a slight difference between these two systems for this building.

2.5 Wisconsin Electrical Employees Benefit Fund Office

This 12,000-square foot office building, located in Madison, Wisconsin, is constructed on a previously undisturbed site. The WEEBF building incorporates an innovative use of prairie grass landscaping to reduce run-off, has a high level of energy performance, use of recycled and local materials, use low impact materials and green power. This building received a one level rating difference between the two systems, Two Green Globes and LEED Certified. This difference was due to the fact that the WEEBF building scored very well in

Table 3. Results of the comparison

Evaluated Buildings	Green Globes	LEED
Clinton Presidential Center	Two Globes (68%)	Silver (34 out of 69 points (49%))
Alberici Headquarters	Four Globes (93%)	Platinum (60 out of 69 points (87%))
Pfizer Clinical Research Unit	Three Globes (70%)	Silver (33 out of 69 points (47%))
Blakely Hall	Two Globes (64%)	Silver (34 out of 69 points (49%))
Wis. Elect. Employees Benefit Fund	Two Globes (55%)	Certified (26 out of 69 points (38%))
RenewAire Facility	Two Globes (66%)	Silver (33 out of 69 points (49%))
Home Saving Bank Branch	Two Globes (55%)	Silver (33 out of 69 points (49%))

the Green Globes' Project Management category. The integrated nature of a design build project was highly valued within Green Globes; LEED has no equivalent category.

2.6 RenewAire

This 37,000-square foot office/industrial building, located in Madison, Wisconsin, is a major remodeling of an existing building. The RenewAire Building reused much of the previous building, has air-to-air heat recovery, has a high level of energy performance, significant reuse/recycling of construction waste, use of low impact materials and green power. This building achieved the same rating level in both systems, Two Green Globes and LEED Silver. However, within that second rating level, Green Globes rated this building slightly higher than did LEED. This was due to the fact that this building scored well in Green Globes' Project Management; LEED does not have such categories.

2.7 Home Savings Bank

This 5,000-square foot branch bank building, located in Madison, Wisconsin, is constructed on a pre-developed site. The Home Saving Bank building incorporates the use of daylighting, provides space for use by the local community, has air-to-air heat recovery, has a high level of energy performance, a rain garden, significant reuse and recycling of construction wastes, use of low impact materials and green power. This building achieved the same rating level in both systems, Two Green Globes and LEED Silver.

3.0 Results

Table 3 presents the results from the seven individual building comparisons that were undertaken. Although, each of these systems addresses slightly different levels of detail, these seven buildings represented a good range of building type, size and geographical location. Both rating systems in their assessment of each of the seven dual certified buildings seemed to have identified similar reduction in environmental impact. Thus, the detailed side-by-side comparison presented in Table 3 indicates a high level of equivalency between the two systems. Where differences exist, they are much more a result of minor criteria differences than with overall system differences.

4.0 Conclusion

The application of LEED within North America has been well documented in the professional press. However, it is becoming increasingly clear that we need a much more rapid uptake of green buildings (since April 2000 only 1500 buildings have actually been LEED certified) and that "one size does not fit all." It seems that many architects, builders and developers that deal with smaller sized projects do not have access to the level of resources, expertise or consulting services necessary to successfully navigate the LEED preparation, documentation and submittal process. A system such as Green Globes, which uses a web-based questionnaire approach with its lower entry threshold and immediate feedback not available from a primarily paper-based system, seems much more appropriate for this audience. Thus, having competing systems that have a recognized level of equivalency is an important prerequisite in moving green buildings into the mainstream of North American building practices. It is hoped that this comparison and the high level of equivalency that was shown between Green Globes and LEED can help achieve this outcome.

Life Cycle Costing as part of decision making - use of building information models

G. Krigsvoll
SINTEF Building and Infrastructure/Oslo University College

ABSTRACT: Building Information Modelling (BIM) is a new approach for being able to describe and display the information required for design, construction and operation of buildings. More extended use of BIMS, with the development of Information Delivery Manuals (IDMs) for environmental assessments, energy calculations and LCC, ensuring more automatically data flow between different data bases, calculation tools and Building Information Models (BIM), will simplify the use of LCC in design. More extended use of LCC, and storing the results for future use may also improve the Facility Management. Several projects have dealt with cost information flow, as information exchange between the BIM and LCC-tool and improving cost data bases, simplifying the data access as well as storage possibilities to ease and extend the use of LCCA. This paper will present the current stage of the different project aiming at increased use of LCCA by use of BIM and IDMs.

1 INTRODUCTION

Building and construction projects may benefit by use of Life Cycle Cost Assessment at early stage of the design process, the results contributing to decision support taking both investment and operation costs into account. Qualitative good results demand good input data to the calculations, even at stages where few decisions are taken.

Building Information Modelling is a new approach for being able to describe and display the information required for the design, construction and operation of constructed facilities. It is able to bring together the different threads of information used in construction into a single operating environment thus reducing, and often eliminating, the need for the many different types of paper document currently in use.

Realistic LCCA, as a good basis for decision making, requires easy accessible data in all phases from brief to construction, where statistic information, key numbers and experience data is valuable information. A well defined classification system for the categorisation of costs and other input data is important for a successful use of LCCA. Increased use of LCCA at several stages in the decision process also requires increased data exchange and storage possibilities. Extended use of LCCA may improve the decision process towards more economic as well as environmental and energy efficient buildings.

More extended use of Building Information Models (BIM), with the development of Information Delivery manuals (IDMs) for environmental assessments, energy calculations and LCC, ensuring more automatically data flow between different data bases, calculation tools and Building Information Models (BIM), will simplify the use of LCC in design. More extended use of LCC, and storing the results for future input to Facility Management may also improve the Facility Management.

Easy access to comparable data gives the building owners' possibilities to benchmark their buildings, with emphasis on energy use and operation cost. This will lead to more focus on operation of buildings, as well as improvement of energy efficiency.

Several projects have worked with improves cost information flow, as information exchange between the BIM and LCC-tool and improving cost data bases, both key number bases and cost data bases related to building parts, and further information flow from FM-information into cost data bases. Key numbers may be found from statistical treatment of collected data. For instances energy use/energy costs pr m2, cleaning costs pr m2, or cost used for management or maintenance for different building categories (function and age). Key numbers may be used for benchmarking, as all users may compare their actual data with the collected data, and hence know how their use and management of the building is compare to others.

2 BUILDING INFORMATION MODELING

2.1 *IFC, BIM, and buildingSmart*

The development, maintenance, implementation and dissemination of Industry Foundation Classes, IFC and IFC enabled products is part of the buildingSMART initiative of the International Alliance for Interoperability, IAI, and its affiliated organizations and companies. “buildingSMART is integrated project working and value-based life cycle management using Building Information Modeling and IFCs”

The purpose of IFC as part of the buildingSMART initiative is "enabling interoperability between AEC/FM software applications". It is embedded in a broader scope of achieving beneficial change in industry, using Building Information Modeling (BIM) and IFCs as the trigger to smarter ways of working. IFCs target both the software development community and the practitioners in the AEC/FM industry.

- Developing software that benefits from the international, single and interoperable schema of construction elements, specifications and structures is the task of software companies. Software developers have to understand the detailed structure, content, and processing of IFC.
- Applying interoperable and IFC compliant software within construction processes requires users that are knowledgeable about their processes, the exchange requirements within each process, and its relevance to the technical, commercial and legal side of the operation. Practitioners have to understand how to map general concepts or parts of the IFC to the detailed exchange requirements within their projects and how to assess and use IFC compliant software.

IFC and use of BIM will have great potential for cost reduction and utilize effects in the value chain at least in these areas:

- Focus on the customers and end-users requirements within the building process and life cycle phases.
- Re-engineering of the building process with new opportunities for new and existing actors.
- A comprehensive and common international knowledge model database with standardized ICT tools, objects and communication rules and available best practices examples.
- Cost reduction and better project economy in the supply chain, between the suppliers and the contractors.
- Improved possibilities for early stage analysis about: best practice design, construction cost, energy consumptions, environmental impacts and lifecycle cost.

2.2 *Planning and construction process*

Planning and design of buildings and constructions are phases in a process with many actors and an intensive process of sharing and/or repeating information. Figure 1 shows the information flows between the different actors in a construction process, both a traditional process and by use of Building Information Models.

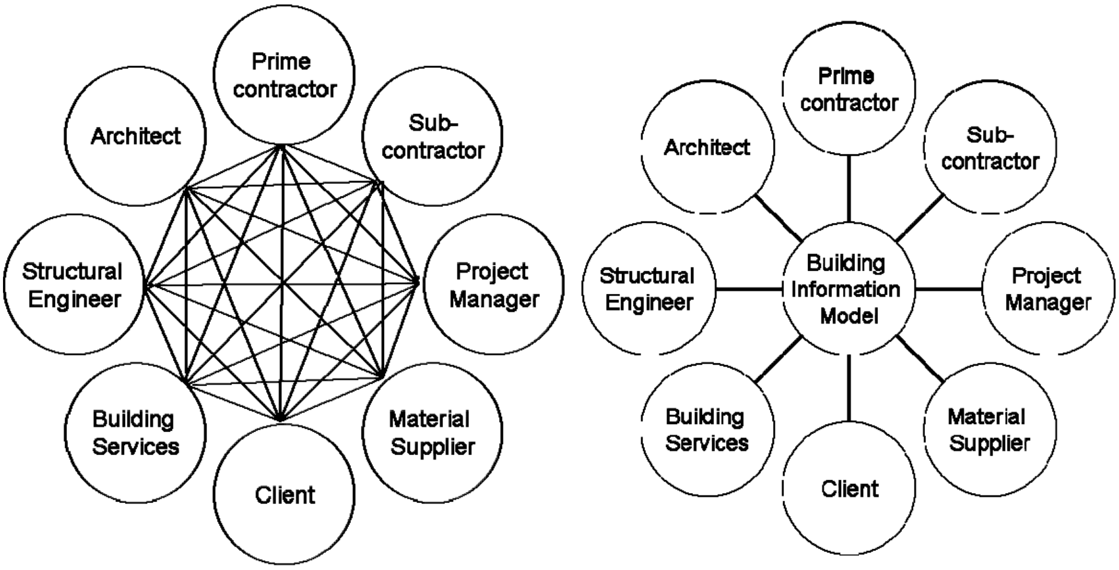

Figure 1 Information flow between actors in a traditional project and by use of Building Information Model

When all actors have access to the same information, and the possibility to transfer information from the model to the different calculation and analysis tools, all decision making can be based on up to date analysis of the interesting aspects. More analysis may be done in an early phase of the project, while it is still possible to make changes. Analysis may also be done on different alternatives.

Life cycle costs analysis or assessment may throughout all stages be done by use of information in the BIM, information from different cost databases, and with application that is ifc compatible ensuring a seamless data transfer. Results from the analysis are then fed back to the BIM for use in other analysis, decision making or for later use in facility management in the operation phase.

3 LIFE CYCLE COSTING ASSESSMENT

3.1 *Life cycle costing used in decision making*

Life cycle costing assessment should benefit that the perspective of decisions is moved from investment costs to the total costs for the whole life cycle of the building or constructed work. Life cycle costing should not be used with the intention of decreasing the costs, but for ensuring the lowest cost over the life cycle when still fulfilling the performance requirements (functional and technical requirements). The assessment should also be used to show the estimated yearly costs before investments are done.

Using LCC as part of decision making requires good accessibility to reliable input data to the analysis at all stages of the planning and design process, starting with generic information (statistic, key numbers) to more and more specific information. Reliable statistic and generic information can be produced by collecting actual costs from management of buildings, using specified and standardized cost classification. The Norwegian Standard NS3454 Life cycle costs for building and civil engineering work – Principles and classification (NS, 1997) does, as also similar German and Austrian standards, give a cost classification system. The Norwegian database owned by Network for benchmarking yearly collect actual costs from their members' buildings, then providing a database with costs to be used for benchmarking and input to LCC calculations. Table 1 shows the main categories in a proposition to a new common Nordic standard.

Table 1 Cost classification for Life Cycle Costs in proposition to new Nordic standard

No.	Main Item	Definition	Sub-categories
1	Capital	All investments towards completion including	11 Project costs 19 Remaining costs

		decommissioning by the end use of the facilities	
2	Administration	Activities for administration, required payments and insurance costs	21 Taxes and fees 22 External costs 23 Administration and management 24 Insurance 29 Various
3	Operation	Include daily, weekly and monthly activities that are repetitive within a one year period for building and technical installation systems that shall satisfy given functional demands and requirements	31 Operation and inspection executed by own employees 32 Operation and inspection executed by external companies 37 Outdoor operation and inspection executed by own employees 38 Outdoor operation and inspection executed by external companies 39 Various
4	Maintenance	Include all activities and efforts put forward in a period of more than one year. For example, planned maintenance, replacement and emergency repairs, so that the building and technical systems satisfies the original level of quality and functional requirements.	41 Periodical maintenance of exterior of the building 42 Periodical maintenance of internal of the building 43 Replacement of exterior 44 Replacement of interior 45 Emergency repair work for exterior 46 Emergency interior repair 49 Outdoor
5	Developing	Includes activities as a result from change in demand from core activities, the authorities, total refurbishment, or all activities to raise the construction standards in relation to the original level	51 Development and upgrading of exterior of the building 52 Development and upgrading of internal of the building 59 Development and upgrading outdoor
6	Consumption	Consumption includes resources in terms of energy, water, and waste handling	61 Energy 62 Water and Drainage 63 Waste Handling 69 Various
7	Cleaning	All activities inside and outside for satisfactorily meeting cleaning demands	71 Daily/Periodic 72 Main cleaning 73 Special cleaning 74 Window cleaning 75 Façade cleaning 79 Outdoor cleaning
8	Service	All non-building related activities in support of the core activity	81 Security and safety 82 Reception/switchboard 83 Mail 84 IT service 85 Moving 86 Catering 87 Accessories/copying 88 Administrative support 89 Furniture and inventories

Life cycle costing can be presented as Net Present Values or Net Present costs, while other options are available, as Annual Cost or Annual Equivalent Value, or Payback. Definition of cost categories and calculation rules are given for example in ISO/DIS 15686-5 “Buildings and constructed assets – Service life planning. Part 5 – Life cycle costing” (ISO, 2006).

3.2 *LCC in different project stages*

The standard exchange requirements published in IDM are identified against project stages defined within the Generic Process Protocol (GPP) (Michail Kagioglou et al, 2000). These are identified below with their stage number as used in the exchange requirements documents, description and definition from the GPP. Stage 10 (disposal) is a modification to the standard GPP list to handle the final stage of a project lifecycle. These are shown in Table 2

Table 2 Project stages defined in Generic Process Protocol

Stage	Description	Definition
Pre-project stages		
0	Portfolio requirements	Establish the need for a project to satisfy the clients business requirement
1	Conception of need	Identify potential solutions to the need and plan for feasibility
2	Outline feasibility	Examine the feasibility of options presented in phase 1 and decide which of these should be considered for substantive feasibility
3	Substantive feasibility	Gain financial approval
Pre-Construction stages		
4	Outline conceptual design	Identify major design elements based on the options presented
5	Full conceptual design	Conceptual design and all deliverables ready for detailed planning approval
6	Coordinated design (and procurement)	Fix all major design elements to allow the project to proceed. Gain full financial approval for the project
Construction stages		
7	Production Information	Finalise all major deliverables and proceed to construction.
8	Construction	Produce a product that satisfies all client requirements. Handover the building as planned.
Post-construction stages		
9	Operation and maintenance	Operate and maintain the product effectively and efficiently.
10	Disposal	Decommission, dismantle and dispose of the components of the project and the project itself according to environmental and health/safety rules

3.3 *Geometric and spatial structure*

A spatial project structure might define as many levels of decomposition as necessary for the building project. The costs might be added to any element. Elements within the geometric and spatial project structure are:

- site as IfcSite
- building as IfcBuilding
- storey as IfcBuildingStorey
- space as IfcSpace
- building elements as IfcBuildingElement
- components as IfcBuildingElementComponent
- products as IfcProducts

The structure from site, building, elements, components, and products is further used as cost levels.

3.4 *Performance requirements*

Before doing the life cycle cost assessment it is important to have the performance requirements for the facilities to study. The BIM makes it possible to start the process by having a performance requirement model, which later will be used as part of the checking systems, analyzing which requirements that are fulfilled. The performance requirement model will then be further developed and improved throughout the planning stage. The alternatives compared should always fulfill the performance requirements.

3.5 *Intangible costs – extra value*

Intangible costs is usually not included in LCC, but if possible, value might be given and used as an additional part of the decision process. There might also be given values to extra functions or performances, for instance based on experience, but these values should also only be used as an additional part of the decision process.

3.6 *Examples of LCC in different stages*

LCC in pre-project stages is used for studying the consequences of the performance requirements, before any decisions are made. In the early stage of a project, LCC forecasting may use 'benchmark costs' based on historical costs of previous projects. As design evolves and more detailed information becomes available, benchmarks should be substituted with first principle project-specific estimated costs. Often (but not always) life cycle costing will include a single lump sum which represents all the acquisition costs (e.g. the purchase cost) and may also take account of residual value/disposal costs. The analysis in pre-project stages are aiming at assign different alternatives, where continuing as to day may be one option.

One example is increasing school capacity, where the alternatives may be as follows:

- Continuing as today – some pupils sent to other schools
- Extension of existing school, with or without refurbishment of existing building
- New school in addition to existing school – different location
- New school with higher capacity instead of existing building

Comparing the different alternatives it is important to include differences in costs for running the core business (school), not only the building related costs. This may be included in category 8 costs. Table 3 shows examples of sources for information at this stage, number of m2 may be statistic information based on number of pupils. At this stage the comparison is on main alternatives, not design, construction, or installations. The main cost differences may be in category 8, the decision at this stage might not be building related, but taking into account the differences in costs for the core business. Almost all costs are statistic or historic information, updated for extra m2. All costs as on building or site level.

Table 3 Cost categories and sources for information

Cat.	Alt 0	Alt 1a – 1b, 2, 3, and 4
1	No investments	Generic information – investment costs pr m2 for new buildings and refurbishment
2	Existing costs	Existing costs – corrected for number of m2 or key number for costs per m2 or per pupil
3	Existing costs – higher costs in future?	Key number for school buildings, per m2, for building from same time period – and new buildings
4	Existing costs – higher costs in future?	Key number for school buildings, per m2, for building from same time period and main materials – and new buildings
5	No costs	Upgrading of existing building – key numbers for upgrading buildings from the same period
6	Existing costs	Existing costs and key numbers, energy use as in regulations
7	Existing costs	Key number for school buildings, per m2, for building from same time period and main materials – and new buildings
8	Existing costs Transport costs pupils to other schools Costs for pupils at other schools	Existing costs Changes in use of staff compared to Alt 0, need for more teachers, need for more administrative staff if 2 schools etc.

The calculated life cycle costs are used for choosing alternative – more than one if more detailed comparison is necessary to decide – and to get financial approval. If the costs for all alternatives are too high, this is also the stage for redefining the requirements.

As alternatives it is possible to add extra requirements to the alternatives, for instance a swimming pool. Results from alternatives with or without swimming pool should then not be directly compared, but results used for deciding whether the value of the gain swimming pool exceeds the costs.

3.7 *Life cycle costing in conceptual and design stage*

With a database for facility management costs from existing buildings, where building information as age, main construction systems and materials, types of ventilation etc are given, statistic cost information can be tagged with those technical and functional descriptions.

When comparing different designs and technical installations, where the performance requirements always are fulfilled, many calculations still can be based on statistic information. Cost information might still be used as input on building levels, adding some specific information on system or building part level. Examples of relevant input costs, sources and level where they are to be used are shown in Table 4.

Table 4 Examples of relevant costs and level to be used in LCC in design stage

Cost category	Site/building	Room	Element	Component	Product (usually not selected at this stage)
Capital	Investments aggregated from element. Demolition costs		X Cost data bases	(X) Cost data bases	Cost data bases
Administration	X Key numbers				
Operation	X Key numbers				
Maintenance	Key numbers, “corrected” for statistic information fro certain systems and installations		X Statistic information/experience	(X)	
Developing	X				
Consumption	X Regulations or energy calculations for different designs	(X) Separate calculation for certain rooms/functions?			
Cleaning	X – aggregated from room, key numbers	(X) Key numbers or experience for different levels of cleanliness			
Service	X				

Information about elements, areas, numbers, etc will at this stage be extracted from the design model(s). As the table shows, statistic information on building level, where tagged information is used, will be sufficient for LCC at early stage, comparing different main alternatives. The LCC calculations will then also give for instance total and annual cost for the whole building life cycle.

Further in the design stage, as more and more information can be linked to elements, components and products, mainly investments and maintenance.

4 CONCLUSION

Using BIMs, from performance requirement models to design models, and different ifc compatible cost data bases, LCC calculations will be more useable as input data will be available and can be automatically transferred between the model, databases and applications. LCC can be done at every stage, and hence be a part of the decision making process early in the design process.

Keywords: PCM, microcapsules, paraffin wax, nano-composite materials, gypsum board, cement

Summary

This report describes the development of novel phase change material (PCM) microcapsules made with paraffin wax, the introduction of a new apparatus for producing the capsules, and outlines the results of a preliminary study undertaken at an experimental house.

We have developed a PCM microcapsule which uses polyurethane resin as the shell material instead of conventional acrylic resin. To improve the durability of the microcapsule, nano-composite materials are dispersed into the shell. Unlike acrylic-type PCM microcapsules, the novel PCM microcapsule can be used in combination with a variety of matrices such as gypsum and cement.

Gypsum boards containing the PCM microcapsules obtained by using the newly developed apparatus were produced at a gypsum board manufacturer. The gypsum boards have a thickness of 12.5 mm and contain 3kg/m^2 of the PCM microcapsules.

The gypsum boards made with PCM were installed at an experimental house in Tsukuba City, northeast of Tokyo.

A computer simulation program has also been developed to predict the effect of gypsum boards containing PCM in terms of energy consumption and indoor thermal fluctuations. In the simulation program, thermal properties around phase change temperatures were taken into careful consideration.

1. Introduction

The Kyoto Protocol came into effect in February 2005 and addressed the urgent need to reduce CO_2 emissions. In Japan, however, such reduction lags behind in the residential sector.

Thermal environmental needs have conversely been augmented in terms of health and safety, accompanied by an ongoing increase in energy use by residential houses. As society becomes an increasingly aged one, there are concerns over health and safety, such as preventing heat shock, and the thermal environment of residential houses must be maintained to ensure that temperature differences do not exceed a certain value regardless of location and time. This will result in increased operation space and operating time of existing air-conditioning equipment, and lead to increased energy use if no measures are taken.

Reducing the amount of energy consumed by detached owner-occupied housing stock is also a major problem. Enhancing heat insulation offers one solution, but may require the addition of heat-insulating material to outside the building or increasing the fill thickness of insulating material inside the walls. As a result, this may involve extensive renovation work for the entire building at high cost. To spread and promote energy saving, it is necessary to alleviate the level of building frame changes in such renovation work through the combined use of insulation enhancement and other air-conditioning load reduction techniques.

2. PCM microcapsules and gypsum board with PCM

2.1 Development of PCM microcapsules

Paraffin wax stores and releases its latent heat upon undergoing a phase change, and the PCM microcapsules of this paraffin wax are encapsulated in a resin shell layer into a microcapsule form.

2.1.1 Examination of shell resin composition

As a two-liquid mix setting resin, three kinds of resin (urethane-based, epoxy-based, and modified silicone-based resin) were examined. Shell layer formation (loss on heat at 100°C for one hour assuming a gypsum board production line) offers barrier performance—an important quality for sealing the core material of heat storage wax. In terms of this quality, the urethane-based resin was found to be superior.

2.1.2 Trial production and examination of urethane-based particles

The problems posed during manufacture of the gypsum board with PCM must be understood, and the ease of working the board obtained and its effect on housing work predicted by applying the board to a model house. For these reasons, PCM microcapsules with a shell layer of urethane resin were produced on a trial basis using the above-stated basic composition by using a batch-type disperser (of 700-liter capacity).

Table 1 lists the physical properties of the PCM microcapsules produced. Productivity is improved as the solid content increases; however, the solid content was set to 33 percent in considering the ease of handling the PCM microcapsule emulsion on the gypsum board production line. In terms of thermal conductivity, a particle diameter of 50 micrometers or less is desirable. In this trial production, the dispersion conditions in water were examined and the mean particle diameter was taken at 6 micrometers. From the optical microscope image shown in Figure 1, one can see that the PCM microcapsule obtained has a diameter of about 6 micrometers with a shell layer being successfully formed.

The amount of heat stored is uniquely determined by the heat fusion of the wax used and the wax content. It was set to 70 kJ/kg considering the size of the shell layer and the particle dispersibility in water.

The reference is an emulsion of particles with the shell layer made of an acrylic-based resin with a solid content of 40 percent. Its particle production method is inferred to be batch-type suspension dropping radical polymerization, which apparently takes about 10 hours to form PCM microcapsules. Its amount of stored heat was 70 kJ/kg, unchanged from that of the particles, and its loss on heat was 3 percent, inferior to the particles.

Table 1 Properties of batch-type trial product of PCM microcapsules

Item	Trial product for molding by actual machine	(Reference)
Solid content	33%	40%
Mean particle diameter	6 μm	10 μm
Shell composition	Urethane-based resin	Acrylic-based resin
Amount of heat stored	70 kJ/kg	• 70 kJ/kg• •
Loss on heat	1%	3%

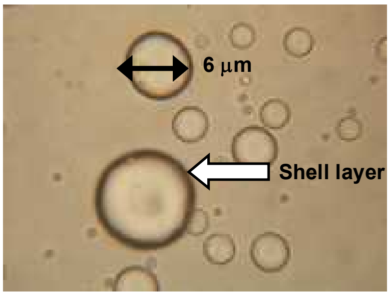

Figure 1 Optical microscope image of PCM microcapsules (in water)

2.1.3 Examination of VOC reduction methods

A test piece was used to confirm that VOC emissions could be reduced using a nano-composite material such as clay (a clay compound in plate form) treated with organic ammonium salt. The baffle effect of clay is believed to improve the sealing performance of the wax and reduce VOC emissions. As shown in the cross-sectional TEM (transmission electron microscope) image below, the depositing of nano-dispersed clay on the inner wall of the PCM microcapsule shell layer can be confirmed.

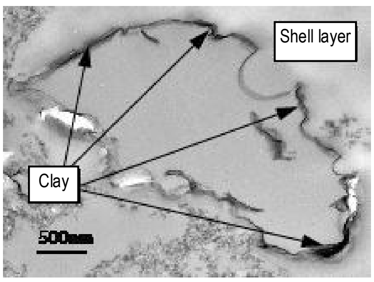

Figure 2 Cross-sectional TEM image of clay-added PCM microcapsule (1)

2.2 Development of manufacturing process of PCM microcapsules

2.2.1 Development and design of new continuous fabrication method

A pilot production machine was developed. This machine can be synchronized with gypsum board production to supply PCM microcapsules continuously.

Table 2 PCM microcapsule formation process and equipment introduced

Process	Equipment introduced	Description
(a) Continuous supporting process of wax on silica	Continuous powder mixer	Sends wax support of a homogeneous composition to the next process continuously.
(b) Continuous fast dispersion process of shell layer urethane resin and wax support in water	Continuous mixer-disperser	PCM microcapsule emulsion (liquid) can be produced continuously and instantly.
(c) Continuous heating and cooling process	Continuous heating and cooling tank	Can heat or cool continuously by moving the liquid from below to above.

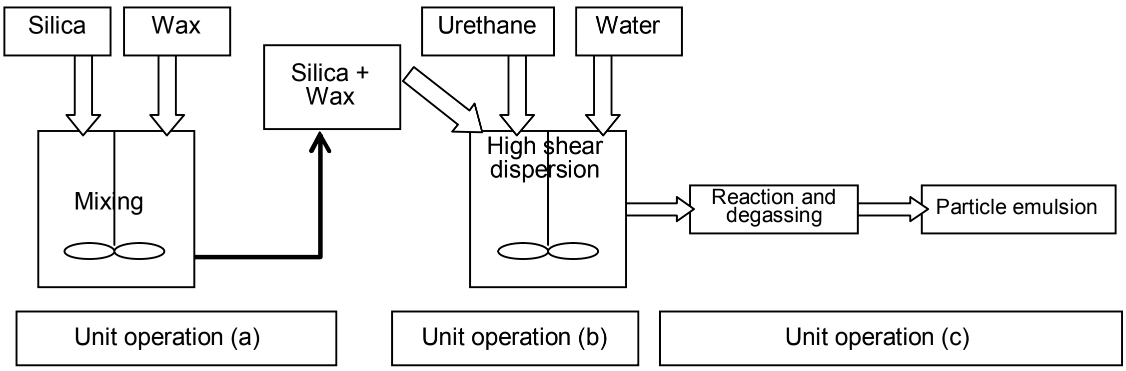

Figure 3 Process flow of PCM microcapsule emulsion

2.2.2 Examination of pilot facility

The pilot facility has a production capacity of 250 kg per hour of solid particle content. Table 3 below lists the examination results.

Table 3 Examination results of pilot facility

Reaction method	Conventional acrylic resin-based process	Fast dispersion and continuous reaction
Reaction method	Batch polymerization	Fast dispersion and continuous reaction
Reaction time	About 10 hours	5 minutes
Facility cost	Up to 800,000,000 yen	Up to 200,000,000 yen
Note: One-hundred tons per month of solid content. Does not include stock supply, product conveyor systems, and building.		

Assuming an operating time of 400 hours per month, a capacity of 100 tons per month is equivalent to about 30,000 square meters of gypsum board with PCM (assuming a mix proportion of 3.1 kg per square meter). Because the developed process is continuous, it offers high potential, including easy scaling-up.

2.2.3 Continuous powder mixer

The role of the continuous powder mixer is to make silica (powder) to support wax (liquid) for a continuously and stable supply to the continuous mixer-disperser in the next process

As the continuous mixing method, the process of constantly feeding silica using a weight-based feeder and feeding wax using a gear pump to charge both in a mixer was examined.

In the continuous powder mixer shown in Figure 4, silica is scattered by centrifugal force of the attrition plate (a disk fitted with blades), with wax flowing down to the blades and being scattered to form fine droplets comparable to a spray. Thus, silica and wax are mixed instantly to obtain a homogeneous wax support.

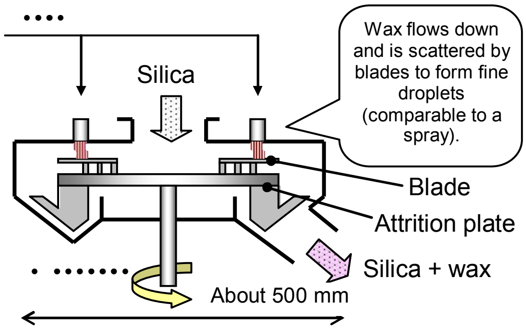

Figure 4 Schematic diagram of continuous powder mixer

2.2.4 Continuous disperser

As the peripheral speed of the continuous disperser's moving blades was increased, the mean particle diameter of formed PCM microcapsules decreased, showing a sharp diameter distribution. Diameter control is possible in our target range of 5 to 20 micrometers.

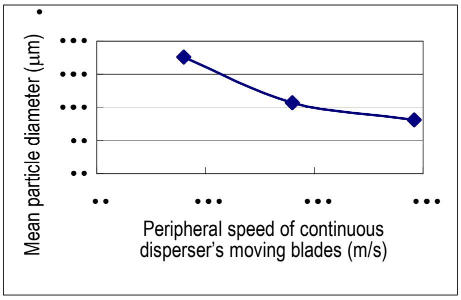

Figure 5 Mean particle diameter versus peripheral speed of continuous mixer-disperser

2.2.5 Continuous heating and cooling tank

In a continuous production process, it is desirable to suppress a rise in liquid level and prevent particle aggregation by increasing the reaction rate of urethane. A tube method and tank method were examined as such a process.

Table 4 Comparison of tube method and tank method

	Tube method	Tank method
Features	PCM microcapsule emulsion flows in the tube. Heating and cooling take place using water around the tube.	PCM microcapsule emulsion is heated and cooled in one tank, then agitated to overflow into the next tank.
Pressure loss	2 Because liquid feeding is done through tubing 200 meters or more in length, there is large pressure loss under high flow velocity.	Because liquid feeding is done only up to the level of one tank, there is low loss of pump pressure.
Scale removal	Removal is virtually impossible. Anti-deposition agent cannot be used.	Can be removed. Anti-deposition agent can be used.
Carbonic acid gas	Because gas cannot be vented at other than outlets, it blows out of outlets intermittently.	Because gas is released from the top of each tank, it has no effect on other tanks.
Particle aggregation	Particle aggregation cannot be avoided by feeding motion in the tubing only.	Particle aggregation can be prevented because cooling occurs while stirring.

As shown in Table 5 below, the tank method can address all problems in the process, and is thus considered suitable for the continuous heating and cooling process.

2.3 Performance confirmation of PCM microcapsules and gypsum board with PCM

Table 5 Properties of PCM microcapsules made by trial production

Item	Unit	PCM microcapsule A	PCM microcapsule B
Particle formation method		Batch	Continuous
Nano-composite	%	0	1
Fusion peak temperature	°C	22	22
Peak particle diameter	μm	11	10
Heat stored quantity	kJ/kg	70	72

For facility validation, PCM microcapsules were produced on a trial basis twice. A continuous pilot production machine added clay (nano-composite material) to particle B. Neither particle had trouble-free properties.

In terms of construction, the gypsum board with PCM contains unwoven glass cloth in its outer surface. For a charge rate of 1.8 tons per hour of plaster of paris and 2.7 tons per hour of emulsion, the mixed particle content was 3.2 kg/m^2.

Table 6 lists the results of a physical property test of gypsum boards with PCM. For all samples made by trial production, the bending failure load satisfied the JIS standard value for gypsum boards.

A formaldehyde and VOC emission test was conducted at a test temperature of 28°C according to JIS A 1901. Table 7 lists the results. Because no melamine-based resin is used in the shell layer, only a small amount of formaldehyde is emitted. A comparison of particles A and B confirmed that VOC emissions tended to be reduced by nano-composite treatment. For TVOC, however, the target value of 400 (standard in Japan) was not attained.

Table 6 Main properties of gypsum boards with PCM

		Unit	PCM microcapsule A	PCM microcapsule B	JIS standard value for gypsum boards
Thickness		[mm]	12.69	12.61	12.5•±•0.5
Weight per unit area		[kg/m^2]	11.5	11.5	7.5 to 11.3 (for information only)
Bending failure load	Length	[N]	668	641	500 or more
	Width	[N]	391	375	180 or more
Thermal conductivity		[W/mK]	0.20	0.22	0.17 to 0.20 (for information only)

Table 7 VOC emission test of gypsum boards with PCM (after 7 days) [μg/m^3]

	PCM microcapsule A	PCM microcapsule B
Formaldehyde	5.6	7.3
Toluene	78.3	61.9
Ethylbenzene	9.3	7.7
Xylene	40.6	34.4
Styrene	5.4	4.5
p-dichlorobenzene	22.9	18.8
n-tetradecane	76.8	13.6
n-heptadecane	548.0 (main ingredient of particle)	499.1 (main ingredient of particle)
n-octadecane	58.5	18.5
TVOC	453.7	450.5

2.4 Compatibility with cement

PCM microcapsule B was mixed with cement and allowed to harden. Because the shell layer of PCM microcapsule B is a urethane-based resin having alkali resistance, heat storage performance was maintained for a long period. For the particle with a shell layer of acrylic-based resin, it was confirmed that the shell layer was affected by alkali and wax exuded from the cement surface immediately after hardening.

3. Thermal evaluation of use in residential houses

3.1 Verification of thermal performance in outdoor experimental building

An evaluation was made in an outdoor experimental model house from September to November 2006 to obtain basic data for understanding and predicting the effects of the produced gypsum board with PCM on its use in a residential house. The model house had two rooms subject to the same external influences, In one room (9.1 m^2), the board was installed on the walls in a two-ply configuration over a total area of 24 m^2.

Table 8 Installation of heat storage building material in outdoor experimental model house

Floor area	Installed area	Installed volume	PCM microcapsule	Latent heat of board	Heat stored/floor area
9.1 m^2	24 m^2	48 m^2	PCM microcapsule A	224 kJ/m^2 of one ply	1,182 kJ/m^2

* Building body heat insulation performance: Equivalent to Q = 2.4 W/m^{2}K, Floor area: 9.1 m^2, Ventilation frequency: 0.5 time per hour

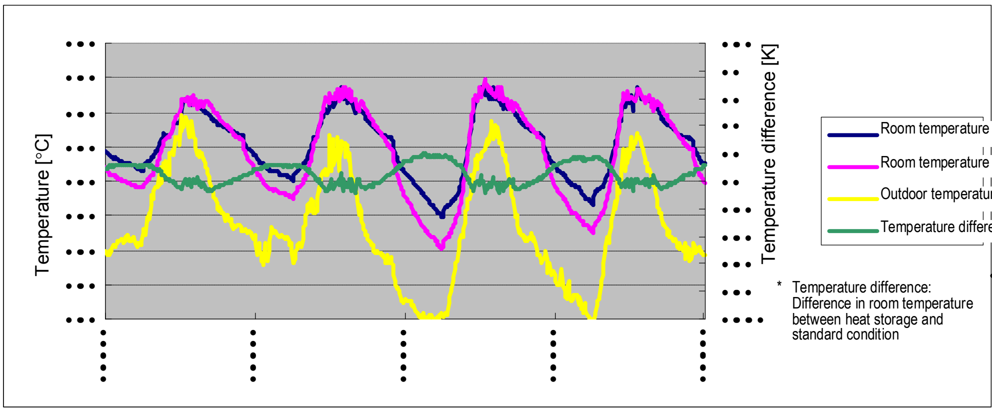

Figure 6 Temperature change for 27°C air-conditioner cooling plus outdoor air cooling at night

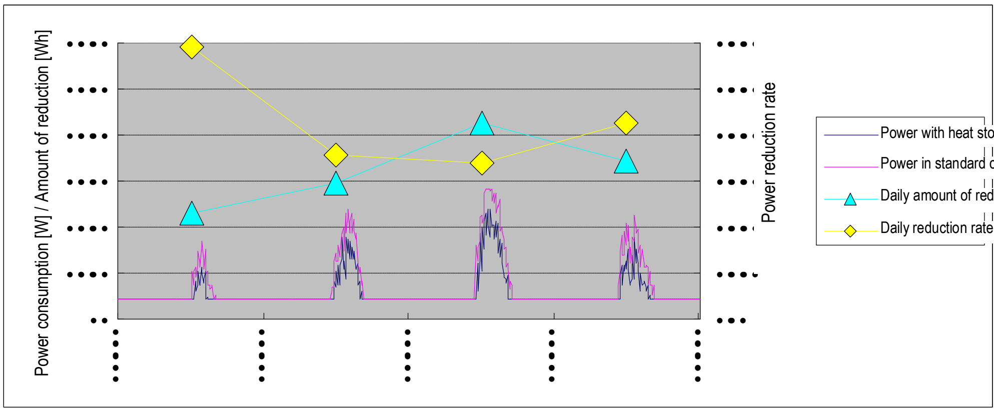

Figure 7 Power consumption of air conditioner for 27°C air-conditioner cooling plus outdoor air cooling at night

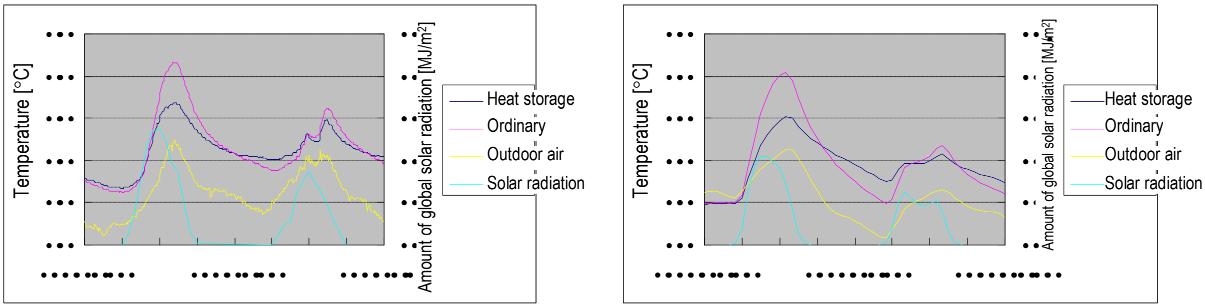
From the experiment results shown in Figures 6 and 7, a reduction in the range of room temperature fluctuations and a reduction in air-conditioner power consumption were confirmed.

3.2 Si Confirmation of consistency

To verify consistency between the above-stated experiment results and thermal simulation, the experimental house was modeled by using thermal simulation software, and a comparison was made of the calculation results on a day having weather conditions approximating those on the day of the experiment. Figure 8 shows that the simulation well reproduced the temperature characteristics obtained as an experiment result. Thus, the possibility of prediction by using the simulation software was confirmed.



Measured results

Simulation results

Figure 8 Measured results and simulation results

3.2.2 Estimation of effects

The effects of the gypsum board with PCM installed in an ordinary residential house were estimated by simulation. The building and conditions were set according to the standard problem model (floor area = 120 m^2 and building body heat insulation performance: Q = 2.7 W/m^2K) provided by the Architectural Institute of Japan. The gypsum board with PCM was installed on the walls and ceiling of the living-dining room (28 m^2) over a total area of 72 m^2.

During the heating period, the solar radiation heat in the daytime was held over; during the cooling period, the cold in the nighttime was held over, thus producing an energy saving effect. From the results, it was estimated that the air-conditioning load of the living-dining room could be reduced by about 10 percent.

Table 9 Amount of heat storage building material set for simulation

	Floor area	Installed area	Latent heat of board	Heat stored/floor area
PCM microcapsule A	28 m^2	72 m^2	224 kJ/m^2 of one ply	583kJ/ m^2

Table 10 Simulation results (air-conditioning load of living-dining room)

	Air conditioning load			Load reduction rate		
	Heating	Cooling	Heating and cooling	Heating	Cooling	Heating and cooling
No PCM microcapsule	5.3 GJ	4.5 GJ	9.7 GJ	—	—	—
PCM microcapsule A	4.5 GJ	4.5 GJ	9.0 GJ	15%	0%	8%

4. Conclusions

4.1 PCM microcapsules and gypsum board with PCM

The basic compositions and production processes for the PCM microcapsules and gypsum board with PCM were successfully established.

- For the shell layer, a urethane-based resin was used instead of an acrylic-based or melamine-based resin.
- This allows the continuous production process of PCM microcapsules to be directly coupled with a gypsum board manufacturing facility.
- Although the use of a nano-composite material in the shell layer reduced VOC emissions, the target value in Japan was not attained.
- This point requires further study in the future.
- The gypsum board with PCM made by trial production satisfied the strength properties prescribed in JIS A 6901 and therefore can ensure functioning as an interior building material (wall material).

4.2 Thermal evaluation in residential house

- A reduction in the range of room temperature fluctuations and reduction in air-conditioning power consumption were confirmed.
- The possibility of prediction by simulation software was confirmed.
- Thermal simulation software estimated the effect on reducing air-conditioning load in the living-dining room at about 8 percent over a full year.

TITLE: TRANSPARENT INSULATION MATERIAL FOR RESIDENTIAL HOUSES AND BUILDINGS

Hitomi MIURA[1]
Masahiko GOTOH[1]
Yasushi NAKATA[1]

[1] High-performance Plastics Company, Sekisui Chemical Co., Ltd., Shimamoto-cho, Mishima-gun, Osaka, Japan, miura015@sekisui.jp, nakata007@sekisui.jp

Keywords: Daylighting performance, heat-insulating performance, sound-insulating performance, heat transmission coefficient (K-value), cold draft

Summary

The objective of the research presented here is to develop transparent insulation material for residential houses and buildings. The key feature of the transparent insulation material we have developed is to achieve a low K-value without using any low thermal conductive gases such as argon, krypton and xenon. In addition to this simple feature, it does not need any Low-E coating film. It just consists of multi-layer films with multi air layers, which form cavities inside the insulation material.

The K-value for transparent insulation material can be set from 0.4 (thickness of 150mm), 1.0 (thickness of 30 mm) to 3.5 (thickness of 4 mm). As for non-flammable types, achieved K-value ranges from 1.3 (thickness of 30 mm) and 3.5 (thickness of 4 mm).

The newly developed apparatus has been designed and introduced to make samples with a maximum width of 910 mm, length of 2,300 mm and thickness of 30 mm, which can be attached to most residential houses in Japan

Six types of applications using the novel transparent insulation materials have been proposed, based on their properties such as K-value and thickness. Of the 6 types, 3 are being tested at an experimental house in Iwamizawa City in the northern part of Japan.

• •

1. Introduction

Household energy consumption and CO_2 emissions from business facilities are increasing every year, thus posing an urgent need to reduce CO_2 emissions as a measure to address the global warming problem. In this situation, energy consumption must be reduced by, for example, improving the thermal performance at openings where heat loss is particularly large. Thus, we began developing techniques and products to improve the thermal performance of such openings without adversely affecting daylighting performance, transparency, or other features

An efficient technique to improve the thermal insulation of an opening is placing transparent insulation material on the panes of the opening. To construct said transparent insulation material, several layers of a translucent plastic film were stacked, between which a spacer was placed in part to form a thin layer of air. This multi-layer air sandwich structure was found to be effective (Figure 1).

• •

2. Outline of transparent insulation material

2.1 Construction of transparent insulation material

The transparent insulation material under investigation consists of a thin film and resin spacer, with no special restrictions on the material, provided that the film is translucent and the spacer can maintain the space. In addition to inexpensive transparent film or design film of various decorative patterns, heat-reflective film, light diffusion film, a prism sheet, and similar films can also be used, making it possible to create an optical design for the efficient use of sunlight.

Although the spacer features a typical stripe pattern with a pitch of 50 mm, this can be changed to discontinuous lines or a narrower pitch. Choosing the proper spacer material and pattern makes it possible to create a sound insulation design. Structures satisfying the noncombustibility requirements prescribed by the Building Standard Law of Japan are possible by limiting materials to the special film and spacer. Moreover, heat insulation design is possible with a K-value of 3.5 W/m^2K (comparable to that of double glazing) to 0.4 W/m^2K (comparable to that of a typical exterior wall in Japan) according to overall thickness and the number of air layers.

As stated above, this transparent insulation material offers a high degree of design freedom and can be selected to suit the needs of residents, both of which embody the major appeal of this material.

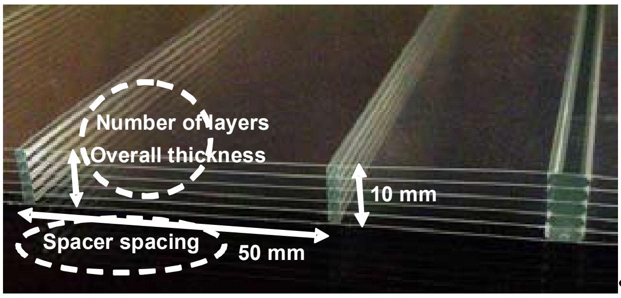

Figure 1 Component details

2.2 How to use

This transparent insulation material does not replace the panes of openings of a building, but is used as an attachment to those panes.

In one application, the transparent insulation material is framed around a frame fixed to the panes of an opening by direct bonding. In another application, the material is placed between hard plastic or glass plates and then framed around this component, which is fit in as an inner window or block. In either case, an attaching method is proposed so as not to damage the house, and components are designed to accommodate this component inside an existing railing or architrave without narrowing the living space. Therefore, it is suitable for renovation and also makes a novel residential house design possible as a new light-transmitting wall, so its deployment in new construction is also considered to be possible.

Applications were broadly divided into six types and research was conducted on Japanese consumers. As a result, three of the six applications were deemed highly necessary, and are being developed not only as a stock material but also as a building component, including the sealing method and related frame materials (Figure 2).

Application	Double-glazed window (inner window)	Daylighting block	Double-glazed window (simplified fixing)
Attaching to the pane of an opening			Typical construction of heat-insulating daylighting	10 layers, 18-mm thick	5-layer 10-mm thick construction installed at 4 places	5 layers, 5-mm thick
Schematic (Section α-α') 			
Figure 2 Three core concepts and construction details

3. Manufacturing process

A process study was conducted using PET film−a general-purpose clear film−as the base film, and a transparent acrylic elastomer having heat resistance of 80°C for the spacer resin.

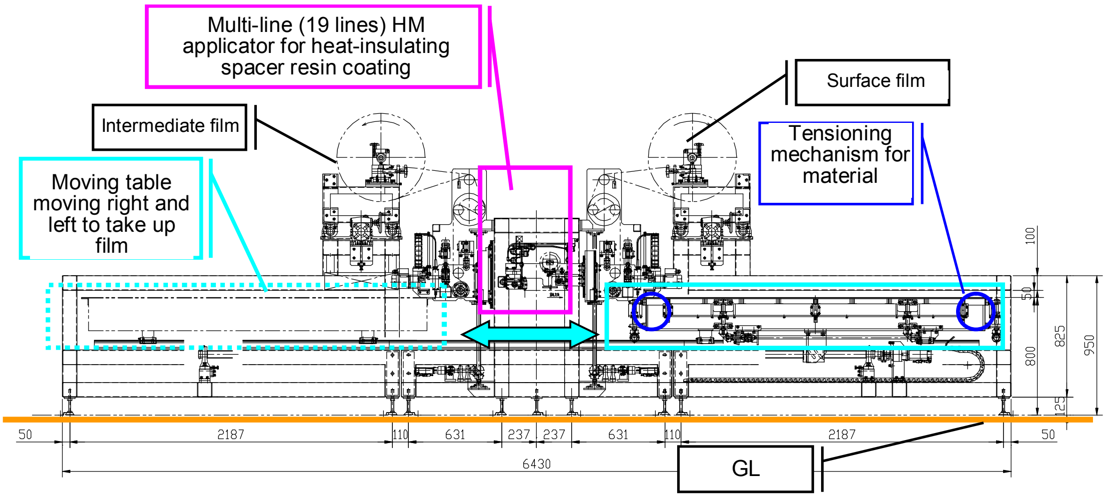

Figure 3 Schematic diagram of multi-layer laminator

The spacer is placed in part on the base film with the prescribed thickness and at the prescribed spacing. For this partial spacer formation, the direct bead application method was employed for its high manufacturing efficiency.

In this method, a hot-melt applicator applies adhesive in beads on the film. A multi-layer laminator was designed and introduced to simultaneously perform spacer formation and lamination, and multi-layer film lamination is now done using this machine (Figure 3). The film end is fixed to the end of the moving table, with film being drawn out of the film wind-off portion. A multi-line bead nozzle (with 17 bead lines) and a film end fixing and sealing coater (with two lines at the right and left ends in the transverse direction) apply the heat-insulating spacers on the film drawn out and fixed to the table as the table moves. Samples up to 910-mm wide, 2300-mm long, and having a maximum thickness of 30 mm can be formed.

4. Heat-insulating performance

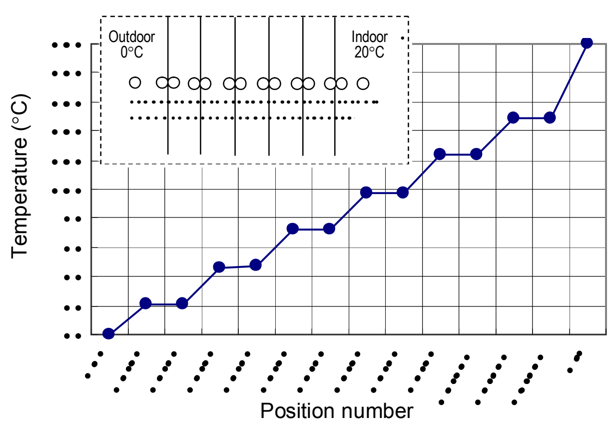
This transparent insulation material employs a multi-layer structure consisting of layers of thin film, between which a thin layer of air is maintained. This structure offers high heat-insulating performance (K-value of 0.4 to 3.5 W/m^2K) without using special deposited film such as a Low-E film or filling the space with argon, krypton, or other gas of low thermal conductivity. Its mechanism is described below.

4.1 Mechanism of heat transfer

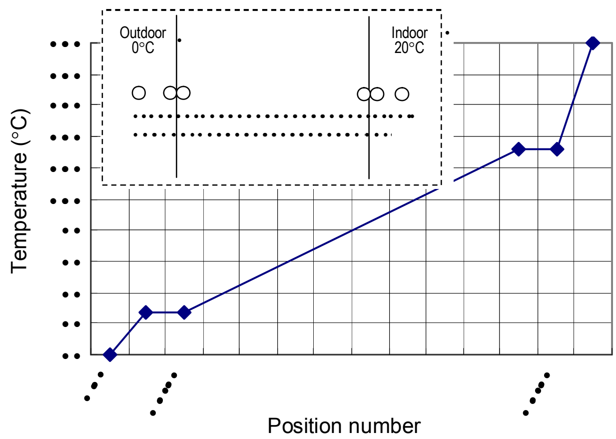
The mechanism of heat transfer via the transparent insulation material has three features: (1) causing no convection due to the set layer spacing, thus restricting heat transfer to conduction and radiation, (2) reduced solid heat conduction due to the use of thin film and partial spacers, and (3) reduced heat radiation due to the multi-layer construction. The third feature of reduced heat radiation follows the Stefan-Boltzmann law of "radiation heat = α x (surface temperature difference)^4".

Figure 4 below shows the film surface temperature of each layer in the case of five and two layers 10 mm in overall thickness. In case (a) of five layers, the temperature difference is about 2.5°C on average, so heat radiation is $\alpha \times 2.5^4 \times 5 = 195\alpha$, while in case (b) the temperature difference is about 10°C, so heat radiation is $\alpha \times 10^4 \times 1 = 10000\alpha$. Thus, for daylighting material of a multi-layer construction, it can be seen that heat radiation is reduced by more layers as long as the overall thickness remains the same.

Through this effect of reducing radiation heat, it is possible to achieve not only the heat-insulating performance of a low K-value in winter, but also the heat-insulating performance of low solar radiation heat gain, which is effective in summer.



(a) 5 layers



(b) 2 layers

Figure 4 Surface temperature of each layer

For a multi-layer structure, the layer spacing is correlated with the K-value, which serves as an index of heat-insulating performance, and this correlation has been clarified by simulation for different overall thicknesses (Figure 5). These simulation results largely agree with the results of a simplified heat-insulating box laboratory test.

For the same overall thickness, the K-value tends to decrease due to the effect of reducing radiation heat as the number of layers increases, provided that the same constituent materials are used. However, this tendency is reduced as the number of layers increases. This is believed attributable to the fact that, as the number of layers increases, the number of films used also increases, thereby increasing the proportion of film material occupying the layers of air, resulting in increased solid heat transfer by the films.

The optimum construction was determined for different overall thicknesses by considering the optimum number of layers in terms of heat-insulating performance, optimum number of layers in terms of daylighting performance described above, and the cost. The shaded area in the figure is considered the optimum region.

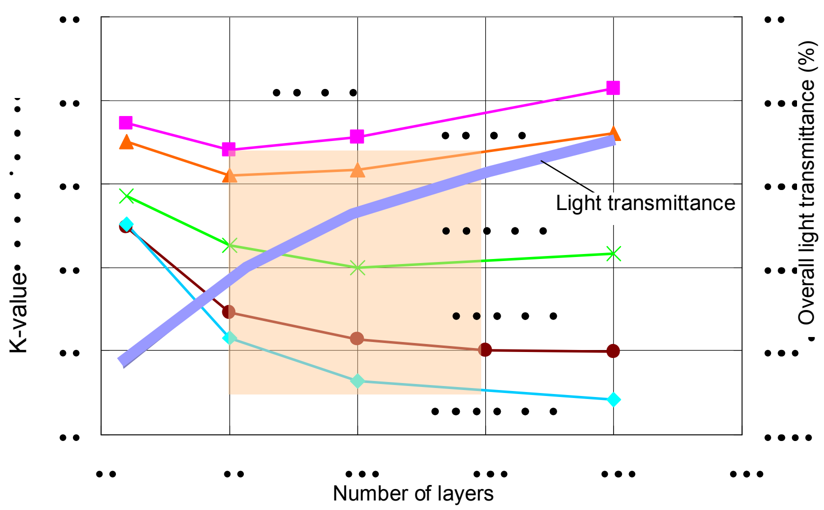


Figure 5 Optimum construction of transparent insulation material

4.2 Verification of heat-insulating performance through field evaluation (in winter)

4.2.1 Surface temperature observation

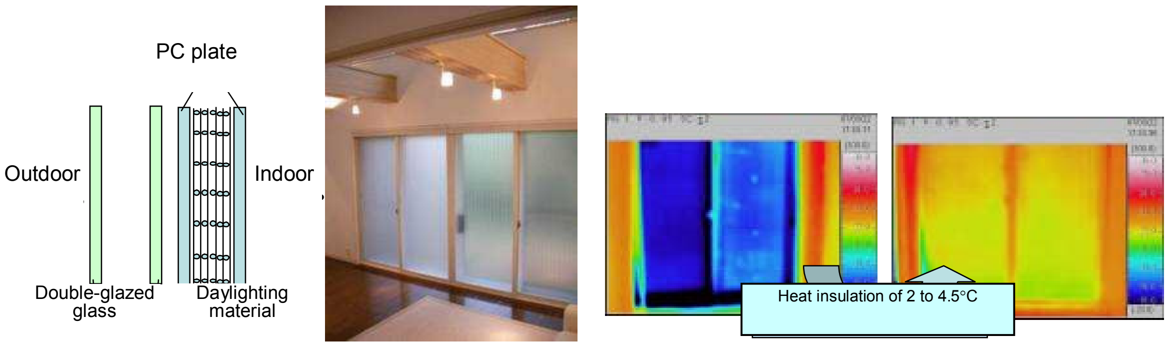
An experimental house in Iwamizawa City (near Sapporo) in Hokkaido, a cold region of Japan, was used to observe surface temperature distribution in winter (February) for case (1) where an inner window was installed and case (2) where a daylighting block was installed.

Figure 6 shows an example of the installed inner window. The transparent insulation material used had a K-value of 2.1 W/m^{2}K, a solar radiation heat gain rate of 47 percent, and consisted of a five air layer construction 10 mm in overall thickness. This transparent insulation material was sandwiched between embossed polycarbonate plates 3 mm in thickness and fit into a resin sash frame. A resin sash railing was then installed in front of the opening, so that the material was assembled as part of an inner window. The pane construction of the opening consisted of heat-reflective glass 3-mm thick, argon 12-mm thick, and float glass 3-mm thick, and its size was 910 by 1820 mm. The transparent insulation material of the inner window had the same size. The surface temperature was measured and, as a result, heat insulation was found to take effect at a temperature of 2 to 4.5°C after installing the transparent insulation material as compared to before installation (Figure 6).

Figure 7 shows an example of the installed daylighting block. Four units of daylighting material of five-layer construction 10 mm in overall thickness (in the daylighting block pattern shown in Figure 2) were set in a frame that was sandwiched between an acrylic plate 4-mm thick on the glass surface side and a ground glass plate 4-mm thick on the indoor side to form a block.

The pane construction of the opening consisted of heat-reflective glass 6-mm thick, argon 12-mm thick, and float glass 6-mm thick, and its size was 1920 by 2500 mm. A total of 42 blocks about 350 by 350 mm in size were attached on this pane surface. The blocks had a K-value of 0.5 W/m^{2}K, solar radiation heat gain rate of 25 percent, and K-value of 0.37 W/m^{2}K at the opening including the panes. This is equal or superior to the K-value of an external wall of 0.4 W/m^{2}K.

Figure 7 also shows the opening's surface temperature on the indoor side after installing the daylighting blocks. From this figure, one can see that the insulation performance is at least equal to or superior that of to the surrounding wall (Figure 7). The block frame temperature of concern was about 1°C higher than the block surface and did not drop below the wall temperature.



(a) (b) (c)

Figure 6 Example of installation as inner window, (a) schematic, (b) photograph of installation, and (c) surface temperature data

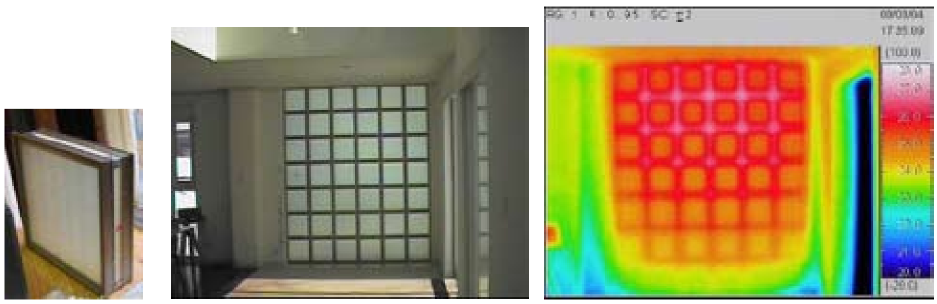


Figure 7 Example of installation as blocks, (a) photograph of blocks, (b) photograph of installation, and (c) surface temperature data

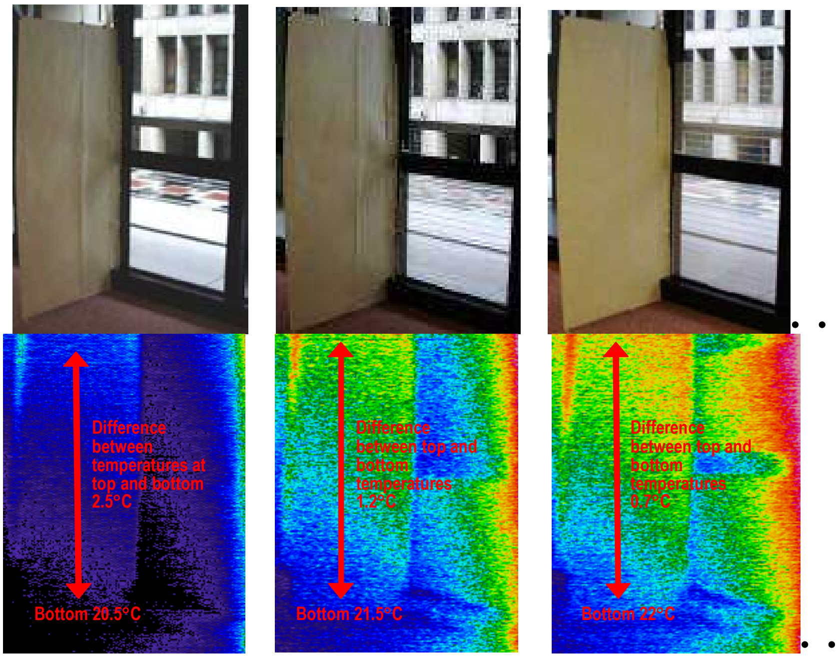
4.2.2 Cold draft phenomenon

Besides its numeric value of K-value, the transparent insulation material has appealing points relative to physical sensation. Among these points is the suppression of a cold draft (i.e., phenomenon of cold air falling near windows from the ceiling to the floor in winter). People who feel chilly near windows can be cited as an example.

Transparent insulation material consisting of five layers 10-mm thick (with a K-value of 2.1 W/m^{2}K and solar radiation heat gain rate of 47 percent) was installed at an opening at a height of 2700 mm in a building in Kyoto Prefecture as a simple fixed inner window, and a confirmatory experiment was then conducted to determine the extent to which the cold draft phenomenon could be ameliorated.

In the evaluation method used, the daylighting material was attached to the opening in question with a screen placed at right angles to that plane, and the state of the screen cooled by cold air falling from the ceiling was observed by using a thermocamera.

Figure 8 shows temperatures measured at the top and bottom. Maintaining a difference within 1°C between the top and bottom temperatures by attaching the material and interposed railing to the lower 1500-mm portion of the opening was successfully confirmed as being possible.



(a) None (b) Installed in 700-mm portion (c) Installed in 1500-mm portion

Figure 8 Confirmatory experiment of cold draft

4.3 Verification of heat-insulating performance through field evaluation (in summer)

A time-lapse observation was conducted in summer (July and August) on the inner window shown in Figure 6. Although the rise in temperature due to heat buildup in the installed daylighting material was of concern, the rise in surface temperature on the indoor side was suppressed (1 to 5•) compared to a blank not fitted with the daylighting material. The material was considered effective because its solar radiation heat gain rate was 47 percent.

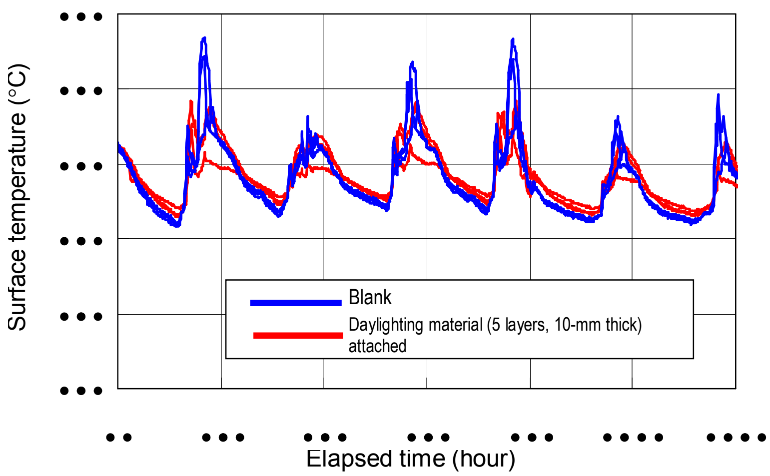


Figure 9 Surface temperature of heat-insulting daylighting material (inner window type) in summer

5. Other performance

Performance other than heat-insulating performance is described below.

5.1 Mechanical properties

The modulus of elasticity in bending of the transparent insulation material is 120 to 290 MPa; thus, the material is sufficiently flexible before being framed. Moreover, the material can also be bent to fit into a curved portion as well.

5.2 Sound-insulating performance

Installing transparent insulation material for use in a sandwich construction between hard plates has the effect of suppressing the transmission of sound, which would otherwise occur if this material had no layer of air between two hard plates. An improvement of at least 5 dB is possible near 500 Hz, which is within the frequency range of human voice.

5.3 Durability

Regarding durability, weathering resistance, water resistance, chemical resistance, and other properties are now under review. Because this is a component to be fit in an opening, weathering is of special concern. Thus, weatherability testing is under way using a xenon weather meter at an irradiance of 180 W/m^2. Even after an elapsed time of 2000 hours, discoloration, cracking, and other remarkable appearance changes have not been seen. Evaluation will continue after this testing to ensure a guaranteed service life of 10 years for use of this material in openings.

6. Energy saving effect

SMASH (Simplified Analysis for Housing Air Conditioning Energy)—thermal load calculation software developed by the Institute for Building and Energy Conservation—was used to estimate the energy saving effect on a detached house (for a family of four) according to its standard schedule and based on the following preconditions:

[Preconditions]

- Outside air condition: Tokyo
- Model plan of 141 m^2 (opening ratio = window area/gross floor area of 29%)
- Ventilation frequency: 0.5 time per hour
- Equipment COP: 4.19 during heating; 3.89 during cooling
- K-value of daylighting material used: 1.0 K/m^{2}K, solar radiation heat gain rate of 37 percent, with lace curtains installed

Compared to the typical combination of aluminum sash and single float glass 3-mm thick (FL3), an energy saving effect of 38 percent in term of annual power load (2.8 GJ/house) can be expected when using daylighting material having a K-value of 1.0 W/m^{2}K and solar radiation heat gain rate of 37 percent (Figure 10).

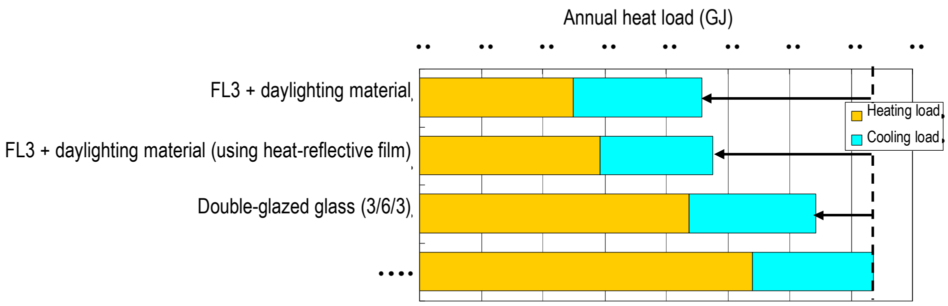

Figure 10 Estimation of energy saving effect on detached house

7. Conclusions

This transparent insulation material has a high energy saving effect combined with high sound-insulating performance. Therefore, the material can be used not only for renovating the openings of an ordinary residential house, but also as a partition member or translucent wall. This material may also be used in a wide variety of applications, such as deployment in commercial buildings (Figure 11).

For this material, a study is under way to make it possible to simulate not only heat insulation but also optical design or sound insulation design through construction and material. Regarding the three applications of this material as a high performance inner window, daylighting block, and simple fixed inner window, future tasks include devising a sealing method and attaching method to suppress dew condensation (Figure 11).

Keywords: earth building, design guide, Uku, sustainable housing, Maori, indigenous, rammed earth

Summary

This paper outlines research that has been undertaken to create an accessible, low-cost, sustainable earthen building solution for Māori (the indigenous people of New Zealand) living in rural communities. Many individuals and families in rural Māori communities live in overcrowded dwellings with a low, inadequate standard of living. Reasons for the poor housing condition that exists can be attributed to legal issues regarding 'Māori land' and land ownership, the urbanization of Māori, and the financial cost of constructing on isolated, undeveloped Māori land.

In July 2003, a four year research grant was awarded to develop a low-cost flax-fibre reinforced rammed earth housing concept into a commercially viable building technology. An important measure of the value of the research was the ability of rural Māori communities to be able to use the outputs of the research directly. Consequently a community reference group was created comprising of representatives from potential Māori user groups/areas. During the research, an optimized Uku soil mix was determined comprising of 8% cement and 0.075% flax fibres. Material tests have also been conducted to determine the lower 5% compressive, flexural and shear design strengths of the material. The construction process was optimized throughout the research with the development of such devices as a mobile flax stripper and a custom-made formwork system. Improvements in construction methodology were also implemented.

The research concluded in April 2008, with the construction of a full-size Uku house on the foreshore of Lake Rotoiti. This research has resulted in the development of a technology that rural Māori communities can immediately benefit from and has created a platform for future research and development of the Uku building system.

1. Introduction

Māori are the indigenous people of New Zealand and migrated to New Zealand as early as 800 AD from Polynesia (Howe 2007). StatisticsNZ (2001) has indicated that there are approximately 84,000 Māori currently residing in rural areas of New Zealand (2.3% of the national population). Slightly more than 5% of the total land area in New Zealand remains in the control of Māori, but many rural Māori communities are unable to fully utilize 'Māori land' owned by their hapu (sub-tribe) to provide adequate housing and living conditions for their members. A report published by Housing New Zealand (2005) showed that a disproportionately high and unacceptable number of individuals living in rural Māori communities reside in overcrowded, substandard dwellings. The New Zealand Housing Research Centre (NZHRC) has identified obstacles (Forrest 2007) that are obstructing the provision of quality and affordable housing developments on rural Māori land. Aid in the form of local government housing funds, accommodation benefits and boosting of state housing around New Zealand have had limited success in increasing the standard of living for rural Māori (Forrest 2007). Uku, a flax-reinforced soil-cement construction technology (Segetin et al. 2006) is a practical housing solution that is being researched at the University of Auckland to address this issue. The difficulties and limitations that rural Māori communities encounter when building on Māori land and how the Uku building system has been developed to manage and overcome these barriers are addressed.

1.1 Māori Housing Obstacles

Obstacles preventing the adequate provision of housing to members of rural Māori communities can be grouped into 3 areas: financial barriers, legal issues and the urbanization of Māori.

'Māori land' is subject to specific laws in New Zealand (Te Ture Whenua Māori Act 1993). One example is the inability to alienate the land from Māori. This has created lending issues because Māori land cannot be used by financial institutions as a security. The majority of Māori land is located in rural areas. A photo of Māori land under the guardianship of the Waimango Papakainga Trust is shown in Figure 1. Papakainga refers to land used for housing a hapu or whanau (extended family). In many areas, especially coastal, plots of Māori land are remote and in a nearly natural undeveloped state. This is desirable because the land is, for the most part, untouched by human activity, but disadvantageous because it often elevates the access costs and the overall cost of developing building infrastructure on Māori land to an insurmountable level. Machinery and building resources are expensive to access, transport, and use, not just because of the distance, but because of other reasons including inadequate road infrastructure and lack of access to amenities and utility networks (e.g. telecommunications, water and electricity). Financial barriers are one of the main obstacles hindering rural Māori communities from utilizing their land to provide adequate housing for members of their community.

Figure 1 Photograph of Māori land owned by the Waimango Papakainga Trust (Morgan 2005)

The Māori population is urbanizing rapidly. Many Māori, particularly young unmarried Māori, have relocated into urban areas in order to secure work, earn money and live a more modern lifestyle. Before the Second World War more than 80% of Māori lived in rural areas. Today 84% of Māori live in urban areas (Meredith 2007). As a result, many rural Māori communities are depopulated and lack a younger Māori labour force. This has increased the cost of building on Māori land because technically-trained skilled labour has to be sourced from surrounding regions to fill shortages that have developed in the local workforce.

Legally, Māori land is owned by the local Māori hapu with historic ties to the land. Māori land is collectively owned, often by over a thousand people spanning several generations. Managing building developments on Māori land is further complicated by the relocation of many owners into urban centres. These distant owners often have weak ties to their ancestral lands and lack the knowledge of genealogical links that are vital to understand in order to make progress towards a meaningful outcome (e.g. building a house).

1.2 Background of the Uku Project

The Uku research aims to develop a cement-stabilized, flax-fibre reinforced, rammed earth building system to provide a method of domestic house construction that overcomes the legal and financial obstacles preventing rural Māori communities from utilizing their ancestral lands to provide adequate dwellings and good standards of living for their members (Morgan 2006). The name given to the building system 'Uku' is the Māori language translation for earth. In 1996 the Waiariki Area Research Unit undertook research investigating the viability of a rammed earth housing solution for rural Māori communities. Two rammed earth panels were constructed and tested, and revealed the potential to develop a low-cost earthen housing solution for Māori. The construction workshops with Uku (2003-2005) developed the earth housing concept further by building two simple rammed earth dwellings on Māori land. The first dwelling was constructed on a rural Māori papakainga located on the foreshore of the Firth of Thames (Waimango Papakainga) shown in Figure 2. The second dwelling was built on urban Māori land in Otara, Auckland City (Kokiri Te Rahuitanga). In June 2003, the Foundation for Research, Science and Technology (FRST) awarded a 4 year grant to develop Uku, an accessible low-cost rammed earth housing solution for rural Māori communities. A major output of this research was the construction of the full-size Uku house in Rotoiti.

Figure 2 Photograph of Te Ahuone - a simple rammed earth dwelling built on rural Māori land owned by the Waimango Papakainga Trust (Morgan 2005)

1.3 Advantages of Building with Earth

Houben and Guillaud (1994) estimated that a third of the world's population lives in earthen structures, with the majority residing in the developing world. For many millennia earthen structures have been the most common building solution in the world and it is still true of earthen structures today. The reasons why earthen construction has remained so widely used are due to:-

- Material availability – In the majority of areas where human settlements are established, there is a nearby source of soil that can be used for earthen construction.
- Low-cost – Earth material is abundant and easily extractable. It requires minimal material processing and is locally sourced.
- Easy to work – Earthen dwellings can be built using simple hand tools.
- Simple and intuitive – Earth buildings can be built without design guides and technical training.
- Strength – Earth has adequate strength for use as a structural material.
- High thermal mass – Earthen materials are capable of absorbing a large amount of heat energy. During hot days the earth keeps the building cool. During the night the heat is slowly released, keeping the building warmer.
- Durable – Earthen structures have long-term permanence. Many well designed and constructed earth heritage structures are still in use centuries later, like the Potala Palace, Tibet and the Great Wall of China (Jaquin et al. 2006).
- Low toxicity – Earthen structures generally do not require significant processing and mixing with chemical additives. Earthen structures are naturally pest and fire resistant. As a result the material is generally non-toxic or of low toxicity (North 2006).

1.4 Seismic Design Requirements of Earth Building in NZ

Morgan (2005) outlined how earth building in New Zealand started with Māori construction of pa (strategic military settlements) and pit houses. Earth building usage as a method of housing increased during the European settlement of New Zealand (Walker et al. 2003). However, following the magnitude 7.5 Marlborough earthquake in 1848 (Grapes et al. 1996) and the magnitude 8.2 Wairarapa earthquake in 1855 (in which many earthen structures were badly cracked or completed destroyed) (GNS Science 2007), earthen construction quickly fell out of favour. Only recently, since 1980, has the earth building industry in New Zealand experienced a significant revival as interest in sustainable construction methods and environmentally friendly buildings has increased.

New Zealand is located at the active boundary of the Australian and Pacific tectonic plates (The New Zealand Landforms 2007). GNS Science, a government owned research institution, records 100 to 150 national earthquakes annually that are large enough to be felt (GNS Science 2007). The majority of earth building knowledge transferred to New Zealand has come from countries where seismic design was not a relevant design consideration. Due to the lack of national research and knowledge of the seismic performance of earth buildings, the majority of earthen designs, particularly before 1998 (when the New Zealand Earth Building Standards were released), had to be certified by a Registered Professional Engineer.

In 1998 three earth standards were released in New Zealand by Standards NZ:-

- NZS 4297 Engineering Design of Earth Buildings
- NZS 4298 Materials and Workmanship for Earth Buildings
- NZS 4299 Earth Buildings Not Requiring Specific Design

The earth standards have simplified the process for gaining building consents for earthen structures in New Zealand but still require the input of professional engineering expertise for non-specific design compliance to certify the suitability of the soil and the construction approach. The lack of professional engineers in Māori communities is an obstacle preventing Māori communities from accessing earthen construction technologies. The Uku project addresses this issue by creating a design guide that provides rural Māori communities with the tools and knowledge to uptake the Uku technology as well as by reducing the need for external input into the design and construction of dwellings built on Māori land. The design guide is a tool that provides greater accessibility to rural Māori communities to build safe structures using the Uku building system.

2 Unique Elements of the Uku Building System

The Uku building system has been conceptualized with the idea of creating a system that is an accessible and sustainable housing solution for rural Māori communities as well as a technology that can be transferred and used independently by the rural Māori community.

2.1 Māori Community Reference Group

The Uku research was conducted with input from a Māori community reference group (MCRG) comprised of representatives from Māori communities and organizations who were potential end users. An important measure of the research value resided in the ability of the target end users to directly apply the research to provide for their own housing needs. By meeting with potential end users throughout the research the Uku technology was developed to better utilize the resources available to Māori communities and to address their specific needs and issues. Working with the MCRG provided a way for the representatives of the Māori groups to gain an understanding and affinity with the Uku project, and relay the research to the people in their community. Relationships have been formed with tribal groups from Taitokerau (Northland), Tairawhiti (East Coast) and Waiariki (Bay of Plenty) shown in Figure 3.

Figure 3 Diagram showing Taitokerau, Waiariki and Tairawhiti Iwi (tribe) locations (Te Puni Kokiri 2008)

2.2 Sweat Equity Financing

A financing concept that uses sweat equity as a mechanism to make the Uku building system more affordable has been incorporated into the building process. The sweat equity concept uses labour and time, invested by the owner (and family) during the construction process, attaches a monetary value to their involvement and uses the monetary value of their work as part of the down payment for the house. The Uku system is able to utilize unskilled labour and as a result, labour contributions are not limited to residents who have undertaken formal technical training. Morgan (2005) documents the success in past trials using volunteer labour and/or residents from the local Māori community during construction to provide the majority of the labour required during construction of the wall elements of a building.

2.3 Use of Local, Low-energy, Renewable Resources

The use of local resources (labour and building materials) was maximized where possible. For the dwelling built at Waimango, local soils were tested and a suitable soil source located 0.5 km away from site was chosen. The soil required a 30% sand addition (sourced 10 km away) in order to reduce the soil shrinkage to within the limits imposed in the earth standard NZS 4298 (Standards NZ 1998).

The soil located on site proved troublesome to use for construction. In total the soil took five weeks to extract, transport and mix in preparation for use in the Uku walls. The additional sand required to reduce shrinkage was mixed into the soil at a local quarry. Using local soils increased the labour and time required for construction. After the Waimango project, earth extracted from a soil quarry was preferred because it required less labour and time, and provided a more consistent soil composition. The soils on the urban site in Otara were not suitable due to a high organic content. For the Otara dwelling, soil was sourced from the Lyons quarry located at Woodhill and the Stevensons Quarry at Waimauku.

Flax leaves were processed into flax fibres using a mobile flax stripper that was developed as part of the Uku project. The fibres used for construction were manufactured from leaves harvested at a flax plantation at Te Hapua, near the Rotoiti Uku house.

It is important to acknowledge that not all the materials used in the Uku building system were locally sourced, low-energy, renewable materials. New Zealand is a very seismically active country and in order to satisfy the seismic demand requirement using the Uku wall panels, vertical D12 reinforcing bars were installed in all structural Uku wall panels at approximately 500 mm centres (e.g. 1200 mm long wall panels have three D12 vertical reinforcing bars). The introduction of steel reinforcing bars was not a desired result but was necessary to satisfy the moment demands on the wall panels. Further testing of the Uku wall system, when subjected to seismic loading, will reveal whether a less conservative ductile design is appropriate. Until this is demonstrated the wall design will assume an elastic system response without a significant displacement or ductile capacity. The Uku mix contains an 8% (by weight) addition of Golden Bay Ordinary Portland Cement which has a high embodied energy. The addition of cement was considered necessary to provide resistance against moisture and advantageous as it improved the strength of the Uku material.

2.4 Machinery and Equipment Requirements

The soil, flax fibres and cement can be mixed and rammed using only hand tools and hand rammers. However access to a large supply of low-cost labour is needed to make this option commercially viable. Mixing, transporting and ramming the Uku mix is a highly labour intensive task. In practice a pneumatic rammer (and air compressor) has been used in conjunction with a hand rammer to compact the Uku soil. Similarly when mixing the soil, in order to minimize labour requirements and decrease the mixing time, a compact loader (and driver) is hired to mix the soil onsite and transport it to the ramming location. The Uku building system requires a minimum of four people on site (including the compact loader driver). Measurements of site-task durations show that, by using the machinery and mechanical devices mentioned above, the shuttering system can be dismantled and erected in 1.5 hours and the ramming process can be completed in less than 3.5 hours.

The use of a pneumatic rammer and a compact loader during construction was not originally envisioned as a part of the Uku construction system. These additions require fuel and machinery / mechanical components that are less accessible to isolated rural areas and greatly increase the energy input during house construction. However due to the practical advantages of constructing buildings in a short period of time and the cost savings achieved by reducing labour requirements, it was decided to use machinery and mechanical equipment during construction where it would make the construction of an Uku dwelling easier to build and more affordable to the owner.

2.5 Design Guide

One of the objectives of the Uku project was to create a design guide that allowed rural Māori communities to make use of Uku technology without needing professional engineering expertise during the design, consenting and construction stages. A design guide was authored that currently is able to show how to verify the structural aspects of the dwelling. The current design guide was used successfully for the Uku house built at Rotoiti. The building consent was issued in November 2007. The design guide is undergoing refinement and will continue to be developed to improve aspects such as the seismic and thermal design methodology (as the performance of the Uku wall system is better understood) and other aspects like defining practical / empirical preliminary soil tests and being translated into the Māori language.

3 Uku Research Objectives

The primary objectives of the FRST funded Uku research project were to:-

- Develop the technology for the earth fibre composite material;
- Optimize end-user adoption of the technology and trial the results;
- Build full scale trials and develop a commercialization strategy.

The FRST funded Uku research was completed in April 2008. A summary of each stage is covered below.

3.1 Developing the Technology

The research has optimized the Uku (flax/cement/soil) mix composition initially proposed by Haab (1998). The present Uku mix (by weight proportions) consists of 8% cement and 0.075% flax fibres (cut to 60-70 mm lengths), mixed with soil at a moisture content of approximately 22%. Haab (1998) proposed a 0.75% flax component but the Uku research found a 0.075% flax proportion was more practical on a large scale because it reduced clumping of the flax and made it easier to mix the fibres homogenously into the soil. The flax content reduction also decreased the labour requirement for separating and cutting the fibres to length.

Testing of the Uku material was conducted following standard test procedures defined by the American Society for Testing and Materials (ASTM). A summary of the results is shown below in Table 1. NZS 4298 specifies that rammed earth material that is used in construction needs to exceed 1.3 MPa in compression and 0.25 MPa in flexure. The measured compressive strength of the Uku material easily satisfied the requirements with an average strength of 7.6 MPa and a lower 5% characteristic design strength of 4.6 MPa. In flexure the material also passed with an average strength of 0.35 MPa. Although the design strength in flexure was below 0.25 MPa (0.18 MPa), all seven test beams failed above 0.25 MPa. The low flexural design strength was due to the spread of the results and the low number of flexural samples tested.

Table 1 Summary of Material Tests of the Uku Material

	Average Strength [MPa] ($\bar{x}$)	Coefficient of Variance [%] ($\sigma / \bar{x}$)	Design Strength [MPa] ($\bar{x} - 1.65\sigma$)
Compression	7.6	23.7	4.6
Flexural	0.35	28.9	0.18
Shear	0.73	17	0.52

3.2 Optimizing End-user Adoption

In order to optimize end-user adoption of the technology, aspects of the construction process were refined as constructability issues were identified. In addition to this a design guide was developed. Following traditional Māori methods, the flax fibres were initially extracted by hand but this proved to be too slow and labour intensive. Consequently the process was moved to the Foxton Museum flax threshing machine. Working in collaboration with various weavers, a mobile trailer-mounted prototype flax stripping machine was designed and constructed at the University of Auckland. This machine now provides the flax fibre used during Uku construction. Another optimized aspect was the shuttering system used to restrain the formwork against the high lateral loads developed when ramming the earth. The formwork system developed by David Easton (a prominent rammed earth expert residing in California, USA) was adopted initially. Using this system the 300 mm wall panels at Waimango took three working days to ram each, including time to set up the formwork. The development of a modular formwork system (used for the Otara dwelling) decreased the wall panel build time to 10 hours. Reducing the wall thickness to 150 mm in combination with the modular formwork further decreased the wall build time to 5 hours (used for Rotoiti house). The modular formwork system developed is shown in Figure 4 and allowed wall panels up to 2.2 metres in length to be constructed per setup. The Otara dwelling and Rotoiti house construction progressed at one wall panel per working day.

Figure 4 Photograph of the modular Uku formwork system developed by the research team

3.3 Full Scale Trials

Construction of the Rotoiti Uku house (90 m^2) in April 2008 satisfied the FRST requirement to build a full scale house using the Uku building system. The plan for the Uku house is shown in Figure 5. Another house with the same floor plan was built 100 metres away from the Uku house using conventional timber frame construction. Both dwellings were built on a reinforced concrete floor and with an exposed rafter timber diaphragm roof. The timber house will be used as a reference point to evaluate the thermal performance of the Uku house. A photograph of the Uku dwelling in Rotoiti under construction in March 2008 is shown in Figure 6. Both houses feature two bedrooms, a lounge, kitchen, laundry, toilet and carport. The construction inputs of both structures have been recorded and a detailed comparative analysis of the embodied energy and environmental impact of the timber and Uku construction methods will be evaluated. Each dwelling will be equipped with 15 thermal sensing buttons located on the interior and exterior of the walls. A memorandum of understanding (MOU) has been signed between the Uku research team and the occupants of the two houses to allow the dwellings to be monitored for two years.

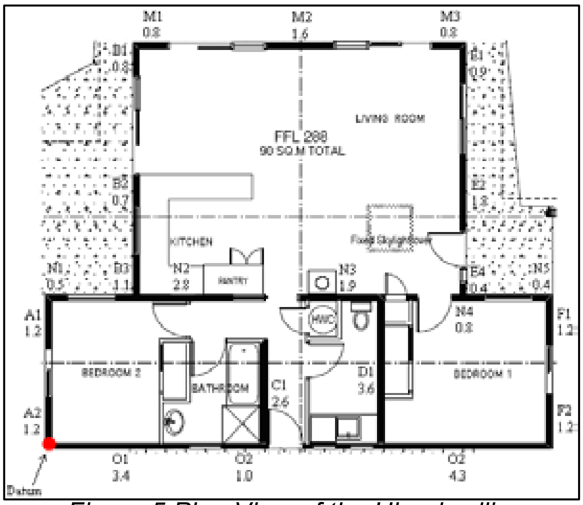

Figure 5 Plan View of the Uku dwelling.

4 Conclusion

In New Zealand there is an issue with providing adequate housing and standards of living for individuals and families living in rural Māori communities. Issues of land ownership, the cost of construction on Māori land and the urbanization of the Māori population have created obstacles to land development that result in overcrowded and sub-standard living conditions for many residents living in these areas.

The Uku research has been conducted with the purpose of creating a low-cost, sustainable building system that is accessible to rural Māori communities. The Uku technology was developed to take advantage of local resources and materials and address issues preventing the adequate provision of housing on Māori land. To ensure that the developed technology was practical and usable by rural Māori communities, the research progressed with input from a community reference group. An important measure of the research project's value was the ability of rural Māori communities to directly apply the outputs of the research.

As a result of the FRST funded research, an optimal Uku soil mix has been determined (8% cement, 0.075% flax and soil) and the construction process has been improved through the optimization of the building process and the introduction of machinery and mechanical devices where appropriate. The completed construction (in April 2008) of an Uku house on the foreshore of Lake Rotoiti using local labour and materials has demonstrated that the proposed solution is constructible and practical.

The Uku building system incorporates a minimal proportion of high embodied energy and/or manufactured materials (cement and steel reinforcement). These additions were required to satisfy the NZ Earth Building Standards and provide adequate seismic capacity in the structure. The use of machinery (compact loader) and mechanical devices (pneumatic rammer and air compressor) was necessary because it improved the constructability of the house and reduced labour costs. Although these devices and materials detract from the original vision of developing a sustainable, low-energy construction system that uses local resources, tools and materials exclusively, compromises were necessary in order to create a practical building system that could benefit the rural Māori community end user.

The FRST funded research has been completed and a usable building system has been created. Aspects of the Uku building system can be refined; there is always scope for improvement and optimization. However the research has successfully provided a working baseline technology, upon which further research can be conducted and which rural Māori communities can begin to use, to benefit their members now.

5 Acknowledgements

Funding for this project was provided by the New Zealand Foundation for Research, Science and Technology. The provision of building materials by Golden Bay Cement and Pacific Steel was much appreciated. Laura Devcich and Rohann DaSilva are thanked for being great fellow researchers to work alongside. Brian Morgan, the main contractor, has been very kind to, and accommodating of, the research team on-site. Hugh Morris has provided a wealth of earthen research knowledge and resources. Thanks also to Colin Nicholas for keeping the Rotoiti house construction in order. Laboratory technicians Hank Mooy, Tony Daligan, Mark Byrami, Noel Perinpanayagam and Jeff Melster readily gave their time, support and advice throughout the project. The Uku research is richer and more useful because of their involvement.

Summary

This paper describes the development of an experimental research facility to assess the effectiveness of Phase Change Materials (PCM), that can be used for passive solar heating. Four test boxes are constructed representing the conventional and future Dutch building practices regarding insulation and glazing. In the future scenario materials to cover walls and floors in the test boxes will be partly filled with PCMs. In this paper the theoretical framework of thermal behaviour of PCMs in buildings, the realisation of the experimental set up and the design of the monitoring system will be explained.

1. Introduction

During the last decade many energy saving concepts have been developed to enable sustainable building design. In Western Europe, with its moderate climate, passive solar energy forms the most promising measure for reducing the consumption of fossil fuels for heating of houses. Traditionally the (Dutch) building designs were not optimized for using solar energy. With the introduction of the Energy Performance Coefficient in December 1995 as part of the formal Building Code (Staatsblad, 1995) the use of passive solar energy became indirectly more appreciated. This paper results from the research project on "exergy in the built environment" at the University of Twente. Within this research project the adoption of conventional energy saving measures and future low cost measures, such as passive solar energy, in building processes are important issues.

On first sight The Netherlands does not seem suitable for passive solar heating, because the average outside temperature of 9.5 °C is relatively low and the incoming solar radiation on a windowpane of, depending on its orientation, is just 1,313 to 2,881 MJ/(m^2·y) (364.7 to 800.3 kWh/(m^2·y)). However, the passive use of solar radiation offers many opportunities in low exergetic heating applications. In common Dutch houses solar irradiance enters the room by large windows oriented to the south, therefore less heating and electric power will be used. Solar irradiance will mostly be transmitted and a small part will be absorbed or reflected by the glazing. Behind the glazing the air in the room will absorb a small part of the energy, before irradiance will be absorbed by the floor covering and constructions beneath it. On the north side of the buildings it is common to install smaller windows than on the south side, since the energy losses by outside transmission are larger than the input of irradiance. Not much is known though about the heat absorption capacity of the interior of buildings and the speed of release of captured solar heat for interior heating during cold evenings or nights.

The specific energy performance of glazing and windows has been regarded by Nielsen et al. (2001). He perceived the issue as a combination of thermal transmittance and total solar energy transmittance. However, it might be more accurate to consider the actual energy performance of glazing and windows within the building design in relation to the absorption factors and heat capacity of the materials used in the interior of the building.

Three major factors to be considered are:

1. <u>The absorptivity of the internal constructions</u> of a building, for example materials used, thickness or mass of internal construction parts, installation of extra internal heat absorption walls, color of the interior, and introduction of Phase Change Materials (PCM, e.g. Peippo et al., 1991, Nepper et al., 2000, Nagano et al., 2006, Shilei et al., 2007);

2. The absorptivity of the external constructions of a building in which the distance of the insulation to the outer surface of the exterior wall and the mass in this section can be regarded (e.g. Yumrutaş et al., 2007);
3. The internal transport system for heat which is normally used to convey heat to the rooms, but in some cases it can be used to stabilize the temperature through the whole object by conveying heat from the one room to the other.

Being substances that are able to store latent heat PCMs might improve the first factor: the absorptivity of the internal constructions. Thermal energy transfers in PCMs take place during melting and solidification (Sharma et al., 2008). Inorganic (e.g. salts) and organic (e.g. paraffins and fatty acids) substances can be suitable to be a PCM (Zalba et al., 2003). Because little is known about the application of PCM and their potential to save exergy[1] within building designs, this paper describes the development and execution of an experimental research project on the use of PCM in concrete floors and gypsum plasterboards. They will accumulate solar energy to obtain a constant indoor temperature during day-night cycles.

The use of a latent heat storage system, which PCMs provide, is an effective way of storing thermal energy (Sharma et al, 2008). Research on the use of PCM in energy-storing wallboard of Chen et al. (2008) shows that energy savings for heating a room are starting at 10% or 17%, and higher percentages are conceivable. In this paper an experimental setup is presented that can be used to gain more insights in the effectiveness and efficiency of these measures. The results of this research can help to improve the energy performance of both new and existing buildings.

In the second section of this paper the background on the use of solar radiance in Dutch dwellings will be given. After that the development of the test boxes will be explained in which the dimensions and used materials will be considered. In the fourth section the test site will be addressed in close relation with the monitoring system that is explained in the fifth section. Finally, the conclusions, recommendations and prognosis on future research will be elaborated on.

2. Basic assumptions in researching solar radiance in Dutch dwellings

The goals of the proposed experiment are to gain insights and data on how solar radiation can be absorbed, buffered and distributed effectively and efficiently within the building shell and how this thermal energy affects the indoor temperature. Before developing an experimental setup to achieve this goal, the following specific considerations need to be stated regarding the thermodynamic aspects of Dutch houses:

- The living room is regarded as the most important room within residential real estate from an energetic point of view. In this room the radiators are controlled by one thermostat that often regulates the working of the heating system for the whole house. The experiment will focus on simulating this space. The inside temperature is in Dutch standards fixed to 18 °C for the heating season. The necessity to cool the building exists, according to Dutch standardization references, when the indoor temperature rises above 24 °C (NNI, 2005);
- The residential building stock in the Netherlands, consisting out of 7 million houses, offers enormous possibilities to save energy. The characteristic row house will be used as point for departure for simulation. This means that in theory there will be no heat transmission to the neighbours. The Dutch agency for sustainability and innovation, SenterNovem, has specified six different residential real estate reference objects to use for energy analysis, of which one constitutes the considered row house (SenterNovem, 2006);
- The ceiling of the ground floor is normally not insulated and consists most of the time solely out of a concrete hollow-core slab with a height of 200 mm. In dwellings where the floors are carried by wooden beams, plasterboard is sometimes used to finish off the ceiling.
- In existing houses the ground floor, roof and walls are often insulated. Starting from 1992 it is compulsory to install insulation in the building shell with R ≥ 2.5 $(m^2{\cdot}K)/W$, but many older houses have been refurbished by installing floor insulation with the same heat resistance. Nowadays insulation with R = 3.5 to 4.0 $(m^2{\cdot}K)/W$ is often applied in the floor and roof of new houses.

The feasibility of the proposed experimental research can be demonstrated by using standardized Dutch figures on solar radiation (NNI, 2004) and the specifications of a standardized reference dwelling for new row houses (SenterNovem, 2006). The energy balances at the glass surface on the south side, north side and roof are shown in Figure 1. On a yearly base more than 33,000 MJ (= 9,167 kWh) of solar radiation could enter through the windows of the referred standard house. The thermal resistance of windows is however quite low (U = 1.8 $W/(m^2{\cdot}K)$) compared to the insulated walls of new buildings. Therefore, more than 11,000 MJ will leave the building, when the temperature inside is set to be 18 °C and average outside temperatures

[1] The concept of exergy is used, because it can better express the effect of low temperature heat and the qualitative difference between solar irradiance and fossil fuels than energy.

are taken of 2.5 to 17 ℃ (depending on the month). Nevertheless, even in The Netherlands the gains (33,000 MJ – 11,000 MJ = 22,000 MJ) are not negligible and can especially during spring and autumn in houses offer great opportunities to reduce the natural gas consumption. Natural gas is the most commonly used fossil fuel to heat houses in the Netherlands. Figure 1 also shows that during winter solar radiation through glazing will not surpass its heat transmittance and that during the summertime a large surplus is available demanding additional measures. With these considerations in mind the setup for the experiment is further developed. The living room of a standard Dutch row house will be modelled in the form of a test box.

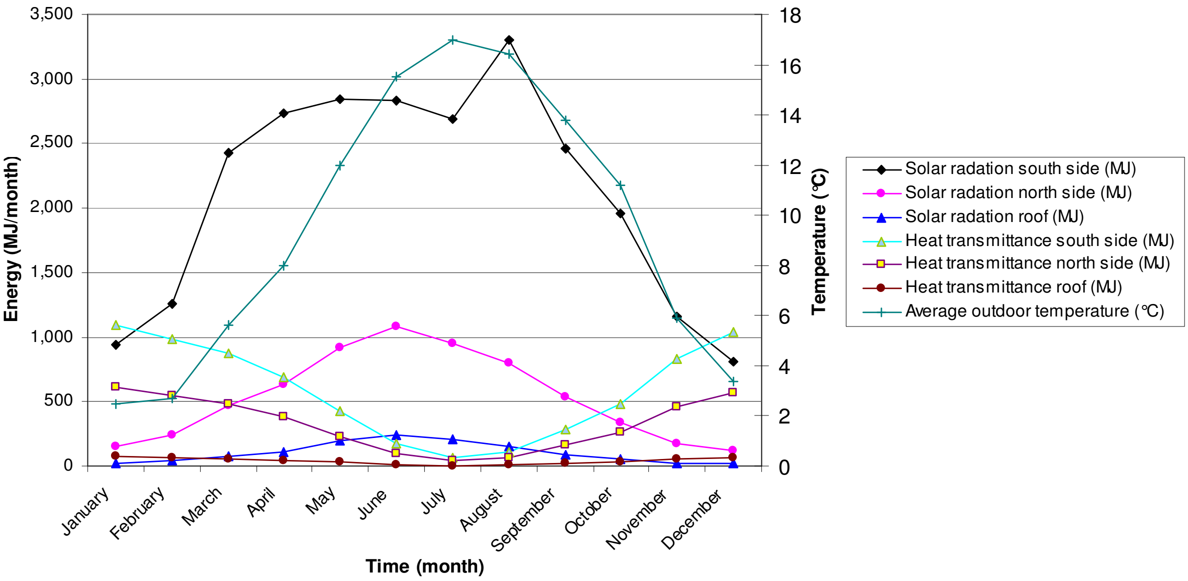

Figure 1 *Accumulated monthly solar radiation and heat transmittance through glazing into a standard Dutch row house (computations are based on NNI, 2004 and SenterNovem, 2006)*

3. Development of the test boxes

In the field of building physics only little research has been published about experiments with test boxes. The use of test boxes for an experimental study of PCM has for example already been described by Kissock et al. (1998). The dimensions of such a box are essential to represent real buildings. In the calculations on the heat capacity of buildings by Nishikawa and Shukuya (1999), the volume of the researched system seemed to be too small. Desta et al. (2005) used in their research on heat phenomena a whole chamber. In this case it was fully constructed out of plexi glass to have a clear view on the ventilation flows. In this paragraph, first the size of the test boxes will be discussed. Secondly, the materials that are involved in constructing the test boxes are addressed.

3.1 Size of test boxes

Because the experimental research has to represent phenomena in real sized houses, the sizing of the test boxes has to be considered. However representative down-scaling of both volumes and surfaces is limited by differences in their scaling factors which are based on resp. cubed and squared relations. The area of surfaces, walls, windows and floors in our test box in relation to the volume of the test box can not represent real(size) houses or living rooms. This will result in a floor surface that is relatively large in relation to the volume of the test box compared to a real size dwelling. This means that the capacity to store heat of a real size living room should be larger than the capacity of the test box. Because of the manageability of the setup, the size of the test field, costs and time restraints, it is obvious that real size testing was not possible and therefore scaling is necessary. The references for the dimensions of the scaled boxes are the living room of the standardized row house of SenterNovem (2006) and the test boxes used by Kissock et al. (1998).

The ground floor of the row house has a surface of 8.92 m by 5.10 m (l × w). The living room takes 26.1 m^2 of the ground floor. The adjacent window in the southern façade of the reference house is 4 m long and 2.4 m high. The internal height of the first floor is 2.6 m. The sizes of the test boxes of Kissock et al. (1998) are 1.22 m x 1.22 m x 0.61 m (l × w × h). To approximate these sizes the test box could be built on a scale of 1 to 5. In that case the size of the test box should be 1.024 m x 1.020 m x 0.520 m (l × w × h). A plastic container with sizes that approaches these dimensions is used as a base for the test boxes (see Figure 2). These dimensions will result in an air volume that is 115 times smaller and a floor surface that is thirty times smaller than the original living room. The impact of this down scaling is expected to be relatively small, because the mass of air and heat capacity per kilogram are low compared to the mass and heat capacity of the floor.

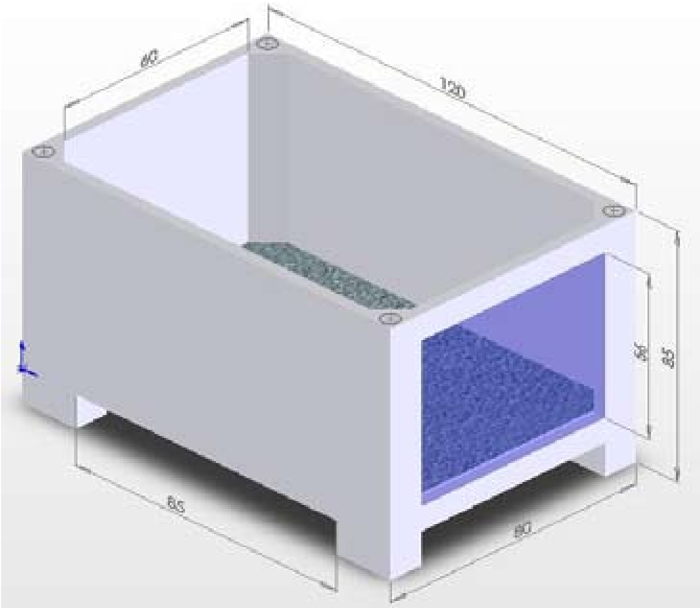

Figure 2 The basis for the test box will be a plastic container (dimensions in cm).

3.2 Materials for the test boxes

The experiment will focus on thermal exergy flows resulting from exposure to solar radiation. The boxes will have at one side a window to let solar energy in. All other sides will be strongly insulated to mimic adiabatic conditions. In this paragraph the materials to construct the test boxes will be specified.

3.2.1 Glazing

The front side of the test box will consist out of 0.36 m^2 glass. Nowadays in Dutch building practice high performance glazing is used with a U-value of approximately 1.2 W/(m^2·K) and a g-value of 0.60. Window frames of wood or plastic have a higher U-value than the glass; approximately 2.4 W/(m^2·K). For windows an overall U-value of 1.8 W/(m^2·K) results (NNI 2004, SenterNovem 2006). The conductivity of the glazing in the test boxes will be 1.1 W/m^2·K and 0.5 W/m^2·K to reflect on the standard Dutch situation and best practice situation. Based on the size of the windows computations on the overall U-values led to 1.3 W/m^2·K and 0.6 W/m^2·K respectively, their glazing have g-values of 0.47 and 0.60 respectively.

3.2.2 Insulation materials

Five sides of the box will consist of a hard insulation material. In this experimental setup fibreglass insulation or mineral wool are not desirable materials, because the homogeneity of the material and a fixed thickness can not be guaranteed after their installation. Furthermore, the heat resistance of these soft materials can unintentionally be lowered by the absorption of rainwater. Therefore a hard and heavy insulation material being cellular glass will be used with a thermal resistance of 3.81 (m^2·K)/W.

In Europe there is a debate on the effectiveness of light insulation products compared to heavy forms of insulation. Our research will contribute to this debate by using also a light form of a homogenous insulation. This product consists of fourteen thin layers of reflective and insulating materials. The producer claims that this product has a R-value of 5.6 (m^2·K)/W, when on both sides a cavity is applied of at least 20 mm deep. The exterior of both types of boxes will be finished by using plywood of 15 mm. They will be painted white, because of its high reflection and low absorptivity.

3.2.3 Phase Change Materials

Sharma et al. (2008) distinguishes three main groups of PCM: organic, inorganic, and eutectic. Within the group of organic PCM there are two different types: paraffin and non-paraffin compounds. In our research a mixture of paraffins in powder form encapsulated in polymethyl methacrylate microcapsules will be used, that has a melting point of 23℃ (BASF, 2005). This micro encapsulated PCM has already been used in gypsum board that is also able to store heat, and that will be used to cover the interior of the test box with exception of the floor and the window frame.

The same micro-encapsulated PCM (Micronal DS 5008 X) will be used to increase the heat capacity of the concrete floor (see Table 1). The amount of PCM in the concrete mixture will firstly be determined by computations on the amount of heat entering and leaving the box. The first target to be set is to avoid temperatures below 0℃. More favourable is a higher target to maintain an indoor temperature of at least

15°C and 25 °C at maximum. Based on local irradiation and temperature data of 2007, the specifications in Table 1, and the dimensions and materials of the box, the concrete floor needs to store at least 3.2 MJ and the PCMs in the concrete floor and gypsum walls needs to store at least 1.4 MJ. This means a floor with a height of 60 mm containing 5 % of encapsulated PCM and 2.7 m^2 of gypsum board having a latent heat of approximately 330 kJ/m² (Knauf, 2006) will be installed.

Table 1 Specifications of the materials involved in the experiment that are able to store heat

	Latent heat capacity (at room temperature)	Specific heat capacity	Bulk density
Concrete	0 KJ/kg	3.3 KJ/(kg·K)	2,400 kg/m^3
PCM	110 KJ/kg	Negligible	250-350 kg/m^3
Gypsum board	0 KJ/m^2	0.85 KJ/(kg·K)	700 kg/m^3
Gypsum board	330 KJ/m^2	1.20 KJ/(kg·K)	770 kg/m^3

Compressive tension tests will demonstrate the impact of this 5 % Micronal on the strength of concrete. It is possible that during the hardening of concrete the Micronal already avoids temperature peaks due to cement hydration heat. This could offer great advantages, when large amounts of concrete are needed. A case (see Fig. 3) was developed to store four concrete cubic moulds during hardening. To approach adiabatic conditions during temperature monitoring this case is closed and well insulated.

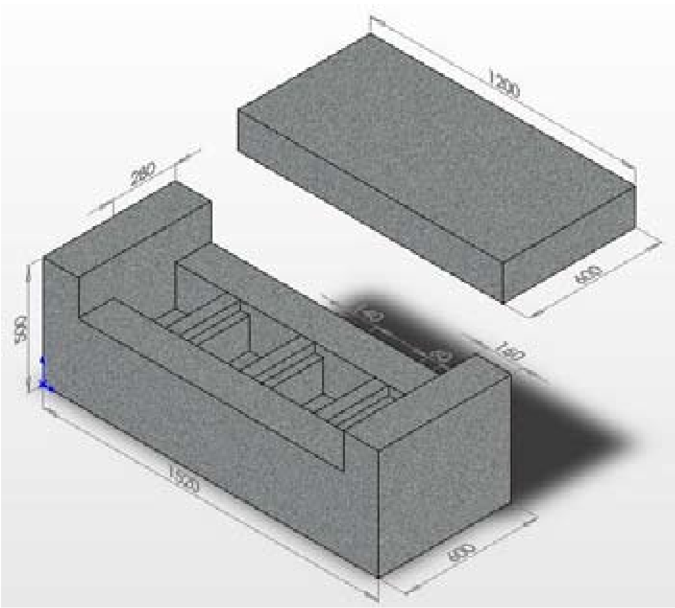

Figure 3 Case to monitor the temperatures of four molds of concrete during hardening (dimensions in mm).

4. Test site

Based on the different materials that need to be tested, four different test boxes will be constructed with the characteristics that are summarized in Table 2. These boxes will be placed outdoors on a test site for a whole year. This enables monitoring of the behaviour of the box and the materials during all seasons. The test site (see Fig. 4) will be located at the Campus of the University of Twente (Enschede, The Netherlands). To give an impression of the solar irradiance at this university Figure 5 shows the daily irradiance on a clear sunny day on different facades of a building. To make sure that there are no obstacles, which can cause shading, the boxes will be placed 2.5 metres above ground level in an open area. A weather station (WS) will be installed behind the boxes to measure the weather conditions.

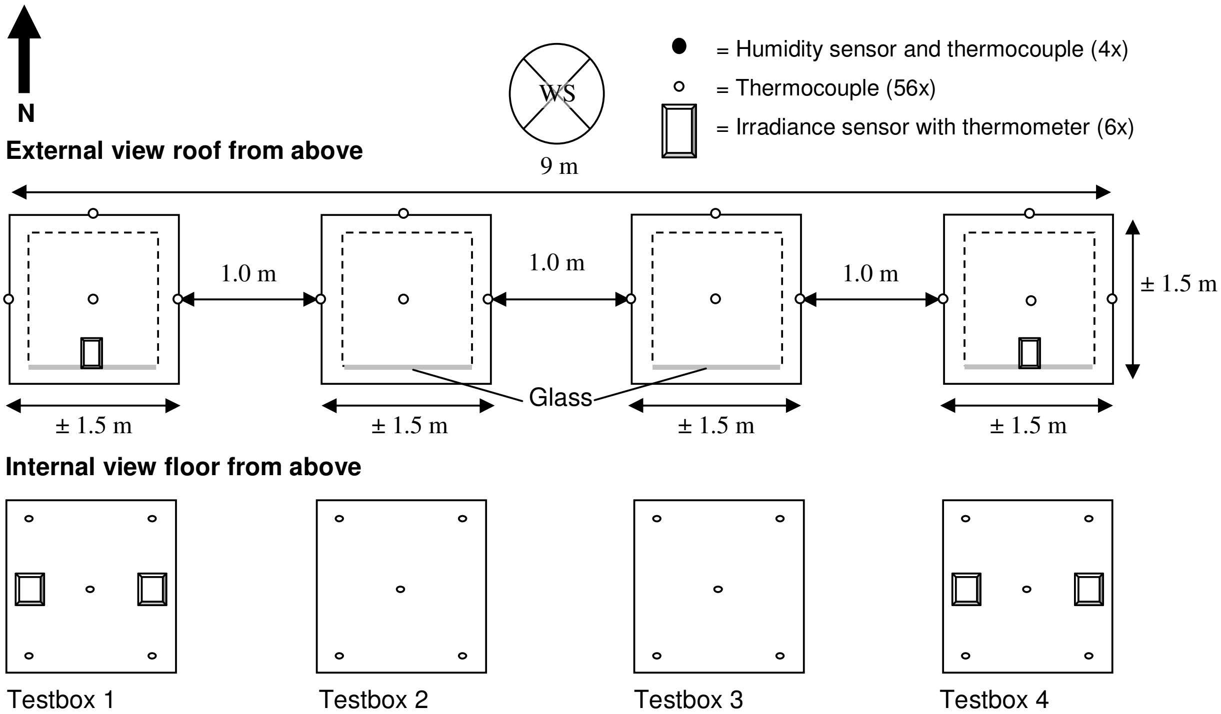

Figure 4 Layout of the test site with an external (roof) and internal (floor) view of the four boxes with their sensors.

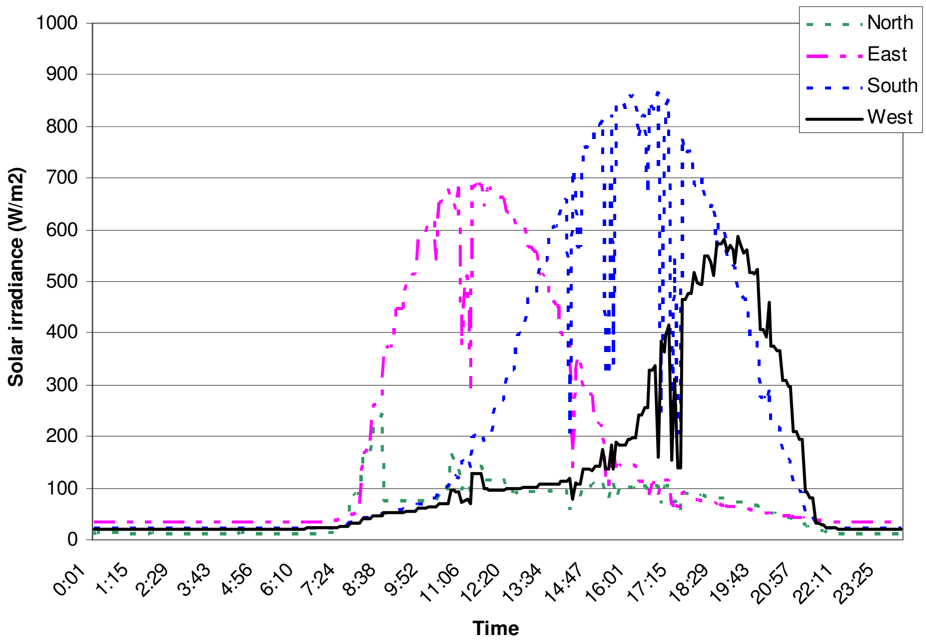

Figure 5 Solar irradiance on a sunny clear day at the four facades of one of the buildings of the University of Twente. Total irradiances are: North 1.41 kWh/m², East 4.39 kWh/m², South 5.57 kWh/m², and West 3.09 kWh/m² (measurements collected on April 26th, 2007).

Table 2 Building physical constitution of the test boxes in the experimental setup

	Testbox 1	Testbox 2	Testbox 3	Testbox 4
Insulation material (thermal resistance)	Cellular glass 3.8 $(m^2 \cdot K)/W$	Cellular glass 3.8 $(m^2 \cdot K)/W$	Light 5.6 $(m^2 \cdot K)/W$	Light 5.6 $(m^2 \cdot K)/W$
Phase Changing Materials in concrete floor (weight percentage)	Present ± 5%	Absent 0%	Present ± 5%	Absent 0%
Thermal resistance glazing (thermal transmittance)	High 1.1 $W/(m^2 \cdot K)$	Low 0.5 $W/(m^2 \cdot K)$	High 1.1 $W/(m^2 \cdot K)$	Low 0.5 $W/(m^2 \cdot K)$

5. Monitoring system

The boxes will be continuously monitored with a sampling interval of 5 minutes. On top of the floor the surface temperature will be measured at five different points. The surface temperature at the underside of the floor will also be measured. Two thermocouples will be located in the middle of both sides, in the middle of the roof and in the middle of the backside. In the middle of the box the humidity degree and temperature are measured. The temperatures at the internal and external sides of the glazing will also be measured. In total twenty thermocouples will be used per box (see Figure 4). Data acquisition will take place by using two USB TC-08 of Pico, two USB 6218 (offering 32 channels each) and two USB 6215 (offering 16 channels each) of National Instruments. Two personal computers will be used to store this data.

All thermocouples will be made out of 400 metres Teflon insulated TX wire. The amount of solar irradiance is measured by six silicon irradiance sensors type Si-01 TC-T of Mencke & Tegtmeyer placed horizontally on top of and within the test boxes. These irradiance sensors each have a sensor to measure their temperature. The humidity of the air inside the boxes will be measured by four A05 Basic Capacitive Humidity Modules with sensor type P14 SMD of LinPicco. The weather conditions are measured by a WS. The weather station is a Vantage Pro 2 of Davis Instruments with thermometer (°C), humidity meter (%), anemometer (m/s and 0° - 360°), and solar sensor (W/m^2).

6. Conclusions and future research

In this paper the use of solar irradiance for saving fossil fuels consumption for residential heating is investigated. Advanced glazing and PCM can offer the necessary storage capacity for heat obtained from solar irradiance.

At this moment strength tests are conducted to determine the appropriate mixture of Micronal with concrete so that construction's strength is not significantly decreased. In the forthcoming months the developed boxes will be put to the test in the open air and data can be collected. The results will give more insights in how buildings can be heated by making use of a passive solar technique. The experiment comprehends different elements, which in former research were considered in stand alone conditions. The interaction between irradiance & window frames, heat & concrete floors and conductivity & insulation are now all brought together in one situation.

In this experiment downscaled models of a living room are used, but future research with real(size) houses could confirm if downscaling is an acceptable method to do this type of experimental research in building physics. In other fields of scientific research this is already common practice.

Acknowledgements

The authors would like to express their gratitude to SenterNovem for providing financial support of the present research. Furthermore, their gratitude goes to Schüco, BASF, Knauf, and Foamglas for providing materials and technical assistance.

Summary

A new cleaning concept has been introduced in the buildings managed by the Norwegian Defense Estates Agency. The aim was to establish cleaning systems, benchmarks and measuring systems that could assure reduced cleaning costs, higher quality of cleaning, reduced environmental load, and improved working environment. The project included analysis of status, establishing a set of benchmarks, development of a new cleaning concept with accompanying tools & systems, and introduction of the concept in buildings. Evaluation of results revealed a "win-win" situation with 27 % reduction in cleaning costs, 86 % reduction in plastic waste, 46 % reduction in use of cleaning chemicals, 40 % reduction in sick leave among the cleaners, 32 % reduction in dust load on surfaces, and satisfied cleaners, users, and customers. Of the remaining chemicals, more than 70 % fulfilled the criteria for the Nordic ecolabel, The Swan. The project was awarded the Norwegian environment prize "The Glass Bear", which was handed out in Oslo by the Norwegian Minister of Environment Protection in May 2006.

1. Introduction

A survey of the environmental impact from professional building cleaning performed in the 4 Nordic countries in 2001 revealed that professional cleaning consumes approximately 73.000 tons of cleaning chemicals annually, whereof 11.000 tons dry matter, 4.500.000 tons of water, 140 million kWh electricity for cleaning machines, and 100.000.000 liters of fossil fuel for transport (Nilsen, 2002). The survey also revealed that cleaning produced annually more than 35.000 tons of waste in the Nordic countries and that 45 % of this waste was from plastic bags for insertion in dustbins.

Cleaning consumes 20-30 % of the facility management budget of Norwegian office buildings, and is often the most costly budget item. Cost reductions are continuously searched for, and can usually be accomplished by introducing more effective cleaning methods (Schneider, Nilsen and Dahl, 1994) together with reduced cleaning frequency. These cleaning methods require a smaller amount of cleaning chemicals and water, and are assumed to be more environmental friendly (Nilsen, Dahl, Jørgensen et al., 2002). On the other hand, reduced cleaning frequencies may result in lower cleaning quality and higher dust load, which increases the risk of Sick Building Syndrome-symptoms (Skov et al., 1987). New tools (Schneider, Løbner, Nilsen et al., 1994; Nilsen, Dahl, Schjønning et al., 2000; Standards Norway, 2000) have made it possible to quantitatively measure cleaning quality, and thereby avoid quality reduction when re-adjusting cleaning systems in buildings (Nilsen, Blom, Rydock, Nersveen and Fostervold 2002).

The Norwegian Defense Estates Agency was established in 2002 as a result of a merger of the facility management organisations for all the properties of the Norwegian Defence and the former Norwegian Defence Construction Services. The vision of the new company was "To make visible all costs related to properties and constructions, and at the same time have focus on the environment and the society". One of the first targets of the new organisation was to reduce cleaning costs, and as a result of this a benchmarking-project called "Best Practice Cleaning" was established. The object of the project was "To establish cleaning systems and benchmarks that can contribute to environmental friendly and cost-effective cleaning of the Defence's buildings". This paper gives a brief summary of the project, which started in 2002 and ended in 2005.

2. Methods

The project was carried out in three steps:

1. Survey of status for cleaning services in the Defence's buildings, compare with other buildings, and develop benchmarks and accompanying measuring system.
2. Develop a new cleaning concept and accompanying tools and support systems.
3. Introduce the new cleaning system in all buildings and measure effects.

2.1 Survey

The survey covered 10 of the Defence's establishments, with a total cleaning area of 340.000 m^2. This represented 20 % of the total cleaning area of the Defence's buildings. Three of the establishments had cleaning services delivered by private cleaning companies. A questionnaire was developed to collect the following data:

- Building related factors: age, maintenance status, traffic load, dirt load, cleanability.
- Cleaning system: frequencies and main methods for regular and periodic cleaning.
- Cleaning time: performance in m^2 cleaned area per hour.
- Cleaning costs: material costs, total costs for regular and periodic cleaning, per m^2 floor surface and year.
- Human resources: number of cleaning personnel, working time, age, length of service, education, turnover, short time and long time sick leave.
- Cleaning quality: visual quality and measurements of dust on surfaces, according to Norwegian Standard NS-INSTA 800 (Standards Norway, 2000).
- Environmental factors: use of 20 kinds of cleaning chemicals, use of plastic bags, both calculated for the year 2001 as mg per m^2 cleaned floor surface, and portion of chemicals with ecolabel in %.
- Internal regulations and quality management system: calculation routines, handbooks for cleaning, quality assurance, trade union agreements.

The results from the survey were compared with other studies as seen below:

- Cleaning costs; survey carried out in 8 comparable buildings in the Oslo area.
- Performance; calculations of average performance in public and private sector carried out by a cleaning consultant as a part of this project.
- Human resources; statistics for sick leave, turnover and education levels for cleaners in public and private sector.
- Cleaning quality; results from measurements in office and school buildings in the Oslo area, carried out by SINTEF Building & Infrastructure and the National Institute of Technology.
- Cleaning system and environmental factors; results from a Nordic survey (Nilsen, 2002), and criteria for the Nordic ecolabel, The Swan, for cleaning services (Nordic Ecolabelling, 2002).

All calculations were done on a spreadsheet.

Based on the results, requirements for the new cleaning concept were developed, and a set of benchmarks were established.

2.2 Development

Step two included the following development activities:

- *Cleaning manual for the new cleaning concept*: 125 documents describing rules and regulations, requirements for cleaning technical products, methods to be used and method descriptions, cleaning surfaces, calculation principles, methods for quality control, and benchmarks and goals.
- *Material standard for cleaning products*: search for products and suppliers, make procurement agreement and select a set of environmental friendly products to be used.

- *Calculation software for cleaning*: develop users' requirements and tender based on this, and select system and supplier.
- *Education program*: develop requirements for an education program targeting three different levels of personnel, develop a tender based on this, and select supplier.
- *Information plan*: develop a plan to inform all customers, users of the premises, and personnel about the new cleaning routines.
- *Standardised tender with requirements, benchmarks, goals, and follow-up routines*: for procurement of cleaning services to be used where external delivery is desired.

2.3 Implementation and evaluation

The implementation process involved carrying out the following activities in all the Defence's establishments:

- Plan new cleaning routines and calculate cleaning time for all the Defence's buildings.
- Select and purchase cleaning materials (chemicals, equipment and machines).
- Carry out an education and information program for more than 800 cleaners, their leaders and their customers, by holding a total of 61 courses.
- Start-up cleaning according to the new concept.

Evaluation of results was carried out after 6 months. Some factors were evaluated again after another year. The evaluation was carried out in 20 of the Defence's establishments and included:

- *Cleaning costs*: total costs for regular and periodic cleaning, per m^2 floor and year, by using the new calculation software.
- *Cleaning quality*: visual quality and measurements of dust on surfaces, acc. to NS-INSTA 800 (Standards Norway, 2000).
- *Environmental factors*: use of chemicals and plastic bags, as described in the criteria of the Nordic ecolabel, The Swan, for cleaning services (Nordic Ecolabelling, 2002).
- *Human resources*: degree of completion of the education program, sick leave.
- *Evaluation of education program*: a questionnaire stating degree of satisfaction from 1–5 (1 = very satisfied), questions answered by all participants after each course.
- *Evaluation of employee satisfaction*: a questionnaire with 7 questions addressing information given, 14 questions addressing the new cleaning concept, and 14 questions addressing the implementation process, answered by all employees, stating degree of satisfaction from 1–5 (1 = very satisfied).
- *Evaluation of customer satisfaction*: a questionnaire with 5 questions addressing information given, 9 questions addressing the new cleaning concept, and 9 questions addressing the quality of the cleaning service, answered by all contact persons for cleaning services at the customers, stating degree of satisfaction from 1–5 (1 = very satisfied).

3. Results

3.1 Step 1 - Survey

Results for cleaning performance compared with average performance in public and private sector can be seen in Table 1.

Table 1 Average cleaning performance in m^2 cleaned area per hour

	Norwegian Defense Estates Agency	Public sector	Private sector
Average	141,5	198,8	261,9
Factor	100	137	185

Cleaning costs were high and showed large variations, see Figure 1. Average cost for internal delivery was NOK 195 per m^2 and year, and the total cleaning cost for all the Defence's buildings was NOK 340 mill. per year. Material costs were only 1,9 % of the total cleaning costs.

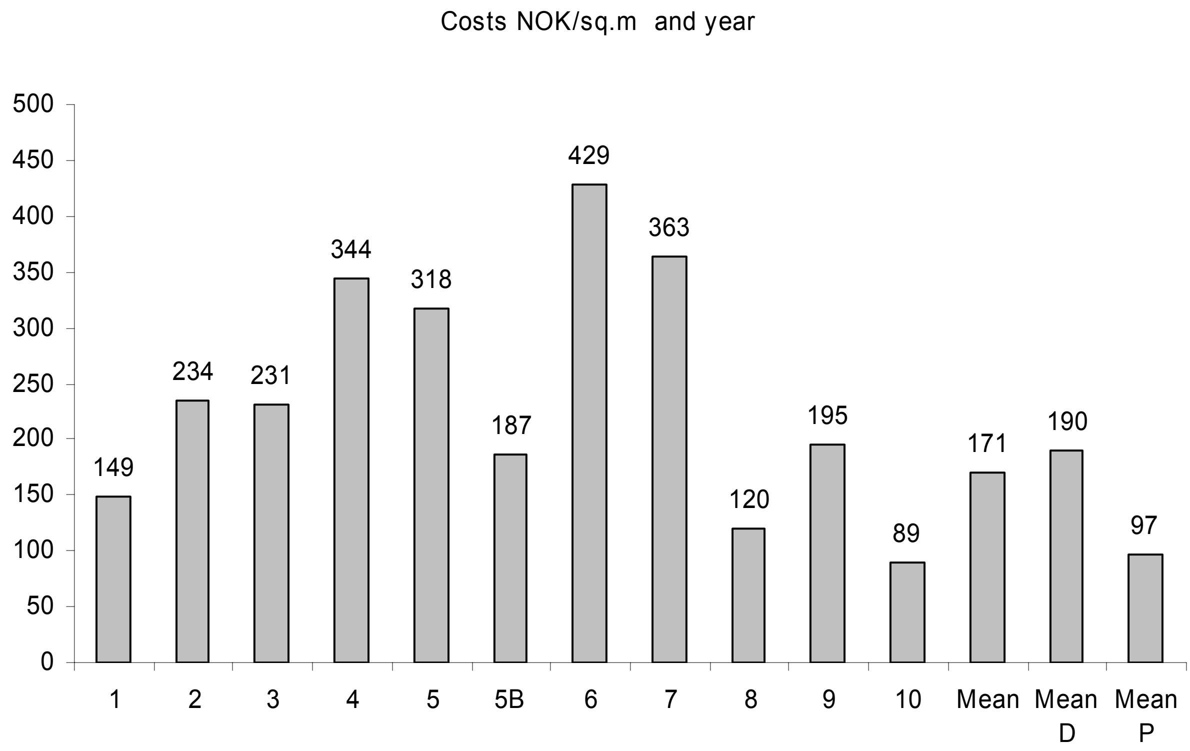

Figure 1 Cleaning costs. Mean D is average costs for internal delivery, Mean P is average costs for external delivery.

Results for human resources are shown in Table 2. The percentage with education in cleaning reflects cleaners with a certificate of completed apprenticeship.

Table 2 Human resources in the 10 establishments surveyed

Number of cleaners	Average age	Average employed	Portion with education in cleaning	Sick leave
215	47 years	18 years	40 %	20 %

The cleaning system was based on programmed cleaning with fixed cleaning methods and frequencies for different surfaces. Quality requirements and follow-up routines were not established. Measurements of cleaning quality revealed high visual quality on furniture and fixtures, walls and ceilings, but low quality on floors. Results from measurements of dust on surfaces in the 10 establishments can be seen in Table 3. Recommended maximum values are based on results from Schneider, Løbner, Nilsen et al. (1994).

Table 3 Dust on surfaces, dust coverage percentage

	Close to person surfaces	Accessible furniture and fixtures	Surfaces above 180 cm	Floors	Average dust load
Average	1,2	1,8	9,7	2,8	3,9
Recom. max.	1,0	1,5	5,0	3,0	2,6

The survey revealed that cleaning was carried out mainly by use of cleaning chemicals and wet or damp cleaning methods. Results from measurements of environmental factors are showed in Table 4. The points given reflect environmental points calculated according to the criteria of the Nordic ecolabel, The Swan, for cleaning services (Nordic Ecolabelling, 2002). Total use of cleaning chemicals was approximately 100 tons, and total use of plastic bags was 20 tons per year.

Table 4 Environmental factors

Property	Value	Points	Max. points given
Dry matter cleaning chemicals, mg pr m^2 cleaned floor	120	2	5
Portion of products with ecolabel	18 %	1	5
Use of plastic bags, mg pr m^2 cleaned floor	151	2	5
TOTALS		5	15

3.2 Step 1 – Develop benchmarks and cleaning concept

Benchmarks and goals for the new cleaning concept are given in Table 5.

Table 5 Benchmarks and goals

Costs	Quality	Environment	Sick leave
Max. NOK 125.- per m^2 and year	Dust-level 4 acc. to NS-INSTA 800	Fulfill the Nordic Swan criteria for cleaning services; min. 9 points	Less than 10 % (for cleaners)

The new cleaning concept was based on the following principles:

- Quality based cleaning system with quality requirements and control routines according to the internordic standard NS-INSTA 800 (Standards Norway, 2000).
- Regular cleaning shall cover all the surfaces up to 3 meters above the floor in all rooms and premises.
- Floor maintenance shall be included in the regular cleaning.
- Periodic cleaning shall only be performed in rooms with fatty deposits or on surfaces higher than 3 meters above the floor.
- Dust and dust depots shall have special attention.
- Cleaning shall be performed without use of water buckets according to the principles of “dryer methods” (Schneider, Nilsen and Dahl, 1994).
- Dustbin bags shall only be changed if contaminated with biological waste.
- The cleaning service shall have focus on the environment in all respects.

3.3 Step 3 - Evaluation

Table 6 shows results from evaluation of cleaning costs, cleaning quality and sick leave after implementation of the new cleaning concept. Visual quality requirements were fulfilled in 79 % of the inspected areas.

Table 6 Results after implementation; costs, quality and sick leave

Average costs	Quality Average dust load	Sick leave
NOK 153.- per m^2 and year (2004) NOK 139.- per m^2 and year (2005)	2,67 % (2004)	14 % (2004) 12 % (2005)

Results for environmental factors can be seen in Table 7. The reduced consumption of cleaning chemicals and plastic bags gave a 50 % reduction in material costs.

Table 7 Results after implementation; environmental factors

Property	Value	Ecolabel points
Dry matter cleaning chemicals, mg per m^2 cleaned floor	65	3
Portion of products with ecolabel	70 %	5
Use of plastic bags, mg pr m^2 cleaned floor	21	5
TOTALS		13

Results from evaluation of education program, employee satisfaction and customer satisfaction can be seen in Table 8. The table shows average score for the questions asked, on a scale from 1–5 (1 = very satisfied).

Table 8 Evaluation of education program, employee satisfaction and customer satisfaction

Factor	Average score
Education program:	
Course 1	2,0
Course 2	1,5
Course 3	1,5
Employee satisfaction	2,0
Customer satisfaction	1,9

4. Discussion

The survey carried out in Step 1 revealed that the cleaning costs for buildings cleaned by the Defence's own cleaners (internal delivery) were almost twice as high as the average costs for the 8 comparable buildings. This was caused by an old trade union agreement which limited cleaning performance to an average of 141,5 m^2 per hour. There was no correlation between cleaning methods used and cleaning costs, showing that there was a great need to introduce new calculation routines. Costs for cleaning delivered by cleaning contractors were at the same level as costs in 5 comparable buildings in the Oslo area. The contractors used mainly methods following the principles of "dryer methods" (Schneider, Nilsen and Dahl, 1994).

The cleaning personnel of the Norwegian Defence were very experienced and had long service time and high level of education compared to cleaners employed by contractors. Only 15 % of the cleaners employed by the two contractors had certificate for completed apprenticeship. The premises for introduction of a new cleaning system in the Defence's organization were therefore good.

The sick leave was high both among the Defence's and the contractor's personnel, and the sick leave was high compared to other professions. Statistics from Statistics Norway showed an average sick leave in Norway of 8 % for the first quarter of 2002.

Visual measurements of cleaning quality showed low quality on floors despite of dust measurements showing low levels of dust on floor. Low visual quality was caused by lack of cleaning related maintenance of the floors. Requirements established for visual cleaning quality for the new cleaning system was only fulfilled by one of the establishments surveyed in Step 1. Dust coverage was higher than recommended levels (Schneider, Løbner, Nilsen et al., 1994) on all surfaces except floors. High levels of dust on surfaces can have negative effects on sick leave among the users of the building and thereby affect the productivity and overall economy of the company (Nilsen, Blom, Rydock, Nersveen and Fostervold, 2002).

Results from measurements of environmental factors in Step 1 revealed high chemical load and waste load. Results from a survey performed in 8 Nordic cleaning companies in 2001 (Nilsen, 2002) can be seen in Table 9.

Table 9 Results from a Nordic survey of the environmental impact from professional building cleaning (Nilsen, 2002)

Property	Result
Dry matter cleaning chemicals, average	55 mg pr m^2 cleaned floor
Lowest / highest	24 / 198
Portion of products with ecolabel, average	37 %
Lowest / highest	16 % / 66 %
Use of plastic bags, average	127 mg pr m^2 cleaned floor
Lowest / highest	11 / 228

Only one of the companies surveyed in 2001 had higher chemical consumption than the 120 mg pr m^2 cleaned floor found for the Defence's establishments. Six of the companies surveyed had a higher portion of products with ecolabel than 18 %. Only one of the companies had higher result for use of plastic bags than the 151 mg pr m^2 cleaned floor found for the Defence's establishments.

Evaluation of the implementation process showed very good results both for the education program, employee satisfaction and customer satisfaction.

Evaluation of the benchmarks after implementation of the new cleaning concept revealed large reductions in cleaning costs, sick leave, environmental load, and dust load, and large improvements in cleaning quality. A summary for some of the factors can be seen in Figure 2. The benchmark for costs for internal delivery of cleanings services was not reached in 2004, but further reduction was achieved in 2005, and the estimate for 2008 is NOK 118.- per m^2 and year. The result for 2005 gave a total reduction in cleaning costs compared to 2002 of approximately NOK 50 mill.

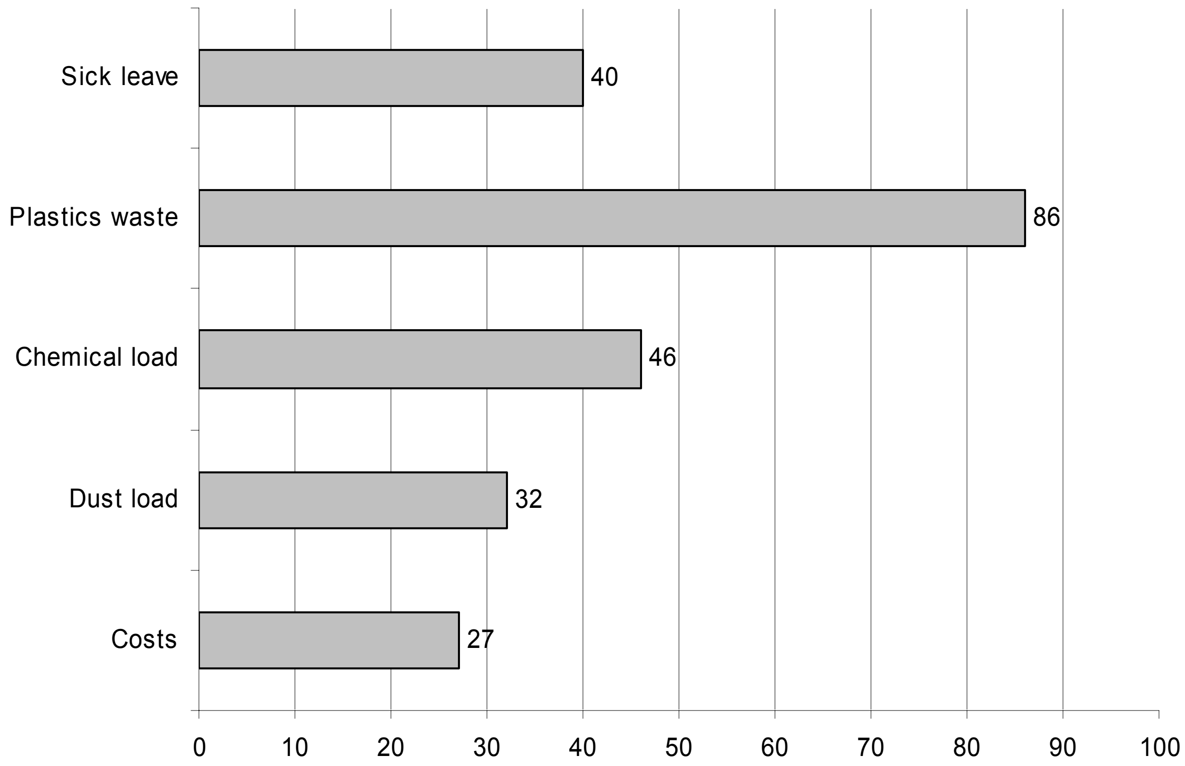

Figure 2 *Reductions in cleaning costs, environmental load, dust load and sick leave, in percent after implementation of the new cleaning concept. Figures for sick leave and costs are from 2005.*

The benchmark for cleaning quality was fulfilled in 73 % of the buildings surveyed, but the average dust load for all buildings was somewhat higher than the maximum level given in the benchmark. This was caused by high results in one of the establishments surveyed.

The benchmark for sick leave was not reached in 2004, but the survey from 2005 showed further improvements.

The benchmark for environmental factors was reached in 90 % of the establishments, and the total result was very good and better than for the 8 Nordic cleaning companies surveyed in 2001 (Nilsen, 2002). The minimum requirement of 9 environmental points was reached with good margin. The new cleaning concept gave a reduction in consumption of cleaning chemicals of 46.000 kg/year and reduction in consumption of plastic bags of 17.800 kg/year.

5. Conclusion

The project showed that introduction of a new and modern cleaning concept in buildings can give large environmental improvements. In addition, other cleaning factors can be greatly improved. Introduction of the new cleaning concept “Best Practice Cleaning” in all of the Norwegian Defence’s buildings revealed a “win-win” situation with 27 % reduction in cleaning costs, 86 % reduction in plastic waste, 46 % reduction in use of cleaning chemicals, 40 % reduction in sick leave among the cleaners, 32 % reduction in dust load on surfaces, and satisfied cleaners, users, and customers. The project was awarded the Norwegian environment prize “The Glass Bear”, which was handed out in Oslo by the Norwegian Minister of Environment Protection in May 2006.

TITLE: CONNECTED, VIABLE, LIVEABLE - THE FACILITIES MANAGERS' ROLE IN DELIVERING BUILT ENVIRONMENTS

Ian KENNEDY,
Regional Facilities Manager[1]
Member, FMA[2]

[1] Brookfield Multiplex Group Limited, Multiplex Services Division, Level 12, Al Attar Business Tower, Dubai
[2] Facilities Management Association of Australia

Keywords: facilities management, sustainable built environment, sustainable building management

Summary

Building performance and design rating tools have helped the property industry evaluate an asset's performance capability. Their proliferation and promotion have offered a range of yardsticks for efficient design, but not without some confusion in the market place, especially as new building performance technologies continually supersede current best practice, locally and internationally. These tools have also mainly concentrated on rating the design principles to obtain efficiencies for *new* buildings, creating a presumption that all such buildings will be managed at an optimum design level.

This preoccupation with the 'new' has overshadowed the property industry's appreciation of gains available from effective management of the *existing* building stock. Whilst a building can be designed with improved technology, it is the expertise and capability of onsite facility teams who are best placed to realise the optimum performance efficiency of that building in a dynamic operating environment.

This presentation will explore two case studies which demonstrate the importance of the facility manager in delivering performance improvements: The KPMG Building in Sydney, with a 4.5 star Australian Building Greenhouse Rating (ABGR) Design Rating, now operating at 5 star ABGR; and the Jesse Street Centre, Parramatta, a building over 20 years old, currently undergoing major refurbishment which has incorporated significant energy and water savings, as a direct result of prudent asset management.

1.0 Introduction

Brookfield Multiplex Services (formerly Multiplex Facilities Management) is pleased to submit a nomination to the World sb08 Conference to be held at the Melbourne Convention Centre, Melbourne.

This paper proposes the importance of the Facilities Management Team in delivering a connected, viable, liveable built environment. Our first case study is on the KPMG Tower facilities team and their efforts ensure the KPMG building (located at Shelley Street, King Street Wharf Precinct, Sydney) achieved its design rating of 4.5 Stars under the Australian Building Greenhouse Rating Scheme (ABGR). Such was the effort, the team successfully improved the building's performance in November 2006 to a 5 Star ABGR rating. The second case study is on the Jessie Street Centre, located in the Parramatta CBD. Efforts from the facilities management team here led to not only improving the performance of an almost twenty year old building, but also provide valuable data for the retrofit to the building's major plant and equipment, commencing in 2007 with a final completion programmed for September 2008. Both case studies are viewed specifically from an energy efficiency measurement, although it should be recognised the facility teams consider all aspects of operating buildings in the most environmentally efficient way.

What is a facility management team? The definition according to the Facilities Management Association of Australia (FMA) is,

"a business practice that optimises people, process, assets and the work environment to support the delivery of the organisations business objective"

'Facilities' can therefore include buildings, properties and major infrastructure; collectively referred to as the "Built Environment".

The primary function of Facilities Management Teams (FMT) is to manage and maintain the efficient operation of facilities on behalf of users. This includes:

- Effective management of the organisation's built assets
- Ensuring services are delivered in a way that contributes to the productivity and profitability of the building's occupants
- Reducing environmental impacts
- Minimising life cycle costs, with repair and maintenance strategies
- Delivering business continuity through sustainable management practices

In Australia, there is a growing expectation about better managing and adapting to the risks of climate change. Australian corporations are increasingly being asked by institutional investors about their awareness and preparedness to manage the business risks of climate change. As part of that process, more businesses are taking steps to review and minimise their operating impact on the environment. In the Australian office market, the flow-on effect is the reframing of building robustness to more extreme weather events, as well as desired occupancy requirements, recognising the value of environmentally friendly work spaces that are not only energy efficient, but provide comfort and quality for a more productive workforce.

Supporting this move is a range of building performance and design rating tools, to help owners understand and evaluate the extent of an asset's energy efficiency capability. A key rating tool for building energy performance is Australian Building Greenhouse Rating (ABGR) Scheme, which measures from one to five stars, with the five stars rating as the highest or most efficient performance. The rating is based on actual energy consumed by a building over a calendar year. The rating reflects the way energy is managed during building operation as well as the efficiency of the building design. To assist Australian building owners and tenants benchmark their greenhouse performance, government agencies have implemented ABGR - now incorporated into the National Australian Built Environment Rating Scheme (NABERS).

Buildings account for a significant proportion of environmental impacts. The OECD has estimated that world wide; buildings consume 32% of the world's resources, including 12% of water use[i]. In Australia, the building industry which includes the residential and non-residential sectors comprises almost a quarter of the (23%) of the nation's greenhouse gas emissions (GHG)[ii]. The non-residential sector alone emits an estimated 10% of GHG in 2005, equal to approximately $130tCO_{2\text{-}e}$ of GHG (CIE 2007) largely through consumption of electricity used to operate the buildings.

It should be emphasised that whilst a building can be designed with improved technology for a high energy efficiency operation, it is the expertise and capability of the onsite facility teams operating the building who are best placed to realise the delivery of optimum performance efficiency of that building.

It is estimated existing Australian building stock, comprises 98% 'older' buildings and 2% being new stock[iii], the latter, designed with the consideration to building efficiencies in plant and equipment and green practices to limit the impact on the environmental resource use. Further, an estimated 61% of the energy used in the commercial sector buildings coming from the base building activities, with the remaining 39% generated from tenant lighting and power requirements[iv]. There cannot be more compelling statistics reinforcing the importance of a facility management team, who can directly impact on building operating efficiency by effectively managing the base building activities.

It is therefore imperative for an onsite team to be appropriately skilled and empowered to successfully deliver a building's optimum performance, to ensure all functions are managed to best practice.

"*Best practice energy efficiency can be defined as using the best available technology and methods to achieve the highest level of energy efficiency and management*"[v]

The attainment of 'Best Practice' in energy efficiency can be verified in this instance by the benchmarking environmental metrics like electricity and gas use and working to deliver progressive, targeted improvements from a clear baseline.

2.0 Case Study – KPMG Building, Sydney

The KPMG Tower was developed, designed, constructed and is now managed by the Services Division of the now Brookfield Multiplex Group, who are also part owner. The development comprises the North Tower on site 6 within the King Street Wharf Precinct. It provides a total of 27,722 m2 of 'A' grade office space in a tower comprising 15 levels, with four levels of underground car parking.

Brookfield Multiplex Group entered into an agreement with the NSW Department of Energy, Utilities and Sustainability to deliver a 4.5 Star ABGR rated conventional office building prior to construction commencing. The Base Building 4.5 Star rating was achieved in July 2005, 12 months after construction was completed.

The Facility Management Agreement provided for a fixed-cost solution for a majority of controllable outgoings, as well as risk transfer from the client to Brookfield Multiplex Services Division. The risk transfer features included responsibility for the capital replacement risk on building services.

The Facilities Management comprehensive responsibilities included conventional air conditioning system (chillers, Variable Air Volume controllers, pumps and cooling towers), ventilation, fire protection, lifts, pest control, building automation and energy management systems, repairs and maintenance, common area cleaning, security and access control, loading dock administration and management.

Brookfield Multiplex Group's 'integrated property model', that being, design, build, own, manage was key to Multiplex FM working with the Construction Division at the design stage and providing advice on core plant and infrastructure.

The result was a building design that had consideration to the long term maintenance and operating requirements at the beginning of the project, and continuation to the end of the construction phase, rather than the facilities service provider being handed a completed project with the initial capital cost of construction being the major driver towards completing the project.

2.1 Design principles employed at KPMG Tower

- Generally open floor layout
- Central Plant
- Conventional VAV air handling system
- Zoned control of the air handling system
- Electric re-heat
- T5 lighting to tenant areas
- Sun shades in varying concentration to the east, north and western faces of the building
- Perimeter light sensors
- Motion detectors for after hours corridor & toilet lighting

The above design criteria are less technologically advanced than some of the modern commercial buildings where chilled beam technology or cogeneration plant has been installed.

The ability of the KPMG Facility Team to firstly deliver the 4.5 Star design rating and secondly obtain the 5 Star ABGR rating was very much reliant on the commitment to energy efficiency and support from all stakeholders within the project:

- Developer Commitment Agreement
- Builder Design and construct in accordance with actual ABGR
- Managers Contractual Energy & Service Responsibility
- Owners Continued Commitment and Agreement Process
- Tenants Parallel commitment to energy conservation

2.2 How was the 5 Star ABGR rating achieved?

Our facilities management strategy for KPMG Tower included the following principles in respect to sustainability and energy efficiency. We employed:

- Accurate Modelling for the Design parameters
- Efficient Design which included installation of external shading systems to reduce the thermal
- impact on the building fabric, while allowing harvesting natural light to reduce the need of artificial reliance;
- Quality installation that meet the design criteria for example the installation of T5 energy efficient
- lighting throughout the tenancy areas and incorporated with this after hour zonings for minimum demand;
- Rigid Control of HVAC system, which included a building management control system which allows real time differential energy metering;
- Effective Management
- Staff with the right technical capability;
- Understand the building design and its relationship to ABGR Scheme;
- Determine where the energy is best used, ensuring measurements are in place, making operational changes based on verifiable data, and continuing to review the results periodically to modify the strategy where necessary;
- Passion for efficient energy management.

The KPMG Facilities Team were able to determine through the monitoring of the energy consumption within the Tower and the performance of individual plant and equipment the key areas to concentrate there efforts to make the greatest gains in reducing the energy consumption.

The main area of concentration was the HVAC system. The gains in energy reduction here have included monitoring operations of the main plant using the Building Management Control System (BMCS), by manually verifying the systems performance and adjusting original design set points, with tenant agreement.

The major gains identified during the twelve months between the initial 4.5 Star rating and gaining the 5 Star rating relate to reducing the chilled water requirements in summer and the heating requirements in winter. One of the key successful strategies was greater use of natural ventilation, modifying the temperature set points to reduce the need for the main air conditioning plant to come into play and relying more on the supply and exhaust ventilation systems, by changing the building purge cycles in summer to reduce the stored heat, and conversely making use of this stored thermal energy in winter to reduce the need to call on supplementary heating.

The Tower has been able to maintain 100% economy mode for the air conditioning system throughout the year, and, combined with the or enthalpy sensors, both exhaust and supply ventilation is used to 100% efficiency.

The resultant reduction in energy can be directly related to the actions of the Facilities Team efforts to manage the Tower services and equipment efficiently. The direct measure of their success can be demonstrated when the achievement of the 4.5 Star is considered the baseline of the buildings energy performance at 366MJ/m^2 p.a. and the achievement of the 5 Star ABGR Base Building rating at the improved energy consumption 347MJ/m^2 p.a. a saving of 19MJ/m2 p.a., or 5.5% reduction per annum.

The following results indicate the continued reduction in the energy consumption from 2004 up to 2008 which equates to a financial saving of approximately $33,648.

	March 04 – Feb 05	March 05 – Feb 06	March 06 – Feb 07	March 07 – Feb 08
Operating Hrs p/wk	54.1301281	54.81192308	54.717	55
Electricity per 12 mths (kWh)	2,772,067.861	2,428,729.16	2,451,702.89	2,397,809
Gas per 12 mths (MJ)	474,493.3794	423,295.35	453,799.22	426,814.88

- Kg CO_2/m^2/annum 83 - 74
- ABGR (Based on Calculator) 4.5

This saving represented a reduction in outgoings and a direct reduction for the tenant, achieved with consultation with the tenant and the owners, to ensure the contractual lease arrangements between the owner and the tenant were not jeopardised and the occupants comfort levels not reduced.

Table 1 below, indicates the environmental performance of the KPMG building using three data streams, electricity, gas and water across the operating years to date, and has a comparison from the building industry as a benchmark to verify both the success of the KPMG facility team and an efficient building and the resultant efforts of other facility management teams during the same period. It can be noted that water used in large commercial buildings can also be used as an indicator for energy use also due to the electrical infrastructure involved in the supply of this commodity, and from Table 1, it can be noted the performance in 2006 was energy increased, as there was an extraordinary high use of water during that period.

Table 1 KPMG Building Consumption Data 2004-2007: Industry Comparison

Electricity Consumption	2004	2005	2006	2007
Electricity per 12 months (kWh)	2,741,620	2,476,999	2,423,789	2,341,459
Consumption Intensity (kWh/m2)	98.89	89.35	87.4	84.4
Industry portfolio average (kWh/m2)vi	135	123	116	108

Water Consumption	2004	2005	2006	2007
Water per 12 months (kL)	41,947	28,041	38,872	30,395
Consumption Intensity (kL/m2)	1.49	1.00	1.38	1.08
Industry portfolio average (kL/m2)	1.12	1.01	0.08	0.77
Brookfield Multiplex average (kL/m2)	1.09	1.18	1.21	0.93

Natural Gas Consumption	2004	2005	2006	2007
Gas per 12 months (MJ)	474,493.3794	423,295.35	453,799.22	426,814.88
Consumption Intensity (MJ/m2)	16.36	15.26	16.3	15.3
Industry portfolio average (MJ/m2)	139	121	87	82

3.0 Case Study - Jessie Street Centre

Jessie Street Centre comprises of a 20-storey freestanding commercial office complex (circa 1988), comprising a single level of basement parking for approximately 342 vehicles, ground floor retail and office tower. The complex also includes two low-rise office wings (North and South) and a magnificent five level-vaulted atrium that links the south wing with the high rise tower. The north wing is stepped from George Street and rises to seven levels while the south wing fronts Macquarie Street.

The Jessie Street Centre provides office accommodation with the following services:

- The Property Service Centre – who is the point of contact for tenants with building service requests, operating 24 hours a day, seven days a week.
- Ground Floor concierge providing security and direction during working days between the hours of 6.00am and 6.00pm.
- 24 hour on-site security.
- 24 hour building access.
- Loading dock attendant providing loading dock services during working days between the hours of 7.00am and 5.00pm.

- A separate goods lift and loading dock facilities.
- After hours air-conditioning is available on a floor by floor basis.
- Emergency power back up for all essential services.
- In-house maintenance staff.
- On-site day cleaner available on working days between the hours of 7.30am and 5.00pm.

The Jessie Street Centre comprises a net lettable area of 54,336m².

Brookfield Multiplex Services provided property management and facilities management to the buildings base building services since 2005. The building can be described as of conventional design for the period, with centralised core, columns supporting each floor level with major chillers and plant rooms servicing indoor air quality and space condition, and building management control software to control the HVAC system.

The original Property Management Agreement provided a management contract with all costs recoverable from tenants and the management fee reviewed against the industry benchmark. The agreement included the facility management responsibility to manage the base building services including, air conditioning system (HVAC), ventilation, fire protection, lifts, pest control, building automation, repairs and maintenance, common area and tenancy cleaning, landscaping and access control.

A key part of the original transition plan and on-going building management was to gather data on the ongoing operations of the building which included a number of environmental metrics, with the focus on electricity, gas and water use. Table 2 represents the data between the commencement of management in 2005 to date, excluding the 2007 data. At the time of writing, the normalised results based on the difference between the retrofit activities to the Jessie Street Centre commencing during this period, and the normal operations were still being compiled and not available.

Table 2 Jessie Street: Consumption Data

Electricity Consumption	2004	2005	2006	2007
Electricity per 12 months (kWh)		6,994,940	6,817,814	
Consumption Intensity (kWh/m^2)		130	126	
Industry portfolio average (kWh/m^2)[1]	135	123	116	108

Water Consumption	-	2005	2006	2007
Water per 12 months (kL)		61,688.0	68,099.9	52,435.3
Consumption Intensity (kL/m^2)		1.25	1.13	0.91
Industry portfolio average (kL/m^2)	1.12	1.01	0.08	0.77

Natural Gas Consumption	2004	2005	2006	2007
Gas per 12 months (MJh)		4,355,978	4,297,486	
Consumption Intensity (MJ/m^2)		80.1	79.8	
Industry portfolio average (MJ/m^2)	139	121	87	82

To obtain energy data, consumption was metered within areas to determine the actual performance of individual plant and equipment. With the availability of hard data, operational changes could be made, and continuing review of results undertaken to identify areas of improvement and modify the management strategy.

Areas where improvements were identified included the BMCS operation, performance of the major plant and equipment, lighting controls and hardware. Further improvements to amenities were also considered, with efficiency initiatives around water consumption including the trialling of waterless urinals. The resultant works and investigations delivered the data helped form the basis of the business case to prepare a retrofit project. This has involved working in conjunction with tenants to deliver a major upgrade of the building to a PCA 'A' grade standard and improve the baseline ABGR 3.5 Star rating to a targeted ABGR of 4.5 stars which is currently in progress.

Close liaison with tenants and owners is required to ensure the floor by floor work program occurs seamlessly and with minimal interruption to the tenants operations.

The project scope includes a major upgrade of the base building amenities, lifts, lighting, facade window treatment to reduce thermal inflow, BMCS and HVAC system which has been integrated with the tenant's fit out. The latest technology is being utilised to improve the building ABGR performance to 4.5 stars.

The future Contracting Model being employed across the portfolio includes the on-site facility team supported by region-based Operations Manager and shared service centres. Performance is monitored and reported against a comprehensive regime of key performance indicators (KPI) at the building level. These KPIs include environmental initiatives, which can also form part of the carbon emissions reporting at a corporate level.

4.0 Financial and Community Value

If as estimated by the Department of Climate Change, stationary energy is estimated to contribute 50% of $C0_2$ emissions[vii] towards global warming in Australia, then initiatives to reduce the energy consumption for the commercial office space are critical contributions to the overall domestic greenhouse gas emission reduction targets.

The potential efficiency impact can be compared on average, to a medium-sized 6 cylinder car traveling 20,000kms per year emits 6.4 tonnes $C0_2$ per year[viii]

The resultant reduction of greenhouse gas emitted yearly when the KPMG Tower facilities team went beyond the 4.5 star ABGR design rating in November of 2006 to achieve the 5 Star ABGR equated to a saving of 291462 kgCO_2/year, or the equivalent to removing 45 medium sized vehicles per year off our roads.

The KPMG Facilities Management Team is evaluating a number of future initiatives including upgrading a number of the base building lighting elements to the T5 efficiency globes. It should however be noted the team takes into consideration the embodied energy already expended in the relatively new equipment installed, against the energy saving that retrofitting equipment with new updated technology will deliver as one part of the decision making process.

Further energy reductions are expected, as both the KPMG and Jessie Street Centre facility teams work through assessing the performance of smaller plant items.

Non-energy related initiatives also being considered at the moment by the team include water reductions and waste minimization, both of which will again, ultimately require the cooperation of the tenant.

5.0 Conclusion

In summary, facility management teams have a number of initiatives available to reduce the impact that the existing built environment has on production of carbon emissions. A key tool is the preparation and implementation of sustainable building management plans.

Developing these plans involves data collection of a range of environmental metrics (electricity, gas, water, waste streams, HVAC leakage and fuel used); determining the baseline data and monitoring against that baseline, rectifying building performance loss identified by variances to the baseline and setting the appropriate reduction targets. Other key areas are conducting audits, performing a re-commissioning of the buildings' major HVAC and control equipment at regular intervals, and conducting indoor air quality audits, especially important when you consider indoor air quality can significantly affect human health, given people tend to spend 90% of their time indoors[ix].

A facility team is also on hand to provide awareness and training programs for the building occupants. This should ideally include preparation of a building users guide, induction packages, fit out guidelines and providing graphical performance data on the environmental measures regularly to the occupants. Successful on-site engagement, includes a communication loop back to the facility team on issues and potential reasons for a variance to baseline data. On site facility teams can also have a positive influencing effect to other building users, tenants, and building visitors.

Whilst a building can be designed with improved technology for a high energy efficiency operation, it is the expertise and capability of on onsite facility teams who are best placed to realise the optimum performance efficiency of that building. The asset owner/manager who has foreshadowed the need for front-end investment to deliver efficient operations across the built assets will need assurance the asset is being managed to its optimum, but must be prepared to take a longer term view on payback, or make a calculated risk weigh against potential obsolescence and ultimately erosion of capitalisation value as a domestic price on carbon is identified within the next two to three years.

The intent is to manage future risks, market perception, operating costs, carbon emissions. All of these elements will have an effect on the value of the asset and therefore the bottom line. At a tactical level, the facility management teams will be key to ensuring older building stock can be efficiently managed. Without enlightened operational expertise, the potential for an existing building to actually realise measurable energy efficiency and reduced operating costs becomes somewhat academic.

The case studies outlined above pro vide a snapshot of the benefits of expertise, capability and dedication of the onsite facility teams. With their expertise, a conventional older office building can also be managed to deliver both dollar savings and energy efficiency, without unduly compromising occupant comfort. There is still more to be done, but the future for opportunities in smarter tactical innovations becomes all the more exciting.

WHAT ENCOURAGE CLIENTS AND CONTRACTORS TO TAKE COMMON ACTION ON SUSTAINABLE ISSUES?

Karin JOHANSSON MSc[1]
Pernilla GLUCH Ph.D[2]

[1] NCC Construction Sweden and Building Economics and Management, dep of Civil and Environmental Engineering, Chalmers University of Technology, Gothenburg, Sweden, karin.mh.johansson@ncc.se
[2] Building Economics and Management, dep of Civil and Environmental Engineering, Chalmers University of Technology, Gothenburg, Sweden, pernilla.gluch@chalmers.se

Keywords: Sustainable building, Environmental Management, Barriers for environmental performance, Incentives, Sweden

Summary

This paper identifies incentives and barriers for future development of sustainable building practice in Sweden out of three perspectives. The first concerns *business advantages* from increased environmental work in construction and property management companies. The second concerns *how environmental action is legitimated and controlled* within these organizations. The third focuses on cooperation and interrelation between them in their relation as *client and contractor in construction projects*. The results are based on a questionnaire survey and an interview study with environmental managers in companies with more than 50 employees.

It is shown that although environmental managers have knowledge to influence strategic decisions their actual influence is constrained by a predominating cost and time efficient culture. In addition, environmental managers perceive that their organisation have too limited control over the market to make a difference as a whole. Notwithstanding, there seem to be a lack of interest for deeper interaction between clients and contactors. In fact both parties, as profitable organisations, experience few business benefits from undertaking an active environmental work. As a key for improved environmental performance in the Swedish building industry it is suggested that companies need to start cooperate more widely and on a long-termed basis.

1. Introduction

Over the last two decades the Swedish building industry has made much effort to develop sustainable building practices. Researchers within the field have provided theoretical knowledge on how to design green buildings and environmental management tools have been developed to guide the practitioners (Gluch, 2005). Nevertheless, the building sector at large is still using similar building techniques and materials as before and green building projects are viewed as one-off experiments (Femenías, 2004).

Development of managerial environmental tools and practices necessitates an understanding of how environmental issues are dealt with in organizations. Resent research show that many environmental managers struggle and devote much time to construct new communicative structures of meaning that objectify, reify, legitimize, and institutionalize corporate environmental management (Meima, 2002). For instance, this is reflected in that environmental managers within both construction and property management companies often experience a conflict of interest. A conflict where they have to middle between their own beliefs based on experience-like knowledge and on weak environmental interest. This weak environmental interest within organizations has been shown in studies to have a strong relation with the interest to finish the project with as little interruptions as possible (Gluch, 2006). There is however a tendency that environmental management techniques and managerial aspects, such as organizational and behavioural aspects, have been handled separately, both by researchers and by practitioners (Baumann, 2004).

This paper identifies incentives and barriers for future development of sustainable building practice in Sweden out of three perspectives. The first concerns *business advantages* from increased environmental work in construction companies and in property management companies. The second concerns *how environmental action is legitimated and controlled* within these organizations. The third focuses on cooperation and interrelation between especially these two parties as *client and contractor in construction projects*. The objective is to provide environmental professionals (such as environmental managers and coordinators) support on how they in their daily work can increase the understanding and knowledge of environmental issues in construction projects. Therefore this paper provides suggestions on measures that improve and strengthen both intra-organisational and inter-organisational cooperation and interaction. To reach the aim, attitudes towards environmental management issues related to environmental impact and strategic decision making are explored through a questionnaire survey and through an interview study.

2. Environmental and project management practices in the Swedish building industry

In her review of environmental management in the construction industry Gluch (2005) found a large amount of methods, techniques and tools, suggested for the management of the sector's environmental problems. Today, many of the companies within the building sector (73%) have developed an environmental management system (Gluch et al, 2007). According to the same study also more than half of them have chosen to certify their environmental management system, where ISO 14001 has shown to be the preferred certification system. A study of the corporate value of an ISO-certification during a tendering process, made by Carrick *et al* (2006), showed that the certification logotype, as an artefact, was used to create an image based on visual impressions rather than on actual performance. According to Schein (2004), it is dangerous to try to infer deeper assumptions from artefacts alone since one's interpretations will inevitably be projections of one's own feelings and reactions. More, Gamson (1994) suggest that the reputation of an organisation might be of more importance as a potential source for performance rather than proof of an organisations actual performance. The over-reliance on the certification as proof for a certain organisations' environmental performance is naturally dangerous.

Moreover, studies have shown that practitioners within the Swedish building industry views environmental issues as something outside the actual construction project or as a sometimes unwanted detail in a contract (Gluch, 2006). In practice, this means that environmental issues are sub ordered money. As a result, many researchers have advocated a need for a paradigm shift in order to promote sustainable development within the building industry. The main objective advocated for this shift is that the building industry needs to reconceptualise and rethink construction in order to handle environmental issues. One suggested way is to increase the number of cooperative actions so that the project scope is widened (Gluch, 2005). This could facilitate a closer relationship between the client and the contractor.

Kadefors (1997) has studied the interaction between client and contractor in the Swedish building industry as this relationship often gets neglected in studies, as opposed to relationships within organizations. An explanation for this lack of research interest given by Kadefors (1997) is the relay race in the building industry, where one player after finishing his part leave the responsibility to carry out the plan for the next part to someone else, and little interaction occurs between the two parties. More, the parties' internal organizations as well as the interaction patterns between them have a great impact on the distribution of power and responsibility in the relationship. Kadefors conclude that lack of knowledge can be a strategic advantage for especially the construction companies in negotiations and that this advantage serves as a reason for not increasing the knowledge on other parties' areas of expertise. Kadefors (1997) continues by pointing out that informal and, to a large extent, intuitive decision processes are a very important aspect for the contract relationship between the client and the contractor. The building practice in Swedish building industry are by Stenberg (2006) explained as an institutionalizing process, where standards and rules for perceiving, interpreting, believing and acting, are inherited from one generation of builders or property managers to another by an apprentice-like system. This process is carried out through the interaction and relationship between parties involved. These informal processes are influenced by individuals personal values and perceptions on a reality based on personal experience and knowledge.

3. Research methods

This paper is based on a questionnaire survey sent to environmental managers within the Swedish building industry and on a interview study with seven environmental professionals. The questionnaire was based on the International Business Environmental Barometer (IBEB) that surveys the state of environmental work in industry in different countries. In order to suite the Swedish building industry, small alterations, mainly wording were made in the original questionnaire. It was directed to environmental managers or alike at all companies within construction, property owners and property management in Sweden with at least 50 employees. Results from the questionnaire survey are based on a population of 453 companies active within either property management (151 companies) or construction (302 companies). The group called "Property management company" consist of companies who either own and manage their buildings or manage buildings on commission. The response rate for property management companies was 52.8% and for construction companies 41.1%. The answers were analyzed in the statistic program SPSS (version 13.0 for Windows).

In order to gain deeper understanding on environmental management in the Swedish building industry, in depth interviews were carried out with seven environmental professionals. To ensure a reliable outcome of interviews it was necessary to take several aspects into account; the selection of interviewees, the design of the interview guide, the interviewing process and the transcription to prepare the data for the analysis. The interviewees were selected from respondents of the questionnaire survey out of the criteria that they represented various sizes of construction companies and property management companies. The interviewees were employed at companies located in Stockholm or Gothenburg. All interviews were carried out in March and April, 2007, with all recorded, except for one where notes were taken instead. The questions asked in the semi-structured interviews originated from the questions in the questionnaire survey. However, the questions were open-ended, meaning that the interviewees were aloud to further elaborate around the issue on environmental management in the Swedish building industry. Interviewees were asked to give suggestions on incentives they believed would improve the handling of environmental issues within the building industry. Answers were later summarized and their relevance was discussed with an environmental professional who had filled out the questionnaire but had not previously been interviewed.

The combination of study methods ensure the reliability and the validity of the results presented in this paper. The results were also discussed with fellow researchers at the department for Building Economics and Management at Chalmers University of Technology, as well as with practitioners.

4. Results from the questionnaire survey

4.1 Business advantages

Table 1 Barriers for environmental performance – related to business advantage

Question	Construction companies, %	Prop. man. company, %
No market demand for green products/services	53%	50%
No competitive advantages	57%	40%
Possibility to increase market share	25%	20%
Opportunity to create and/or enter new markets	43%	20%
Lack of laws and other legal demands	20%	13%
We have performed green marketing	10%	12%
Lack financial recourses	37%	34%

Table 1 shows that especially construction companies perceive lack of competitive advantages to be the business barrier that hinders the environmental work within the company the most. The most hindering business factor for property management companies is that the market does not ask for green products. Lack of a market asking for green products is also a significant hinder for construction companies. On the other hand have few companies, within both groups, performed green marketing. Also, a large majority of both groups have not seen any effects from the environmental measures taken regarding market shares or the possibility to explore new markets.

Many environmental managers within construction companies (37%) experience that lack of financial resources hinders the companies' environmental work to some or a large extent, the corresponding figure for property management companies is 34%. Environmental managers within neither one of the two groups think that lack of laws or other legal demands hinder the internal environmental work.

4.2 Legitimacy and control of environmental issues

Table 2 Barriers for environmental performance – related to legitimacy and control

Question	Construction companies, %	Prop. man. company, %
I lack knowledge to affect strategic decisions	8%	13%
I lack authority to influence strategic decisions	20%	33%
I lack mandate to stop activities that cause environment impact	18%	39%
Environmental concern are integrated in the company's strategic decisions	70%	70%
Lack of information	42%	25%
Lack of support from top management	31%	34%
The organizational structure contradicts with the environmental work	36%	34%

As seen in *Table 2*, most environmental managers perceive that they have enough knowledge to affect strategic decisions in an environmentally sound way. About 80% of the environmental managers within construction companies perceive that they can influence strategic decisions and promote environmental issues. The corresponding figure for environmental coordinators within property management companies is 67%.

Most environmental managers within construction companies experience that they have a mandate to stop activities that causes negative impact on the environment. The figure here is a little bit lower for environmental managers in property management companies. However, environmental managers within both groups experienced that they lack authority to influence strategic decisions.

Neither lack of information nor lack of managerial support seems to be a major hindrance for the environmental performance within the building sector. More than one third of the environmental managers in both types of companies experienced that the organisational structure work in contradiction to the companies environmental work to some or a large extent. Most companies in both groups have integrated environmental concern in their strategic decisions.

4.3 Cooperation and interrelations

Table 3 Barriers for environmental performance – related to cooperation and interaction

Question	Construction companies, %	Prop. man. company, %
The sector lack spirit to cooperate	31%	22%
Our clients/customers lack interest to cooperate	32%	30%
We have set environmental demands on our suppliers	90%	93%
We consider environmental performance when choosing suppliers	85%	80%
Our suppliers lack interest to cooperate	36%	32%
We have performed cooperation projects with other organisations	20%	35%

Table 3 reveals that most property management and construction companies have set environmental demands on suppliers. The majority of the companies in both groups have also taken environmental performance into account when choosing supplier. More, one fifth of the construction companies and little more than one third of the property management companies have used cooperation projects to minimize negative environmental impact.

One third of the companies within both groups think that lack of cooperation between client/customer hinders the company's environmental work to some or a large extent. Also, lack of cooperation with suppliers is viewed by 36% of the construction companies and 32% of the property management companies as a hinder to the company's environmental work.

4.4 Summary of the results from the questionnaire survey

The questionnaire survey shows that environmental managers within construction companies experience that they have a greater possibility and knowledge to influence strategic decisions. Nonetheless, more environmental managers in property management companies than within construction companies experience that they have support of higher management to pursue environmental issues. However, the situation appears to be the opposite when it comes to financial resources to work on environmental issues in a sufficient way. In all, the view environmental managers within construction companies and property management companies have on their situation at work are quite similar. Both groups also experience major hindrances concerning lack of competitive advantages, the possibility on entering and/or creating new markets. In sum, the questionnaire survey show that the companies within the building sector have a similar attitude as well as approach towards the environmental challenge and which barriers one face.

A questionnaire survey can only provide a general picture of which barriers that hinders sustainable development within the Swedish building industry. To gain deeper understanding on which consequences these barriers may have for the organisations we have performed interviews with environmental managers.

5. Results from the interviews with environmental managers

Environmental managers within property management companies often have some kind of environmental education from a university. Also, most of them have for some time during their career been working at construction companies to get practical experience.

Within construction companies on the other hand it is more common that one works ones way up from foreman on site to a managerial position. Higher positions often come with other responsibilities than just managing production on site and making profit. Environmental work is traditionally viewed by the construction companies as a sideline position and most environmental managers have no formal environmental education. Instead they gather information and experience by practically working with the issues. Also, environmental managers within construction companies often have multiple tasks of for example quality, safety, purchasing, and cost estimations.

5.1 Business advantages

None of the interviewed property management companies had performed market investigations concerning for example the attitudes towards environmentally friendly products and services. They also had in common that they all viewed money as the largest external hinder for more environmentally sound working routines. Most interviewees believed that environmental solutions are connected with increased costs.

Results from governmentally controlled demands were well illustrated by the effect from the prescribed demand on energy declarations on all properties. All interviewees from the property management companies especially emphasized that they had carried out optimization of energy systems measures, i.e. the right usage of the system, and the choice of materials. Since the law on energy declarations for properties, interviewees witness an intense focus on this issue which the following quote illustrate:

"Energy use is in a class of its own…"

[Interviewee, Property Management Company]

The environmental managers at construction companies think that property management companies view the financing of the project as the largest barrier for environmental issues. In fact, all interviewed environmental managers from both construction companies and property management companies agreed that financial incentives would be an effective driving force for sustainable development within the Swedish building industry. They also agreed on that the economical benefit from working in an environmentally benign way is not evident today, which the following quote illustrates.

"99% of all choices have to do with money, if it is more expensive it is not considered, we can only give them options but the decision is not ours to make."

[Interviewee, Construction Company]

5.2 Legitimacy and control of environmental issues

The interviewed environmental managers in property management companies emphasized lack of authority to steer and control the environmental work performed within the organization to be internal hinders. Interviews with environmental mangers in property management companies showed that little room is given to environmental issues in the company's strategic efforts. Even though an environmental policy exists and an environmental management system to ensure that the policy is followed is in place, its use and integration is scarce in daily practice and routines. Also mentioned as a large internal hinder was the difficulty for each worker, despite competence and position, to make decisions on environmental issues.

A reason stated by the interviewees for not using the environmental management system more consistently was lack of time and to some extent also because of economic reasons. According to the interviewees, the environmental system is mainly used when planning a project, especially during the tendering process, i.e. when purchasing a construction contractor. Moreover, in most cases, few attempts are later made to follow up the demands put on the construction companies through out the realisation of the project.

Interviewees from the construction companies stated that environmental management systems often have been developed out of current quality management systems. This way of developing an environmental management system is believed to facilitate and fasten the implementation of the system into the organization. However, as mentioned by one interviewee, environmental management systems may only be a demand on paper, with the risk of not being used in practice as indicated. The following quote indicates the amount of space environmental issues are given in negotiations before the production starts and why so little may be realised throughout the project.

"The environmental issues are often talked about, but more seldom considered, especially not by our clients…."

[Interviewee, Construction Company]

The above quote may also be an indication on a perception that the environmental work is an inflated issue and perhaps an illusion of active environmental work. More, interviewees from both parties pointed out the lack of evaluation of completed projects. The consequence from this, as said by the interviewees, is not only a disrupted learning process but also a running risk that environmental management tend to become paperwork without substance. Especially contractors expressed an annoyance with clients who demanded environmental management systems during tendering, but later did not follow up the actual environmental performance during the execution of the project.

Moreover, the interviewees from the construction companies found it hard to describe what exactly sufficient environmental knowledge is. They in fact seemed pressured when asked to estimate if they had enough knowledge on environmental issues to lead and predict environmental outcomes of measures taken. Many referred to television programs, daily press and environmental reports as main information source for keeping themselves updated on news and changes in environmental issues and legislations. In addition, most interviewees saw lack of knowledge among their own staff as an internal hinder for improving the environmental work of the company.

5.3 Cooperation and interrelations

The interviewed environmental managers in property management companies said that they assume that, in order to last in the Swedish building industry, it is in the construction companies' interest to maintain their environmental performance as well as their environmental management system. Hence, the interviewees trust their appointed construction companies to fulfil their environmental obligations and also to ensure that those they in turn use as sub-contractors do the same.

“We don’t have time and we lack the competence to compare the contractors’ environmental management system with our demands, we have to trust them…”

[Interviewee, Property Management Company]

However, when asked what they thought the construction companies viewed as the largest external hinder for their environmental work, the interviewees with property management companies mentioned themselves to be a large hindrance, since they set the budget for each project. In addition, interviewees with property management companies thought competence development on environmental issues among employees to be the largest internal hinder for construction companies. Also, according to these interviewees, smaller actors on the property market considered it up to the whole of the property industry to improve a collective environmental behaviour among the industry.

Although the interviewees from the construction companies said that the environmental knowledge within their company was deficient, they did not find this to be a large hinder. Furthermore, they were also of the opinion that few environmental decisions are made on site anyway. Instead, environmental decisions are made by the client in early phases of the construction project why the responsibility also is theirs. The interviewees form the construction companies therefore saw the clients limited environmental knowledge as the largest external hinder also for the construction companies’ environmental work, which also coheres with the property management companies’ conclusion.

Measures to pursue environmental improvements are, by the interviewees from the construction companies, said to be controlled by the client. Interviewees from the construction company also think that they have worked harder to fulfil environmental demands than their clients have, e.g. the property management companies.

More, even if cooperation projects are viewed by all interviewees as a positive way of constructing buildings, monetary and not environmental reasons are given for the positive outcome of cooperation projects.

5.4 Summary of results from interviewees

The interviewees agree with the researchers that there is a need for a shift of focus in the Swedish building industry in order to be sustainable. However, they also see themselves as too small actors on the building market to make a difference by taking action alone. This in turn results in a “wait-and-see” strategy, i.e. no one take on the role as first-movers. As a solution the environmental managers set hopes on governmental policy directives. From the interviews, one can discern two types of policy directives that are perceived as fruitful enough to strengthen the knowledge and position of environmental issues within building projects and organizations; subsidies and legislative measures.

Subsidies that stimulate knowledge and technology development - Several interviewees expressed the need to further educate their project members, such as project leaders and foremen, in order to better communicate the impact of environmental performance in projects. As money is one of the main drivers in the Swedish building industry, interviewees felt that a governmental subsidy would help stimulating an increased environmental knowledge. This would be beneficial for all companies in the Swedish building industry. The interviewees also express the need for subsidies on sustainable materials, passive house techniques and handling of natural water. Interviewees believed these actions would steer the way the Swedish building industry handle environmental issues in projects and organizations.

Legislative measures - Many interviewees, with both parties, expressed the need for more environmental legislations in order to legitimize to their own organization the importance of handling environmental issues in day-to-day business. Also, according to the interviewees, environmental legislations should be followed up by project external inspectors, preferably an agency appointed by the government.

The Swedish building industry has throughout decades been subject to different governmental subsides and legislative initiatives in order to stimulate numerous measures, e.g. energy use. Hence, these suggestions are not revolutionary and would probably not be enough for any larger changes to occur. They would surely not be a sufficient trigger towards the necessary shift in perspective as claimed by, for example, researchers.

6. Discussion

Results from the questionnaire survey show that most environmental mangers perceive themselves having enough knowledge, authority and mandate to affect strategic decisions that have a negative environmental impact. However, the interviews reveal another reality where respondents found it hard to describe what sufficient environmental knowledge was. Many even appeared stressed when asked to estimate whether or not they felt they had enough knowledge to predict environmental outcomes of decisions. In fact, somewhat contradictory to the questionnaire survey, the interviewees stated that little room is given to environmental issues in strategic decision making.

The interviews also indicated a lack of interest in environmental issues in the interaction between client and contactor. Even though meeting protocol for projects and internal meetings handle environmental issues, little was made use of in day-to-day practice. The reason given was primary time and money constrains. It also seemed as if there is no pressure on having environmental routines and little attention is given to these issues. As a result, the person or department responsible for environmental issues, even though highly competent, lack mandate to interfere in daily work or develop effective routines followed by the whole organization. Another finding was that the practice where parties through silent negotiations agree on not perusing certain issues in projects (Kadefors, 1997) also has bearing for environmental issues. Lack of knowledge among employees at all levels within the Swedish building industry has, according to the interviewees, made both clients and contractors perform follow-ups on irregularities. As a consequence the importance of the environmental work performed by environmental managers is belittled. So what can be done to ensure environmental issues enter and get a righteous place on the project agenda? The interviewees have suggested subsidies and strengthen legislation as a solution.

Subsidies for environmental education for all personnel are suggested by the interviewees as mean to improve both the common knowledge of, and the competence on, environmental issues within the Swedish building industry. However, there is an imminent risk that the action, i.e. the education of personnel, will stop as soon as the subsidy disappears. Also, the environmental managers demanded more environmental legislations in order to justify the importance of handling environmental issues correctly to their own organization and in projects. To secure that these laws and demands are followed there is a need for increased control of the environmental performance. This could be a work task for environmental managers that could strengthen their authority in the organisations, which today not always is strong (Gluch, 2007). However, legislation implacably nurtures bureaucratization and standardization, which is known to restrain the companies' incentive to approach the challenge out of different (and innovating) perspective. Previous research has, for example, shown that regulation may hamper innovation, especially if the regulatory process is too complex and too prescriptive (Gann *et al.*, 1998). In addition, as long as time and money are key success factors for construction projects, the incentive in form of subsidies for improving environmental knowledge, or the penalty for not following environmental legislation, must exceed the delay fine in order to not be neglected. Thus, it takes more to improve the status of environmental issues in the Swedish building industry than the incentives suggested by the interviewees. Both parties are aware of the impact their business has on the environment. However, neither one of them perceive that there is a market for green products and services.

The need for cooperative activities, both within and between different organisations, has also been emphasized as important for innovation (Harty, 2005; Keast and Hampson, 2007; Ling *et al.*, 2007). Ling *et al*. (2007), for example, conclude that for a successful implementation of innovations there is a need for involvement of a variety of organisational units. Partnering is a cooperative mode that during the past years has become more common in Sweden (Kadefors, 2005). However, although the interviewees state that they are positive to cooperation projects, they see primarily monetary benefits from creating such an alliance with their counterpart. Thus, since increased focus on sustainable development has not been acknowledged as a possible benefit from partnering, the issue most likely will not become an important issue to consider in the negotiating process preceding the partnering contract.

7. Conclusion

We have investigated barriers for future development of sustainable building practice in Sweden out of three perspectives; business advantages, how environmental action is legitimated and controlled within organizations, and cooperation and interrelation between especially the client and contractor in construction projects. The objective was to provide suggestions on measures that support sustainable development within the Swedish building industry.

One conclusion made is that the property management companies and construction companies would benefit from a more long termed cooperation. A long-termed cooperation would signal that poor environmental work has negative effect on corporate profit for both organisations in a construction project. Hence, as an incentive to emphasize environmental issues in the relationship between property management companies and construction companies, a 10 year environmental guarantee on all work performed in the Swedish building industry is suggested. The increase of project costs, that both parties believe would be the out come of a more thorough environmental work, would be a good motivation for the Swedish building industry to increase the number of partnering-like cooperation projects. Also, the need for cutting costs caused by the effect the Swedish building industry has on the environment will, in turn, enhance the knowledge on environmentally sound materials and techniques. Part from avoiding the problems caused by the relay race in the Swedish building industry, as a result, this incentive could also nurture and contribute to an increased market for green products and services.

Key words: Sustainable Construction, Private Finance Initiative, Financial Incentives, Newport Southern Distributor Road, Economic Benefits, Recycled Aggregate and Whole Life Costing

Summary

The purpose of this paper is to examine the sustainability performance of an individual highway Private Finance Initiative (PFI) scheme in the UK, mainly to scrutinize its economic benefits at three levels: project, local and national. The fieldwork was undertaken through a detailed and specific set of semi-structured interviews in the case study of Newport Southern Distributor Road (SDR). Five main drivers for the sustainability approach are identified and the transferability is analysed. Research finds that the Newport PFI case demonstrates whole life cost savings for both the client and the contractor. The social-economic contribution of the PFI project is critical to the local urban regeneration programs and sustainable community development. Furthermore, effectively applying the government's financial incentives and advanced technology could efficiently reduce the capital cost without negative impact on the project's quality and time. The sustainability aspects of this project could be extracted and transferred to other highway projects, in particular through the PFI procurement system.

1. Introduction

Internationally, sustainable construction has become the hottest research topic in the built environment over last decade. However the argument for the importance of sustainability is now won and the emerging and fundamental issue is how to embrace the practical implication of sustainability into both public and private estates, particularly under a tight budget (Zhou, 2004). In practice, there is a critical economic challenge of sustainable construction (Bon and Kutchinson, 2000 and Zhou and Lowe, 2003). Many projects avoid a sustainable solution because economic benefits are unidentified. Their concern is that the assumed extra cost of sustainable construction might shrink profits and bring extra risks. Although most recent research works express the benefits of whole life costing and highlight that the long-term benefits are more important than the capital cost, there is still a lack of direct incentives and evidence to make obvious short-term financial benefits for both the client and the contractor.

This type of problem commonly appears in the UK too. In order to achieve their ambitions of sustainability, the UK central government employs political and fiscal tools to stimulate the construction industry, particularly through the public procurement practice. Nonetheless, figures reveal public buildings were far short of their sustainability targets (NAO, 2007). One of the main reasons is that there is little clear evidence to demonstrate the short-term business benefits from sustainable construction and it lack of interest in practitioners to promote sustainable innovation in their projects. At the same time it should be noted that traditional procurement methods have failed to support sustainability (Zhou, 2004) while literature reveals that PFI/PPP has natural advantages in delivering sustainability due to the long-term contract and stronger partnership between the client and the supplier (Zhou, 2004). In principle, PFI is predicted as an effective delivery mechanism for sustainable construction that demonstrates a high sustainability performance along with an acceptable price level (Logan and Mills, 2003).

This paper attempts to fill the knowledge gap and provide demonstrative evidence to prove that a sustainable PFI project would not cost more but at the same time could reduce capital cost and provides a significant contribution to support local economy growth and environment enhancement.

2. The Economic Challenge of Sustainable Construction

In 1994, Kibert defined sustainable construction as *"The creation and responsible management of a healthy built environment based on efficient resources and ecological principles."* Hill and Bowen (1997) then divided Kibert's principles in four 'pillars': social, economic, biophysical and technical and successfully explained the four themes of sustainable construction. In 1998, the International Council for Research and Innovation in Building and Construction (CIB) created a global agenda for sustainable construction – 'Agenda 21 on Sustainable Construction' at the World Building Congress in Gävle, Sweden. Agenda 21 is a conceptual framework that defined the links between the global concept of sustainable development and the construction sector.

In principle, sustainable construction has a number of benefits. Yates (2001) explored the business benefits of sustainable construction and concluded that the benefits are diverse and potentially very significant. Heerwagen (2000) highlighted that green building contributes positively to business performance and organisational effectiveness. First, green buildings are relevant to business interests across the full spectrum of concerns, from portfolio issues to enhanced quality of individual workspace. Second, the high performance of green buildings will influence the outcomes of organisations such as workforce attraction, retention, quality of life, work output, and customer relationships. Third, green building can provide cost reduction benefits and value added benefits.

While sustainable construction has many potential economic benefits, difficulties and barriers still exist in practice. Literature shows that there is an apparent lack of evidence of market demand for sustainable development that together with a lack of information and expertise are recorded as the most important obstacles to a more sustainable built environment (Zhou, 2004). Keeping (2000) argued that few investors have a significant desire to own sustainable buildings. Moreover Bordass (2000) found that the UK's pioneering green buildings have often been procured by owner-occupiers, who are less constrained by market norms. One of the main reasons causing such market failure is unidentified short-term business benefits. For example the clients widely believe that sustainable construction will cost more and bring high risks (Johnson, 2000; Landman, 1999; Hydes and Creech, 2000; Bon and Kutchinson, 2000, Castillano, et al, 2000 and Zhou 2004) and they believe that cost will increase by using new technologies and green materials. There is little market incentive for clients to put more additional money into the innovation without extra return over the short-term period. Smith et al (1998) argued that developers were encouraged to think of short-term profits rather than the long-term consequences of their action.

3. The UK Approach and the Advantages of PFI

3.1 The UK approach for sustainable construction

In 1999, the UK government published the first sustainable construction strategy and it outlined 10 themes for the industry action plan. In addition to setting up the policy the government also applied the fiscal instrument to motivate the construction industry (Addis and Talbot, 2001), for example:

- The Landfill Tax (1996) is influencing waste management practices by encouraging greater diversion of waste from landfill. Costs of disposing of construction and demolition waste to landfill can be minimised through more efficient construction and innovative re-use and recycled materials.
- The Aggregate Levy (2002) is introduced to reflect the environmental costs of aggregate quarrying and encourages demand for and supply of alternative materials, such as mineral waste and recycled construction and demolition waste.

In addition, the Government's Sustainable Procurement Group recommended setting requirements for recycled content in the procurement of Government construction (for projects > £500K) in 2003 and in particular that a requirement for 10% of the materials value to be derived from recycled content should be in Building Regulations and a higher standard adopted as a minimum requirement in the Code of Sustainable Building (DTI, 2003). However, a recent government survey shows that 80% of public building failed their sustainability target (NAO, 2007). One of the most important reasons is that widespread perception of conflict between sustainability and value for money – partly because the project team fails to access the long-term costs and benefits of more sustainable approaches

3.2 PFI and its Sustainability Advantages

The Private Finance Initiative as a modern public procurement system was firstly introduced by the UK government in 1992. The International Project Finance Association (2002) defined PFI as:

"*The procurement of public services and assets by government and local authorities where the private sector is responsible for the design, construction, finance and operation of an asset or service for a specified period of time after which it is transferred back into the public sector..*"

According to the latest figure from the HM Treasury Website (HM Treasury, 2007), 747 projects had been signed as PFI contracts, amounting to a total capital investment of over £47.56 billion. Almost every central government department and local authority is now using PFI contracts. They include most types of public estates, for example, roads, prisons, hospitals, schools and office buildings, etc. Furthermore, £26 billion of PFI investment across 200 projects is currently in the pipeline to close by 2010 (HM Treasury, 2006).

In terms of sustainability PFI could offer real scope to promote sustainable construction (Addis and Talbot, 2001; Logan and Mills, 2003 and Zhou, 2004). The long-term and integrated nature of PFI contracts offers incentives to the contractors to consider the synergies between the design of an asset and its ultimate operating cost (OGC, 2002). The stronger partnership between the client and the contractor make it possible to apply a holistic approach to achieve their common sustainable objectives. However, as in other sustainable construction studies, most research examine the sustainability performance from the environmental aspects for instance energy efficiency or reducing use of natural resources. In general they lack consideration of economic benefits especially in a short-term life span. For its wider acceptance it is critical to find out what direct business benefits there are from the existing PFI projects.

4 Research Methodology

The previous section of this paper examined the concepts of sustainable construction and the UK's approaches. It highlights that that one of the biggest barriers is the assumed high cost of sustainable construction. Contrasting with traditional methods, literature finds that PFI procurement had the potential to deliver sustainable construction, but there is a lack of practical evidences of its economic benefits.

This paper is based on a part of a PhD research programme which was designed to investigate the sustainability performance level of the whole UK PFI market. It endeavors to develop a sustainability framework for PFI procurement system and its practice. Based on the systematic literature review, the PhD research was designed to use a combined method to gather both quantitative and qualitative data and provide a more complete picture of the sustainability issues addressed in PFI industry. It includes a national level questionnaire survey, follow up in-depth interviews and case studies. The initial national level survey examined over 65 existing PFI projects' current sustainability performance level and then 12 follow up in-depth interviews scrutinized the clients and project directors' willingness; and also value and risks to implement the sustainable approach. Moreover, four representative cases was selected from the national survey to gather information on successful experience in sustainable PFI projects from different aspects (economic, social, environmental and technical). This paper summarizes the findings in the case of Newport Southern Distributor Road. Four interviews were conducted with senior representative from the Newport Southern Distributor Road (see table 1). The first three interviewees are directly involved in the Newport SDR project. The fourth interviewee was indirectly involved with the project but was in charge sustainability strategy plan and day-to-day sustainability business management of the operating company (Ringway). The interview was designed to find out:

- Key stakeholders' experience and attitudes in terms of sustainability
- The project's objectives, client sustainability priorities and how the supplier responded
- The project's sustainability performance level and benefits from social, economic, environmental and technical aspects

A secondary study is used to gather other data to identify the impact of this PFI project on the construction industry and local community.

Table 1: Interviewee's background

No	Type of Stakeholders	Interviewees' occupation	Organisation
1	Client's Project Management Consultant	Project Manager	Capita Gwent
2	Special Purpose Vehicle (SPV)	Project Director	Morgan Vinci Ltd
3	Operator	Operator Manager	Ringway
4	Operator	Sustainability Manager	Ringway

5 Case Study of Newport Southern Distributor Road (SDR)

5.1 The Context

Newport is the third largest city in Wales, a traditional small city on the bank of the River Usk. Following the UK central government's sustainable development strategy the Newport City Council created its own 21 agenda action plan and devised a new sustainable urban regeneration strategy for the residents for next decade in 2000 (NCBC, 2000). However, the existing transport network did not fulfill the demand especially on the south side of the city.

In order to relieve the transport congestion and improve the local transport network, the Newport County Borough Council (NCBC) decided to adopt the PFI model to develop a new road on the south side of the city. The proposed plan was to build a dual carriageway link from Junction 24 of the M4 (Coldra roundabout) to the east Junction 28 (Tredegar roundabout) on the Southern edge of Newport and it includes a major crossing of the River Usk. The Morgan Est, one of the largest civil engineering contractors in the UK, together with Vinci, an international contracting company, formed a joint venture 'Morgan Vince Ltd' which won the £55 million contract and undertook Design, Build, Finance and Operation (DBFO) of the project over a 40-years life span. This project is the biggest local authority PFI project in Wales and also recongised as a pathfinder project by the Welsh Assembly Government. The principal objectives of the scheme are:

- To enable traffic to avoid the town centre and inner residential areas
- To improve the environment of the inner residential areas
- To improve road safety
- To improve access; and
- To contribute significantly to achieving the emerging integrated transport policy for Newport

Construction started during summer 2002 the road was made fully open to traffic in December 2004. As such the Southern Distributor Road (SDR) was finished half year ahead of schedule (May 2005). Ringway Highways Service Ltd has carried out the operation and maintenance work.

The Southern Distributor Road is Newport City Council's highest priority scheme for the improvement of Newport's highway network. The project brings major economic and environmental benefits to the city including improved access to major investment opportunities in the southern areas of the city.

5.2 Perceived Economic Benefits

In brief the Newport SDR project demonstrates outstanding economic benefits. Table 2 categorises the economic benefits at three levels: project, local and national and divides them for different stakeholders and the wider community.

At the project level, approximately £1 million initial cost was saved through the use of around 450,000 tonnes of recycled and secondary aggregates instead of purchasing primary materials. A variety of secondary aggregates is used as granular fill materials and unbound sub-base. In the recycle programmme, specific cost savings included:

- The avoidance of waste disposal charges and Landfill Tax
- The avoidance of Aggregates levy payments, from which recycled and secondary aggregates are exempt

- The lower costs and improved performance of maintenance techniques such as 'crack and seat', Rhinopatch and cold-lay foamed asphalt mix
- Reduced costs of transporting aggregates when recovered materials are available locally

Table 2 Perceived Economic Benefits of Newport SDR

Outcomes Levels	Perceived Economic Benefits and Business Value	Beneficiaries
Project Level	• Capital Cost saving • Whole Life costing saving	Newport City Council (Client) Morgan Vinci Ltd (Developer) Ringway (Operator)
Local Level	• Support local urban regeneration • Attract new business investment in Newport • New business opportunity between the supplier and Local Authority	Newport City Council Local Community Local Residents Road Users
National Level	• Reducing government borrowing and increasing investment in public infrastructure • Support Wales Economic development • Support Recycle Scheme in the UK • Increasing the PFI firms' competition rate	Welsh Assembly Government Newport City Council UK Central Government Morgan Vinci Ltd Ringway UK Construction Industry Capita Gwent Consultant

The Action Sustainability (2006) has examined both capital cost saving and whole life cost saving of the project in detail. They outline:

"*the use of recycled material did not incur additional capital or maintenance expenditure for the project; however, it did result in direct cost savings in construction costs (£1,034,135), carbon emissions (£106,481), avoiding landfill costs (£941,360) and health benefits from reduced emissions of PM10 (particles measuring 10mm or less).Overall, £2,098,801 was saved, offset by no costs, which amounted to 3.82% of savings of the total project cost or to £219,609 per kilometer of road constructed.*"

At the local level: the Newport SDR helps to release the congestion of Newport Transport Network and reduces the traffic in the city centre. These outcomes provide massive benefits to promote new business investment to Newport. Figure shows that the new attracted business investment is about £1bn after the Southern Distributor Road completed (Newport Unlimited, 2007)

More evidences from the interviewee and secondary data shows that the SDR project also supports the local urban regeneration programme: the Old Town Dock Development and the re-use of Brownfield Land..

'It maximises the potential for the development, enhancement and re-use of inner urban land in order to improve the vitality and attractiveness of area such as town centre and encourages development of the available Brownfield land' – the client's consultant project manager, Capita Gwent,

The current upgrade of the Southern Distributor Road is of significant benefit to Newport. The road provides a main arterial route and is considered to be of vital importance to the future success and regeneration of Newport and also will assist in the creation of a gateway to the south of the City (Knight Frank, 2003)

At the national Level, this project is the first pathfinder PFI project in Wale. It serves as a successful model for future PFI development reducing government borrowing and increasing investment in public infrastructure. It has observed the green standards by using recycled aggregates and winning a number of national and international awards. For instances, the PFI project has been selected by the Department of Trade and Industry as a flagship case study. Newport recently won a Green Apple award – presented for environmental best practice around the world. The Newport SDR has become an exemplary case study on the Waste and Resource

Action Programme (WRAP) website as a shining example of environmental best practice within the industry for other companies to follow (NCC, 2004a). The positive publicity gives Newport city a fresh image as a sustainable city and also improves the Morgan Vinci Ltd's business opportunities in the high competitive PFI market.

5.3 Perceived Social and Environment Benefits

In addition to environmental benefits derived from the construction process that has been already noted the project reduced traffic in the city centre. In addition using recycled materials reduced local waste and use of natural resources. Green Transport plan and video meeting technique helped to reduce energy use and cut down on CO2 emissions. Moreover, the road project relieved the traffic congestion problem in the city centre and reduced air pollution and noise level. This is encapsulated by the client's project manager who noted that the aim of the project is to:

'Enable traffic to avoid the town centre and inner residential areas and improve the environment of the Inner Residential Areas: avoid traffic noise and air pollution' – The client's consultant project manager, Capita Gwent

This project provided massive social benefits and support for local sustainable community development too. Firstly it enables the south area of Newport City to be a safe place for all residents to live, work and play. It changed local residents' behaviours and helps to promote sustainable trips to work and school by encouraging alternative modes of transport such as cycling, walking, public transport and car-sharing and avoided the travel route through city centre. Second reduction of traffic noise and air pollution improved the local residents' health and wellbeing. Thirdly the £55 million 40-years project employed local labours and increased the local employment rate. And finally, the SDR project regenerated the community spirit. Without this project, both the city centre regeneration and Old Town Dock regeneration programmes could not be established. They are vital to support Newport City Council's strategic ambition in building a sustainable community and economic growth.

This is reflected in the council's aspiration for the project when they write:

Old Town Dock will be transformed into a new neighborhood, creating a new gateway into the City Centre from the south. The completion of the Southern Distributor Road (SDR) and the new bridge, along with improvements to Usk Way will provide a significant new level of connectivity in southern Newport. Old Town Dock and Pill provide an excellent opportunity for development close to the City Centre building on the land assembly work carried out previously by the Newport Development Board. (Newport Unlimited, 2007)

5.4 Main Drivers for success

The reasons for the perceived success of the Newport SDR PFI are many and varied. Five main drivers are discussed below:

Client Demand

The Newport City Council has a strong commitment to sustainability and implements this in its transport policy. The City Council also provides a strong demand in sustainable construction. Waste Minimisation and Recycling has a high priority in its Local Agenda 21 as all recyclable waste should be recycled (NCBC, 2000). Secondly it is recognized that an integrated transport network is crucially to support the local economic development and to reduce the city centre pollution level. The SDR is recognized by Newport City Council as its highest single priority scheme for the improvement of Newport's principal highway network as an essential component of its integrated transport policy and as key project which will enable its delivery.

Financial Incentives

Evidence shows that this project utilized both Aggregates Levy and Landfill Tax extremely efficiently. As WRAP (2004) highlights:

"*The Landfill Tax and Aggregate Levy together provide a tangible financial incentive. In effect, an authority can save money twice: by recycling highways waste to eliminate waste charges, and by using this recovered materials on new schemes to cut the cost of buying virgin materials*"

In this project effectively using financial incentives and achieving maximum cost saving has been seen as the biggest internal driver for both the main contractor and the operator to achieve sustainable development.

Whole Life Costing

Whole life costing was employed in this project to test value for money by examining the public sector comparator (The PSC is the total whole life cost of the project if procured through the traditional route). This unique route ensures the PFI project is at an acceptable price level and would not increase the expenditure of Newport City Council in the long term. Secondly whole life costing is used in choosing the alternative material, for instance the selection of street light columns. As one of interviewees highlights:

The use of whole life costing can provide cheaper solutions in the long term e.g. the use of stainless lamp columns which have a residual life of approx 70 years whereas conventional galvanized columns although cheaper in terms of initial capital have a life only of approx 25-30 years

Advanced Technology

Another exceptional feature of this project is that it applies an advance green technology: foam base to deal with the recycled aggregate. Foambase is a new type of cold-mix plant. It uses recycled materials in premium bituminous mixtures that take the place of hot mixes in the base and binder layers of highways. Effectively use of advanced technology could stimulate the business benefits of sustainable construction.

Use less bitumen and energy, fewer lorry movements and we divert waste from landfills. We also save taxpayers up to 25%, material using crushed asphalt, concrete and recycled aggregates. Most Foambase is laid as road base now. It's proved a very economical form of construction - Sustainability manager, Ringway

Effective Procurement Model

Without PFI funding, Newport City Council could not afford the highway project and would not be able to design, build and operate it over 40 years as a small local authority. Hence Newport City Council did both 'value for money' test and the affordability test in the early procurement stage. Through the options appraisal they identified that PFI is the most suitable option for the delivery of this project (NCBC, 2002). Moreover, in PFI the project's profit is at risk depending on private sector performance. Therefore, there is a very strong incentive for the private sector to maintain high and reliable service standards throughout the life of the contract. It forces the contractor involving earlier and working closer with the client and building a robust partnership to deliver the best outcomes and add value to this project. On the other hand, the partnership has aligned both its objectives and benefits, so it allows all parties - client/designer/contractor - to work together early in the scheme's development and design towards a shared sustainable goal till the end of the contract.

6. Discussion

a) Capital Cost vs. Whole Life Cost

Interestingly, through this case, evidence shows that capital cost saving is extremely important. Making initial cost saving is one of the ultimate motivations for applying the sustainability principles. The Client project manager argues:

In my limited experience in the PFI field it appears that contractors are only interested in the bottom line of their accounts and are not interested in sustainability unless it improves their financial position!

More interestingly, after comparing the capital cost saving, whole life cost saving and predicted new business investment the capital cost saving (£1m) is equal to the long term saving (£1m), but the social-economic value (£1bn) appears at the highest level. The total project cost saving becomes relatively tiny at the local outcome level (See figure 1, figure sourced from ActionSustainability 2006 and Newport Unlimited, 2007).

b) Transferability

Comparatively, economic benefits can be easily checked against valid financial figures and the cost-benefit analysis and risk management models can easily demonstrate to both client and developers willing to use of recycled materials and the advanced technology: *Foambase*. Evidence shows that those successful sustainable construction practices, for example the use of the new technology Foambase at highway project are directly transferred to the operator's daily business due to its massive economic benefits. As the Ringway's internal magazine (Ringway, 2006) highlights:

There is a big marketing push on (Foambase) and a big opportunity to recycle the huge amount of waste generated by our term maintenance works

Furthermore, the best practice in this project is currently disseminated by the UK central government through its sustainable construction initiatives, such as WRAP, the UK government recycle scheme (WRAP, 2004).

However, some special conditions in this project are not able to transfer to others; for instance, the local availability of cumulated recycled materials might not exist in other circumstances. In addition the reward from the financial incentive from both aggregate levy and climate change tax will be limited if applied to building projects due to the additional need of the quantity of secondary aggregate.

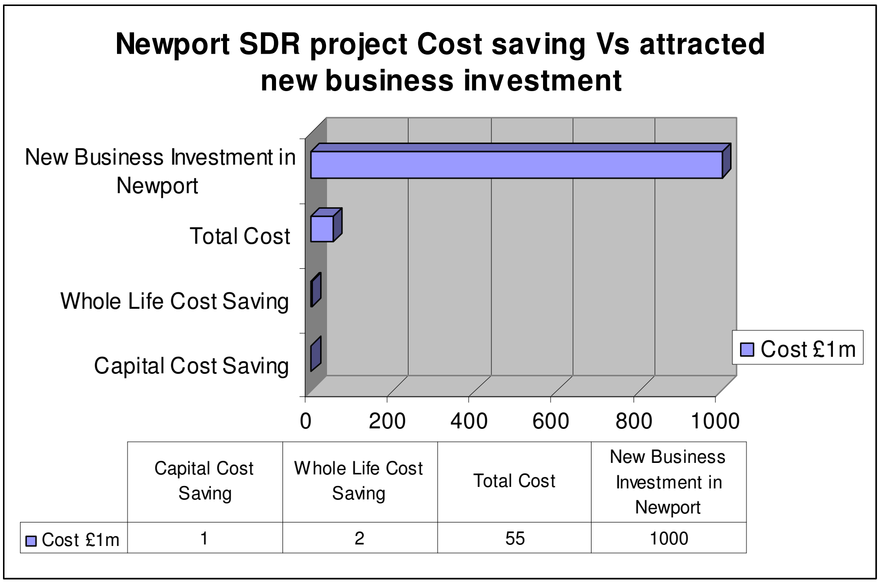

Figure1. Comparing of the direct cost saving in the Newport SDR and the value of new business investment

c) Research Limitation

The case study provides significant evidence to prove that sustainable construction could save money if applied effectively within the government financial incentive and advanced green technology. The transferability of the economic benefits is also identified. However due to research findings based on the individual case it is difficult to generalise in terms of the average sustainability performance level in the whole PFI industry.

7. Conclusion

The analysis in this paper has highlighted the successful experience of Newport Southern Distributor Road in cost saving and five main internal and external drivers of the sustainable approach in the context of this project. Without PFI model, New City Council could not afford this project and the main contractor and its suppliers might not have the motivation to adopt the advanced green technologies and financial incentives to achieve the maximum financial return. It also demonstrates that financial incentives could be the most important internal driver for both the main contractor and its suppliers to push themselves towards more sustainable and innovative solutions. This paper also discusses the economics at three levels: project, local and national. Sustainability has different meanings to different stakeholders. For the private sector, the positive impacts of sustainable solution could increase the business profit capacity and win new business opportunity. For the public sector and its service users, the economic benefits could save taxpayer's money. For the central government, sustainable PFI project could ensure reducing their short-term financial expenditure, increase investment in infrastructure and assist in achieving their ambitious sustainability target in public buildings within a longer period. In addition to economic benefits, the PFI project has also made a major contribution to local sustainable community development and environment enhancement. Moreover, the Newport PFI project provides qualitative evidence to support the PhD study's in-depth investigation, particularly in the economic impacts. Comparing with traditional procurement methods it concludes that PFI is undoubtedly the best mechanism to delivery sustainable development in the public building. As a result, this paper adds value to the existing limited work on the capital cost of sustainable construction. It demonstrates the cost of sustainable construction is lower than conventional method and also for the first time demonstrates in detail that PFI has practical advantages to lead the sustainability revolution in public procurement.

INFLUENCE OF PAST POLICIES ON TODAY'S ENERGY SAVING INITIATIVES

A.G. ENTROP Eng.[1]
H.J.H. BROUWERS Prof. Dr. Eng.[1]

[1] Department of Construction Management and Engineering, University of Twente, Enschede, Overijssel, The Netherlands, a.g.entrop@utwente.nl, h.j.h.brouwers@utwente.nl

Keywords: policy, regulation, energy saving, historical research

Summary

In this paper the Dutch situation regarding national policies influencing the energy performance of dwellings is analysed by using Mahlia's theory on the hierarchy of energy policies.

The National Insulation Program is the first policy to be discussed. It was developed from 1974 to 1978 and remained in force till 1987. The objective of this program was to (re-)insulate 2.5 million dwellings to save 1.6 billion m^3 of natural gas per year. This high ambition required a broad scope affecting consumers, industries and institutions. Consumers received information on energy saving techniques and subsidies. Industries flourished, because of the increasing demand on insulation materials, and at institutions the administration of the policy and research on energy saving techniques were executed. By the end of the program annual energy savings had risen to 50 PJ.

With the proclamation of the National Energy saving Plan in 2007 a new annual objective of insulating 200,000 to 300,000 buildings was formulated for the next ten years. To achieve this goal, in a country with approximately 7 million dwellings, more information should be needed about the current physical state of buildings. However, the Energy Saving Plan does not consider yet the achievements of former policies, such as the National Insulation Program.

1. Introduction

The Dutch energy supply changed radically when at the 22nd July of 1959 the extraction of natural gas from the earth started at the small village of Slochteren. The reserve of natural gas of $2.7 \cdot 10^{12}$ m^3 was to be one of the biggest in the world. Because of this apparently endless supply of natural gas, social housing was provided with central heating systems based on natural gas already in the sixties. The use of natural gas was strongly stimulated by the government, because its price was expected to drop rapidly as soon as cheap nuclear energy would set in.

However, the price of electric energy never dropped and nowadays the existing building stock receives much attention in energy saving policies around the world. In Europe the built environment accounts for more than forty percent of the energy consumption (EC, 2002). Especially the existing building stock that was constructed before energy saving policies were commissioned, offers many opportunities to implement measures, which lower the energy consumption and which rely on renewable energy sources. Nevertheless, little is known about which policies were commissioned when and how these past policies influence the effectiveness of new energy saving regulations or objectives.

In this field Mahlia et al. (2002) aimed at developing a comprehensive theory on energy efficiency standards and labels usable for policy makers. They specified a hierarchy of test procedures, standards and labels (see Fig. 1). They claimed that their theory can be used for revisions in a country that already has standards. In this regard The Netherlands forms an interesting research field, because two standards to express the energy performance of dwellings already were introduced more than seven years ago, namely the Energy Performance Advice (SenterNovem, 2003) and the Energy Performance Coefficient (NNI, 1995). An official label was only recently, i.e. January 1st 2008, introduced and the conditions of incentive programs in adopting energy saving or renewable energy techniques were changed multiple times.

The foundation of the triangle is formed by energy test procedures, which are, according to Mahlia et al. (2002), well-defined protocols or laboratory test methods. Using these protocols or methods a relative ranking of the energy efficiency among alternative technological designs that provide an energy consuming service can be obtained. The standards form the next level of the triangle. They can define a minimum level of energy performance or maximum level of energy use. Labels are the visualization of the standards. The top of the triangle is formed by incentive programs that can influence the adoption of labels and standards among consumers, being the users of the energy consuming product, and manufacturers, being the developer and/or producer of the energy consuming product.

Using this triangular model this paper will explain the Dutch situation regarding the energy consumption in residential real estate, in which a major energy saving policy plan from the past with the name of National Insulation Program (NIP) influences the feasibility of recently set targets in the National Energy saving Plan (NEP). In the time period between the NIP and NEP, which both have an effect on existing buildings, other regulations in the national Building Code were introduced to lower the energy consumption of new buildings. Combining the results of these different governmental initiatives can provide insight in the constitution of the Dutch building stock.

Although Beerepoot et al. (2007) have already paid much attention to the energy performance regulation in the Dutch residential building sector, they did not include in their analysis the former policy that influenced the energy performance of existing residential buildings, i.e. NIP. Furthermore, the NEP forms a new policy variable to be regarded in this paper, that will describe and relate the initiatives regarding residential real estate in a chronological sequence. Firstly, the intentions and results of the NIP will be presented. Secondly, the impact of the Building Code will be discussed. And thirdly the targets and presumed effectiveness of the recently presented NEP will be related to the current residential building stock. In doing so, the number of policy independent and dependent variables of the research model of Beerepoot et al. (2007) can be chronologically extended.

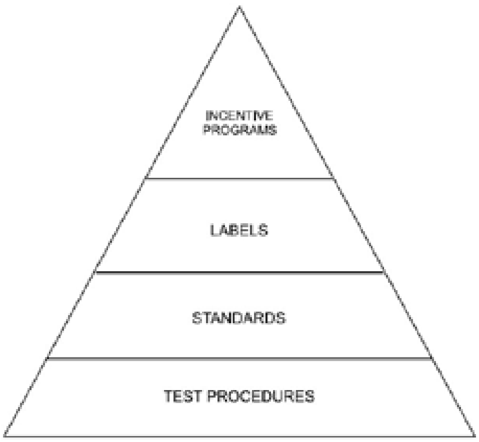

Figure 1 Hierarchy of test procedure, standards and labels according to Mahlia et al. (2002).

2. National Insulation Program (1978-1987)

In the year 1973 the first oil crisis quadrupled the Dutch oil price and therefore the costs of living were increasing tremendously. The finiteness of fossil fuels, mentioned by the Club of Rome (Meadows et al., 1972), in combination with the present increasing needs for them had its financial impact. The consensus to save energy in the built environment was growing in those early seventies, in which the first national Note on Energy was proclaimed. The global and national energy situations were discussed in this note and guidelines were set for the nearby future. There were also chapters written about the main energy sources: natural gas, oil, coal, and nuclear energy (Min. EA, 1974).

However, this political act did not provide the practical action that was needed in the built environment. An organizing committee was established, consisting of officials of different ministries and public utilities. In February 1978 they presented their program with the target to annually improve the insulation of 250,000 houses to an adequate level for the next ten years. The residential building stock counted approximately 4.6 million objects at that moment. Before presenting the program, the feasibility of this task was being tested from 1974 to 1977 by insulating 400 public housing units in the city of Enschede, 292 low-rise dwelling in the city of Apeldoorn, and 274 single-family dwellings in the city of Delfzijl (SNIP, 1988).

2.1 Scope and targets

The National Insulation Program was discussed by the Dutch cabinet. At the 30th of June 1978 it was decided that the following main items would give the program its final shape (SNIP, 1988):

1. The target of improving the insulation of 2.5 million houses in total was adopted, but the annual target of 250,000 was reduced to 200,000 dwellings. The total duration would therefore increase from 10 to 12.5 years;

2. The average subsidy on insulating techniques to be provided was stated to be € 1089,- with the possibility to increase the maximum sum of subsidy from € 1361,- to € 1815,- per dwelling[1];
3. Until 1980 the maximum amount of subsidy per dwelling could only be 30% of the investments, instead of the originally proposed $33^{1}/_{3}$%.
4. Dwellings without central heating system could also apply for the subsidy on insulating techniques;
5. Social housing corporations were enabled to invest in insulation by offering them a special type of loan in cooperation with the banks;
6. The available budget for the program was set on € 157 million for 1978 and 1979. This budget included the costs for the organisation, information and execution of the program. The national budget of 1978 showed that total governmental expenditures were € 50,145 million and total revenues were € 45,663 million (SN, 2008);
7. Furthermore, it was decided that the Association of Dutch Municipalities became member of the organizing committee.

The foreseen reduction in energy consumption was estimated to be 650 m^3 per dwelling (SNIP, 1980). At the end of the program the total target was to save annually 1.6 billion m^3 of natural gas. Using a caloric value of 31.65 MJ/m^3 to 35.17 MJ/m^3, this would mean an annual reduction of 50.6 to 56.3 PJ. In 1978 the total energy consumption of the Netherlands was 2,797 PJ (SN, 2007). The energy use of dwellings in that year was approximately 381 PJ. The NIP could reduce this by 14%.

2.2 Experience and the development of knowledge

Approximately 400,000 dwellings were already insulated in the Netherlands, before NIP was introduced (SNIP, 1988). This meant that not even ten percent of the Dutch dwellings were insulated at that time. Three quarters of these insulated dwellings were privately owned and one quarter was owned by social housing corporations. Therefore, not much experience or knowledge was available on how to insulate dwellings properly, and knowledge that was available was not centralized. In four fields research was needed (SNIP,1988):

1. The effectiveness of the use of insulation in buildings;
2. Alterations in comfort caused by the use of insulation;
3. The influence of insulation on the technical quality of the buildings (for example rotten wood caused by condensation);
4. The occurrence of physical phenomena, for example thermal bridging.

In 1979 the first publications for consumers came available regarding the effectiveness of building insulation. Because insulating a dwelling was and is a technical matter, this brochure explained the effectiveness and application of common insulation materials. The consumers were able with help of this brochure to calculate the investment costs and benefits of double glazing and insulating floor, walls, and roof (SVEN, 1979).

Although the first attempts to come to standardisation regarding the thermal insulation of dwellings originate from 1964, it would take to 1992 before national regulations were drawn up. The norm of 1964 demanded insulation values of 0.43 up to 1.29 $m^2 \cdot K/W$ for outer walls, depending of the weight of the wall and of the aspired classification; moderate, sufficient or good. According to that norm a heat resistance of 0.17 to 0.52 $m^2 \cdot K/W$ for floors was considered to be sufficient. The roof insulation was rated between 0.69 and 1.29 $m^2 \cdot K/W$ (NNI, 1964). In 1981 a new standardisation was suggested incorporating the average heat transmittance coefficient of a building and a thermic insulation index (NNI, 1981).

In addition to the four fields of research mentioned, research had also been undertaken to limit the dependence of fossil fuels. The possibilities to use solar energy were explored to heat space and tap water. An early report mentions four interesting results (TPD, 1975):

- When using a solar collector with a surface of 60 m^2 and a low temperature heating system, a Dutch dwelling of approximately 400 m^3 and an average heat transmission coefficient of 0.8 $W/m^2 \cdot K$ could be supplied of energy for 70% of its needs at that time;
- The additional investment to construct a dwelling conform Figure 2 could be financially compensated for when the parts were fabricated en mass and the price of natural gas would exceed € 0.136 /m^3;
- The use of collective heat storage systems for several dwellings could be profitable starting from € 0.182 /m^3. These systems were designed to store enough heat for a period of six months;

[1] Price levels are generally related to the year mentioned in the lines.

- The development of low temperature heating systems based on 35℃ was considered to be favourable, because the efficiency of the collectors would be maximised. Nowadays, low temperature heating systems are already quite common, but in most cases the temperature does not drop below 55℃;
- The use of solar energy to heat space seemed to be less practicable for constructions of more than four floor levels.

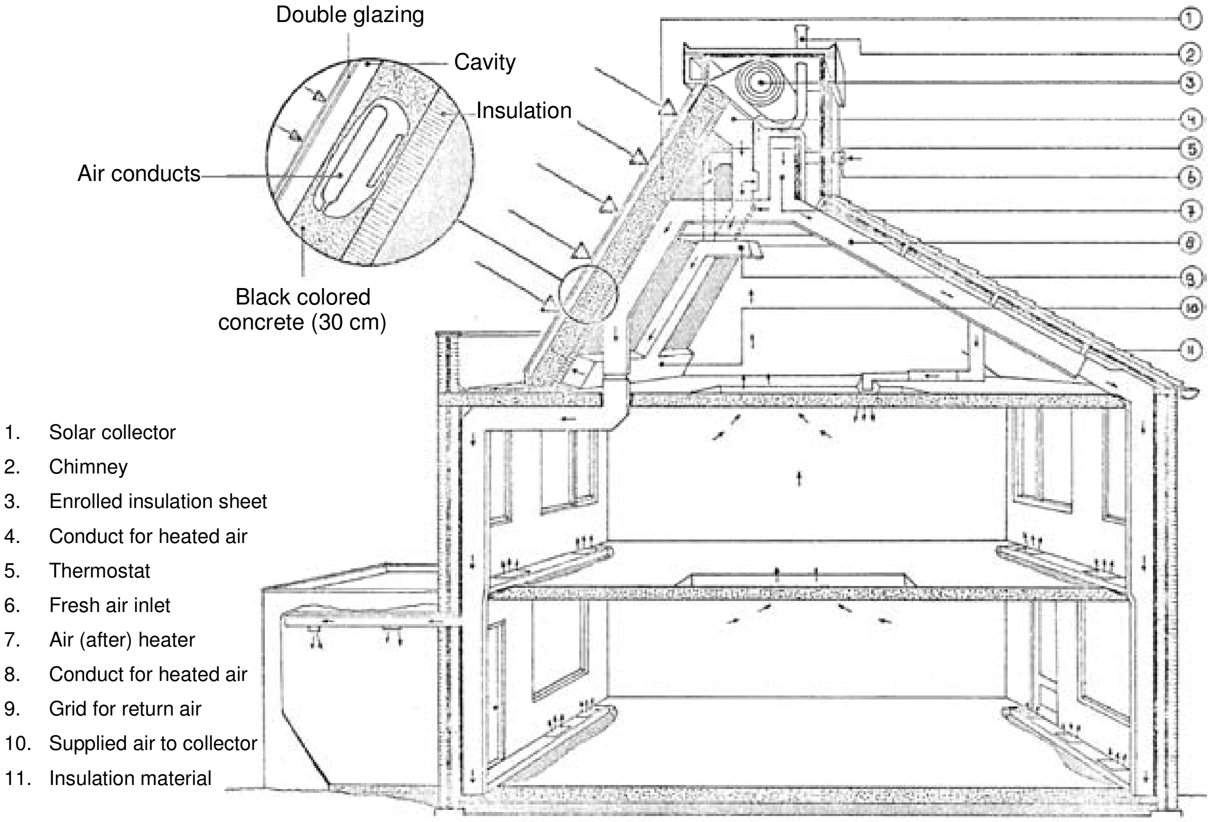

Figure 2 Design of an early solar air heated Dutch dwelling (TPD, 1975).

2.3 Financial and economic considerations

The decreasing consumption of fossil fuels should reduce the import and benefit the Dutch economy directly. The Dutch economy was also supported by generating economic activity. By producing insulation materials, installing insulation measures, conducting research, and manning the staff the employment was estimated to be stimulated by 7,500 years of labour (SNIP, 1980). A report on the evaluation of NIP even speaks of 12.500 years of labour (SNIP, 1988). The annual turnover in the new industry of re-insulation was in 1979 € 280 million, which was € 6.2 million higher than predicted (SNIP, 1980).

On micro scale the Dutch households would benefit from reduced costs on energy consumption. At least if they were willing to invest. In 1979 the average investment was € 1385 per participating dwelling. The value of the investment rose up to € 1,833 in 1987. Originally the average subsidy per dwelling was € 309 that increased to € 733 (SNIP, 1980, St. NIP, 1988). The payback period of these investments was strongly related to the natural gas price, which increased in the time period 1974-1987 from € 0.052 /m^3 to € 0.209 /m^3. In that period the highest price for natural gas was paid in 1985 with a price of € 0.300 /m^3 (SNIP, 1988).

2.4 Results

The NIP offered a broad range of stimuli to reduce the energy consumption of dwellings. The target to improve the insulation of 800,000 private dwellings and 1,700,000 rented dwellings was almost reached. The program was however brought to an end in 1987, by that time 1,803,000 subsidies with a value of € 820.9 million were approved (see Table 1). The provided subsidies formed 91 % of the total costs. At the end the annual energy consumption was reduced by 45.9 PJ to 51 PJ, depending on the use of the low (31.65 MJ/m^3) or high (35.17 MJ/m^3) caloric values of natural gas. Considering that the Dutch natural gas price nowadays is € 0.55 per m^3, then the reduction in natural gas use of $1.45 \cdot 10^9$ m^3 per year still offers consumers an annual cost reduction of almost € 800 million.

Table 1: Results of the National Insulation Program at the end of 1987

	Targets 1978-1990	Results 1978-1987	Relative Performance
Natural gas	$1.6 \cdot 10^9$ m^3	$1.45 \cdot 10^9$ m^3	90.6 %
Private houses	800,000	602,000	75.3 %
Rented houses	1,700,000	1,201,000	70.6 %

3. Building Code (1992-…) and the Energy Performance Certificate (2008-…)

The Dutch Building Code was instituted in 1992, when the buildings stock comprised 6 million dwellings. The Building Code prescribes the minimal quality a construction needs to comply with. Originally the Building Code mainly focused on the safety of constructions. Since 2001 a chapter on the environmental impact of constructions has by name been included, but this chapter has not been given any contents yet. In other words the chapter only consists of a title at this moment. The minimal thermal resistance of buildings is specified and should be at least 2.5 $m^2 \cdot K/W$. This regulation was already introduced in 1992. The total energy consumption of buildings has been regulated since 1995 by using a so called Energy Performance Coefficient (Building Code, 2003).

3.1 Minimal thermal resistance of buildings

The construction process of a new building is not allowed to start without a permit from the municipality. However, some refurbishment projects or small extensions are allowed to be constructed without a permit. In general all these projects should be subject to the minimal thermal resistance of 2.5 $m^2 \cdot K/W$. Where different construction parts are joined, a minimal heat resistance factor should also be obtained. However, often thermal bridges do occur when small extensions and bays are constructed (see Fig. 3); especially when a permit is not a necessity. In the existing building stock the connection between gable roof and walls often shows infiltration leaks.

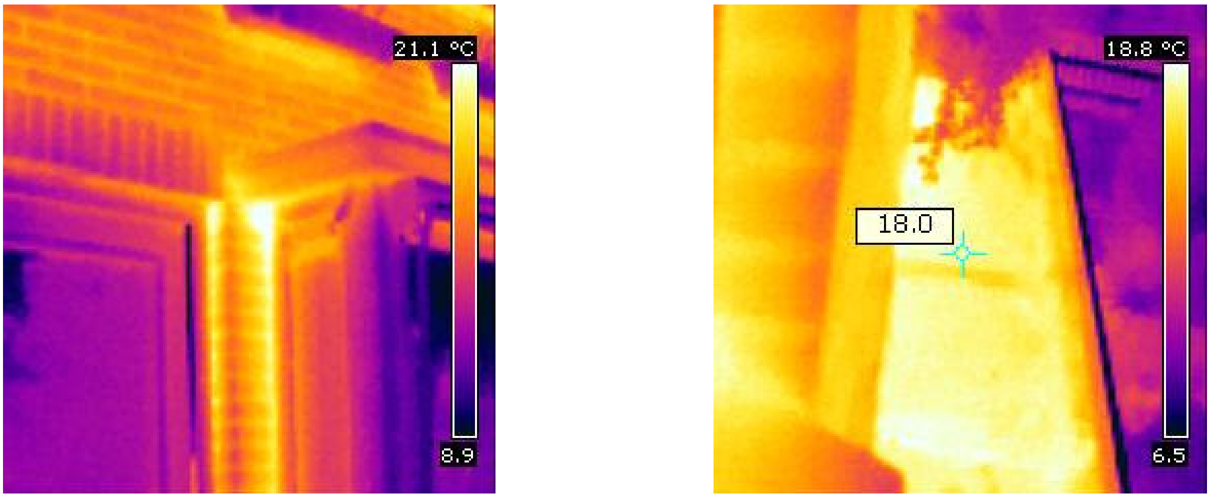

Figure 3 Pictures demonstrating the lower heat resistance of the side and roof of a bay.

3.2 Energy Performance Coefficient

Since 1995 the Energy Performance Coefficient (EPC) is being used to express the energetic quality of new buildings by relating the forecasted building related energy use to a permissible energy use based on the surface area of the object. The building's related energy use roughly includes space heating, water heating, ventilation, lighting, cooling and (renewable) generation.

During recent years the coefficient has been gradually reduced and therefore the energetic quality of new buildings has been improved. The reduced energy consumption of new dwellings resulted in a lower average on natural gas consumption of all dwellings. The average annual energy consumption per dwelling was 2,000 m^3 in 1997 and reduced to 1,736 m^3 in 2004 (SenterNovem, 2007). Nowadays, offices need to comply with a maximum EPC of 1.5 and dwellings with a maximum of 0.8 (Building Code, 2003).

Since 2008 the energy label, expressing the energy performance of houses by using letters, is compulsory in The Netherlands when dwellings are sold (see Fig 4). This label is based on the certification process of the Energy Performance Building Directive of the European Council (EC, 2002). A so called Energy Index has been developed to express the energy performance of existing and new buildings. This Energy Index leads to a specific label. The best performance is expressed by A and the worst by G. Dwellings with an EPC of 0.8 will be labelled with the status A++.

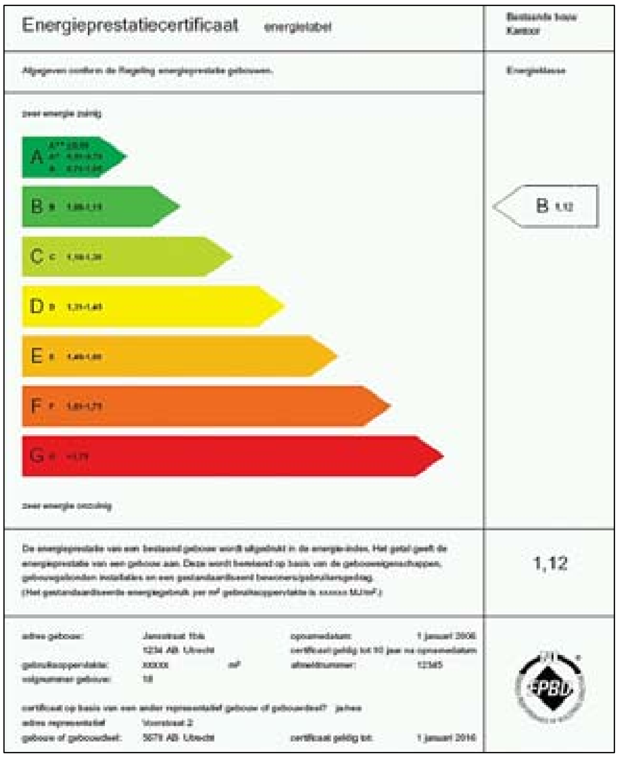

Figure 4 The energy performance of dwellings has been labelled since the 1st of January 2008.

3.3 Results

The Building Code has been stimulating the reduction of the energy consumption of buildings since 1992. In the last fifteen years around 1 million dwellings were newly constructed and were therefore provided with insulation having a heat resistance of at least 2.5 m^2·K/W. The EPC has already exerted influence on 720,000 dwellings. The Dutch government plans to have energy neutral dwellings and offices in 2020. Therefore the EPC will be further reduced to 0.6 for dwellings in 2011. In 2015 the EPC for dwellings needs to be 0.4. For offices similar reductions are planned (Min. HSPE, 2007).

Although the energy performance certificate is not addressed in the Building Code, the label can be based on the EPC, provided that the building license of the dwelling was submitted less than ten years ago. In that case the EPC has a value of 1.2 or less. In 2007 it was already possible to voluntarily obtain a label. At the 31st of December 2007 more than 50,000 dwellings had received a label. Most dwellings (23%) of this group have a D-label and only 1.75% has an A-classification or better (SenterNovem, 2008). According to Gram-Hanssen et al. (2007), the energy labels should be seen as one input, among others, to people's own knowledge and communication about their house and its renovation. Their vision is based on the Danish and Belgium experiences among homeowners regarding energy labeling.

4. National Energy saving Plan (2008-2020)

In June 2007 a proposal was prepared by EnergieNed (the Dutch Federation of Energy Companies), PeGO (the organisation for Energy Transition in the Built Environment), and Aedes (Association of Housing Corporations) to reduce the energy consumption in the built environment with 100 PJ/year in 2020. Although they gave it the name of National Energy saving Plan (NEP), it was more a proposal than a plan. In this chapter no results can therefore be included yet.

4.1 Scope and targets

The NEP proposes to annually improve the energetic performance of 200,000 to 300,000 buildings during twelve years. The investments needed for these improvements are estimated to be € 15 to 25 billion. By implementing the plan approximately 10,000 jobs are expected to be created within the construction industry. The value per dwelling is expected to increase with € 4,000 to 6,000. In 2020 the annual natural gas consumption should be reduced by 2.0 billion m^3 and the electric energy use by 3.9 billion kWh. This reduction is based on the assumption that the energy consumption without changing current policies will increase to 1140 PJ/year in 2020 (PEGO et al., 2007).

At the 23th of January 2008 the Netherlands ministries of Economic Affairs and of Housing, Spatial Planning, and the Environment adopted the National Energy saving Plan by signing an agreement to have saved 100 PJ in 2020. Till 2011 the energy performance of at least 500,000 existing buildings should be improved. Besides reducing the energy use, also the adoption of renewable energy techniques will be stimulated. In 100.000 dwellings renewable energy techniques should be applied before 2012 (Min. HSPE, 2008). However, it should also be mentioned here that renewable sources do not decrease the energy consumption. They only offer a sustainable way of fulfilling this need for energy.

4.2 Proposed approach

The suggested approach focuses on rearranging the economic market for investments in energy saving. Thresholds need to be taken away and proper policies should be adopted. Commercial organisations are asked to commit actively in reaching the objective. A new organisation by name of Energiecentraal (Energy Central) will facilitate and monitor this process.

Within NEP privately owned dwellings and offices are hold responsible for the highest energy consumption in the built environment of 310 PJ/year each. In total the energy consumption in buildings was estimated to be 950 PJ/year. Most of the savings should be accomplished among the privately owned dwellings, namely 43 PJ/year in 2020 (PEGO et al., 2007).

5. Conclusions

In this paper three important Dutch policies in reducing the energy consumption in the built environment were addressed:

1. National Insulation Program (1978-1987)
2. Building Code (1992-…) and the Energy Performance Certificate (2008-…)
3. National Energy saving Plan (2008-2020)

According to Mahlia et al. (2002) a hierarchy is manifested among energy saving policies. It seems however that the regarded policies lack elements of this hierarchy. Ad 1; The highly profitable National Insulation Program, saving up to 51 PJ and € 800 million per year, did not incorporate a label for example. Standardization developed before and during NIP still forms the basis to specify the quality of thermal insulation in social housing and therefore the permissible amount of rent. Ad 2; Since 1992 the Building Code refers to standards regarding minimum thermal insulation and energy performance, but does not refer to a label either. The EPC, specified in the Building Code, can however be used to obtain an energy performance certificate, being the compulsory Dutch energy label for buildings part of a transaction since 2008. Ad 3; The NEP forms the latest addition in reducing the energy consumption of the building stock. It tries to be an incentive program, but does not comprise research activities on the current state nor account for diversity of the building stock, does not incorporate any standards, and lacks financial resources.

However, the combination of the former two policies has resulted in a residential building stock with a large diversity regarding its adoption of energy saving measures. The annual energy consumption of dwellings was lowered on average. One out of four dwellings has been partially energetically improved by the National Insulation Program. One out of seven dwellings was built conform the Building Code and the EPC had its impact on one out of ten dwellings. Furthermore, many houses have been extended to create more living space. These extensions should also be insulated conform the Building Code. Furthermore, in the time period between NIP and NEP, there were, regarding budget and geographical considerations, some smaller incentive programs stimulating the adoption of energy saving measures. Accordingly it can be concluded that the target of NEP to improve the energy performance of 3 million houses is unfeasible, when not a proper inventory is made and no financial incentives tailored to individual cases are provided.

Acknowledgements

The authors would like to express their gratitude to the SenterNovem for providing financial support of the present research.

Keywords: thermal performance, mandatory disclosure, energy efficiency, building stock

ABSTRACT

In a world that is increasingly moving to mandate the disclosure of building energy performance, does the market recognize the benefit of better energy efficiency?

The thermal performance of building shells of houses in Australia has been modelled for voluntary and regulatory purposes using software under the Nationwide House Energy Rating Scheme since the mid-1990s. In 1995 the Australian Capital Territory (ACT) introduced a requirement that new houses reach a 4 star energy standard, and this stringency was increased to 5 stars through the Building Code of Australia in 2006.

From 1999 mandatory disclosure of energy performance was required for all houses sold in the ACT, as a policy to influence the energy performance of existing houses. The resulting data represents a unique opportunity to establish whether information on house energy efficiency rating (EER) affects sale price. This policy analysis was undertaken in the context of commitments by all governments in Australia in 2004 to develop mandatory disclosure of energy performance for all residential and commercial buildings.

The Analytical Services Branch of the Australian Bureau of Statistics was commissioned to undertake a project using Hedonic analysis. The prices of detached houses sold in the ACT in 2005 and 2006 were modelled as a function of land, distance, neighbourhood, socio-economic and EER data. The results provide a clear indication of a robust Hedonic price model (R^2>0.8), with a highly significant coefficient for EER, and evidence that the market values energy performance.

This research will be of strong interest to all countries considering disclosure as a means to drive energy efficiency improvements in the existing building stock.

1. Policy context

Governments in Europe and elsewhere have recently considered that mandating the disclosure of energy or environmental performance of buildings would facilitate a more efficient real estate market where all players could recognize the inherent performance characteristics and be better able to determine value.

In Europe, the Energy Performance in Buildings Directive has moved mandatory energy performance disclosure to the forefront of the energy and climate change policy agenda.

Securing Australia's Energy Future, the Energy White Paper released by the Australian Government in 2004, committed to ensuring that all commercial and residential building owners disclose the building's energy performance prior to sale or lease. This concept has been supported by all Australian State and Territory jurisdictions through the Ministerial Council on Energy, and is part of the National Framework for Energy Efficiency (NFEE).

The Department of the Environment, Water, Heritage and the Arts (formerly the Australian Greenhouse Office), on behalf of all jurisdictions, was asked to develop a nationally consistent framework that will allow the mandatory disclosure of energy performance on sale or lease of buildings. This study of the relationship between house price and energy efficiency was conducted as a key part of that research with the goal of understanding the effectiveness of providing energy performance information to a mature housing market place.

2. The ACT housing market

In 1999 the government of the Australian Capital Territory (ACT) mandated that the energy performance be calculated and disclosed as a part of all house sales, as a policy to encourage improvements in the energy performance of existing houses. This policy has created a large data set of building energy performance and sales information unparalled in the world, and represents a unique opportunity to establish whether the provision of information on house energy efficiency rating (EER) affects sale price.

Mandatory disclosure of building energy performance ratings, as required in the Australian Capital Territory, is designed to provide accurate and standardised information about inherent building energy efficiency to the market, similar to energy labelling of appliances such as refrigerators.

The ACT housing market is small but robust, servicing the needs of a population just over 330,000 who live in Canberra, Australia's national capital. Canberra was settled from 1912 but grew rapidly during the 1960s and 1970s.

The ACT market represents a relatively homogeneous stock of detached housing in suburban neighbourhoods. Over 87 per cent of existing homes sold in 2005 and 2006 were detached dwellings, mostly with 3 to 4 bedrooms. The average dwelling size in the study sample was around 141 m^2 on a block of 836 m^2 located in a suburban setting averaging 11 km from the central business district.

The cool temperate climate of the Australian Capital Territory is one of extremes. With its major city Canberra elevated at 580 metres above sea level in the Great Dividing Range, winter night-time conditions can reach minus 10^{o}C while summer daytime temperatures can exceed 35^{o}C. The main climate characteristics that impact energy efficient design are: low humidity; high diurnal temperature range; four distinct seasons; summer and winter conditions that regularly exceed human comfort range; cold to very cold winters; hot dry summers; and variable spring and autumn conditions.

3. Process of disclosure

The process of disclosure in the ACT consists of an energy efficiency rating (EER) of the building fabric using a nominated thermal performance software package. The disclosure is provided in the form of a star rating, from 0 to 6 stars (recently extended to 10 stars) in half star increments, 0 stars being very poor and 6 stars being significantly more thermally comfortable.

The EER rating is required to be provided to consumers in all advertising material, and the full certificate which also indicates possible energy performance improvements to the building, is required to be provided during the sales transaction process.

The thermal performance of building shells of houses in Australia has been modelled for voluntary and regulatory purposes using software under the Nationwide House Energy Rating Scheme since the mid-1990s. In 1996 the Australian Capital Territory (ACT) introduced a requirement that new houses reach a 4 star energy standard, and this stringency was increased to 5 stars through the Building Code of Australia in 2006.

Prior to the introduction of minimum energy performance standards homes were typically built to a standard lower than 2 stars. The study sample of over 5,000 house sales, which excluded those impacted by new building standards, found that the average performance of existing homes was just below 1.7 stars, with examples ranging from 0 to 6 stars.

The disclosure of energy efficiency performance in the ACT does not include the assessment of the hot water system, lighting system or other fixed appliances.

4. Purpose of the study

This study examines the relationship between the energy efficiency rating and house price. In other words, does a higher EER rating lead to a higher sales price? For example, if a person buying a house knows from the disclosed energy performance rating that a building is energy efficient relative to available alternatives, they may be willing to pay more for the property because the additional cost will be offset by expected savings in energy bills, or conversely, they may wish to pay less for homes with a low rating, recognising the ongoing energy costs to maintain thermal comfort.

If it could be established that there is a positive relationship between EER and sales price, knowing there may be a return in a higher sale price creates an incentive for property owners to invest in improved energy efficiency. This in turn could drive improvements in the energy performance of the existing housing stock, and encourage builders of new residential buildings to create homes above the minimum energy performance requirement.

5. Unique data set

To build the data set the ACT Planning and Land Management Agency (ACTPLA) was commissioned to examine all house data files that matched house sales records in the calendar years 2005 and 2006 to collate relevant house characteristics necessary for the hedonic model. These characteristics included house size, block size, window area, floor and wall material, the number of floors, the potential for cross ventilation, the presence of shading schemes, and many others. ACT Government held sales information was collated for the same dwellings including settlement date, transfer date, and transfer price. After the necessary data cleaning and quality checks, removal of unexplained outliers, and the linking of the ACTPLA and EER records using the suburb, block and section information, the final dataset consisted of 2,385 and 2,719 house records for 2005 and 2006, respectively.

The years 2005 and 2006 were considered for this study because they represented the latest possible complete data set for a mature market. Earlier periods were avoided to reduce the likelihood of program start-up influences. All houses built after 1995 were excluded from the dataset to avoid any impact of the new minimum performance standards.

As per all hedonic models, it is impossible to collect a dataset that contains every possible influence in the sales price, and the limitations of the dataset are acknowledged. However, it should be emphasised that, despite these limitations, it is nevertheless a large, high-quality sample, probably unique in the world, certainly in Australia.

6. The hedonic model

The Analytical Services Branch of the Australian Bureau of Statistics (ABS), the Australian Government's primary statistical collection and analysis agency, was commissioned to undertake a project using hedonic analysis (Chen *et al* 2004, Hansen 2006). The prices of detached houses sold in the ACT in 2005 and 2006 were modelled as a function of land, distance, neighbourhood, socio-economic and EER data. This study was careful to allow all major influences such as location, size and construction of house, value of land, etc, to be treated in a consistent manner to that of the energy efficiency rating.

Hedonic regression regresses price against a host of explanatory variables, where in this case it decomposes the house price into its constituent characteristics, and obtains estimates of the value of each characteristics. For this study, five main categories of variables were considered: (a) structural variables which covered the design and construction features; (b) distance variables which described the relative location to shops, schools, hospitals, and the central business district; (c) neighbourhood variables which cover key social and economic conditions surrounding the home; (d) locational variables which can explain elements of suburb prestige; and (e) energy efficiency characteristics.

The impact of house price inflation was removed from the house price data using the ABS house price index for the ACT.

7. The results

The study has found that there is a statistically significant relationship between the house price and the following house characteristics: floor area, block area, distance to CBD, socio-economic advantage, window area, percentage of 5 bedroom homes in local area, whether the house had previously been a government rental property, and the energy efficiency rating.

EER was found to be positively associated with house price and had a strongly significant relationship. The association on average for 2005 was 1.23 percent for each 0.5 EER star, and 1.91 percent in 2006, holding all other variables constant.

The results provide evidence of a powerful hedonic price model ($R^2>0.82$), with a highly significant coefficient for EER ($p < 0.0001$, t-Statistic > 4), and substantiates that the market values energy performance.

Factors such as double glazing, which also provides a noise benefit, was found to have a strongly positive benefit, while ceiling and wall vents were found to have a negative relationship with house price. Attributes pertaining to the EER such as brick wall, timber flooring, largest window facing north, were not found to have a significant relationship with price.

8. What do the results mean?

While there is a statistically significant relationship between EER and house price, the energy rating explains only a small proportion of the total value of a house. As is to be expected, factors such as block and house size, and location have a greater influence on house price. However, *other things being equal,* a house with a high EER will command a higher price than one with a lower EER.

This study shows that mandatory disclosure of energy performance on sale of property in the ACT has been a successful mechanism for allowing the housing market to recognize the value of energy efficiency. It is clear that the ACT market place has shifted from the traditional real estate industry trio of factors *location, location, location*, to a scenario that rewards *location, location, EER*.

This study concludes that if the energy performance of a house is improved by one star level, on average its market value will increase by about 3 per cent (range 2.5 – 3.8). For example: for a detached house sold in Canberra in 2005 at the median price of AUD365,000, increasing the EER rating by one star would be associated with, on average, an additional price increase of about AUD11,000.

This creates multiple incentives to invest in energy efficiency. First, there are benefits of reduced operational energy costs. Second, the higher capital value of the property due to the improvement in energy efficiency is likely to be greater than the cost involved in achieving the improvement. Third, there are direct and indirect consumer benefits of energy efficiency including thermal comfort, physical health, and mental satisfaction associated with lower environmental impacts.

For example, installing R4 ceiling insulation will cost approximately AUD1,200 and will on average improve the energy performance of a poorly insulated home by at least 1 star. That increase in energy performance corresponds to an average increase in sales price of over AUD11,000. Of course, each house sale transaction is impacted by many circumstances and the exact premium for performance can not be calculated from this study, nevertheless, the study has found that the ACT market strongly favours better energy performance when the information is disclosed.

The research will be of strong interest to all governments considering disclosure as a means to drive energy efficiency improvements in the existing building stock.

9. Thanks

The Australian Government would like to recognize the support of the ACT Government in collecting the dataset necessary for this report, and recognizes the expertise of the staff of Australian Bureau of Statistics. This study was funded by all Australian jurisdictions under the National Framework for Energy Efficiency managed by the Ministerial Council on Energy.

Keywords: Buildings, energy efficiency, policy instruments, effectiveness, efficiency, cost-effectiveness

Summary

Approximately one third of the GHG emissions from buildings can be saved at a net benefit to society (IPCC 2007). However, this substantial potential is not realized due to numerous barriers. Various policy instruments such as building codes, subsidies and information campaigns are applied to overcome these barriers. Since they differ considerably in their effects and costs, 20 commonly used policy instruments were assessed in this study according to their emission reduction effectiveness, cost-effectiveness and success factors, based on over 80 case studies and evaluations of their implementation from over 50 countries.

Many policy instruments achieved high savings at low or even negative costs for society. The highest GHG emission reductions were achieved in the sample by appliance standards, building codes, DSM programs, tax exemptions and labelling. Appliance standards, energy efficiency obligations, DSM programs, public benefit charges and labelling were found as the most cost-effective instruments. Regulatory and control instruments were revealed in the sample as the most effective and cost-effective category of instruments if enforced well. Economic and fiscal instruments and fiscal incentives lead to diverging results. The effectiveness of voluntary and information instruments was usually lower, but depended on the context as well as on accompanying policy measures.

However, as no single policy instrument can overcome the numerous barriers alone, appropriate combinations of policy instruments are most effective. Developing countries require an integrated policy framework including regulations, incentives, capacity-building as well as measures to increase awareness and the trust of stakeholders such as demonstration programs. Choosing the most appropriate policy instruments is very difficult and requires a detailed analysis of the barriers present, the local environment in terms of institutions and existing energy market, the available resources and goal of the action.

1. Introduction

In 2002, 33% of all energy-related CO2 emissions worldwide were due to buildings (Price et al. 2006). However, buildings offer important energy saving potentials through technical, educational and other means: approximately 30% of this energy consumption can be saved economically or at a net benefit to society even at zero carbon price (IPCC 2007, Urge-Vorsatz and Novikova 2008). Considering the baseline projections, this estimate represents a reduction of approximately 45 EJ for buildings in 2020 (IPCC 2007).

Although this large cost-effective potential has been known for decades, many of these energy efficiency possibilities have not been realized. Actually, certain characteristics of markets, technologies, and end-users make difficult rational, energy-saving choices in building design, construction, and operation, as well as in the purchase and use of appliances. These market barriers and failures can be divided into six categories (Carbon Trust 2005): financial hurdles, hidden costs and benefits, market failures, behavioural constraints, information barriers and institutional/ structural barriers.

In order to overcome or limit the impact of these barriers, a wide variety of policy instruments and programs are used by policy-makers worldwide. However, the effectiveness and cost-effectiveness of these various policy instruments is poorly understood and rarely compared on an international level. Thus, this study developed at the Central European University originally for the Fourth Assessment Report (AR4) of the Intergovernmental Panel on Climate Change (IPCC) (2007) and deepened for the UNEP Sustainable Buildings and Construction Initiative (UNEP-SBCI) (Urge-Vorsatz and Koeppel 2007) reviews comprehensively the policy mitigation options for the buildings sector.

This paper aims at assessing and comparing the various policy instruments available for CO2 mitigation in buildings through improved energy-efficiency, according to evaluation criteria such as emission reduction effectiveness and cost-efficiency. A special focus is placed on developing countries. The paper presents information on 20 policy instruments from around the world and provides an overview of the effects, strengths and weaknesses of these policy instruments. It also briefly presents the ongoing follow-up project which aims at elaborating a tool for supporting policy-makers in choosing the most appropriate policy instruments.

2. Methodology

First, the most important policy instruments to promote energy efficiency in the buildings sector were identified in the general literature on policy tools for energy efficiency (Crossley et al. 1999, Crossley et al. 2000, Verbruggen 2003, Grubb 1991, EFA 2002, Vine et al. 2003, and Wuppertal Institute 2002), classified into the following four categories and included in the first column of the table: regulatory and control mechanisms, economic/ market-based instruments, fiscal instruments and incentives and support, information and voluntary action.

Subsequently, we searched for as many ex-post evaluations of these instruments from as many countries as possible. Only a few ex-ante assessments were included in the analysis. In total, over 80 studies, review articles and other relevant publications from over 50 countries, covering each inhabited continent except for Africa were identified. All findings were collected in a database and a table showing the evaluation of the instruments, based on selected best practice examples – see Table 1. Due to space limitations this paper only shows the short version of the table, the long one is included in the report (Urge-Vorsatz and Koeppel 2007). The second column assesses the effectiveness in reducing emissions of each policy instrument in the buildings sector in a qualitative way either in absolute or in relative terms (i.e. compared to a logical baseline, such as the total national emissions in the particular location). The collection and analysis of all cases included in our database was used to assign grades such as “High”, “Medium” and “Low” to policy instruments for their effectiveness in reducing energy use and GHG emissions. Ideally, such grades should be assigned in a systematic objective way based on numerical limits of emission reductions, but this method was not possible due to lack of baselines in some cases. In addition, due to differences in the temporal and spatial scale the numerical values of emission reduction, even in relative terms, as well as the total emission coverage of the case studies and of the policy instruments could not easily be compared, even in relative terms. Thus, this criterion was evaluated in a qualitative way, based on emission reduction figures, but taking into account the overall applicability and potential of the instrument. According to the Delphi technique, an internationally recognized method for obtaining comments from experts in at least two rounds, the results of the comparative evaluation table were circulated several times for review to numerous experts recognized as leading scholars or practitioners in this field.

Column 3 of the table evaluates the cost-effectiveness of each policy instrument with qualitative verbal grades similarly to Column 2. In our study, the cost-effectiveness is viewed from a societal perspective, taking into account, when possible all the direct costs and benefits from the policy-making perspective, but excluding the indirect or external costs. However, many policy evaluations assessed the cost-effectiveness of energy savings only according to the cost required to conserve energy (capital costs and investment costs). These figures are often used to compare the costs of demand and supply side investments for “producing” a unit of energy, and therefore are not corrected for the benefits, i.e. saved energy costs. However, assessing societal cost-effectiveness requires including these financial benefits (Koomey and Krause 1989; Atkinson et al.1991). For this reason, in our calculations we subtracted the country-specific energy price from the cost per unit of saved energy before multiplying with the emission factor.

The final columns present success factors or success conditions, co-benefits and other remarks.

3. Results

3.1 Comparative assessment of policy instruments

As can be seen on table 1 and on figure 1, our study does not characterize any single policy instrument as the most effective or most cost-effective one, but it shows that many of the policy instruments can be effective and cost-effective when certain criteria are respected during their design, implementation and enforcement (success conditions). Appliance standards, building codes, voluntary labelling and tax exemptions achieved the highest CO_2 emission reductions in our sample. Costs per tonne of carbon dioxide saved varied widely ranging from a net benefit of 216USD, i.e. a negative cost, to a positive cost of 109USD/ tCO_2 saved. Appliance standards, utility DSM programmes, public benefit charges, energy efficiency obligations and mandatory labelling were identified as the most cost-effective policy tools in the sample, achieving significant GHG emission reductions at negative costs. Appliance standards were very cost-effective with negative costs of 65-190USD/tCO_2. Appliance standards, energy efficiency obligations and tax exemptions were identified as most effective and cost-effective policy tools in our sample (see highlighted rows of table 1).

When comparing the four broad categories of instruments (see table 1), regulatory and control instruments have been found to be among the most effective policy instruments with particularly high negative costs (i.e. very low costs) of mitigation, although the rebound effect can limit the overall effectiveness and correct enforcement is necessary. Within this category, appliance standards, energy efficiency obligations and building codes were especially effective. Appliance standards and energy efficiency obligations were also very cost-effective.

Economic instruments are still difficult to evaluate since some of them such as Kyoto Flexible Mechanisms and White Certificate are still relatively new; but their effectiveness and cost-effectiveness seems to depend significantly on the instrument and the country. The effectiveness and cost-effectiveness of project-based mechanisms, such as the Kyoto flexible mechanisms (JI and CDM) are currently limited, probably due to high transaction costs involved with small projects in the building sector.

Fiscal instruments and incentives also lead to very diverging results: subsidies are not cost-effective in contrast to the reviewed cases in tax exemptions (income taxation). However, they are useful to kick-start the market for new energy efficient products especially in developing countries where funding is often lacking.

Table 1: Table summarizing the effectiveness and cost-effectiveness of policy instruments

Policy instrument	Emission Reduction Effectiveness	Cost-effective-ness	Special conditions for success, major strengths and limitations, co-benefits
Regulatory instruments			
Appliance standards	High	High	Factors for success: periodical update of standards, independent control, information, communication, education
Building codes	High	Medium	No incentive to improve beyond target. Only effective if enforced
Public leadership programs, incl. procurement regulations	Medium/High	High/Me-ium	Can be effectively used to demonstrate new technologies and practices. Mandatory programs have higher potential than voluntary ones. Factors for success: ambitious energy efficiency labeling and testing.
Energy efficiency obligations and quotas	High	High	Continuous improvements necessary: new energy efficiency measures, short term incentives to transform markets
Mandatory audit requirement	High, but variable	Medium	Most effective if combined with other measures such as financial incentives
Demand-side management programs (DSM)	High	High	Tend to be more cost-effective for the commercial sector than for residences.
Economic instruments			
Energy performance contrac-ting (EPC)/ESCO support	High	Medium/ High	Strength: no need for public spending or market inter-vention, co-benefit of improved competitiveness.
Cooperative procurement	High	Medium/ High	Combination with standards and labeling, choice of products with technical and market potential
Energy efficiency certificate schemes/white certificates	Medium/ High	High/Me-dium	No long-term experience. Transaction costs can be high. Institutional structures needed. Profound interactions with existing policies. Benefits for employment.
Kyoto Protocol flexible mechanisms (CDM and JI)	Low	Low	So far limited number of CDM &JI projects in buildings
Fiscal incentives			
Taxation (on CO_2 or fuels)	Low/ Medium	Low	Effect depends on price elasticity. Revenues can be earmarked for further efficiency. More effective when combined with other tools.
Tax exemptions/ reductions	High	High	If properly structured, stimulate introduction of highly efficient equipment and new buildings.
Public benefit charges	Medium	High	Success factors: independent administration of funds, regular monitoring &feedback, simple &clear design.
Capital subsidies, grants, subsidized loans	High	Low	Positive for low-income households, risk of free-riders, may induce pioneering investments.
Support, information and voluntary action			
Labelling and certification programs	Medium/High	High/ Medium	Mandatory programs more effective than voluntary ones. Effectiveness can be boosted by combination with other instrument and regular updates.
Voluntary and negotiated agreements	Medium / High	Medium	Can be effective when regulations are difficult to enforce, combined with financial incentives, and threat of regulation
Public leadership programs	Medium/ High	High/ Medium	Important as demonstration programs. Mandatory programs are usually more effective than voluntary ones.
Education and information programs	Low / Medium	Medium/ High	More applicable in residential sector than commercial. Success condition: best applied in combination with other measures.
Detailed billing and disclosure programs	Medium	Medium	Success conditions: combination with other measures and periodic evaluation.

Support, information and voluntary action instruments vary significantly in their effectiveness. However, awareness raising instruments are nevertheless important to complement other instruments by limiting the rebound effect. Voluntary instruments are usually less effective than mandatory ones. Public leadership programs are often effective and important, not only for the public sector.

These results can be explained by the especially numerous barriers to energy efficiency in the buildings sector which are probably higher than in any other sector (Urge-Vorsatz et al. 2007). Among them, high transaction costs for information search for example is a major barrier. Regulatory and control instruments eliminate these transaction costs by simply mandating the same measures for all actors which seems to be one of the reasons for their high effectiveness and cost-effectiveness.

These results are confirmed by other studies such as the Mure database (MURE 2007) which contains numerous policy instruments from various European countries (but usually not with quantitative values). According to this database, legislative – normative instruments for buildings, such as building codes, are most often ranked as effective compared to other instruments.

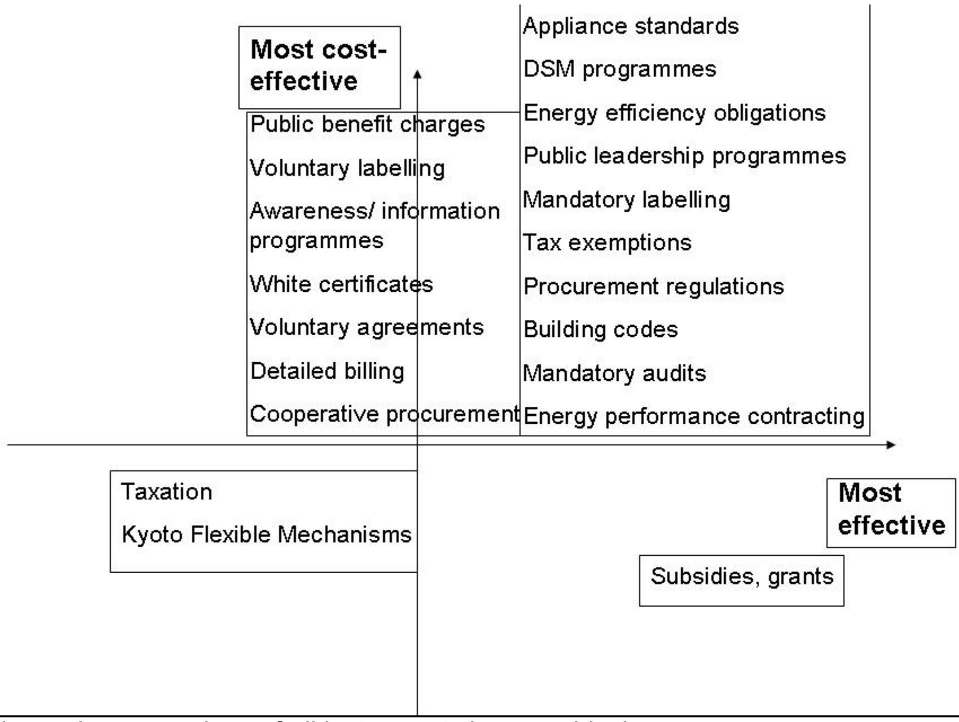

Figure 1 shows the comparison of all instruments in a graphical way.

Note: The positions of the instruments towards each other don't indicate differences in effectiveness- only the position of the instruments in one of the corners is important.

3.2 Combination of policy instruments

However, no single instrument can capture the entire or even a large part of the economic and low-cost mitigation potential in the sector alone. Due to the especially numerous and diverse barriers in the buildings sector, and to the variety of local conditions and cultures, a portfolio of instruments is necessary to overcome several barriers, to take advantage of synergistic effects and thus to maximize the impact of policies. Informative and financial as well as, to a lesser extent, market-based instruments are usually implemented in combination with other instruments which makes assessments of single policy instruments as we presented very difficult. The following policy instruments can for example be successfully combined:

- Standards and financial incentives
- Regulatory and information programs
- Public leadership programs and energy performance contracting
- Financial incentives or procurement initiatives and labeling

Combinations of policy instruments are especially important to achieve a market transformation which is however much less frequently aimed at and achieved for buildings than for appliances for example. In order to stimulate the market it is recommended to aim at and implement measures for achieving 3 different levels of building performance: a minimum performance level, mandatory for all buildings which can be reached through minimum standards; a best practice level which is often used as a basis for defining subsidies, tax exemptions, loans etc.; and finally a state-of-the art level which is often set a long-term target to provide incentives to industry to further improve (Klinckenberg et al. 2007). Table 2 shows possible combinations of instruments.

Table 2: A selection of possible policy instrument packages and examples of commonly applied combinations

Measure	Regulatory instruments	Economic instruments	Financial /Fiscal Incentives	Information instruments	Voluntary Agreements
Regulatory instruments	Building codes and labelling	Standards and ESCO support	Building codes and subsidies	Standards and information programs	Voluntary agreements with a threat of regulation
Economic instruments	Energy efficiency obligation and ESCO support		Cooperative procurement and subsidies	EPC and information campaigns	Cooperative procurement and information campaigns
Financial/Fiscal Incentives	Appliance standards and subsidies	Cooperative procurement and tax exemptions	Taxes and subsidies	Energy audits and subsidies Labelling and tax exemptions	Technology procurement and subsidies
Information instruments	Appliance standards and voluntary labelling	EPC and information campaigns	Labelling and subsidies	Labelling, campaigns, and retailer training	Voluntary standards and labelling
Voluntary Agreements	Voluntary agreements with a threat of regulation		Industrial agreements and tax exemptions	Industrial agreements and energy audits

3.3 Measures recommended for developing countries

Table 3 shows which policy instruments can overcome which type of barriers. Developing countries are facing special barriers such as lack of awareness, lack of financing for energy efficiency measures, shortage of qualified personnel and insufficient energy service levels (Urge-Vorsatz and Koeppel 2007). Stakeholders sometimes don't trust energy efficient technologies because of negative experiences with these. In addition, frequently, subsidized non-cost reflective energy prices provide little incentive for energy efficiency improvements (IPCC 2007). In many developing countries, the priority of the government is to improve access to electricity without understanding that energy efficiency improvements are also important in order to start with efficient technology from the beginning and thus limit the expected increase in demand to manageable levels. Often, energy shortages provide a good incentive to improve energy efficiency which happened for example in Brazil and South Africa where compact fluorescent lamps are already widely used (Glynn pers. Comm., Gomes, per. Comm.).

Table 3: Barriers to energy efficiency and selected policy instruments as remedies

Barrier category	Instrument category	Policy instruments as Remedies
Economic barriers	Regulatory-normative/ regulatory-informative	Appliance standards, building codes, energy efficiency obligations, mandatory labelling, procurement regulations, DSM programs
	Economic instruments	EPC/ESCOs, cooperative procurement, energy efficiency certificates
	Fiscal instruments	Taxation, public benefit charges, tax exemptions, subsidies/rebates/grants
Hidden costs/benefits	Regulatory-normative	Appliance standards, building codes
	Economic instruments	EPC/ ESCOs
	Support action	Public leadership programs
Market failures	Regulatory-normative/ regulatory/informative	Appliance standards, building codes, energy efficiency obligations, mandatory labelling, procurement regulations, DSM programs
	Economic instruments	EPC/ESCOs, cooperative procurement, energy efficiency certificates, Kyoto Flexibility mechanisms
	Fiscal instruments	Taxation, public benefit charges, tax exemptions, subsidies/rebates/grants
	Support, information, voluntary action	Voluntary labelling, voluntary agreement, public leadership programs, awareness raising, detailed billing
Cultural/ behavioral barriers	Support, information, voluntary action	Voluntary labelling, voluntary agreement, public leadership programs, awareness raising, detailed billing
Information barriers	Support, information, voluntary action	Voluntary labelling, voluntary agreement, public leadership programs, awareness raising, detailed billing
	Regulatory/informative	mandatory labelling, procurement regulations, DSM programs, mandatory audits
Structural/ political	Support, information, voluntary action	Public leadership programs

Sources: Adapted from IPCC 2007, Carbon Trust 2005, Urge-Vorsatz *et al*. 2007b

Due to these special barriers developing countries require an integrated policy framework combining regulations, (financial or other) incentives, demonstration initiatives, capacity building and measures to increase not only the awareness about energy efficiency, but also to increase the trust of stakeholders (Urge-Vorsatz and Koeppel 2007). Capacity-building, technical assistance and training are indispensable to educate experts in these countries. As this will take time, external experts are needed at least for a transitional period (Lihidheb, pers. Comm.). In addition, demonstration projects in the public and private sector such as those selected and supported by MED-ENEC are important to overcome barriers such as the lack of knowledge and trust (Wenzel pers. Comm. 2007). Similarly, information and awareness raising programs can inform the population about the possibilities and potential for energy saving measures. To support, design and implement such programs, institutions specifically dealing with energy efficiency are needed. For example, most developing countries which are considered as relatively successful in terms of energy efficiency improvements such as Tunisia, Thailand, South Africa, Brazil and Mexico have created either energy efficiency agencies or departments dedicated to energy efficiency at the relevant ministries or even special ministries to publicize the importance of energy efficiency among the population (Wenzel pers. Comm. 2007).

Regulatory measures are important also in developing countries. However, compliance is often low due to lack of information, lack of political will, lack of enforcement, high share of black or grey economies (esp. in the construction industry) and especially lack of funding (Mueller pers. Comm. 2007). Thus, enforcement activities and financial resources to support implementation and compliance are necessary, but not sufficient: special efforts and incentives are needed such as awards, subsidies, loans or tax exemptions to facilitate energy savings. In fact, the lack of available financing to cover the investments necessary for energy efficiency measures is often the major barrier in developing and transition countries. Banks are often not willing to finance energy efficiency measures due to lack of knowledge and trust. Some countries such as Thailand or Tunisia have therefore introduced funds for energy efficiency measures which are fed by taxes on cars for example (du Pont 2006). In Brazil, utilities are obliged to spend 1% of their annual revenues for DSM-measures ESCO-financing is another possibility which is already widely used in some developing countries such as China, but much less in others such as India. However, energy performance contracting requires certain institutional structures for being successful which are not present in all developing countries (Urge-Vorsatz and Koeppel 2007). A number of less developed countries completely lack funds and therefore, international funding is thus one of the only options in these cases for reducing energy efficiency.

Finally, there is a need for regular monitoring and evaluation of energy efficiency programs and subsequent revision of programs- in developing as well as developed countries.

3.4 Development of a tool for helping policy-makers to choose most appropriate instruments

Current research (April 2008) is focusing on developing a software tool for supporting policy-makers in choosing the most appropriate combination of policy instruments under particular circumstances and policy targets. Since this is very difficult the tool includes a detailed analysis of the present barriers, the local environment in terms of institutions and existing energy market, available power and capacities and the available resources. The policy goal as well as the target area and target group of the action are also important factors determining the choice of the most effective policy tool package.

Finally, no policy instrument will be effective if its most important success conditions are not fulfilled. Success conditions depend on the instrument and may include regular update, appropriate enforcement, and combination with other policy instruments etc. Despite of the development of such a generic tool it has to be recognized that all policy instruments always must be adapted to the local context in their detailed design.

4. Conclusion and recommendations

This study has probably for the first time comparatively assessed 20 policy instruments for reducing GHG emissions from buildings in terms of their effectiveness and cost-effectiveness based on more than 80 quantitative evaluations of their implementation from over 50 countries. The highest GHG emission reductions in the sample were achieved by appliance standards, building codes, DSM programs, tax exemptions and labeling. Among the most cost-effective instruments were appliance standards, energy efficiency obligations, DSM programs, public benefit charges and labeling. In general, regulatory and control instruments such as appliance standards and building codes were revealed as most effective and usually also cost-effective category of policy instruments for the buildings sector if they are correctly enforced. Economic and market-based instruments as well as fiscal incentives vary widely in their effectiveness and cost-effectiveness: the latter are especially useful for stimulating the market for new products as well as for developing countries. Voluntary, support and information instruments are often essential in combination with others.

Developing countries require specific measures and support due to their lack in financing and human resources. However, each of these instruments can only overcome a limited number of barriers. Thus, in order to capture synergistic effects and address the broad range of barriers always present in every country, they have to be combined appropriately in policy packages. Since evaluations of policy packages are very rare, they could not be included in the paper. It is therefore recommended that a few typical, often used, well-matching combinations of instruments as well as some combined but actually confronting instruments should be evaluated in several countries. The paper summarized a new initiative to develop a tool that develops optimal policy package recommendations for particular circumstances. Finally, further comparative studies focusing also on developing countries as well as evaluations of (new) policy instruments for mitigation options in buildings such as white certificates are needed in order to confirm our preliminary conclusions.

Keywords: Peak-load, Space conditioning, Air-conditioner, Demand management, Modeling, Benefit/Cost

Summary

A growing number of energy supply authorities now struggle to meet summer electrical peak load demands. In Australia, these demands, driven largely by recent increases in air-conditioner ownership (see figure 1) now pose an immediate threat to the security of supply.

Traditionally, supply side solutions have been used to deal with peak load issues. However, these have proven very costly and place a drain on limited resources that some argue would be better directed towards demand side solutions. Unfortunately, benefits in terms of reduced peak loads accruing from demand side measures, particularly those relating to building shell improvements, have in the past proven difficult to accurately quantify.

In 2006/7 the then Australian Greenhouse Office (AGO) (now Department of the Environment, Water, Heritage and the Arts), in collaboration with Energy SA, engaged Energy Efficient Strategies (EES) to develop and test an appropriate model of peak load demand in South Australia. The aim was to establish a relationship between weather conditions and the weather sensitive component of the state electrical load as estimated through building simulation analysis.

When gauged against actual demand, the model that was developed was found to provide an average maximum demand error of ±2.8%. The model is now being harnessed to estimate future peak load reduction as a direct consequence of energy efficiency programs. Consequently, this model will allow claims of additional economic benefits for energy efficiency measures to be incorporated into future benefit/cost analyses.

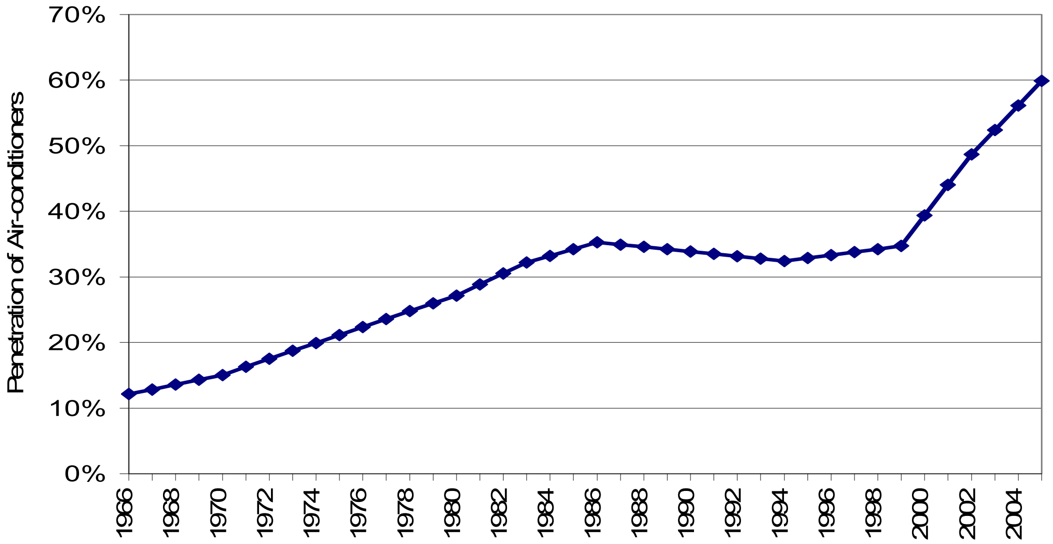

Figure 1 Percentage of Australian Households with One or More Air Conditioners (EES 2008)

1 Background

In Australia, summer electrical system peaks in demand invariably coincide with severe weather conditions (high temperatures). The ten highest peak demand days between 2000 and 2004 in South Australia all had maximum daytime temperatures in excess of 35C. Whilst other factors play a part, it is apparent that these peaks in electricity demand are being driven largely by the use of space conditioning equipment (principally refrigerative air-conditioners). Generation capacity and transmission and distribution capacity can also be reduced by extremely high temperatures, further exacerbating the problem.

In 2004, EES was commissioned by the Victorian Energy Corporation (VENCORP) to assist them to develop a new model of electrical peak demand in that state. Up until that time VENCORP had relied upon a largely econometric model for forecasting state electrical maximum demand. The incumbent model was proving to be less and less reliable and a new approach was sought.

Energy Efficient Strategies undertook the development of a new model. This model utilized building shell simulation tools to model expected cooling loads at a state level, these forecast cooling loads were then matched to a model of space conditioning equipment ownership and attributes to derive estimates of actual electrical demand arising from space conditioning use. These estimates were then added to estimates of the weather insensitive component of the load to derive a maximum demand value. Modeling was undertaken on an hourly basis.

The model was tested/calibrated by applying historical yearly weather data for the previous 5 year period to the simulation model. The outputs of the model were then compared to actual hourly electrical demand data as provided by VENCORP and the accuracy of the model was found to be very good.

In 2006/7 EES were commissioned to apply the same modeling techniques to South Australia. South Australia, the state with the highest ownership of air-conditioners in Australia (excluding the Northern Territory), suffers the worst state electrical load factor of any state or territory. A mild day in South Australia typically produces a daily maximum electrical demand of just over 1500MW (2000-2004) whereas a series of days of extreme weather during the summer can push maximum demand to more than 2800MW

For the purposes of short term forecasting of likely peak demand, supply authorities in Australia have tended to rely on the use of simple metrics such predicted dry bulb temperature. Longer term forecasting has also included some econometric modeling. But the correlation between dry bulb temperature and maximum daily demand is not as strong as one might expect (see Figure 2) and as such these existing models have been proving less and less reliable in recent times. Furthermore, these models have little or no value as a tool for developing demand side policy options. The model detailed in this paper has sought to redress these shortcomings.

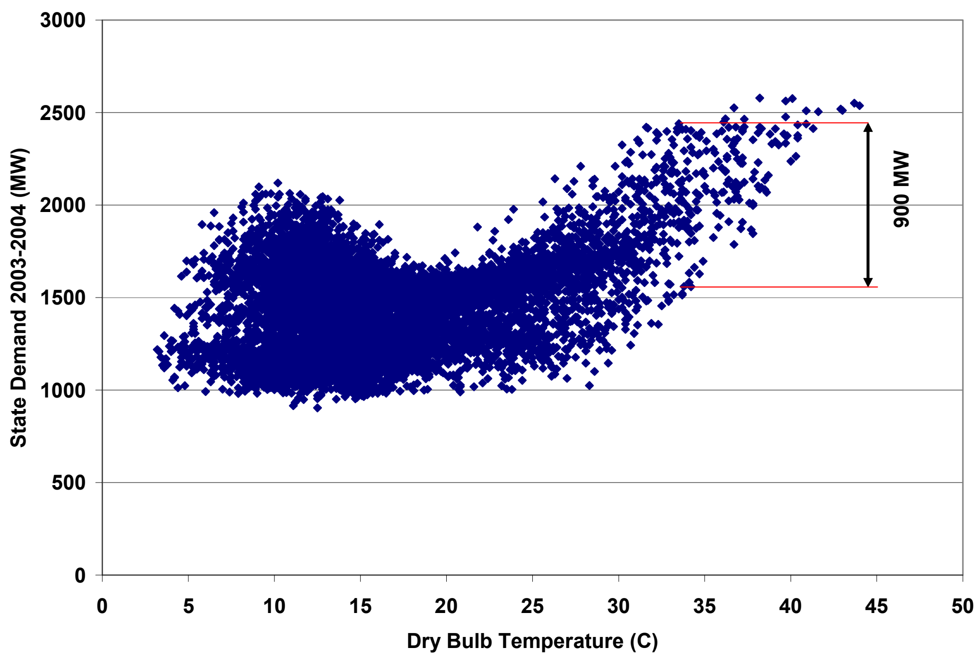

Figure 2 State Maximum Daily Electrical Demand V Maximum Daily Dry Bulb Temperature - SA

2 The Concept

Building shell simulation software has now been used for decades to estimate the expected heating and cooling loads associated with a range of building types. To accurately simulate space conditioning loads these models synthesize a diverse range of relevant parameters including:

- Building Design/Form
- Building construction characteristics
- Thermal properties of construction materials
- Shading geometries
- Air flow characteristics
- Climate data
- User Behavior

Using the above factors and applying the principals of thermodynamics many models are now available that can provide reliable estimates of expected space conditioning loads. In the early days of model development (1970s) these tools were primarily the domain of researchers. In more recent times in Australia the most common use for these tools has been as the basis for rating tools such as the Nationwide House Energy Rating Scheme (NatHERS).

Whether used as a rating tool or for research purposes these tools have primarily been used to make estimates of annual cooling and heating loads. That is, the annual quantum of heat that will need to be added to the internal spaces or removed from the internal spaces of a building in order that an agreed set of thermal comfort conditions will be maintained.

Primarily these tools were intended to simulate the space conditioning loads associated with an individual building. However, some researchers (including EES) have coupled these building shell simulation tools[1] with building stock models and appliance stock models to produce models of energy demand from space conditioning at a state or even a national level. Such analysis can facilitate the benefit/cost analysis of building shell improvement policy options. In this form of analysis, benefits can be described in terms of expected reductions in annual energy demands associated with a particular building improvement policy option (eg retrofitting of ceiling insulation to older housing stock for instance) and this can be further translated into benefits in terms of greenhouse gas emission abatement potential.

Increasingly however, a significant cost associated with the supply of electricity in Australia is the cost of meeting demand for electrical supply during periods of maximum or "peak" demand. During times of peak demand the supply cost in Australia typically grows by a factor of 100! Added to this cost is the cost of providing the necessary distribution infrastructure to deal with these relatively short periods of elevated demand. In South Australia, almost half its generating and transmission capacity could in theory be avoided if not for the need to deal with other than favorable (mild) weather conditions.

Because benefit/cost analysis of building improvement policy measures have not in the past adequately accounted for potential benefits arising from reductions in peak demand, the scope and stringency of such measures that could be justified on economic grounds has been to some degree constrained. Sophisticated building shell modeling software (such as the CSIRO's AccuRate) now offers the researcher the capacity to accurately simulate space conditioning loads on an hourly basis. Consequently, state level models of energy demand can also be configured to provide outputs on an hourly basis. By inputting historical weather data into such models then comparing the outputs with the matching historical records of the weather sensitive component of the state electrical load the accuracy of the model can be assessed.

3 The Model

Modeling of state electrical demand was undertaken by splitting the electrical load into two discrete components:

- The "Weather insensitive component" ie that portion of the state electrical load that remains relatively constant despite fluctuations in weather conditions (particularly temperature). These loads would include such things as lighting, appliances other than space conditioning appliances, water heating, cooking, industrial processes, pumping and so on.

[1] The standard rating tools are typically modified to more closely match reality. Default settings, as adopted in these simulation programs, whilst adequate for comparative rating purposes were not considered adequate for the purposes of estimating expected space cooling loads

- The "Weather sensitive component" i.e. that portion of the state electrical load that varies according to the prevailing weather conditions. These loads primarily consist of space conditioning loads from the commercial and particularly the residential sectors but would also include minor fluctuations in process refrigeration and heating loads.

Modeling of each component was undertaken separately on an hourly basis then the outputs summed. To prove the model, historical hourly state electrical data was obtained for South Australia for the period 1999 to 2004, this data was then compared to the output of the model over the same period.

3.2 Estimating the Weather Insensitive Component

Estimation of the relatively constant weather insensitive component of the load is important as it provides the basis for quantifying the magnitude of the significantly more variable weather sensitive component.

For this component, the approach was to examine historical records of the state electrical system demand. In particular, periods where the weather sensitive component was reasonably neutral were examined. Naturally this required the exclusion of any periods of overly warm or cool weather. In addition, holidays and the Christmas period needed to be excluded as atypical.

In each of the study years a period of one week (known as a reference week) was identified during the summer months during which mild conditions prevailed (see figure 3). It was important that the "reference weeks" occurred during the summer months as the profile during other seasons was found to exhibit subtle differences (e.g. time at which street lighting is activated for instance).

This process lead to the development of a standard set of 24 hour profiles for the weather insensitive component of the load. Load shapes were found to be very similar for Monday to Thursday, so a single shape was developed for those days. Separate shapes were developed for Friday, Saturday and Sunday. Load shapes were developed for each of the years in the study period, noting however that there was little variation year to year.

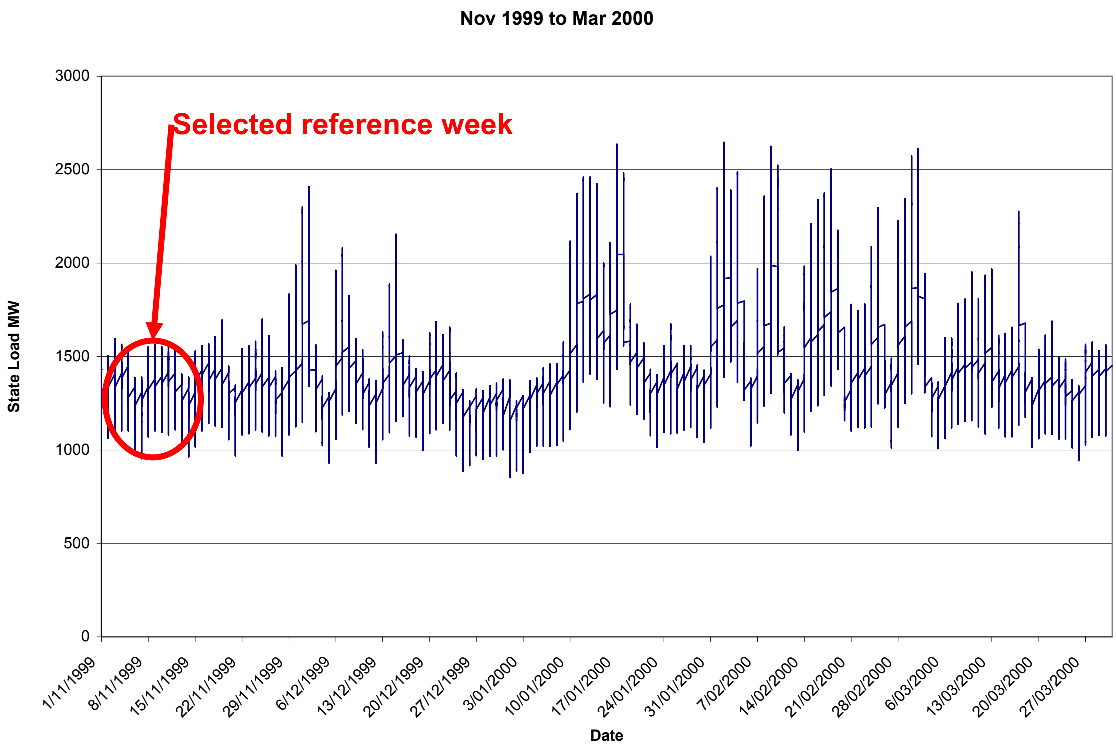

Figure 3 State Maximum Daily Electrical Demand - Summer 1999 to 2000 - SA

3.3 Estimating the Weather Sensitive Component

2.3.1 Overview

Estimates of the weather sensitive component of the state electrical load began with a model of the state's building stock. This was derived from various statistical sources. The main forms of building type in the stock model were identified and representative sample buildings were then selected to represent these forms.

Each building form was then input into the building shell modeling software (AccuRate) along with the historical weather files to derive outputs of unconstrained space conditioning load for each building type.

Using the building stock model, the modeled loads for individual buildings were then scaled up to state level loads. These loads were then constrained using a model of the states space conditioning equipment stock (including number and type) to derive an estimate of actual state space conditioning load. Finally this load estimate was input into a space conditioning performance model that converts the cooling load into an electrical load based upon the average efficiencies of the various equipment types. The overall process is described in Figure 4.

The model was largely constructed as a set of interrelated Microsoft XL spreadsheet files. However, the data outputs from the building simulation modeling were significant (i.e. hourly load data for each zone within each sample building) and generated approximately three hundred million data points (40 GB of data). The volume of this data was beyond the capacity of XL to manage so this data was loaded onto an SQL server database and queries applied to that database to derive weighted outputs suitable for use in the spreadsheets.

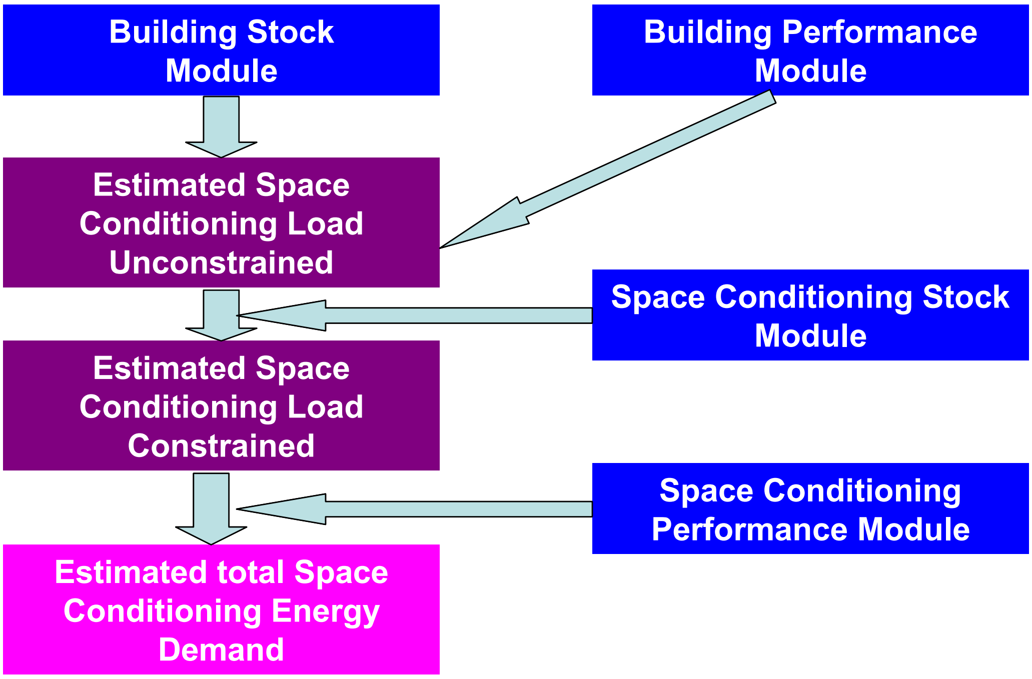

Figure 4 Schematic of Peak Load Weather Sensitive Component Model Structure

2.3.2 Building Stock Module

The building stock model developed for this study drew upon available data to establish a profile of buildings[2] in South Australia over the past 20 years with projections into the future.

The major inputs into the model included:

- *New Buildings Entering the Stock*
- *Retirements of Existing Stock*
- *Conversions of Existing Stock* - Stock numbers for particular construction types were adjusted to account for the retrofitting of insulation to their roof spaces.
- *Augmentation of Floor Area Through Renovations* – Floor areas were adjusted upwards annually according to the rate of floor area augmentation through renovations

[2] A detailed model of residential buildings was developed, this being the major source of peak load demand in South Australia. A simpler model of commercial buildings was also included, although data regarding the profile of such buildings is scarce.

2.3.3 Building Performance Module – Cooling Load Estimates

The models cooling load estimates are based upon simulation modeling outputs from the thermal performance modeling software developed by the CSIRO known as "AccuRate". Thermal performance modeling was conducted upon a sample of buildings selected to be broadly representative of the stock of conditioned buildings in South Australia. This sample also included performance based housing as has become the norm in recent times.

For the purposes of this study the default assumptions within the AccuRate software relating to occupancy profiles and the operation of thermostats were varied to more closely match reality. Settings as adopted in AccuRate whilst adequate for comparative rating purposes were not considered adequate for the purposes of estimating expected space cooling loads.

By default, for each climate zone, AccuRate software uses a set 12 month weather profile based on a "typical mean year" (TMY) as the basis for making comparative assessments of building shell thermal performance. For this study actual weather data for the period 1998-99 to 2003-04 was substituted for the TMY data. This substitution allowed the impacts of actual weather conditions to be compared with observed changes in maximum electrical demand over the same period.

Figure 5 below provides a graphical outline of the space conditioning load model and its key inputs.

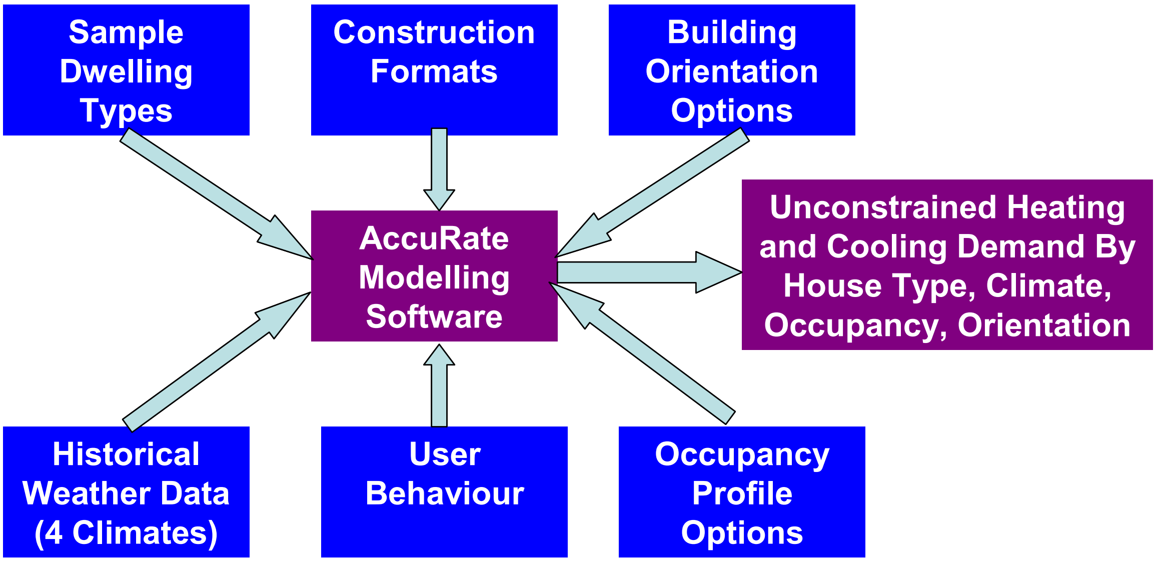

Figure 5 Schematic of Building Performance Load Module

2.3.5 Space Conditioning Stock / Performance Module

An end use stock model of space cooling equipment was developed to take into account the average technical characteristics of both new appliances entering the stock and old ones leaving the stock to provide a stock weighted average for each year during the modeling period.

The main inputs into the appliance end use model were:

- Ownership of space conditioning equipment in South Australia
- Appliance attributes, in particular the efficiency (EER) of the space conditioning appliance and its capacity which can limit the extent of conditioning
- Appliance usage parameters

2.3.6 Climate Zones/Files

For the study period, actual climate files for the 4 main SA climates (as identified in the AccuRate software) were used. The 4 climate zones incorporated into the model were, in order of significance:

- Adelaide
- Mount Lofty
- Mount Gambier
- Mildura

Modeling was undertaken using the climate files from each of these climate zones then the results weighted according to the proportion of building stock in each zone. The climate files included data relating to:

- Dry bulb temperature
- Humidity
- Wind speed and direction
- Direct and diffuse radiation
- Cloud cover

Whilst elevated dry bulb temperatures was found to be the main driver for increasing cooling loads, solar radiation levels were also found to be a significant determinant.

4 Performance of the Model

As noted, the model developed for this study was tested by inputting actual weather data for the period 1998-99 – 2003-04 and then comparing the model outputs (predicted hourly state electrical demand) with actual observed demand over the same period. The modeling tool included a graphical output facility that could plot over any three day period hourly plots of; the actual state electrical demand, the state electrical demand as simulated by the model and the dry bulb temperature in the dominant climate zone (Adelaide). A sample of the output can be seen in figure 5.

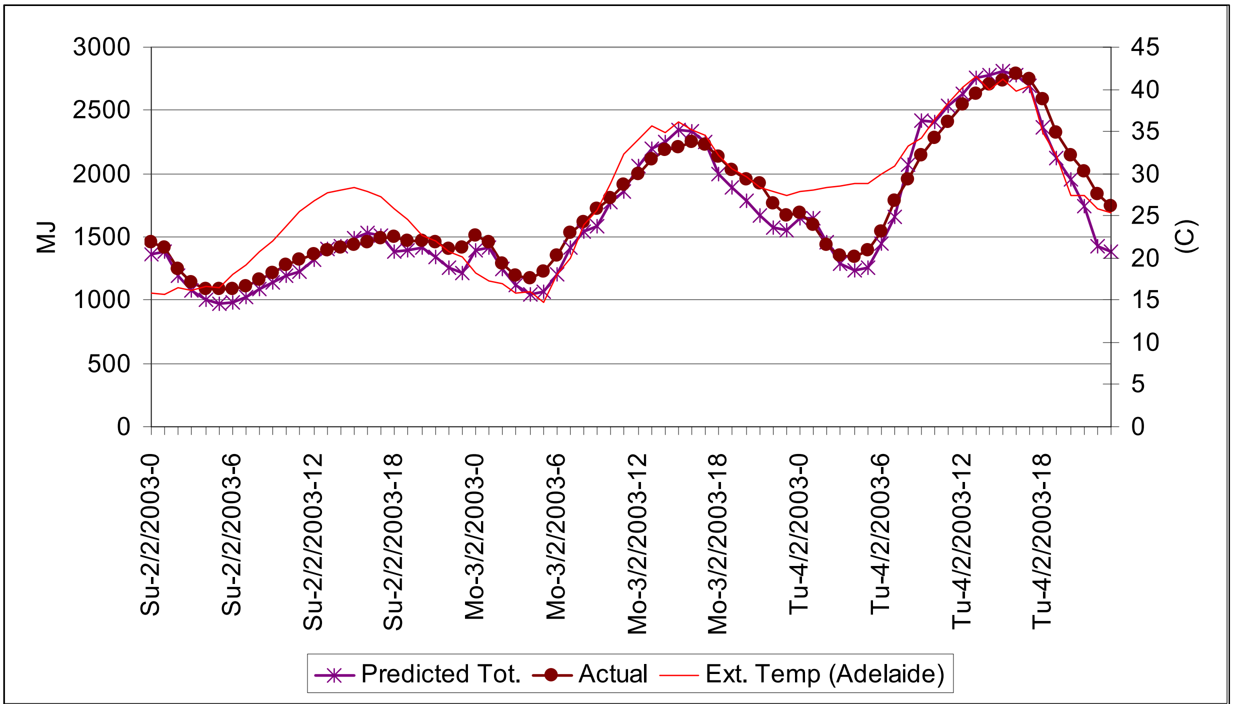

Figure 5 Modeled Demand V Actual Demand – South Australia 02– 04/02/2004

As can be seen from the sample output, the modeled electrical load closely aligned with the actual observed load. The precision of this match was found to be best during the most extreme weather events. The accuracy of the model tended to decline both overnight and during minor peak load events. Whilst accuracy throughout the range of peak load events is desirable, in terms of the objectives of this study it is only the accurate modeling of load during the most severe weather/peak load events that is important.

An assessment of the models accuracy was undertaken on each of the 50 days of maximum electrical demand (>2200MW) during the study period. The model was found have an average accuracy of +/- 2.8% with a standard deviation of 55MW (noting that the maximum demand over the period was in the order of 2800MW). Further improvements to the accuracy of the model may be achievable. Better modeling of occupancy profiles already appears promising and improved modeling of the commercial sector (if and when better data becomes available) would also assist. But such improvements are likely to have only a minor impact on the models accuracy which is now considered to be adequate for policy assessment purposes by the South Australian government.

6. What Next?

The next phase in the development of this model is the application of the model to determining the projected reduction in peak demand arising from various policy measures. The range of measures that can be modeled include:

- Building shell improvements to the existing stock, particularly shading and insulation options.
- Improved building shell performance standards for new stock – particularly summer performance standards.
- Improved performance standards for space conditioning equipment.

Various scenarios relating to growth trajectories for the number, type and size of the building stock as well as the ownership and type of space cooling equipment can also be modeled. Even scenarios relating to climate change could be modeled provided the necessary climate files could be made available.

As a test of the modeling capabilities, modeling was undertaken on the available data (1998-99 to 2003-2004). Various scenarios were modeled as if they had been implemented 20 years prior to this period such that the stock in this period met the improved standard. These results were then compared to the business as usual case (i.e. without improvements).

In the scenario shown in figure 6 below it was assumed that by 2003 all housing stock had been retrofitted with both ceiling and wall insulation. The model predicted that such a policy would have reduced the maximum demand in that year (which occurred on 4/2/2003) by 261 MW or almost 10% of total load. Effectively this means that the cost of a 260MW power station (and associated infrastructure) could have been avoided had that policy been implemented. Further modeling revealed that, if by 2003, the performance of all building stock had been raised to a 6 star NatHERS performance standard and the performance of the space cooling stock to an EER of 3.0, then double these savings would have been yielded!

Modeling of actual policy options proposed for the next 15 years in South Australia are now scheduled to be completed in 2008.

Keywords: reuse, recycling, reclaimed materials, design process

Summary

It is generally recognized that the use of recycled materials and the reuse of components in buildings can lead to lower environmental impacts. However there are many reasons why construction professionals do not embrace the wider reuse of components. The practical implications of component reuse strategies on the way buildings are designed and procured are not well understood. How does the design team have to adapt its working methods to maximize the potential for reusing components? What are the contractual and liability issues?

Designers need additional information to effectively design with reclaimed components for new projects. They need to understand the risks, economics and implications to the program. The design process needs to accommodate more flexible design and specification. The design team may need additional skills and collaborations to source and evaluate components. Appropriate construction contracts are needed to accommodate component dismantling and reuse. The paper is based on a survey and other data collection that was undertaken as part of a study at Ryerson University funded by the Natural Resources Canada and Canadian Institute of Steel Construction. It highlights the lessons learned from reusing salvaged and reclaimed materials in these Canadian construction projects as well as providing a summary of issues important to the success of re-use in the construction industry based on survey results.

1. Introduction

The widespread adoption of the green building rating systems such as Leadership in Energy and Environmental Design, or LEED^{TM}, (USGBC 2002) has had a considerable impact on the industry in North America and has increased interest in reuse and recycling in construction. In addition, difficulties with waste disposal and limitations on land filling have stimulated interest in the potential economic benefits of alternatives. Waste is becoming regarded as a lost resource and a loss of potential profit. Processes that add value to waste materials can lead to significant financial benefits. This has driven considerable interest and research into issues of deconstruction, design for deconstruction, and reuse of components and material recycling. Publications such as “Old to New – Design Guide for Salvaged Materials in New Construction”, published by the Greater Vancouver regional District (Kernan 2002), and “Design for Deconstruction SEDA Guide for Scotland” (Morgan & Stevenson 2005) illustrate the increased interest from local government in North America and Europe for the potential for building material reuse to address waste minimization. In California, the Integrated Waste Management Board published a Technical Manual for Material Choices in Sustainable Construction (IWMB 2000) which outlines the opportunities for reuse in construction, and lists potential components that can be successfully reused. In 2001 the IWMB also published a Deconstruction Training Manual (IWMB 2001) which aims to grow a viable industry and reduce the amount of construction and demolition debris that makes its way into California’s waste stream.

Existing buildings are huge reservoirs of materials and components which can potentially be mined to provide much needed resources. Reuse of many components from old buildings can significantly reduce the life cycle environmental impact of new buildings. It can also create new jobs and business opportunities. There is increasing recognition that use of recycled materials and reused components extracted from an old building can potential lead to a reduction in waste that needs to be disposed of, a reduction in primary resources used and savings in greenhouse gas (GHG) emissions (Gorgolewski et al 2006).

However, current, standard construction and demolition practices focus on the fastest, easiest and most economical way to get the job done. When this is combined with a lack of clear information and guidance for designers and owners about the implications of specifying reclaimed components and recycled materials, it creates barriers to a more ecologically sound use of resources.

At present, in Canada the perceived difficulties inherent in the incorporation of reclaimed materials into new buildings often discourage clients and designers from embracing reuse unless it is for principled rather than financial reasons. Although materials costs can be lower through reuse, it must be recognized that these may be offset by higher labor costs and increased design time, and fees, resulting from more research required by the design team. In addition, there is likely to be greater uncertainty over costs and program as delays can occur if key components cannot be readily sourced or there are delays in the demolition process. Thus, using reclaimed components has significant implications on the "process" of how to design a building as well as its construction. Traditional relationships and design procedures may not be best suited to maximize material reuse. These issues need to be understood by the design team and client so that appropriate strategies are put into place.

Figure 1 In Canada the Mountain Equipment Coop has pioneered component reuse in many of its retail stores. This one located in Ottawa reused many parts of the previous building on site, including the foundations..

2. Methodology

This paper considers the implications of materials reuse strategies for the process of designing and procuring buildings. The intent is to understand the changes that a design team need to make to the design process to facilitate greater reuse of components in construction and to indicate strategies and recommendations about how to maximize reuse potential. The focus is on how the desire to use salvaged and reclaimed materials affects the design process, and what designers need to know and how they need to adapt their standard processes to fulfill the potential for component reuse.

This paper is based on work carried out to examine the processes used for building component reuse in Canada. The discussion below focuses on key aspects of the design process and how they are affected by component reuse, particularly those aspects that have been identified as potentially varying from standard design processes as outlined in the Canadian Handbook of Practice for Architects (RAIC 2003). The work is based on a survey that was carried out of the Canadian construction industry. This survey focused on Canadian projects that included significant amounts of component reuse. Key participants in these projects were interviewed or filled out a questionnaire, and this information was analyzed. In addition, a literature review was carried out of international practices for integrating reused components into buildings. A full report of this project is available elsewhere (Morettin & Gorgolewski 2008).

3. Types of reuse

Reclaimed and salvaged materials and components (RSMC's) available for reuse can be generally categorized into 4 types:

- On site reused component - which may be whole structures or individual components such as bricks from an old building on a site into a new building.
- Salvaged from other sites – components such as bricks, timber or steel taken from a demolition site and used in another project (usually local), and requiring little reprocessing.
- Reconditioned components – these are components that are taken from a demolished building and require some improvement to be sold again for use in a new location. This may include radiators, doors, staircases, etc.
- Recycled content building products (RCBP's) – these are often readily available building products that include significant amounts of feedstock material that is taken from demolition or other reuse sources. This may include some gypsum boards, steel components, etc.

It is important to keep in mind that use each of these in a building project requires different tasks and strategies that happen at different stages of the design. In addition, current market conditions have an impact on the availability of all these components. Recycled content building products have the least impact on the design process as they are often available directly from manufacturers "off the shelf". Components salvaged from other sites are often the most difficult to integrate as they need to be identified and sourced at the appropriate time in the design process which may be difficult. On site reuse allows the design team to assess what is available and design the new building around the components that are already at the site.

Therefore, assessing the potential for different types of reuse and the sources that are available at the pre-design stage of a project is essential for future scheduling, resource planning and cost estimating.

4. Lessons from completed projects

4.1 Commitment

In the absence of a legal compulsion to reuse and recycle, it is essential that the client or developer is supportive of the principle of component reuse. Projects quickly founder when the client has doubts about this strategy, as inevitably there will be times when the standard product option looks tempting. Also, the client may have to fund the purchase (and thereby securing) of materials and components as they become available throughout the project, which may occur earlier than in a typical project. For this reason it may be helpful to appoint a contractor as part of the design team. This will have implications on the form of contract used, so alternative contractual arrangements need to be discussed with the client, particularly if high levels of salvaged material use are planned.

Expectations for the design may require some tolerance to the duration of the design and construction phases since they will depend entirely on the supply of suitable materials and goods.

The survey of projects that reused components clearly indicated that the decision to focus on RSMC needs to be made early in the design process. Approximately 80% of respondents stated that the decision in their projects was made at the Concept Design stage, with a few making the decision right from the beginning during the Design Team Selection. It appears from evidence of completed projects that if a decision to use RSMC is left until the outline or detailed design stages it is far more likely to have a detrimental effect on costs during construction and schedule while material was being procured. This is often because the design of the building has progressed too far without consideration of what components may be available.

4.2. Costs

Almost half of responses to the survey indicated no impact on design fees, but others did indicate a significant increase in workload for the design team which should be recompensed. It is to be noted that the projects which had higher design fees also had a higher proportion of RSMC and were considered to be pilot or ‘test’ projects.

There is a strong consensus that material cost (including refurbishment/reprocessing) are decreased by use of RSMC – 95% of responses indicated a decrease of either minimal or significant savings most likely attributed to the lower costs of used materials even when refurbishment was factored in. Conversely, there is a strong indication that construction labor costs increase, possibly due to additional dismantling and handling costs. Particular cost savings were noted when major components of an old building are reused on the same site in a new structure as they are directly offsetting the purchase of new materials. However, good documentation of the old components is useful to avoid unexpected surprises. It was also noted that transportation costs and the consequent environmental impacts are reduced if components are reused close to their original location, and this is usually the case as most reused components are sourced locally.

Surprisingly, the survey did not identify issues and additional costs related to storage of reused materials. Since purchase may have to occur at a time when materials are available rather than when they are needed on site, there may be longer storage times, but these were not identified as a problem, nor were there additional costs identified as linked to this.

4.3. Setting goals

There is inevitably hesitance to set ambitious goals for reuse without previous experience of salvaged materials use. The decision as to what level of use of salvaged material should be determined based on some or all of the following criteria:

- Because of the nature of the supply of salvage materials and the different acquisition processes involved salvaged materials are most readily and cost effectively obtained in relatively small volumes. More efficient use can therefore be achieved in smaller buildings.
- The knowledge and experience of the design team about how and where to located and acquire salvage materials can improve the efficiency and cost effectiveness of the process. Therefore, previous experience of the design team and contractor with the use of salvage materials is significant.
- The process of locating and acquiring salvaged materials can be longer and more unpredictable than regular construction materials. Therefore, flexibility in time available during both design and/or construction phases is helpful.
- Opportunities for up to 25% use of salvaged materials can easily be achieved provided that the design uses readily demountable materials such as steel or heavy timber construction since these products represent the largest category of salvaged materials. It is not uncommon to reach 50-75% salvaged material on small to medium sized projects of this nature although these targets may increase the time and effort needed to achieve them.

4.4 Design process

A factor that clearly emerged from the survey was the importance of integration in the way the design team functions as a key reason for utilizing a higher than average amount of RSMC’s into their project as well as achieving building energy performance exceeding normal standards. Design teams that employ the Integrated Design Process (Larsson 2003) provide a clear benefit, as this leads to early involvement and buy in from the whole design team. Furthermore, it is important for the design team to be enthusiastic about the reuse/recycle route, and to accept that this may require the team to adapt the normal working practices, and be prepared to take the initiative when it comes to overcoming the unpredictable hurdles that may present themselves. This is clearly linked to remuneration and design fees, but as noted above, if decisions are made early enough the additional design costs need not be substantial.

Previous experience of design consultants with the use of salvaged materials, or willingness to accept the concept and adapt their processes is important. Some firms hire a specific person to source reused materials which may be an opportunity for new specialist roles within design consultancies and for young and enthusiastic employees to learn and benefit from the process. Similarly, the commitment of contractors and sub-contractors to reuse/recycle is recommended as they can assist or be responsible for the sourcing of suitable materials and components. This may require that contractors become involved during the schematic design/design development phases since material acquisition happens much earlier than for typical projects. Beyond having potential contractual implications, inexperienced or disinterested contractors may have a negative influence on the project team in their use of pressure tactics such as increasing the construction costs due to 'unfamiliar practices' or by not being able to properly locate salvaged/recycled materials. This results in the undermining of the project's intentions by reverting back to new materials and components, albeit with more familiar methods. Thus, the goals of the project need to be clearly explained to, and embraced by, potential contractors before or during the time of tender or contract negotiation.

When reusing buildings and their parts in situ a structural engineer is needed with expertise or past experience in appraising the existing structure and, if necessary, defining work to be undertaken to make the structure reusable, and adapting the existing building for the incorporation of new uses and features (e.g. staircases, lifts, building services plant and distribution). Again however there is the potential issue of an engineer's reluctance in using RSMC by disputing or dismissing the need to properly assess and approve the conditions of potential materials and components. It may be necessary that other building science expertise be sought to also appraise the existing building services, envelope and other features, and to define work to be undertaken to make them reusable, depending on the scope of the reuse.

Figure 2 It is often most practical to reuse components or whole structures on the same site. This directly offsets costs and environmental impacts of primary materials.

4.5. Factors deciding what to reuse

When selecting which reused components of a building or recycled materials to use, one starting point that has been used is to base decisions on embodied energy content. It would be appropriate, therefore, to concentrate on reusing and reclaiming goods and materials with high embodied energy as savings will have the greatest potential energy saving impact. This would suggest reuse of metals, plastics, bricks and generally high value processed components. Another approach could be based on the quantity of material available and if used, could theoretically be the total amount diverted from landfills. For this environmentally beneficial scenario, determining the quantity would then be based on the weight or volume of the materials used. In this instance, the focus would be on larger components and concrete which represent the heaviest/bulkiest items to divert.

Unlike traditional projects where designing the structure, mechanical and electrical and other main systems take precedence over final material selection and procurement, when incorporating RSMC the task of sourcing materials is often the driver during the schematic design phase and one of the key influences on the layout, structure and other systems used.

4.6. Sourcing reused materials and components

Sourcing RSMCs required designers to foster new relationships with organizations they may not traditionally be in touch with. Some demolition contractors, and salvage companies now have sales staff specifically intended to identify and market construction components they have identified as of value to the building industry. These may range from whole buildings, such as prefabricated industrial buildings that can be readily dismantled, to individual components such as beams, stair cases, doors, etc. They often know beforehand when existing buildings are scheduled to be demolished, so establishing contact with them can provide sources for appropriate materials. However, briefing demolition contractors to ensure minimum damage to components scheduled for reuse is sometimes necessary. The UK's National Green Specification (NGS), for example, calls for demolition contractors to indicate what is to be reclaimed and produce a method statement indicating how the goods will be extracted in good condition, palletized and protected during transportation and storage.

Designers may have to visit local used building materials yards, demolition contractors and salvaged materials suppliers to establish general availability and quality of materials, and to discuss the scope of their project and provide a preliminary list of materials that they are looking for. Larger, or more committed design firms are beginning to develop an expertise in locating salvage components, and may have dedicated staff for this purpose.

Local municipal departments may know when demolitions are likely to occur and can direct design teams to potential sources of materials and components. Furthermore, there are an increasing number of locally based materials exchange schemes often web based that provide access to a range of materials sometimes for free.

Both reconditioned goods and recycled content building products (RCBPs) can generally be sources in the same way as regular materials and components, although additional research may be necessary to identify appropriate suppliers. RCBPs and reconditioned goods are generally easier to acquire due to their availability, and can be incorporated and procured in a similar way to new material up to and during the schematic design phase. For reconditioned goods, during schematic design, responsibility for component acquisition would still need to be allocated as there may be additional tasks associated with locating appropriate supplies. It needs to be established who will source the particular components? Will the design team specify the performance requirements and pass this function on to the contractor with a general requirement that reconditioned components should be used, or will the design team locate the specific component? Most of the survey respondents suggested that in existing projects building components were generally defined by a performance specification and that the contractor was responsible to source the components. This would therefore require that the specification, in addition to a performance statement similar to goods made with new materials, indicate either the amount of recycled content required within the material or that the component be reconditioned.

If the intention is to reuse all or part of an existing building in situ, the search for available existing buildings for reuse in their entirety will need to commence at the pre design stage of the project. Once an existing structure is identified, a full survey of the building to be reused is needed and if possible, original drawings and specifications should be located to assist with identifying potential material re-use opportunities and dismantling efforts.

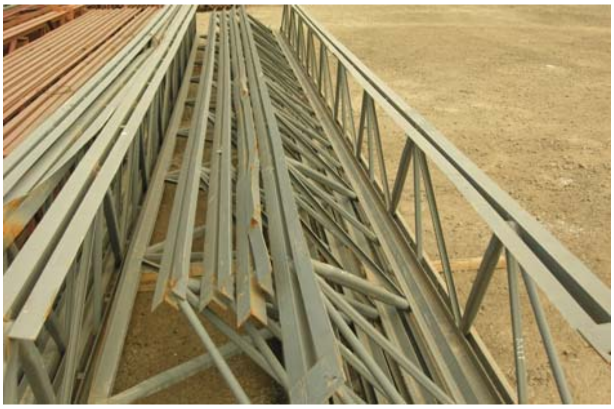

Figure 3 Open web steel joists can often be dismantled for reuse, but the new structure needs to be designed around the available spans.

4.7. Construction process

When reusing buildings and their parts in situ, preferably a deconstruction specialist should be hired if possible, or a contractor with an interest in deconstruction, in order to dismantle the salvaged materials designated for re-use. Some projects in Canada have used not-for-profit / youth programs / government job skills training program as sources for lowering the cost of dismantling and re-conditioning as well as providing economic opportunities for the less-fortunate.

The design team needs to establish procedures for grading salvaged components to ensure they meet functional requirements and regulatory standards. This may require visual inspection, structural or other testing, and possible refurbishment.

5. Conclusion

Certain key factors emerge from the pioneering projects that focus on reuse. These include:

- It is important to have commitment of the entire design team at the early stage of the process.
- Projects need clear goals with commitment of all the design team and client.
- The Integrated Design Process facilitates a great likelihood of successfully using RSMCs
- Sourcing RSMCs required designers to foster new relationships with organizations they may not traditionally be in touch with.
- Responsibility for identifying RSMCs needs to be clearly established - who will source the particular components?
- Procedures for grading salvaged components need to be established and any regulatory issues identified.
- Cost savings are possible in material costs, but some of these are offset by additional labour costs.
- There can be additional design costs. This can be due to redesign to suit when sourcing reused components.
- Projects with the highest savings usually focused on reuse of the existing building already on site.

Designers need to recognize that there are some significant differences to the design process if reuse of construction components is a goal of a project. Reused components have different patterns of availability which need to be accommodated. Also, the limited range of components requires the design team to be more flexible and to develop the building design around the available reused components rather than the traditional process of designing the main features of the building and then identifying the components that will meet the required specifications. This means that ideally the specific reused components need to be identified at an early stage in the design process, perhaps when traditionally a contractor may not yet be involved.

The standard design stages as outlined in the Canadian Handbook of Practice for Architects (and other similar manuals in other countries) will need to be adapted with new tasks included that focus on what needs to be achieved and at which stages, to facilitate successful component reuse. It is hoped that the next stage of this work will develop a manual of tasks to help design teams that wish to design with reused components.

HOLISTIC APPROACH TO SUSTAINABLE CONSTRUCTION PROJECT MANAGEMENT

Nicole SUNKE[1]
Frank SCHULTMANN Prof. Dr.[2]

[1,2] Chair of Business Administration, Construction Management and Economics, University of Siegen, Siegen, Germany, nicole.sunke@uni-siegen.de and frank.schultmann@uni-siegen.de

Keywords: sustainability, building, deconstruction, supply chain, reverse logistics

Summary

The construction industry is characterised by a project-based organisation and deals with all phases of the life cycle of a building. Each of these phases requires specific methods for project planning and resource management. Moreover, regarding the trias of sustainability -ecologic, economic and social balance- integrated approaches are needed. In particular, these approaches have to focus on project planning as well as on resource management throughout the life cycle of a building. The efficient utilisation of these resources can be supported by optimisation models from Operations Research. The planning of construction materials can be tackled by methods known from supply chain management or, as far as deconstruction is considered, by methods adopted from reverse logistics to establish closed-loop supply chains. A holistic view on the various planning problems is given and solution approaches for sustainable construction are proposed.

1. Introduction

The construction industry can be considered as one of the oldest ancient industry built on a project basis. A well known example is, for instance, the Cheops pyramid in Egypt around 2500 years BC. Thereby, construction has always been characterised by taylorism due to the complexity of the products and the heterogeneous mix of materials and components as well as diversified construction activities. Hence, comparing the supply chain of the construction industry with those of the manufacturing industry, it can be observed that construction supply chains are more complex due to the unique nature of the projects, the highly uncertain planning environment and the numerous stakeholders involved in a construction project. Concluding, if the focus is drawn to individual construction standardized construction processes are not appropriate.

In construction, the project based organisation structure has mainly remained the same for centuries. Apart from recent achievements of standardization of construction with modular or pre-engineered housing and prefabricated standardized components -concepts taken over from the manufacturing industry- concepts in construction remain specific (e.g. Barlow et al. 2003; Gann 1996). However, although being one of the most established industries, construction still often suffers poor performance, mainly in terms of time and cost. Furthermore, approximately 30-40 % of global energy consumption as well as 20-30 % of greenhouse gas emissions can be traced back to the construction industry (UNEP 2007) and makes it to one of the industries that deserve special attention with regard to sustainability.

For construction project planning, methods such as the Critical Path Method (CPM), Project Evaluation and Review Technique (PERT) or Gantt charts are still applied and have maintained their role for many decades. However, these rather simple techniques do not pay sufficient respect to the complex planning environment in construction where more difficult planning problems are faced. This reaches from pure project characteristics, like simultaneous projects, to external constraints opposed to construction projects, such as different stakeholder interests, and environmental concerns, like waste accumulation and disposal. Concluding, sophisticated project planning approaches are required to tackle construction seriously taking the construction project environment into consideration. In contrast, the complexity of construction projects has lead to a research gap in production planning and control approaches tailored to the construction industry. While supply chains of the traditional manufacturing industry have been well researched and have been tackled with qualitative as well as quantitative approaches construction supply chains still deserve intensive research efforts.

In the following a holistic view on the various planning problems in construction is given and solution approaches for sustainable construction are proposed. The contribution of project planning models from Operations Research to construction project planning is stressed and it is shown how methods of supply chain management and reverse logistics can contribute to efficient project coordination and sustainable construction processes.

2. Project Scheduling and Materials Management

2.1 Construction Project Performance

The construction industry, more than any other industry, still suffers a poor image and is often faced with poor quality of its products. Moreover, construction projects often are over budget and beyond time. While some authors claim, that the main reasons for disputes cover aspects such as risk allocation, design changes and handling during project execution others mention fairness and clarity of contractual arrangements, payment as well as construction delays as main causes for disputes in construction (Assaf and Al-Hejji 2006; Al-Momani 2000; Kumaraswamy 1997). Both, the late delivery as well as cost overruns in projects jeopardise project success leaving the client of the construction project unsatisfied and the contractor with expensive and time consuming dispute resolution and extensive claim management efforts.

Several studies on causes of delays of construction projects have been conducted and it has been shown that approximately one-third of all construction projects are beyond time and budget although these are key competitive factors (see Yeo and Ning 2002). According to surveys among construction practitioners the causes are, among others, constant changes in project requirements, the development of multiple projects at the same time delaying less important projects, deficient communication between project partners, a lack of available resources,—e.g. a shortage of site workers and technical personal, late delivery of construction materials, insufficient number of equipment— and equipment allocation problems as well as a vague definition of the scope of project budget and schedules (Ogunlana et al. 1996; Yeo and Ning 2002). In a survey among owners, contractors and consultants the 10 most important causes of delays mentioned by owners are ineffective planning and scheduling of the project by the contractor as well as conflicts encountered with sub-contractors schedule in project, besides, for instance, a shortage and low productivity of labour and inadequate contractor's experience. Contractors however, mention the delay in progress payments by the owner, design specifications as well as late procurement of material as causes, while consultants refer to, among others, the type of project bidding and award, a shortage of labour as well as ineffective planning and scheduling of the project by the contractor (also mentioned by the owners) and a delay in material delivery (Assaf and Al-Hejji 2006). A similar result is gained in a survey among 150 construction practitioners (Sambasivan and Soon 2007). Hence, from several studies two major causes for delays which refer to the planning of the project as well as to materials management can be identified, i. e. delays are caused by insufficient scheduling and the non-availability of material and resources on-site. Causes which are related to the planning of projects, hence, to scheduling and materials management, are well known problems in many projects and significantly influence project success (Assaf and Al-Hejji 2006; Chan and Kumaraswamy 1997; Faridi and El-Sayegh 2006). Concluding, a key factor to ensure project success in addition to the selection of appropriate project partners, the experience of the project planner, the project organisation, and appropriate information flow between project partners is an (1) *efficient resource allocation during the scheduling of the project* and a (2) *proper materials management*. The latter aspects are considered in more detail in the following.

2.2 Resource-Constrained Project Planning

2.2.1 Resource planning with optimisation approaches

Project planning and scheduling in practice, especially in the construction industry, is still often conducted with rather simple techniques, such as common project planning approaches like the Critical Path Method (CPM), the Metra Potential Method (MPM), as well as the Program Evaluation and Review Technique (PERT) or Gantt charts focussing on time oriented objectives and network diagrams when activity durations and precedence relations are known and deterministic (e.g. Allam 1988 and related literature). Their main advantages are the explicit representation of activity relations and their easy application. Paradoxically, however, even though a lot of scheduling procedures have been developed and tested for construction purposes, the scarceness of resources is often either neglected in scheduling approaches or seen as of minor importance in initial schedule generation in practice (Herroelen and Leus 2005) and the project schedule has to be adjusted to limited resource availabilities afterwards.

Simulation or optimisation approaches from Operations Research, such as resource-constrained project scheduling with the well-known resource-constrained project scheduling problem (RCPSP) integrating the scheduling as well as the resource allocation process, represent an appropriate alternative to traditional planning methods, such as CPM, MPM and PERT. RCPSP models offer freedom for the integration of construction specific particularities into the generation of a construction project schedule. Thereby, various objectives are considered in the planning and resource allocation process. Common objectives in construction project management and scheduling are, for instance, the minimisation of project durations under multiple resource constraints (Moselhi and Lorterapong 1993), the minimisation of the total project delay (Tsai and Chiu 1996) as well as the minimisation of costs of total resource consumption, including time and a levelled resource distribution (Karshenas and Haber 1990). Furthermore objectives like maximizing the total project net present value by considering project delay penalties and early completion boni (Chiu and Tsai 2002) as well as finding the optimal resource selection optimizing time and cost objectives of a construction project (Burns et al. 1996) are pursued.

Additionally, considering the case of repetitive activities, objectives might address the minimisation of crew idle time (El-Rayes and Moselhi 1998). Finally, project management can address the generation of a schedule-dependent site layout planning (Elbeltagi et al. 2001).

2.2.2. Basic model formulation

The RCPSP in its basic formulation describes a single project which consists of activities, also known as jobs, operations or tasks, with a known constant duration of periods. It is characterised by a deterministic finish-to-start precedence relation in an activity-on-node (AON) network, which means, that an activity cannot be started before all its predecessors have been finished. In the RCPSP a job requires constant units of the renewable resource type during every period of its duration. The resource types are known and available in a constant amount over the whole planning horizon. Thus, jobs might not necessarily be scheduled at their earliest possible (precedence feasible) start time. The objective of the RCPSP is to find a non-preemptive schedule by assigning starting times to the jobs such that the precedence and resource constraints are satisfied following one or more targets. An early mathematical programming formulation was given in (Pritsker et al. 1969). Objectives of the RCPSP might be (Klein 1999; Kolisch and Padmann 2001; Tsubakitani and Deckro 1990): Minimisation of the project make span, resp. finishing time of the project, minimisation of the project delay, maximisation of the net present value, and minimisation of activity- and/or resource-costs.

The most commonly considered objective of the RCPSP is the minimisation of the project finishing time because, for instance, the majority of income payments of projects (e.g. in the construction industry) occurs at the end of a project or at the end of predefined project phases and finishing the project early reduces the amount of tied-up capital.

With the assumptions made the RCPSP can be modelled as mixed integer program (MIP) as introduced in the following:

$$\text{Min } \theta(x) = \sum_{t=EF_J}^{LF_J} t \cdot x_{Jt} \quad (1)$$

subject to

$$\sum_{t=EF_j}^{LF_j} x_{jt} = 1 \qquad j = 1,\ldots,J \quad (2)$$

$$\sum_{t=EF_h}^{LF_h} t \cdot x_{ht} \leq \sum_{t=EF_j}^{LF_j} (t - d_j) \cdot x_{jt} \qquad j = 2,\ldots,J; h \in P_j \quad (3)$$

$$\sum_{j=1}^{J} \sum_{\tau=t}^{t+d_j-1} q_{jr} \cdot x_{j\tau} \leq Q_{rt} \qquad r \in R; t = 1,\ldots,\overline{T} \quad (4)$$

$$x_{jt} \in \{0,1\} \qquad j = 1,\ldots,J; t = 1,\ldots,\overline{T} \quad (5)$$

with the following notation

j : activity j, $j = 1,\ldots,J$, with 1 = single source, J = single sink

d_j : duration of job j

EF_j: earliest finishing time of job j

LF_j: latest finishing time of job j

r : renewable resource type $r, r \in R$

q_{jr} : per period resource consumption of renewable resource type r by job j

Q_{rt} : availability of resource type r in period t

P_j : set of immediate predecessors of job j

$\overline{T}$: end of planning horizon

x_{jt} : $\begin{cases} 1 & \text{if job } j \text{ finishes in period } t \\ 0 & \text{else} \end{cases}$

The objective function (1) minimises the project finishing time with T being the end of the planning horizon. Constraints (2) ensure that every job is processed once. Constraints (3) are precedence constraints of jobs with P_j denoting the set of immediate predecessors of job j. The duration of job j is represented by d_j. Constraints (4) limit the resource demand q_{jr} of the renewable resource $r \in R$ of jobs j

which are currently processed in order not to exceed the constant resource availability per period Q_{rt}. Finally, constraints (5) define the decision variable $x_{jt} \in \{0,1\}$ as binary, with $x_{jt}=1$ if job j ends in period t, 0 else.

The basic model can further be extended to integrate various objectives, such as the maximisation of the net present value and the consideration of multiple execution modes for a project activity (Multi-Mode RCPSP). Furthermore, it can be adjusted to schedule multiple projects simultaneously (RC multi-PSP) and stochastic as well as fuzzy information on resource availability and activity durations can be incorporated.

2.2.3 Strength of resource-constrained project planning

In particular, the strength of the RCPSP refers to the integrated time and capacity planning and the consideration of various resources. This is especially important, as construction projects are characterised by a high consumption of a heterogeneous mix of different equipment and labour. Furthermore, it is applicable in construction for a wide variety of objectives, which accommodates the various direct and indirect stakeholders of a construction project. The possibility to extend the constraints of the model allow for the consideration of externally given limitations, such as regulations on waste management. The explicit representation of possibilistic values for the duration and resource consumption of activities compensates the lack of knowledge on the exact distribution of these occurrences.

In the construction industry, first case studies about the appropriateness of the RCPSP for project planning were undertaken, for instance, by Tsubakitani and Deckro (1990) and Chiu and Tsai (2002). Tsubakitani and Deckro originally developed a heuristic for multi-project scheduling under constrained resources for a Japanese operating firm in the housing industry building approximately 6000 custom-order homes per year. Chiu and Tsai develop an efficient search procedure for the resource-constrained multi project scheduling problem with discounted cash flows and apply it to home building company in Taiwan. Additionally, a successful implementation of the RCPSP with multiple modes was given by Schultmann and Rentz (2002), who applied the model to deconstruction projects considering environmental constraints.

2.3 Materials Procurement

Project success not only depends on an efficient resource allocation during the scheduling of the project but also on a proper materials management. The construction materials management is based on the construction activities schedule denoting the time, the amount and the location at which construction material or components have to be made available (Ibn-Homaid 2002). The underlying problem is to shorten processing times and lower inventory costs by an efficient communication, information flow and cooperation between the partners of the Supply Chain (SC), i.e. by Supply Chain Management (SCM).

SCM can be defined as “… a set of approaches utilized to efficiently integrate suppliers, manufacturers, warehouses, and stores, so that merchandise is produced and distributed at the right quantities, to the right locations, and at the right time, in order to minimize system wide costs while satisfying service level requirements.” (Simchi-Levi et al. 2002) Materials to which SCM could be applied are bulk materials which require stock on site and are consumed in roughly known but still variable amount as well as materials with known amount and specification, high value and high on-site space requirements. Examples for bulk materials are concrete, insulation materials, aggregate, lime, technical gases, cement. High value and materials which require large space on site are, for instance, construction steel and pre-cast concrete units.

Current logistics practice involves the construction or site manager sending an order to the purchasing department if stock of materials on site reaches a certain level (Sobotka 2000). This causes additional permanently occurring control effort for the observation of the stock level. This additional effort could be reduced, if the responsibility for the refilling of stock could be shifted to the suppliers within the construction SC. Techniques suitable are, for instance:

- just-in-time
- continuous replenishment, or
- vendor managed inventory.

Just-in-time, a delivery right at the time and to the place of consumption without the need for inventory on site, is already applied for, e.g. pre-cast concrete units for bridges. In contrast, approaches like continuous replenishment with defined delivery intervals and vendor managed inventory, where the responsibility for material availability is shifted to the supplier while simultaneously realising small inventories, have not yet been acknowledged. This is, however, remarkable as space on site is limited and on-site congestion is to be avoided due to the accessibility of the site, the building as well as for on-site safety.

3. Sustainable Deconstruction of Buildings

3.1 Construction Planning and Sustainability

Research about sustainability in construction has up to now mainly focussed on the design and construction phases, the sustainability of buildings materials and their recovery. However, the highest amount of construction and demolition (C&D) waste over the life cycle of the building occurs during deconstruction. Taking into account limited dumping capacities, the depletion of scarce resources (e.g. wood, metal and natural gravel), the increasing amount of energy and resource consumption for the production of building materials, and emissions and hazardous substances released into the environment, the development of sustainable construction has to be extended to the planning of deconstruction projects. Current project planning approaches, however, mainly address the planning of construction projects with respect to time and cost objectives only. Environmental objectives, as aimed at with the establishment of closed-loop supply chains, need to become integral part of project planning. Hence, project planning procedures as common in construction practice significantly need to be upgraded or innovated. If logistic activities are considered as part of project planning procedures these activities can be treated summarised under the term of reverse logistics.

3.2 Reverse Logistics in Construction

The motivation for construction companies to participate in the establishment of closed-loop material cycles is likely the same as in the manufacturing industry. Regarding profit–orientation a reduction of costs for disposal by selective deconstruction and separation of C&D waste can be realised. Additional gains are expected from the resale or recovery of valuable components and materials, for instance deconstructed aluminium framed windows, steel bars, wood, or bricks. Legislative pressure is put on the enterprises by construction specific legislation. This legislation comprises regulations for the handling of C&D waste. In Germany, this is mainly laid down in the European Council Directive 91/156/EEC (revised Framework Directive on Waste, amending Council Directive 75/442 EEC) and Council Directive 91/689 EEC on Hazardous Waste, amended by national legislation as the Recycling and Waste Management Act (Kreislaufwirtschafts- und Abfallgesetz: KrW-/AbfG) in Germany. While the first two drivers for reverse logistic tasks focus on economic and legal aspects, the third factor addresses the society and the fact that an enterprise depends on the “license to operate” issued by the people and institutions in its living environment. Due to environmental concerns, also construction enterprises face pressure to act according to the principle of sustainability, i.e. waste avoidance and reuse in order to foster resource preservation and emission avoidance. The “green image” gained by environmentally friendly business operations can help to win the favour of the public.

Reverse logistics is not only considered to comprise logistic activities to move products from the point of use to the point of disposition but the phases from product acquisition to remarketing, depicted in figure 1 (Fleischmann et al. 2000).

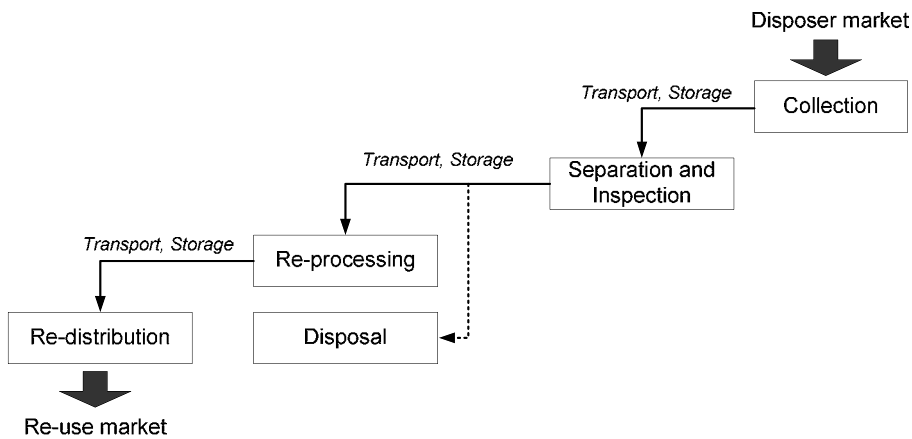

Figure 1 Stages of reverse logistics

Collection comprises all activities necessary to make products available and physically moving them to locations or facilities were further treatment takes place. Well known examples are the take back of electrical and electronic equipment as well as used batteries and cars (e.g. Daniel et al. 2003; Schultmann et al. 2006). Briefly, the collection includes the activities purchasing, transportation, and storage (Fleischmann et al. 2000). Inspection and separation includes all operations for the determination of the type of re-usability of a product. Therefore, the flow of used products is separated according to the various recovery or disposal options, e.g. inspection of goods for hazardous substances. The inspection and separation span disassembling, shredding, testing, sorting, and storing the products within the reverse logistic process. The recovery of a used product for further use in the same or another constitution is defined as re-processing. Re-processing or Recovering represent activities such as recycling, repair, or remanufacturing. Additionally, cleaning, replacement, and re-assembly activities are included. In comparison, disposal is applied to products not suitable for recovery due to technical or economic reasons; for instance, rejected products during separation level due to excessive repair effort or products without market potential due to their age. Thereby, disposal includes transportation, land filling, as well as incineration. After re-processing, products are re-distributed to the potential market place and future customers. Re-distribution encompasses the steps sales, transportation but also storage activities; e.g. sale of recycled materials or refurbished electronic equipment.

Furthermore, transportation and storage activity are usually required between each of the stages and are limited by a number of constraints, such as the availability and capacity of transport vehicles or storage space and inventory requirements. Thereby, transport and storage processes, like in the traditional manufacturing industry, also take place between all stages of reverse logistics in construction and significantly contribute to the complexity of the problem of establishing closed-loop construction supply chains. For deconstruction projects, two major fields of research were identified and are tackled in the following sections: (1) energy recovery from C&D waste and (2) material management in terms of logistic activities for the collection of C&D waste.

3.3 The Need for Deconstruction

In construction, major effort towards closed-loop material flows concentrated on the recovery of C&D waste from underground engineering. Problems occur with C&D waste and materials from the building construction sector arising during the deconstruction, modification or renovation of buildings.

Severe problems in deconstruction project planning occur when the building has not been designed and constructed with the intention to recover its used components and materials. Further complexity is added by the uncertainty of the composition of the buildings. As the recovery of components and materials depends on the deconstruction technique, deconstruction techniques have to be assessed for their ability to supply components and materials in a quality sufficient for the recovery purpose after the determination of environmental beneficial treatment of deconstruction waste.

However, although deconstruction and recovery generally permit the decrease of demolition waste which would otherwise be land-filled or incinerated, it can cause pollution and resource use which would not have occurred if the recovery of components and materials had not been processed. Hence, the various recovery options have to be weighted against the use of virgin raw or primary materials, and perhaps final disposal has to be preferred to recovery for the sake of environmental preservation when comparing the energy savings of the options. Schultmann and Sunke (2007) have developed an integrated deconstruction and recovery planning approach for deconstruction projects based on the multi-mode RCPSP mentioned before. They consider the energy embodied in construction materials and the advantageousness of recovery or disposal in dependency on the deconstruction technique to be employed. The application of quantitative planning models like the RCPSP thereby allows additionally considering external project constraints like time or budgeting limitations.

3.4 Collection and Handling of C&D Waste

The responsibility for C&D waste management in deconstruction projects is usually assigned to the general contractor, i.e. the construction enterprise or the responsible sub contractor. The aim of the contractor is to reduce disposal costs. This is usually realized by selective deconstruction and a high degree of C&D waste separation. After deconstruction and sorting, either the contractor delivers the waste to recovery facilities or disposal sites against a fee or directly contracts with a specialised reverse chain actor, e.g. a recycling company, who picks up the containers of C&D waste on site for money and resells, recovers or disposes the C&D waste itself. Thereby, the contractor usually sets orders (call services) to the waste management company to request pick up of C&D waste to avoid site congestion. As deconstruction projects are usually conducted using selective dismantling, i.e. C&D waste is separated right after deconstruction, the collection takes place as separate routing of shared resources. This means, that one vehicle collects one particular waste type, for instance wood or bricks. Additionally, in case of collection of C&D waste in containers, the delivery task of an empty container might be combined with the preceding pickup of a full container from the construction site. After the collection and transport to the recovery facilities or direct consumers in case of direct reuse, recovered components and materials are lead back into the material cycle, either as low quality material for road construction or as input for other production processes, such as glass or aluminium or insulation manufacturing.

Especially for reverse supply chain actors, the efficient transport of C&D waste is difficult. In contrast to the manufacturing, the location of the deconstruction sites is varying and usually the only accessible way is road transport mode. Hence, trucks with special equipment (for instance, special hangers to safely store deconstructed windows for resale) or container trucks are used. Thereby, also the composition of C&D waste hampers efficient reverse logistic activities. The size and quality of C&D waste is usually not standardised and the waste often contains unexpected hazardous substances. Deadheads cannot be avoided due to the missing planning certainty with respect to the forecast of the amount, place and time of the pick up of goods or collection from the construction sites and usually different role of the actor (a recycling plant usually does not deliver a deconstruction site with recovered components or recycled material). Instead, pick up tours have to be calculated every time an order is made by a contractor and complicated vehicle routing problems occur every time a new order arrives. Concluding, depending on the actors involved in reverse logistics processes in construction different networks of collection points (supply sources) and recovery facilities or disposal sites (demand points) for C&D waste exist. If third party service providers, like waste management companies (WMC), are authorized with the pick up and recovery or disposal C&D waste, numerous collection points (construction sites) exist and difficult transport problems, i.e. vehicle routing problems, occur. If the construction contractor itself is responsible for the collection and transport of C&D waste to the recovery facility or disposal site against some charge, easier network structures and planning problems occur. However, this situation is only evident for very small deconstruction projects usually processed by small construction enterprises, which are most commonly engaged in regional business and contracts with private persons. Therefore, also in construction common problems occurring are to be found in transportation activities, i.e. inefficient route planning and empty truck loads (Fleischmann et al. 2000).

For the collection of C&D waste it is necessary to develop an optimisation model which includes both the contractor's as well as the WMC's view. Due to the highly unstable planning environment and short time orders complex optimisation problems would arise. Hence, the decomposition of the resulting optimisation problem is advised. Two main planning problems can be differentiated in dependency on the material and actor:

- Construction contractor: determination of collection times and amounts for bulk C&D waste
- Waste management company: determination of optimal routing decision for specialised C&D waste

The objectives of the contractor as well as of the WMC are somewhat adverse. While construction contractors usually seek to have their site clean at minimum costs not exceeding maximum available space on site, WMCs try to minimise their transportation costs while servicing as many clients as possible. However, the contractor usually reports to the WMC when to pickup a certain amount of a waste type and does not pay respect to the available amount of vehicles and their related capacities of the WMC, i.e. the capacity utilisation of the WMC. Hence, the WMC can rarely define optimal routings for the vehicles nor can it properly assign vehicle capacities to contractor's orders in accordance to the available number of vehicles.

Methods from Operations Research can help tackle these problems. While in the first case, bulk material usually accumulates in such high amounts, that the vehicle capacity would be fully utilised, the WMC has the opportunity to service multiple deconstruction sites with one vehicle if the C&D waste consists of valuable or hazardous waste usually accumulating in low amounts. Especially the latter case can be depicted as a vehicle routing problem with time windows (VRPTW). In the VRPTW the contractor gives information on the amount and a possible time window for service while the WMC assigns its vehicles to the contractors to be serviced in accordance to its capacity.

4. Conclusion

The sketched planning problems in construction underline the need for an integrated consideration of the construction supply chain. Although the examples given rather highlight planning problems than present a solution, awareness is created for the need of a holistic consideration of the construction industry. Current practice usually differentiates between the different issues such as project planning, materials procurement and end-of-life aspects.

While the integrated time and capacity planning of the RCPSP serves the achievement of monetary and time objectives in construction projects, it can be extended and enriched with environmental aspects such as the selection of the most appropriate deconstruction technique for end-of-life considerations in construction to ensure proper material recovery. Furthermore, concepts of SCM from manufacturing industries can be applied to construction materials procurement and direct relations can be drawn to the collection of C&D waste at the end of the life time of a building.

To complement the problems addressed research effort in the future now has to investigate in detail, were the potential of the proposed solution approaches can be found and how they could be exploited.

Keywords: Carbonation, calculation of CO_2 absorption quantity, concrete, apartment

Summary

A cement which is used in construction and a concrete which is a hydration product of cement are considered anti-environmental materials because of lots of CO_2 emission in progress of producing and making it. But a concrete absorbs CO_2 gas in atmosphere from before and after hydration to its lifespan. It is called carbonation. Based on Papadakis' theses, this research is carried out to find out how to calculate of the CO_2 absorption quantity in concrete from the view of environment friendly performance. After research, we did an accelerated carbonation test for each specimen which has surface-finish. And then with using a carbonated depth and some equations, we calculated CO_2 absorption quantity in each specimens. At the conclusion, we simulate assessment income and outcome of CO_2 to an apartment building in Korea.

1. Introduction

1.1 Study background and objective

Recently, a rising in a temperature of atmosphere because of increasing CO_2 makes iceberg melted, as a result, it makes a level of the sea arise. This phenomenon is considered dangerous factor for people to live on in the future. So, all the nations are trying to reduce the quantity of CO_2 emission. By the way, a cement and a concrete which is used in construction need much energy to make and to produce them. Also they emit much CO_2 gas to the air. Therefore both materials are considered unfriendly-environmental ones. But people usually ignore that a concrete has a material that absorbs CO_2 in the air during its lifelong. And we call this phenomenon carbonation. That is enough to make people's thought change for the concrete from unfriendly one to friendly one.

Therefore, in this research we studied about method to calculate CO_2 absorption quantity in concrete theoretically through the carbonation. With using this method, we calculated CO_2 absorption quantity in specimens of concrete which has some kinds of surface-finishes and compared the absorption quantity according to surface-finishes in 100years. In the end, an assessment income and outcome of CO_2 to an apartment building were executed.

2. Reference study

Chemical reactions, models, equations and some datum which are used in calculation of CO_2 quantity refer to Papadakis' theses.[1),2),3)]

2.1. How to calculate CO_2 absorption quantity in carbonated concrete.

A mechanism of carbonation is well known to eq. (1). In this equation, we knew that $Ca(OH)_2$ is the only reactant related to carbonation. But under exiting moisture, reactants related to CO_2 in the air are C_3S, C_2S(before hydration), $Ca(OH)_2$, CSH.(after hydration).

$$Ca(OH)_2 + CO_2 \rightarrow CaCO_3 + H_2O \qquad (1)$$

In order to calculating CO_2 absorption quantity in carbonated concrete, it is required to calculate these four reactants quantity. At first, the quantity of C_3S, C_2S like table 1 can be calculated with using oxide analysis[4] and Bogue's equations.[5] In this study, the concrete specimens are made of type I portland cements. So type I cement is only considered herein.

Table 1. Compound composition of Portland cements

Compound composition	Cement No.1 (%)
$C_3S(3CaO{\cdot}SiO_2)$	53.7
$C_2S(2CaO{\cdot}SiO_2)$	19.9
$C_3A(3CaO{\cdot}Al_2O_3)$	11.4
$C_4AF(4CaO{\cdot}Al_2O_3{\cdot}Fe_2O_3)$	8.8

After mixing, the molar concentration of each compound composition can be calculated as follows:

$$[i]_0 = \frac{m_i m_{cl} c}{MW_i} \qquad (2)$$

Where i refer to C_3S, C_2S, C_3A, C_4AF, m_{cl} is the weight fraction of clinker, c is the content of cement in 1m^3 concrete, MW_i is the molar weight of component i. MW_i of each compound composition refers to table 2. Like calculating [i], the molar concentration of gypsum as follows:

$$[C\bar{S}H2]_0 = \frac{m_{gy} c}{MW_{gy}} \qquad (3)$$

in which m_{gy} is the weight fraction of gypsum and the value is calculated by $m_{gy} = 1 - m_{cl}$.
At second, The molar concentration of $Ca(OH)_2$, CSH which is reactant with CO_2 can be calculated according to eq. (4)-(7).

$$\begin{aligned}[Ca(OH)_2]^0 &= \frac{3}{2}[C_3S]_0 + \frac{1}{2}[C_2S]_0 - 2[C_4AF]_0 F_{C_4AF}(t^*) - 4[C_4AF]_0(1 - F_{C_4AF}(t^*)) \\ &\quad - [C_3A]_0(1 - F_{C_3A}(t^*)) \\ &= \frac{3}{2}[C_3S]_0 + \frac{1}{2}[C_2S]_0 - 4[C_4AF]_0 - [C_3A]_0 + (2[C_4AF]_0 F_{C_4AF}(t^*) \\ &\quad + [C_3A]_0 F_{C_3A}(t^*)) \\ &= \frac{3}{2}[C_3S]_0 + \frac{1}{2}[C_2S]_0 - 4[C_4AF]_0 - [C_3A]_0 + [C\bar{S}H_2]_0 \end{aligned} \qquad (4)$$

$$[CSH]^0 = \frac{1}{2}[C_3S]_0 + \frac{1}{2}[C_2S]_0 \qquad (5)$$

$$[C_3S]^0 = 0 \qquad (6)$$

$$[C_2S]^0 = 0 \qquad (7)$$

Equation (4)-(7) are based on chemical reaction equation (8)-(13).

$$2(C_3S) + 6H \xrightarrow{r_{H,C_3S}} C_3S_2H_3 + 3CH \qquad (8)$$

$$2(C_2S) + 4H \xrightarrow{r_{H,C2_3S}} C_3S_2H_3 + CH \qquad (9)$$

$$C_4AF + 2CH + 2C\bar{S}H_2 + 18H \xrightarrow{r_{H,C_4AF}} C_8AF\bar{S}_2H_{24} \qquad (10)$$

$$C_3A + C\bar{S}H_2 + 10H \xrightarrow{r_{H,C_3A}} C_4A\bar{S}H_{12} \qquad (11)$$

$$C_4AF + 4CH + 22H \xrightarrow{r_{H,C_4AF}} C_8AFH_{26} \qquad (12)$$

$$C_3A + CH + 12H \xrightarrow{r_{H,C_3A}} C_4AH_{13} \qquad (13)$$

Among the equation (8)-(13), eq.(8)-(11) are reactions when the gypsum exists, eq.(12), (13) are reactions when the gypsum is used up. To calculate the hydration content of each compound, the time t^* when the gypsum is used up should be calculated. With using eq. (14)-(16), the value can be calculated.

$$F_i(t) = 1 - \frac{[i]}{[i]_0} = 1 - \left[1 - k_{H,i} t (1 - n_i)\right]^{1/1-n_i} \tag{14}$$

$F_i(t)$ is fraction of compound i, which has been hydrated at time t(in sec) after mixing.[1)] Every $F_i(t)$ can be calculated by substituting $k_{H.i}$,n_i for value in table 2. t^* is the time when gypsum is used up. So formula (15) means at time t^*, initial concentration of gypsum is equal to sum of terms in left side which multiplies concentration by Fraction. The second term in Eq. (15) is almost zero[1)]. Combined Eq.(14),(15), we can calculate the value t^* such as Eq.(16).

$$[C_3A] \cdot F_{C_3A}(t^*) + 2[C_4AF]_0 \cdot F_{C_4AF}(t^*) = [C\bar{S}H_2]_0 \tag{15}$$

$$t^* = \frac{1}{k_{H,C_3A}(1-n_{C_3A})}\left[1 - \left(1 - \frac{[C\bar{S}H_2]_0}{[C_3A]_0}\right)^{(1-n_{C_3A})}\right] \tag{16}$$

The process of concrete carbonation can be described by eq.(17)-(20).

Table 2. Parameters of major constituents of ordinary Portland cement[1)]

	C_3S	C_2S	C_4AF	C_3A	$C\bar{S}H_2$
Exponent n_i, Eq. (9)	2.65	3.10	3.81	2.41	-
Coefficient $k_{H,i}$ (20C)×10^5(s^{-1}), Eq. (9)	1.17	0.16	1.00	2.46	-
Molar weight MW*10^3(kg/mol), kg/mol	228.3	172.22	485.96	270.18	172.17

$$Ca(OH)_2 + CO_2 \xrightarrow{r_{CH}} CaCO_3 + H_2O \tag{17}$$

$$3CaO \cdot 2SiO_2 \cdot 3H_2O + 3CO_2 \xrightarrow{r_{CSH}} 3CaCO_3 \cdot 2SiO_2 \cdot 3H_2O \tag{18}$$

$$3CaO \cdot SiO_2 + 3CO_2 + \cdot rH_2O \xrightarrow{r_{C_3S}} SiO_2 \cdot rH_2O + 3CaCO_3 \tag{19}$$

$$2CaO \cdot SiO_2 + 2CO_2 + \cdot rH_2O \xrightarrow{r_{C_2S}} SiO_2 \cdot rH_2O + 2CaCO_3 \tag{20}$$

The calculation of carbonation depth as follows:

$$x = \sqrt{\frac{2 \cdot D_e^c \cdot [CO_2]^0}{[Ca(OH)_2]^0 + 3[CSH]^0 + 3[C_3S]^0 + 2[C_2S]^0}}\sqrt{t} \tag{21}$$

Where, $[Ca(OH)_2]^0 + 3[CSH]^0 + 3[C_3S]^0 + 2[C_2S]^0$ is the content of CO_2 absorbed in 1 m^3 concrete. (mol/m^3)

$$D_e = 1.64 \times 10^{-6} \cdot \varepsilon_p^{1.8} (1 - \frac{RH}{100})^{2.2} \tag{22}$$

$$[CO_2]^0 = \frac{P_{CO_2} V}{RT_0} = \frac{C_0 \cdot 1000}{0.08206 \cdot 298} = 40.89 C_0 \tag{23}$$

$[CO_2]^0$ is a molar concentration of CO_2 in atmosphere, T=25℃, R=0.08206 is constant, C_0 is equal to 0.03% (CO_2 content in atmosphere).

3. Evaluation for the resistance of concrete which has various surface-finishes.

3.1 Experiment Plan

Each surface-finish was constructed on the surface of concrete whose size is 100mm×100mm×400mm such as table 3. Constructed specimens were carbonated in acceleration condition like table 3. And the carbonated depth of each specimens were estimated according to terms of carbonation.

Table 3. Experimental factor and outline

	Surface finishes	Material depth (mm)	Term of carbonation	Acceleration Condition
1	No finish	×	7day 14 day 28 day 42 day 70 day	- Concentration of CO_2: 10% - RH: 40% - Temperature: 20℃
2	Water Repellent	0.1		
3	Water paint	0.2		
4	covering material	0.5		
5	Recovering material	10		
6	Remitar	10		
7	Bon-tile	0.5		

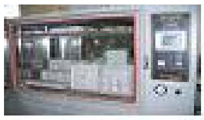

Table 4. Mixing proportion of concrete

W/C (%)	S/a (%)	Unit weight (kg/㎥)				
		W	C	S	G	AD
55	50	181	326	895	890	1.63

3.2 Experiment Result

3.2.1 Measurement of carbonated depth in concrete which has various surface-finishes.

After experiment, carbonated depths according to materials are like Figure 1. From term and carbonated depth, eq.(23), the value A can be calculated. And using eq.(24),(25), we can change the value A(accelerating condition) into A_{air}(general air condition). The changed values are like table 5, with using these, we estimated the carbonation depth after 100years.

$$x = A\sqrt{t} \qquad (23)$$

In which, x is a carbonation depth(mm), t is accelerating term(week). A is carbonation velocity coefficient.

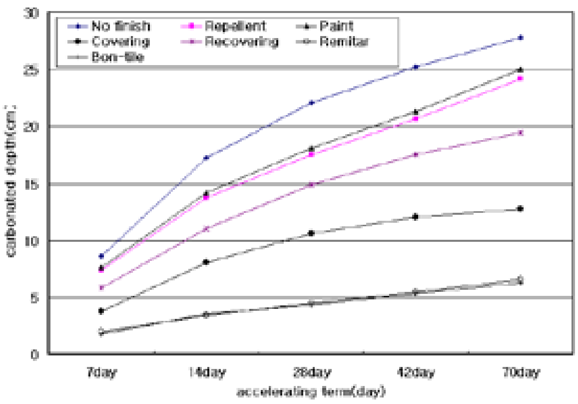

Figure 1. Carbonated depth according to materials

$$A_{STD} = A_{size} \cdot A_{mcure} \cdot A_{icure} \cdot A_{idry} \cdot A_{Tem} \cdot A_{CO_2} \cdot A_{Hu} \qquad (24)$$

A_{STD} is a carbonation velocity coefficient in standard carbonation condition. With using eq. (24), A_{STD} can be calculated.[6)]

Table 5. Calculation of velocity coefficient according to conditions and estimating carbonation depth.

	No finish	Bond-tile	Remitar	Recovering	Covering	Paint	Repellent	unit
A(20℃, RH: 40%, CO_2:10%)	3.33	0.78	0.93	1.76	2.31	2.87	2.88	
A_{STD}(20℃, RH: 60%, CO_2:5%)	5.89	1.38	1.64	3.11	4.08	5.07	5.09	$\frac{mm}{\sqrt{year}}$
A_{air} (CO_2:0.03%)	8.73	2.02	2.45	4.62	6.06	7.5	7.5	
Carbonation depth in 100yrs	87.3	20.2	24.5	46.2	60.6	75	75	mm
CO_2 absorption quantity	100.5	23.3	28.2	53.2	69.8	86.4	86.4	g

$$x = A_{air}\sqrt{\frac{CO_2}{5}} \cdot \sqrt{t} \qquad (25)$$

A_{air} is a carbonation velocity coefficient in general air condition. With using eq. (25), A_{air} can be calculated.[6),7)]
Eq.(23)-(25) refers to reference (6),(7).
After experiment 3.2, we found that Bon-tile is the most resistant surface-finishes against carbonation, and the resistant function of Paint and Repellent against carbonation is poor among them.

3.2.2 Calculation CO_2 absorption quantity in carbonated concrete and comparison the result.

With using datum in table 5, CO_2 absorption quantity in carbonated concrete according to surface-finishes was calculated and the result is in table 5.

From this result, after 100years, the specimens whose section size is 100mm×100mm is to absorb CO_2 in the air is like figure 2. With no doubt, no finish specimen is to absorb CO_2 most among them, and the absorption content of CO_2 is about 100.5g. Bond-tile which has the most resistance against carbonation absorbs about 23.3g of CO_2. This value is one-fifth one of concrete with no finishes. The more surface-finishes have resistance against carbonation, the smaller concrete absorbs CO_2.

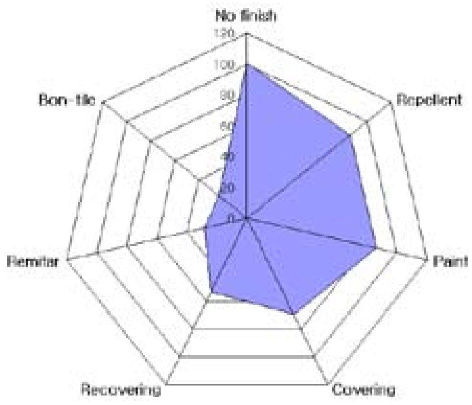

Figure 2. CO_2 absorption quantity according to finishes after 100 years (unit:g)

3.2.3 How to calculate CO_2 emission quantity

CO_2 emission quantity to produce concrete can be calculated by using datum of concrete component that indicate emitted CO_2 quantity when they were produced. Table 6 shows that how much each component emit CO_2(kg-CO_2) when they were used(m^3). Therefore, if the amount of concrete that was used in producing building, CO_2 emission quantity to a building can be calculated with using this table and concrete mix table.

Table 6. CO_2 emission quantity to concrete components when they used in amount of m^3 (Unit : kg-CO_2/m^3)

Component	Water	Cement	Fly ash	Fine Aggregate	Coarse Aggregate	AE reducing water agent
kg-CO_2/m^3	-	0.7466	0.6197	0.0037	0.0028	0.25

3.2.4 Assessment income and outcome of CO_2 to a real apartment.

3.2.4.1 Calculation CO_2 emission quantity

To an apartment whose plan is like figure 3, considering concrete strength to each story zone like table 7, with using and calculating amount of a concrete mix table according to strength(table 8), CO_2 emission quantity was calculated and the result is table 9,10.

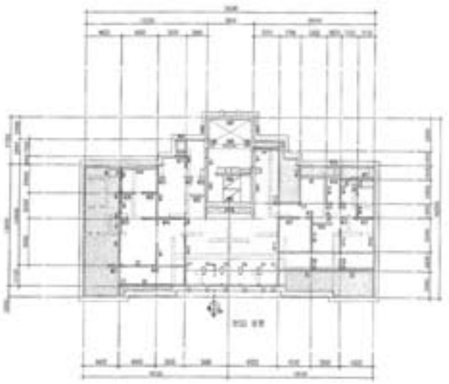

Figure 3. Base floor plan

Table 7. Calculation amount of concrete to strengths (m^3)

Story	Column+Wall	Slab	Total	Strength(MPa)	W/C(%)
Basement 1st	185.96	0.00	185.96	35	39
1st~ 9th	178.40	155.73	334.13		
10th~19th	178.40	155.73	334.13	30	43
20th~26th	178.40	155.73	334.13	27	46

strength	CO_2 emission quantity (kg-CO_2)	
35MPa	1,152,689	**3,527,227**
30MPa	1,013,033	
27MPa	657,102	
24MPa	704,405	

3.2.4.2 Calculation CO_2 absorption quantity

To calculate CO_2 absorption quantity to the apartment, it is required to know surface area exposed to air, carbonation depth to time. To estimate carbonation depth, time should be defined. In this study, 40, 60, 80 years are considered. Carbonation depth to each strength was estimated by using equation proposed by Ko Kyung Taek(Fig.4) and the results are like table 12. And amounts of concrete to strengths and planes according to story are like table 11. And surface area to strength are like table 13. CO_2 absorption quantity to strength in time are like table 14. Molar concentration of CO_2 to each strength are like table 15. With using these datum, CO_2 absorption quantity can be calculated and figure 5, equation 26 shows the concept to describe how to calculate it.

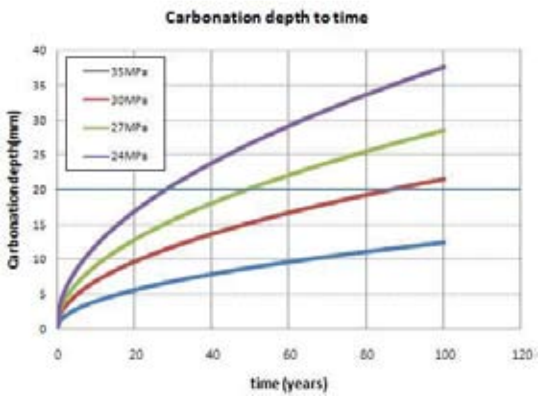

Figure 4. Carbonation depth to strength in time

Table 11. Amounts of concrete to strengths, planes(m^3)

Story	Left Wall	Rear Wall	Right Wall	Front Wall	Slab	Inner Wall	strength (MPa)
basement	0	0	0	0	596.15	947.00	35

Figure 5. Calculation CO_2 absorption quantity

3.2.4.3 Assessment income and outcome of CO_2 to an apartment in times

The amount of CO_2 emitted to produce this building was calculated and the the result are like table 10. And the amount of CO_2 absorbed in concrete was calculated in 40, 60, 80years and the result are like table 14. Therefore, using these two result and equation (27), income and outcome of CO_2 to an apartment in times 40, 60, 80 years can be assessed quantitatively. And the ratio of absorption to emission can be calculated using the equation (28). And the result are like figure 6,7, table 16.

income and outcome of CO_2 = emitted CO_2 – absorbed CO_2 (27)

Ratio of absorbed CO_2 to emitted CO_2 (%) = absorbed CO_2 / emitted CO_2 × 100 (28)

Table 16 Assessment result of income and outcome of CO_2

contents / time	40yrs	60yrs	80yrs	unit
emitted quantity		3,527		
absorbed quantity	120	147	169	kg-co$_2$
(emitted - absorbed) of CO_2	3,407	3,380	3,357	
ratio of emitted to absorbed of CO_2	3.4	4.17	4.81	%

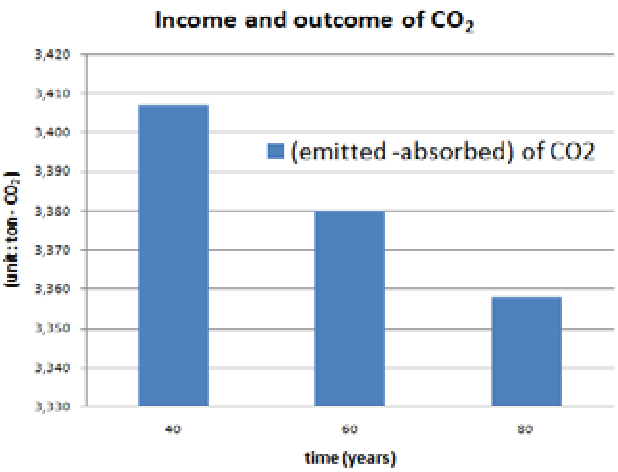

Figure 6. Result of income and outcome of CO_2

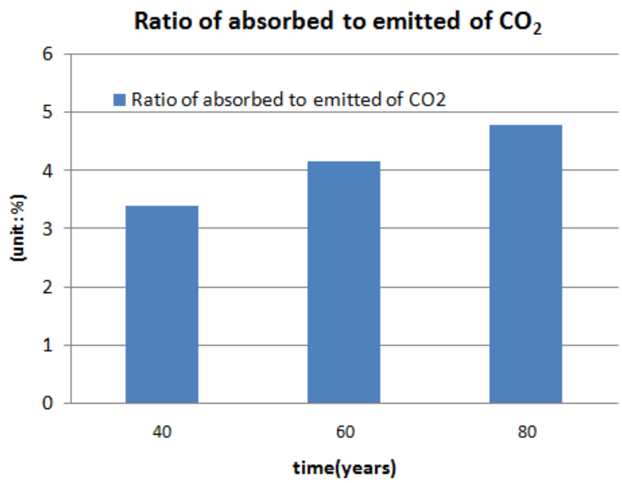

Figure 7. Result of ratio absorbed to emitted of CO_2

After assessment income and outcome of CO_2, the amount of concrete that was used in building apartment will absorb about 5% to emitted CO_2. This figure may be thought to be very small amount. But this study is important to evaluate the amount of absorbed and emitted CO_2 quantitatively. Besides this study is important in that these result can change people's thought to concrete that is an unfriendly-material. In another research[8)], there are another try for concrete to absorb CO_2 much more by increasing surface area of concrete after its demolition by crashing it in northern Europe countries. Therefore in further study, it is important to consider and study increasing surface area of concrete exposed to the air.

Conclusions

In this study, we studied how to calculate CO_2 absorption quantity in carbonated concrete and we did an experiment that which surface-finishes has more resistance against carbonation, compared with other specimens. And emission of CO_2 when $1m^3$ of the concrete was produced was calculated with using reference. Finally, with using these method, emitted and absorbed of CO_2 in the concrete was calculated to an apartment building.

From this study, conclusion are as follows:

1) Absorption and emission quantity of CO_2 can be calculated quantitatively.

2) Restraining effect of surface-finishes against carbonation can be also calculated and compared among them.

3) Using building longer is also another important factor because the amount of emitted CO_2 is much more than that of absorbed CO_2 when a concrete was used the amount of $1m^3$.

4) The surface area of concrete is a important factor to increase the amount of absorption CO_2.

5) After building demolition, it is required to use crushed concrete actively because they have so much larger surface area that can absorb CO_2 in the air with time.

Keywords: material efficiency, environmental performance, high performance concrete, recycled materials, optimization

Summary

Development of progressive materials, structures and technologies for sustainable buildings is based on the struggle for the reduction of primary non-renewable material and energy resources, while keeping safety and durability of the structure on the required high level. Material effective structures for buildings can be based on several structural principles and their combinations: optimization of structural form, use of recycled waste materials, use of natural and renewable materials, use of composite and high performance materials. New composite high performance silicate materials can be used for thin "shell" elements enabling design with significantly reduced use of materials and leading to reduction of environmental impacts. Several preliminary research results followed by applications in construction practice showed already possibilities of the reuse of waste materials (preferably from municipal waste) for lightening fillers used in optimized concrete structures. Experimental investigation and case studies performed by authors in the frame of long term research, focused to environmental optimization of building structures, support the expectation that it will be possible to reach factor 3 or even more while keeping structural reliability on the needed high level. Developed structural concepts have been proved not only by theoretical and experimental results, but also by practical application in construction of several buildings.

1. Background

During the twenty years from 1974 to 1994 the world population increased by 40%. Cement and steel production and municipal waste generation are increasing even faster (Hajek 2006) (Fig. 1).

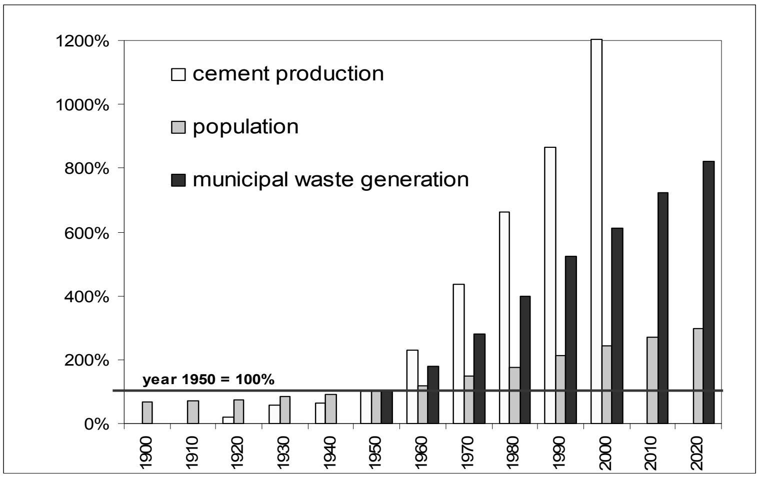

Figure 1 Tendencies of cement production and generation of municipal waste (OECD data) are compared with the population growth and its expected development up to the year 2020

The need for material saving was clearly specified in general Rio Agenda 21 (Changing Consumption Patterns) published in 1992: "To promote efficiency in production processes and reduce wasteful consumption in the process of economic growth".

Buildings in EU and other developed countries are responsible for more than 40% of the total energy consumption, and the construction sector generates approx. 40% of all man-made wastes (CIB 1999). The extraction of raw materials for construction of buildings, manufacturing of building products and waste landfill or incineration are associated with corresponding environmental impacts, including greenhouse gas emissions. Buildings are thus consequently responsible for more than 30% of released CO_2 emissions.

Development of new materials, structures and construction technologies for construction of buildings should be thus based on the struggle for the reduction of primary non-renewable material and energy resources, while keeping performance quality, safety and durability on a high performance level.

Performance quality and safety of construction in all its life cycle stages, including exceptional situations (natural disasters, explosions, fires, etc.) comes to prominence in the hierarchy of the design criterion importance. This is also due to the increasing risk level resulting from the rise of exceptional situations caused by global climatic changes, as well as terrorist attacks.

Both, the requirements, (i) the reduction of material consumption (leading to more slender structures) and (ii) the increase of performance quality, reliability, durability and safety can be at first sight considered as being in contradiction. Using traditional construction materials and technologies, the typical result of the effort to ensure a higher level of structural reliability and safety is the robust structure (which needs more construction materials). However, using high performance materials it is possible to design more slender structures, while performance quality, structural reliability and safety is kept at the required high level.

2. Optimization of material consumption in building structures

The problem of sustainability of structures is very complex and includes a large number of parameters and criteria from different areas of technical as well as non-technical sciences. One of the most important criteria in the optimization of load bearing structures is consumption of non-renewable materials and associated consequences during the whole life cycle of the structure (transport and manipulation with material during construction, demolition, recycle ability etc.).

Material effective structures (with reduced amount of structural material) can be based in general on several structural principles and their combinations:

- optimization of structural form and shape of structural elements,
- use of high performance silicate materials,
- use of recycled waste materials (including municipal waste),
- use of renewable materials.

The reduction of primary non-renewable resources and consequent reduction of waste amounts can also be achieved by the use of waste from construction, as well as other industries as a secondary material for production. Some secondary materials (such as fly-ash, silica fume, slag, etc.) can be used in production of new concrete. The initial optimization steps, covering the use of the ribbed or waffle shape and use of recycled materials, result in the reduction of embodied values (CO_2, SO_2, energy). The cut in consumption of natural (non-renewable) sources (limestone, granite, oil, etc.) is evident, and can be very significant.

2.1 Optimization of structural form and shape of structural elements

The typical outcome of the shape optimization of the concrete structure with the objective to reduce structural material consumption (while high level of reliability is kept) is the ribbed or waffle structure. The basic structural advantages of waffle and ribbed elements are demonstrated in the layout of the structural material in a cross-section. The “T” shape of RC ribs allows a convenient distribution of the structural material, saving material in the tension part of the section. In comparison with the full RC slab, the basic shape of waffle or ribbed slab structures reduces concrete use by 40-55%, and also the corresponding steel use. Consequently, the reduction of the total self-weight acting on vertical bearing structures and foundations can decrease their sizes.

Due to their shape, the reinforced concrete waffle and ribbed structures represent the effective types of structures given by the relation between the material consumption and structural characteristics. This principle is traditionally applied in construction of floors (e.g. ribbed and waffle RC slabs) and walls (e.g. timber framed structure) and could be thus used in sustainable optimized design.

2.2 Use of high-performance silicate materials

The process of optimization of structures from silicate materials (different types of concrete, ceramics, geopolymers) is generally based on the following principles:

- optimization of production technologies of components,
- optimization of concrete mix composition,
- optimization of the shape and reinforcement of structural elements,
- life cycle optimization of the whole structure

There is a good chance to achieve the required reduction of primary material sources and simultaneously the increase of structural reliability and safety (mainly in the case of exceptional load cases) by the use of new high performance fiber concrete (with optimized mechanical properties) in an optimized shape of the structure (which uses less structural material in a cross section in a more efficient way).

Using new types of composite materials with programmed mechanical properties, it is possible to achieve significant improvements in environmental parameters of the structure. This can be achieved mainly by the design of more slender shell structural forms saving primary resources and by the reduction of environmental impacts from depositing and recycling the structure at the end of its life cycle.

Several examples from abroad show, that new composite fiber silicate materials and corresponding technologies can be used for realization of thin "shell" elements with the thickness less than 30 mm (e.g. Ductal – France).

2.3 Use of recycled waste materials

Building construction typically uses large amounts of materials in relatively less demanding techniques. Therefore, there is a high potential for the use of secondary materials obtained from recycling of waste generated by other industrial processes and from municipal waste (Hajek 2006). This approach permits to keep materials in the material cycle longer (considering usually longer service life of the building compared to the service life of the primary product disposed in municipal waste). This results in reduction of consumption of primary material sources and reduction of waste generation and emissions including GHG emissions. Using recycled materials including recycled municipal waste it is possible to keep once used primary material in a many times longer life cycle, and therefore considerably support saving of natural resources.

The main concern should be paid to those waste materials which are produced in large amounts and just a small amount is recycled. Such waste materials are e.g. non-sorted plastics (yellow collecting containers) and laminated carton drink boxes from municipal waste.

The technical value of recycled material is often lower than that of the material when first used in the primary product (down-cycling). Preference should be given to the high-value reuse of recycled materials replacing high-quality primary non-renewable raw materials. In some specific cases, new products from recycled waste can have a higher performance value in comparison with the primary product (up-cycling).

The most of plastic waste and drink boxes from laminated paper are still as a part of mixed municipal waste incinerated with all consequential negative environmental impacts. However, separated salvage of municipal waste particles (plastic, glass, paper, laminated carton) is becoming common in developed countries.

Further recyclability of the newly developed construction with recycled waste materials represents an important aspect that has to be considered. A feasible, effective and environmentally-sound recycling technique should be available for the specific case to avoid the necessity and uncertainty of development of a special recycling procedure. Preferably, the technology process should not limit the number of recycling cycles. An example in Figure 2 shows the potential of use of recycled plastic from throwaway plastic drink bottles for production of plastic shell elements to be used as a permanent formwork in construction of ribbed or waffle RC floor slabs. The utility period of primary raw material could be thus prolonged several thousand times in comparison with waste disposal (incineration) of used plastic bottles in non-sorted municipal solid waste.

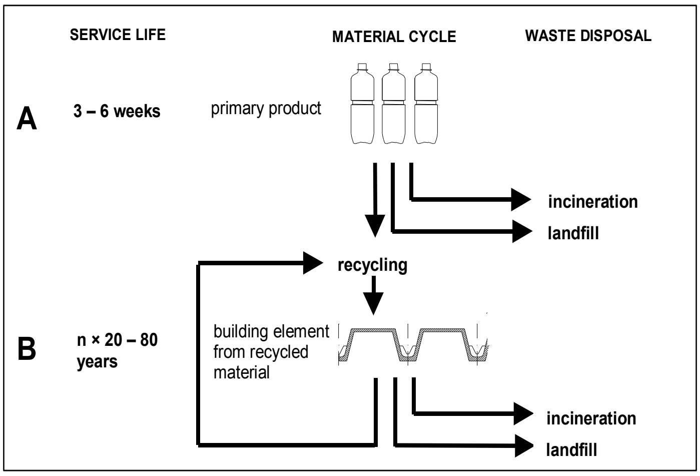

Figure 2 Life cycle of plastic throwaway bottles. A – without material recycling – lifetime 3 – 6 weeks, B – recycled plastic is used for production of building elements – lifetime n x 20 – 80 years

Another material that utilizes waste products is geopolymer concrete. Geopolymer concrete is formed by the alkali activated polymerization of aluminosilicates. Fly ash or granulated blast furnace slag (GBFS) are used as cementitious materials instead of Portland cement. There are two motives for replacement of Portland cement in concrete. Firstly, its production consumes large amount of energy (3.7MJ per kg) and secondly, there is a need for utilization of waste materials that are recently being dumped in landfills. Geopolymer concrete gives significant carbon dioxide emissions reduction while having some excellent properties such as high strength, durability and acid resistance. The disadvantage of this material is that efflorescence can appear on its surface as a result of leaching alkalis reacting with atmospheric carbon dioxide and forming carbonates.

2.4 Use of renewable materials

There is a wide range of possible applications in building construction for renewable materials. The use of wood, wooden based materials, clay unburned bricks and or non-traditional natural materials like palm tree fronds, bamboo etc. leads to reduction of environmental impacts, including savings of natural non-renewable natural materials. Especially wood is due to its properties and availability the most challenging material. However, the utilization of wood and wooden based materials is limited by fire safety, strenght and durability and thus large multistory buildings, buildings for heavy industry or transport will be still dominantly built from more strong and more fire resistant materials like concrete or steel.

3. Comparison of environmental profiles of building structure alternatives

Two presented case studies – one comparing alternatives of RC floor slabs, the second comparing alternatives of external walls - show the potential for reduction of environmental impacts by optimization of material concept of basic structural components. The alternatives have been designed for the same performance quality (spans, imposed load, flat surface etc.). The results show differences associated just with the structural alternatives themselves. However, several additional savings can be expected in supporting structural elements (columns, walls, foundations) due to lower self weight of optimized lightened structures. Further savings in the case of lightened alternatives is in construction and demolition phase due to lower transport demands.

Evaluation of environmental impact of any structure is highly determined by the quality of available data. There is no standard data set of unit embodied values for all components used in construction. In the both analyses was used data set updated according to currently published Passivhaus-Bauteilkatalog by Waltjen (2008). These data were used in the following studies for evaluation of embodied energy, embodied CO_2 and embodied SO_2. Unit embodied values for recycled non-sorted plastic were calculated using energy and production statistical data provided by recycling company Transform a.s. The data used for UHPC (Ultra High Performance Concrete) were taken from Schmidt (2007).

3.1 Case study 1: Environmental assessment of selected alternatives of RC floor structures

Several previously performed LCA (Life Cycle Assessment) analyses of RC floor structures showed that using the optimized shape and recycled materials it was possible to reduce environmental impacts, such as consumption of non-renewable silicate materials, the resulting level of embodied CO_2, embodied SO_x and embodied energy. Some results of previous LCA analyses have already been presented by Hajek (2006 and 2007). The goal of the current analysis is to show how the use of different material base and optimized shape of an RC floor slab can contribute to the reduction of environmental impacts.

In total, six alternatives of RC floor structures have been analyzed. All alternatives were designed for the same performance – live load 2.0 kN/m^2, span 4.5 m, same thickness 200 mm and final flat ceiling finish. The overview of all the analyzed alternatives is presented in Table 1.

Table 1 Floor slab alternatives used in the environmental analysis

Floor slab alternative			Self-weight Kg/m^2
A		composite / monolithic full RC slab from ordinary concrete	478
B		precast RC panel with lightening shell elements from recycled non-sorted plastic	302
C		precast UHPC panel with lightening shell elements from recycled non-sorted plastic	212
D		composite floor slab with filligran panels and lightenning fillers from polystyrene	305
E		RC ribbed floor slab with ceramic hollow core fillers	311
F		RC ribbed floor slab with lightening fillers from recycled laminated carton boards	213

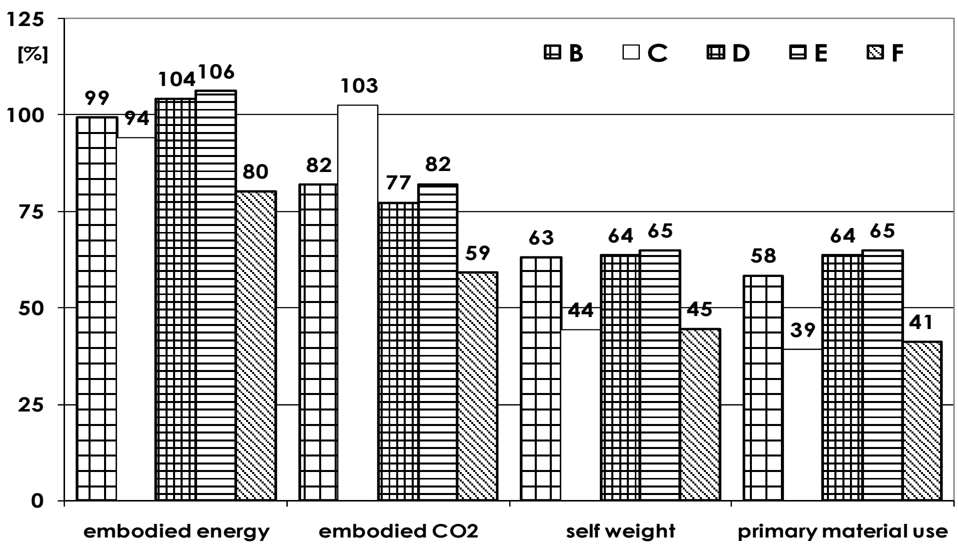

Figure 3 Comparison of environmental parameters of RC floor slab alternatives. Reference level 100% is represented by a full RC floor slab – alt. A

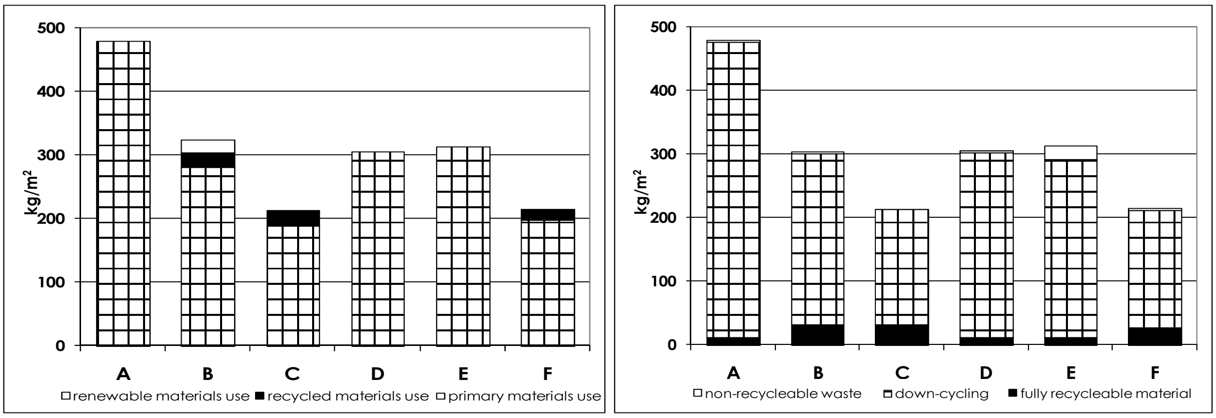

Figure 4 Input and output material flows for analyzed RC floor slab alternatives

Fig. 3 and 4 present graphs showing potential savings of environmental impacts. The reduction can be in some cases more than 50 %. These results cover just the floor structure itself. More savings are associated with the reduced use of material (savings in transport) and lower load from lighter structure acting on supporting structures (columns, walls, foundations). From this point of view major savings will be for alternatives C and F.

3.2 Case study 2: Environmental assessment of selected alternatives of external walls

The basic idea of this case study was a complex comparison of different external wall structures that are more or less typical for family and residential houses. All designed structures have the thermal performance set to recommended U values according to the Czech national standard ČSN 73 0540-2, Thermal protection of buildings - Part 2: Requirements. This means that the structures with weight per unit area over 100 kg/m^2 have the U value set to 0.25 W/m^{2}K, the structures with weight per unit area less than 100 kg/m^2 have the U value set to 0.20 W/m^{2}K.

All the structures are designed with ETICS (External Thermal Insulating Composite System) which consists of mineral wool thermal insulation and a thin silicate glass-fiber reinforced plaster (except alternative 8 which uses porous wood fiberboard as an insulation). The decision to use mineral wool as the thermal insulation have several reasons. Namely the perfect fire resistance enabling universal use, better water vapor permeability, and finally a good sound proofing. Concerning the load bearing part of the structure, there are several types of massive structures i.e. reinforced concrete wall (1), concrete hollow block wall (2), aerated concrete block wall (3), calcium silicate block wall (4), and honeycomb brick (5) wall and also lightweight structures i.e. load-bearing laminated wood panel (6), timber frame panel with mineral wool insulation (7), and another timber frame panel with cellulose fiber insulation (8).

Table 2 Exterior wall alternatives used in the environmental analysis

	Exterior wall alternative		**Thickness** mm	**Weight per unit area** kg/m^2
1	Reinforced concrete wall with ETICS *	Interior plaster, Reinforced concrete wall 150 mm, ETICS (mineral wool 170 mm, silicate glass-fiber reinforced plaster)	334	403
2	Concrete hollow block wall with ETICS *	Lime cement plaster, concrete hollow block 250 mm, ETICS (mineral wool 140 mm, silicate glass-fiber reinforced plaster)	410	346
3	Aerated concrete block wall with ETICS *	Lime cement plaster, aerated concrete block 250 mm, ETICS (mineral wool 120 mm, silicate glass-fiber reinforced plaster)	390	207
4	Calcium silicate block wall with ETICS *	Lime cement plaster, calcium silicate block 250 mm, ETICS (mineral wool 160 mm, silicate glass-fiber reinforced plaster)	430	483
5	Honeycomb brick wall with ETICS *	Lime cement plaster, honeycomb bricks 240 mm, ETICS (mineral wool 150 mm, silicate glass-fiber reinforced plaster)	424	258
6	Laminated wood panel with ETICS *	Laom plaster 30 mm, laminated wood panel 100 mm, ETICS (mineral wool 130 mm, silicate glass-fiber reinforced plaster)	270	128
7	Timber frame panel with ETICS */**	Gypsum plasterboard 12,5 mm, OSB panel 18 mm, timber studs 60/150 mm filled with mineral wool, MDF panel 15 mm, ETICS (mineral wool 60 mm, silicate glass-fiber reinforced plaster)	260	64
8	Timber frame panel with ETICS (wood-fiber board) */**	Loam plaster 30 mm, OSB panel 18 mm, timber studs 60/150 mm filled with cellulose fibers, MDF panel 15 mm, ETICS (wood fiberboard 60 mm, silicate glass-fiber reinforced plaster)	278	85

* ETICS - External Themal Insulating Composite System; ** U = 0,20 W/m^{2}K; in other cases U = 0,25 W/m^{2}K

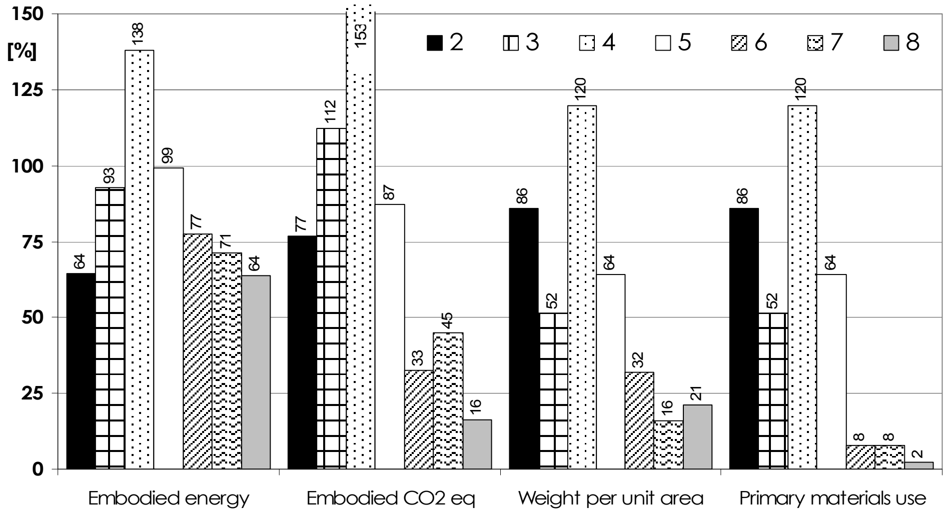

Figure 5 Comparison of environmental parameters of exterior wall alternatives. Reference level 100% is represented by a RC wall with ETICS mineral wool 170 mm – alt. 1

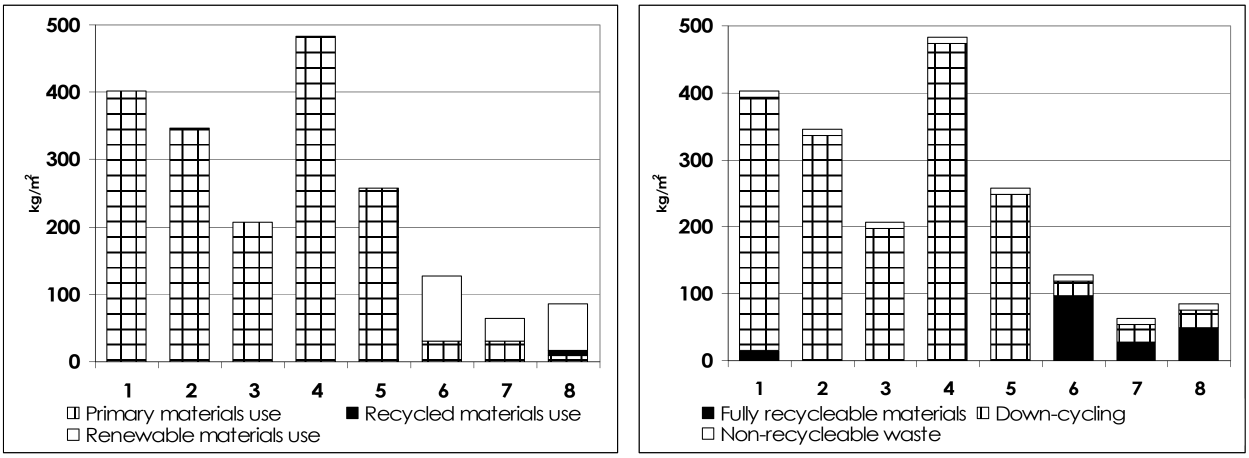

Figure 6 Input and output material flows for analyzed exterior wall alternatives

Fig. 5 and 6 present graphs showing potential savings of the environmental impacts. There are significant differences between massive and lightweight structures. The lightweight structures benefit from the low weight per unit area, small thickness, and its renewable nature that result in the superb values in all the evaluated criteria. Concerning the massive structures, good results show the alternative with concrete hollow-blocks (2) even though having a pretty high weight per unit area. On the contrary, the alternative with calcium silicate blocks show relatively bad results namely due to its high weight per unit area.

4. Application in construction practice

Two types of lightening fillers from recycled waste plastic and one type from structural boards from recycled laminated cartons were developed. The shapes of fillers were determined as a result of integrated environmental design and optimization considering environmental criterions, as well as structural parameters of the resulting composite RC structure. The initial optimization steps, covering the use of the ribbed or waffle shape and use of recycled materials, resulted in the reduction of embodied values (CO_2, SO_2, energy).

Three selected alternatives of fillers for waffle and ribbed slabs were experimentally produced and tested:

- shell installation fillers from recycled non-sorted plastic from municipal waste,
- waffle fillers from recycled non-sorted plastic from municipal waste,
- waffle fillers from structural boards from recycled laminated cartoons from municipal waste.

Installation shell plastic fillers were used in the construction of the two storey building of Senior Centre in Moravany near Pardubice in the Czech Republic. The original design of the floor structure – a composite RC slab was changed to a composite RC slab with shell installation fillers. This resulted in reduction of concrete consumption up to 0.08 m^3 per m^2, i.e. 34%. The self weight of the floor structure was reduced by 2.0 kN/m^2. The installation space inside the floor structure was used for the wiring and for the heating system in plastic tubes. This brought additional cost savings compared to the originally assumed installation system to be placed in the upper layers - inside the flooring (Fig. 7a).

The reconstruction of the two storey RC factory hall into a storage hall required an increase of the load bearing capacity of the intermediate floor structure so that the new structure would facilitate a new function with a higher live load of 5 kN/m^2. The existing cast-in-place RC slab with a thickness of 120 mm did not meet such requirements; moreover, there were a lot of openings unsuitable for the new way of use. The removal of the inconvenient RC floor slab was, due to the time limits, technological demands and total costs, unfavourable.

With respect to the limited load bearing capacity of the existing vertical load bearing RC structure, the originally expected alternative (solid full RC slab) would require strengthening of RC columns and footings. Thus, a specific solution was requested to lighten the floor slab compared to a solid one.

The new RC waffle floor slab was placed directly on the existing floor structure (Fig. 7b). Plastic fillers were placed on the floor so that the existing RC floor structure provides sufficient fire safety. Plastic formwork fillers were made in the Transform Lazne Bohdanec Company in a total amount of 650 m^2 of the fillers.

Figure 7 a - Construction of Senior Centre Moravany – composite RC slab lightened by installation fillers from recycled non-sorted plastic from municipal waste, 2000, b - Reconstruction of floor slab in Skoda factory hall. Slab is lightened by waffle fillers from recycled non-sorted plastic, 2003-2004

5. Conclusions

The theoretical analysis, optimization and performed case studies have supported preliminary assumptions about the undisputed significance of the selection of materials, including recycled materials and optimization of the shape of the structure. The performed case studies have showed that using recycled waste materials and the optimized shape of the floor structure, it is possible to reduce environmental impacts, such as consumption of non-renewable silicate materials, the resulting level of emissions (embodied CO_2, embodied SO_2) and embodied primary energy. The evaluated factor of environmental impact reduction in the range 1.2 – 1.8 can be considered insufficient, compared with the range of the needed improvements (factor 4 and more). However, these impact reductions are associated just with material savings in a structure itself and do not cover other related impact reductions in supports and transport.

Nevertheless, there is a big potential for the use of high performance silicate materials to form thin shell (ribbed, waffle, etc.) structures with reduction of the use of primary raw materials, and correspondent reduction of associated environmental impacts. Consequently, there are other possibilities how to reuse waste materials, preferably from municipal waste.

Summary

Current assessment of the indoor air quality in buildings focuses on the measurement of pollutants for comparison with air quality standards. The potential impacts of new building materials and contents on Indoor Air Quality can be controlled by labelling programs for low-emission materials but, with only limited materials labelled, especially in Australia, being able to estimate the impacts on indoor air quality of choices of building materials, contents and ventilation practices at the design stage can serve a similar purpose and be much more flexible. Such an innovative approach to estimating indoor air pollutant concentrations at the design stage, based on emissions over time from large area building materials, furniture and office equipment has been developed to consider volatile organic compounds, formaldehyde and airborne particles from indoor materials and office equipment and the contribution of outdoor urban air pollutants affected by urban location and ventilation system filtration for a single, fully mixed and ventilated zone in an office building. Criteria levels of pollutant exposure were derived from Australian and international health-based standards. The model acquires its dimensional data for the indoor spaces from a 3D CAD model via IFC files and the emission data from a building products/contents emissions database. This paper outlines the approach to estimating indoor air quality in enclosed spaces, describes the development of the emissions database and demonstrates the tool by its use with a new building.

1. Introduction

Current assessment of indoor air quality (IAQ) focuses on the measurement of pollutants in the constructed building to assess compliance with mandatory or advisory guidelines. Pollutant emissions from indoor materials and products are known to exert a significant influence on IAQ (Brown et al. 1994, Brown 1999a) while the building is new (up to about six months old) from paints, adhesives, floor-coverings, and furniture, and over the life of the building from office equipment and some reconstituted wood-based panels.

At the design stage, experience is used to select low emission materials, if available, but the prediction of indoor air quality is poor. No model or tool exists which is specifically aimed at predicting the indoor air quality of a building at the design stage, yet such a method/tool would assist designers in creating optimum indoor air environments. A method for estimating optimised indoor air quality would allow key decisions on the selection of materials during design to minimise environmental and occupant health consequences. Such a method would support the implementation of IAQ guidelines in building codes (Brown 1997).

This paper describes the development of a design tool, the IAQ Estimator (Tucker et al. 2007), with which the impacts of major pollutant sources in office buildings can be predicted and minimised. The prediction is made using a software tool for building designers so that they can select materials and appliances that, in combination, are sufficiently low emitting to prevent guidelines for indoor air pollution from being exceeded.

IAQ Estimator consists of:

- A database of air pollutant emission rates for typical large area building materials and contents, with typical examples of paints, adhesives, floor coverings, plasterboard, reconstituted wood-based panels, office furniture and copiers/printers;

- A procedure to estimate urban particle and air toxics levels in mechanically ventilated office buildings from outdoor urban air pollution, emissions from copiers/printers, and ventilation system filter efficiency;
- Combining the effects of product selection and ventilation scenarios on indoor air quality for a single level one zone office building;
- Integrating the above three factors to estimate indoor air pollutant levels within a building directly from the products information available in a 3D CAD model; and
- Promoting design decisions on product selection according to the relative impacts of products on IAQ estimates in comparison to health-based IAQ exposure guidelines.

2. Emissions to indoor air

The primary sources of indoor air pollution in office buildings, as illustrated in Figure 1, are considered to be:

- Emissions from large-area building products;
- Emissions from office furniture and equipment; and
- Pollutants from urban air introduced by ventilation.

Emissions from large area building products are Volatile Organic Compounds (VOCs) and formaldehyde from paints, floor-covering systems, painted plasterboard and wood-based panels (Brown 1999a, Brown 2002) and from office furniture such as work-stations (Brown 1999b). These emissions are generally proportional to the area of product exposed indoors and are expressed as an Emission Factor in units of pollutant mass/area/time.

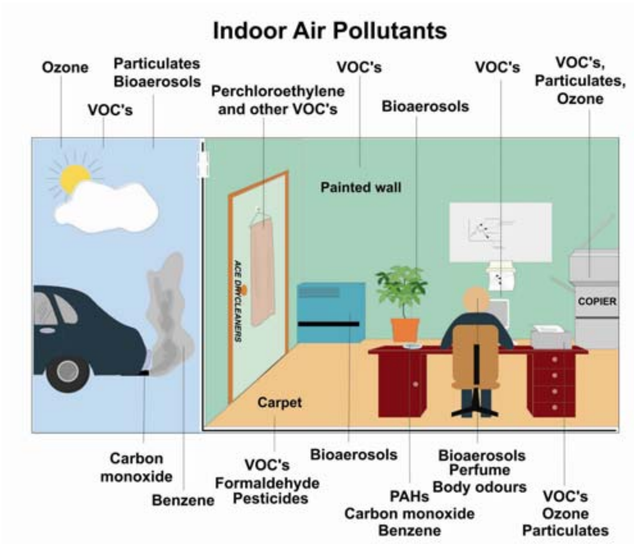

Figure 1 Primary sources of indoor air pollution

Emission Factors of building products are highly variable from product to product and generally decrease rapidly to background levels in the first weeks to months after construction, as illustrated in Figure 2. An exception to this behaviour is formaldehyde emission from wood-based panels with emissions reducing only to elevated steady-state levels within a few months of manufacture, this emission then persisting for some years (Figure 3). For IAQ Estimator, estimates were considered for the first 1 to 28 days for product emissions that decay rapidly and additionally at 6 months for persistent product emissions.

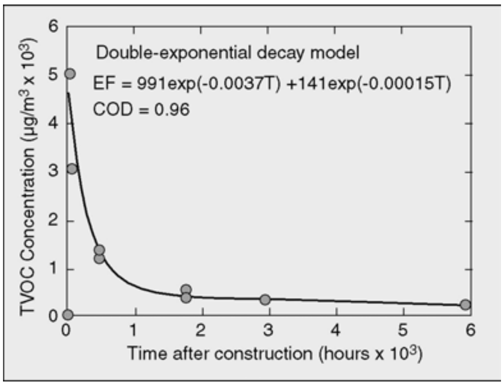

Figure 2 Total VOC decay in a new building after construction (Brown 2001)

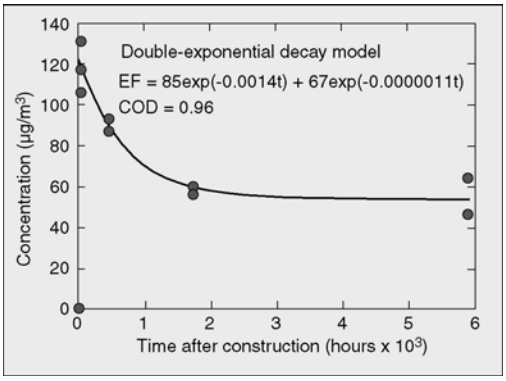

Figure 3 Formaldehyde decay in a new building after construction (Brown 2001)

Emissions from office equipment are VOCs and respirable and sub-micrometre particles (Brown 1999c,d; He et al. 2007). Such emissions occur predominantly while the equipment is operating, linked to the number of copies produced. Emission Factors for these products are in units of pollutant mass/copy/time. The impact on IAQ depends on the frequency of operation of the equipment but is independent of equipment age. For IAQ Estimator, the designer must know what office equipment will be used and its frequency of operation.

Pollutants in ventilation air for mechanically ventilated office buildings are from outdoor urban respirable and sub-micrometre particles and air toxics pollution. In Australia, there are health-based National Environmental Protection Measures for these pollutants (NEPC 2007). Generally, these urban air pollutants will occur at higher levels in city centres or close to busy roads. Ingress of these urban air pollutants into buildings will depend on the type of ventilation used (e.g. natural or mechanical), the ventilation rate, and the efficiency of filtration. For the IAQ estimator, the designer needs to input the building's location, the ventilation rate and the filter efficiency.

3. Indoor air emissions

IAQ Estimator considers the basic IAQ factors described above but also simplifies the building scenario by:

- Considering only key, large area materials and contents;
- Identifying the dominant VOCs and airborne particles present in indoor air of office buildings;
- Developing a database of Emission Factors for the selected product types and pollutants;
- Loading the building space, considered as a single fully-mixed zone, at quantified ratios with materials and contents;
- Interfacing with pollutants introduced from outdoor air and the effect of ventilation filtration;
- Aggregating each pollutant contributed from the indoor sources and outdoor air to estimate a profile of pollutant levels over time after construction; and
- Comparing the estimated pollutant levels with guidelines derived from health-based criteria, such that products causing guidelines to be exceeded can be easily identified and substituted.

3.1 Emissions for selected building materials and pollutants

A list of twenty key VOCs (including formaldehyde) was derived from existing knowledge of the VOC species found in Australian buildings and emitted from materials and equipment (Brown 1999a-d; Brown 2002). It was essential that a health-based environmental guideline existed for each (NHMRC 1996, WHO 2000, NEPC 2007, California EPA 2005, Calabrese and Kenyon 1991, Nielsen et al. 1998, ISIAQ 2004); where more than one guideline existed, values were averaged to provide a criterion for IAQ Estimator. No pollutant was included if such a guideline was not established. The compounds and maximum concentration goals within IAQ Estimator are presented in Table 1. Available Australian air emission data for building and furniture products for these twenty VOCs were collated into a database of representative products, covering emissions considered to be low, typical and high:

- Paints (zero emission, low odour and acrylic, solvent-based) on plasterboard or other substrates;
- Floor covering systems (carpet/underlay/low and high emitting adhesives, tile, wood panel floorboards, timber pre-coated with lacquer);
- Wall boards (plasterboard and reconstituted wood-based panels, including medium density fibreboard (MDF)); and
- Fixed furniture materials (shelf units, workstations).

Table 1 Pollutants and goal values for IAQ Estimator

POLLUTANTS	IAQ Estimator Goal (μg/m³)		IAQ Estimator Goal (μg/m³)
VOCs:			
Acetaldehyde	300	Isobutyl methyl ketone	500
Benzene	60	Naphthalene	30
2,6-Di-tert-butyl-4-methylphenol	500	Phenol	300
1,4-Dichlorobenzene	800	Styrene	500
1,2-Dichloroethane	700	Tetrachloroethylene	100
Dichloromethane	1,100	Toluene	300
Diethylene glycol ethyl ether	6,000	Trichloroethylene	150
Ethylbenzene	800	Total VOC (TVOC)	500
Ethylene glycol ethyl ether	200	m-/p-Xylene	300
Formaldehyde	40	o-xylene and o-/m-/p-xylene	300
Particles:			
PM2.5	25	PN1 Particles	5,000 particles/cm^3

3.2 Emissions from operating equipment

Previous research (Brown 1999c,d) developed a room chamber methodology for assessing emissions from office equipment and showed that VOCs (ethylbenzene, xylene isomers, styrene, toluene) and respirable particles were the dominant emissions from dry-process copiers and printers, these being proportional to the number of copy operations. However, office equipment changed shortly afterwards to digital copier technology, in which documents were scanned one time (instead of one scan per copy) and then reproduced in multiples as needed. A recent study of laser printer emissions (He et al. 2007) reported the emissions from some printers of high levels of sub-micrometre particle numbers (0.02 to 1 micrometre diameter, and referred to here as PN1).

IAQ Estimator emission data for office equipment includes VOCs, respirable fine particles PM2.5 (mass concentration of particles smaller than 2.5 micrometre (µm) cut-point) and sub-micrometre particle numbers as PN1 from the studies described above (goals for the latter two are also presented in Table 1). Since emissions data were lacking for the currently produced digital copiers, further assessment was undertaken with the same chamber method used previously, but including PN1 emissions. While both copiers were below detection for formaldehyde emission and exhibited very low ozone emissions (old printer emissions were previously found to emit ~70 µg/copy), they exhibited similar emission levels for VOCs. However, the 2007 copier exhibited lower respirable particle emissions by an order of magnitude. This copier was also a high emitter of PN1, emitting at a similar level to the high-emission printers reported by He et al. (2007).

Generally, estimates should be based on actual emission data for specific office equipment, but default values based on the higher emission equipment were recommended for equipment absent from the database. IAQ Estimator requires an estimate of copy rate per hour for copier or printer operation. Ideally, actual copy rates would be imported into the estimate, but in practice (especially at the design phase) IAQ Estimator provides the following guidance on specifying copy rates:

- a high usage value (2,000 copies per hour) should be applied to multifunction copiers unless actual usage data is available; and
- medium-use (18-35 copies/minute) and low-use (15-20 copies/minute) copiers and personal printers should apply a usage value based on the average copy rate for office workers of 50 copies per day for each person sharing the equipment.

3.3 Emissions from office furniture

Typical air emissions of the twenty key VOCs from office furniture were included in the database. Office furniture emissions can be expressed as pollutant mass/workstation/time, but the approach used here was to estimate workstation areas (a typical workstation included desk, desk return, drawers, shelf unit, chair) and express the emissions as pollutant mass/area/time. This proved a useful approach where additional furniture items (fixed shelving, work benches etc) were included.

3.4 Pollutants in urban air used for building ventilation

Three real-world categories of outdoor pollution were incorporated into IAQ Estimator according to building location (busy road, urban and rural), as in Table 2.

Table 2 Pollutant levels outdoors (µg/m³ unless specified)

Location	PN1 (p/cm³)	PM2.5	Benzene	Toluene	Ethyl-benzene	Xylenes	TVOC
Busy Road	100,000	25	6	17	<2	10	150
Urban Area	10,000	15	4	4	<1	3	60
Rural Area	1,000	10	1	1	<0.5	1	20

The particle filtration system of mechanically ventilated office buildings was linked to the PN1 and PM2.5 levels to estimate the impact of different filtration performances on indoor particle levels, as in Table 3. Particle deposition was ignored in estimates for simplification purposes.

Note that urban air levels for VOCs of health concern, commonly referred to as BTEX (Benzene, Toluene, Ethylbenzene, Xylenes) and total VOC (TVOC) levels were also included in IAQ Estimator, but with no removal process considered.

Table 3 Filter efficiencies

Filter Type	Filter Efficiency(E)	
	PN1	PM2.5
Bag (95%)	0.65	0.65
Bag (85%)	0.55	0.58
Bag (65%)	0.23	0.28
Pleated	0.035	0.092

3.5 Product emissions database

A product emissions database was constructed for individual products within the classifications: Paints, Floor coverings, Furniture/wood-based panels, and Copiers/printers. For each product, an Emission Factor (EF, mass of pollutant/area/time, or mass of pollutant/copy) was documented for each pollutant at specific times considered relevant to occupancy of new buildings: 1 day, 3 days, 7 days, 14 days, 28 days and 6 months, with data at the latter two times often being unavailable and having to be extrapolated from measurements at earlier times. IAQ Estimator estimated an indoor air concentration for each pollutant at each of these times by aggregating the pollutants contributed by the indoor products and outdoor air, with consideration of the product loading, the filter efficiency and the ventilation rate and air recirculation strategy.

Generally, this required a simple summation for VOCs and formaldehyde for products x_1, x_2, …, as follows:

$$\text{Estimated Concentration} = \Sigma(EF_x.Area_x)/(\text{Indoor Volume.Ventilation Rate})$$

but a more complex treatment was required for particles due to filtration in the mechanical ventilation system.

3.6 Particle filtering of air

IAQ Estimator is based on a general ventilation system design used by most mechanical ventilation systems operating in an air recirculation mode (Figure 4) whereby:

- Outdoor air, at a flow rate (Q_{OA} m^3/h) specified in building codes, is drawn into the building through one filter (Filter 1, particle efficiency E_1); and
- Building air is recirculated through the system at a return rate (Q_{RA} m^3/h) with the combined return air plus the outdoor air being passed through a second filter (Filter 2, particle efficiency E_2).

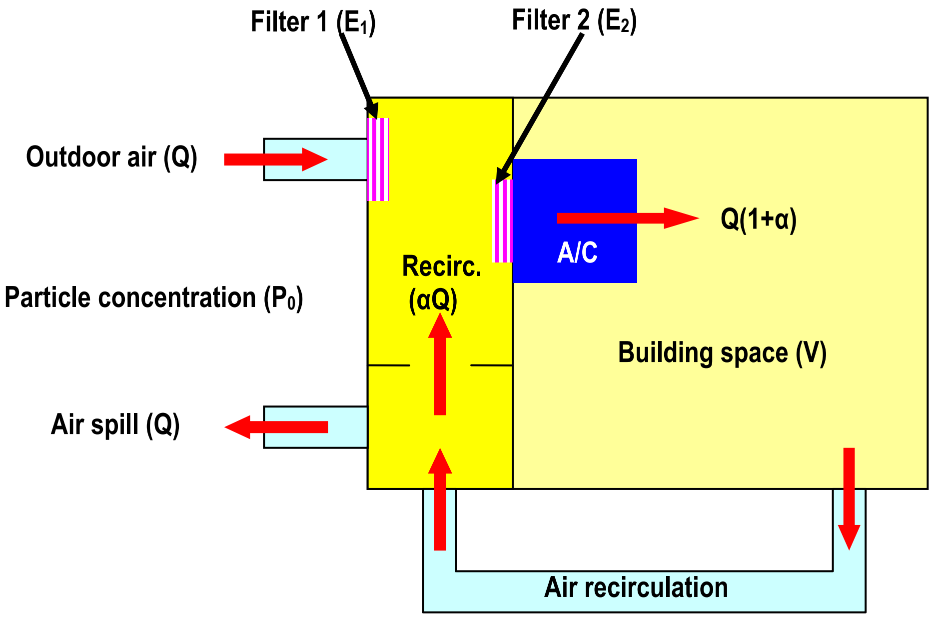

Figure 4 Schematic diagram of air circulation and filtering (Tucker et al. 2007)

Note that an estimate can be made for a natural ventilation scenario by setting particle efficiencies to zero. The indoor particle concentration (C) over time (t) for this ventilation system can be simplified to (Jamriska et al. 2003) to steady state conditions. Also note that this model ignores deposition losses of particles to interior surfaces since this was considered to be too variable a factor, and such simplification prevents the under-estimation of particle levels. Similarly, it was assumed that there would be no removal of VOCs and formaldehyde by the ventilation system, or by surface losses ('sink' effects) within the building. As for particles, this prevents under-estimation of pollutant levels.

4. IAQ Estimator

The computer model was assembled as an integration of:

- acquiring dimensional data for the indoor spaces from a 3D CAD Building Information Model via IFC files, an application of DesignViewTM software (Egan et al 2007);
- pollutant emissions from products within office buildings;
- impacts of outdoor air quality, ventilation rate and filtration efficiency; and
- comparison of IAQ estimates with goals such that the designer can identify unacceptable products.

The prototype software acquires its dimensional data for the indoor spaces either from a 3D CAD model or alternatively from manual entry of building components and their sizes. Specific building products in the 3D CAD model and the types of office equipment are identified by the user. The user also inputs outdoor air and return air flow rates which then link to the building volume as ventilation rates. Ventilation system filtration was limited to three scenarios of typical particle filtration. Outputs are indoor air pollutant concentrations that are estimated at six times after construction. The tool then designates a pass/fail scenario for each time by comparison with IAQ goal concentrations (Table 1).

The use of the DesignViewTM platform as the driving engine of the workbench for IAQ Estimator provided powerful functions besides the ability to view IFC files, such as:

- A plug-in architecture based on the Eclipse Rich Client Platform (Eclipse 2007a) and Eclipse Modeling Framework (Eclipse 2007b) which allowed multiple analysis applications to sit alongside and interact with DesignViewTM;
- A navigator panel which allowed selection of a particular model for viewing;
- A "tree view" which allowed the user to rapidly select sections of the building model to visualise, synchronised with the viewing panel;

- A properties panel which displayed tabular information which was attached to a selected building component in the viewer panel or the tree view;
- A problems list which displayed a list of missing information that had been identified by DesignViewTM on loading a building model; and
- A tasks list that allowed people to enter “to do” lists to ensure that things were not forgotten during design development.

The open and flexible plug-in architecture of DesignView^{TM} provides a foundation for other tools to be built on top of it, allowing developers to concentrate on the particular problem that the tool addresses. The key feature of DesignViewTM which was attractive to IAQ Estimator was the ability to add finishes to any building object in the 3D CAD model and see the object visually. The system was modified to add paints and panels from the material emissions database and expanded to be able to add office furniture and equipment into the space. These finishes could be visually inspected in the 3D Viewer (Figure 5).

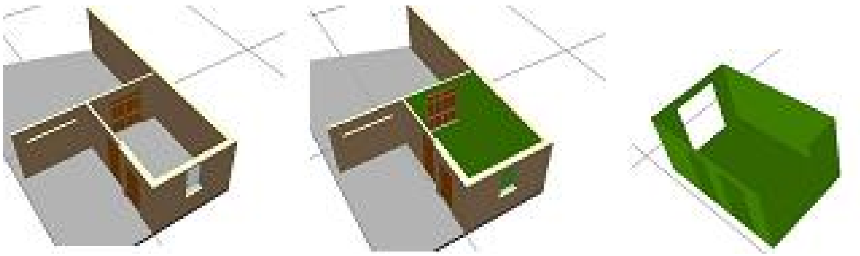

Figure 5 3D viewer of DesignViewTM (Tucker et al. 2007)

The key features of DesignView^{TM} most useful in IAQE are the 3D Viewer, the Model Outline and the Navigator views:

- The 3D viewer displays a real-time, fully rendered 3D view of the active building model. The user may explore and interact with the model. The camera can be panned, zoomed and orientated in any direction, and the user can select individual building elements using the mouse;
- The Model Outline displays the hierarchy of the building model in a tree structure. The model may be traversed according to four different hierarchies; Building, Element Type, Space Type and Material Type. Selecting elements in the Outline will highlight their visual representations in the 3D Viewer (if they are visible). Conversely, selections made in the 3D Viewer will be reflected in the Outline; and
- The Navigator view is used to display and navigate through the workspace and functions just like Explorer in MS Windows.

5. Proof of concept

Validation of the IAQ Estimator tool was limited to comparing estimates with published building data (Brown 2002) and specific data collected for one test building. Currently available, IAQ Estimator is considered a proven concept tool and a significant step towards a commercial product. For hypothetical buildings, it showed the impacts of high-, medium- and low-polluting sources; and it was possible to refine the building design to meet goals by not only selecting low-emission products, but by reducing surface areas, increasing ventilation rates or delaying time to occupancy.

Proof of the tool in a test building is a complex task since it requires documentation of all of the following:

- the building materials used, their quantities, date(s) installed;
- the building furniture used, their quantities, date(s) installed;
- office equipment and its frequency of use;
- pollutant emission properties of all the above;
- the ventilation rate (fresh air exchange rate) of the building;
- air filtration used in the ventilation system, its efficiency for the IAQ pollutants;
- levels of pollutants in urban air;
- the time schedule for the building construction in relation to its occupancy; and
- indoor air quality measurements for the building at several times after construction.

Proof-of-concept for IAQ Estimator was sought with one building (Brown 2007) and was based on a restricted number of materials and pollutants for which data were available or were specifically measured. The building was a nine storey office building in a central city location, designed to be a landmark, green building. Most wall and ceiling surfaces were bare concrete and it used a low-VOC paint on a small proportion of walls. Low emission carpet tiles, mechanically fixed (i.e. no adhesive), were used throughout.

Shelf units and work benches consisted of a low-formaldehyde plywood sealed with a water-based lacquer. Workstations were constructed from powder-coated low-formaldehyde MDF panels. Pollutant concentrations estimated for one Level of the building, and based on emissions from only the above products, are presented in Table 4.

Table 4 Pollutant concentrations estimated for one Level of a green office building

Pollutant	Pollutant Concentration (μg/m³) at time after product installation					
	1 day	3 days	7 days	14 days	28 days	6 mo
Formaldehyde	0.7	0.8	0.8	0.6	0.8	0.08
Octyl acetate	2	3	1	0.4	0.4	0.4
Ethyl hexanol	>0.2	0.2	0.4	0.4	0.4	0.4
Acetaldehyde	n.a.	n.a.	n.a.	1	0.5	0.3
4PC	n.a.	n.a.	n.a.	0.2	0.2	0.2
TVOC	26	>6	>4	>3	>2	>2

Formaldehyde and VOC measurements in the building are presented in Table 5. Note the limitation that the time from occupancy will differ from the time after installation due to construction schedules; it is considered likely that delays of 1-6 weeks occurred between installation of some products and building occupancy.

Table 5 Pollutant measurements for one Level of a green office building

Pollutant	IAQ Goal (μg/m³)	Concentrations (μg/m³) at ~time from occupancy			
		15 days		4.5 months	
		range	average	range	average
Formaldehyde	40	-	9	<5-16	11
Octyl acetate	n.a.	-	<6*	<2	<2
Ethyl hexanol	n.a.	-	n.a.	3-4	3
Acetaldehyde	300	-	n.a.	n.a.	n.a.
4PC	n.a.	-	n.a.	<2	<2
TVOC	500	-	18*	110-160	130

** the 15 day VOC measurements are likely to be under-estimated due to use of a different analytical procedure*

Generally, IAQ Estimator predicted that the concentrations of formaldehyde, acetaldehyde and TVOC would be much below the IAQ goals. The formaldehyde measurements agreed with this, the levels being much below those typically found in office buildings (20-100 μg/m³; Brown 1997), showing that formaldehyde pollution in the building was very low, probably due to the low emission building products used. Quantitatively, IAQ Estimator has underestimated the formaldehyde and VOC levels, probably because there are other sources of these pollutants in the building that were not considered in the estimation. Table 4 and Table 5 also show the following:

- Ethyl hexanol was found in the low emission paint used in the building; its six month estimate was 0.4 μg/m³ in comparison to a measurement of 3 μg/m³, both considered very low indoor air concentrations;
- Octyl acetate was also emitted from the low emission paint (in fact, at higher amounts than ethyl hexanol) but was not detected in measurements;
- 4-Phenyl cyclohexene (4PC), the odorant commonly found with new carpets, was below detection (<2 μg/m³) in both estimates and measurements;
- Despite differences described above, in no case did estimates and measurements differ in showing that IAQ goals were met;
- Overall, it is clear that proof-of-concept for IAQ Estimator requires;
- A building where medium to high pollutant levels will be measured so that the comparison to estimates will have a broader range of pollutants, more of which will be in a measurable range; and
- A scenario where the materials used in the building are fully characterised for emissions over a 6 month period.

6. Comments

IAQ Estimator will enable building designers to estimate the impacts on indoor air quality of different materials, finishes, office equipment and ventilation practices. By selecting different scenarios, the possibility of IAQ goals being exceeded can be understood, different strategies can be adopted (short-term increase in ventilation, delayed occupancy) and pollutant exposures can be reduced. The tool has many simplifying assumptions, such as:

- A building level is treated as one, fully-mixed zone;
- Only large area materials are included;
- The emissions database is not extensive in the materials considered (though it can grow with applications);

- Only the 'dominant' VOCs found in building air or product emissions are included;
- Pollutants without health-based goals are not included;
- Losses of pollutants to surfaces are not considered; and
- Filtration efficiencies are for new filters.

In general these assumptions will lead to overestimates of indoor air pollution and so this should not be considered a fully predictive tool. The key benefit of IAQ Estimator is that it will allow avoidance of polluting products at an early stage. It is not expected to replace the need for IAQ assessment of new buildings but it should reduce the likelihood of indoor air quality being found to be unacceptable.

7. Acknowledgements

The work reported in this paper was part of a research project conducted by the Cooperative Research Centre for Construction Innovation which receives funds from the Australian Government's Cooperative Research Centre Program. Also, the authors acknowledge the technical contributions received from Fanny Boulaire, CSIRO, and Lidia Morawska and Congrong He, QUT.

Summary

This paper shows the evaluation of thermal comfort of human who moves from outdoor to indoor by experiments in summer. And it also shows a building example which positively uses the environmental change to improve the thermal comfort in destination, and it's evaluation by field experiments in summer.

1 Introduction

With the rapid development of office automation in recent years, non-uniform thermal office environments occur with the increasing adaptation of partitioned space. It has become more difficult to ensure thermal comfort for all office workers simply by use of an air-conditioning system set to a fixed indoor temperature.

There are some widely used practical comfort standards, such as SET* (Gagge et al. 1971) and PMV (Fanger 1972). However, these are static standards, which are intended to optimize the thermal acceptability of users in a steady condition in an indoor environment. On the other hand, in the adaptive model hypothesis, people's contextual factors and past thermal history affect their thermal expectations and preferences (de Dear et al. 1997).

This paper shows the evaluation of thermal comfort of persons moving from outdoors to indoors by experiments in summer. And it also shows building example which makes positive use of environmental change to improve the thermal comfort in destination, and its evaluation by field experiments.

1.1 Evaluation of thermal comfort of persons moving from outdoors to indoors

Climatic conditions usually change when a person moves from cold or hot outdoor space to an air-conditioned indoor space. Thermal comfort also changes according to the climate change. These changes incur both physiologically and psychologically influences. Sometimes people experience different levels of thermal comfort even under the same thermal conditions.

In this study, as the first step, these changes were measured by experiments in summer. They were measured by using questionnaire survey, a mobile measurement device which analyzes the environmental conditions around the subject, and a near infrared oxygenation monitor which measures the oxygen saturation level of blood in the brain to examine the subject's physiological condition.

Results of these experiments show that real thermal comfort differs from the stationary standard, and that it is important to know the history which the person experiences.

1.2 Building example which makes positive use of environmental change to improve the thermal comfort in destination, and its evaluation by field experiments

A performing arts center including a Grand Hall used both for opera and concerts was analyzed in this study. The visitors pass thorough several spaces including the Main Entrance, Piazza and Foyer as they move from outdoors to the Grand Hall, and they experience several different environments. In this study, effectiveness of human thermal comfort during movement from outdoors to indoors and optimization of air-conditioning control were investigated by field experiments.

2 Evaluation of thermal comfort of persons moving from outdoors to indoors

2.1 Outline

Each space on the path along which a person moves has its own thermal environment, and he/she perceives the change of thermal environment. Not only in the movement from outdoors to indoors, but also in the movement through indoor space, the air and temperature distribution changes. Perceiving the thermal change, sometimes a person feels more comfortable. However, sometimes he/she feels discomfort. To provide thermal comfort and energy saving, task-ambient air-conditioning systems and personal air-conditioning systems have been introduced in buildings. These systems use the spatial distribution positively. For appropriate HVAC control and thermal comfort, it is necessary to know the influence of thermal change on human perception both physiologically and psychologically.

In this study, human comfort was examined corresponding to the thermal environmental change by the field experiment and questionnaire survey in summer for the first step.

2.2 Method

Three kinds of spaces with different thermal environment, a cold space, a hot space, and a comfortable space respectively, were prepared (see Table 1). Five subjects, all healthy adult males, wore clothing ensembles consisting of a long-sleeved shirt, trousers and socks. All subjects wore their own underwear. The clo value was estimated to be 0.7 clo. To keep their metabolic rate at 1.4 met, subjects were asked to walk on walking machine for 10 minutes.

Table 2 shows the measurement items.

Table 1 Thermal condition of each space

Space / Condition	Cold Space	Comfort Space	Hot Space
Temperature	19-20 °C	24-26 °C	30 °C
Humidity	70%	55-60%	65%

Table 2 Measurement items

Items		Measuring instruments
Tissue oxygenation index (TOI)		Tissue oxygenation monitor used near infrared spectroscopy NIRO-200 (Hamamatsu Photonics)
Normalized tissue hemoglobin index	Concentration change in the oxygenated hemoglobin	
	Concentration change in the deoxygenated hemoglobin	
	Concentration change in the total hemoglobin	
Body temperature	Groin	NR-1000 (KEYENCE)
Skin temperature	Arm, chest, thigh	
Air temperature		101AM (Kyoto Electronics)
Relative humidity		
Radiant temperature		
Wind velocity		
PMV, PPD		
Thermal comfort	Comfort sensation : +3 (comfort) - -3 (discomfort) Thermal sensation : +3 (hot) - -3 (cold)	Questionnaire survey

TOI shows the oxygen saturation level. In this study, because the correlation had been observed between the TOI and the the stationary state temperature in the surrounding, TOI was used as a monitor of the temperature in the surrounding that a person felt.

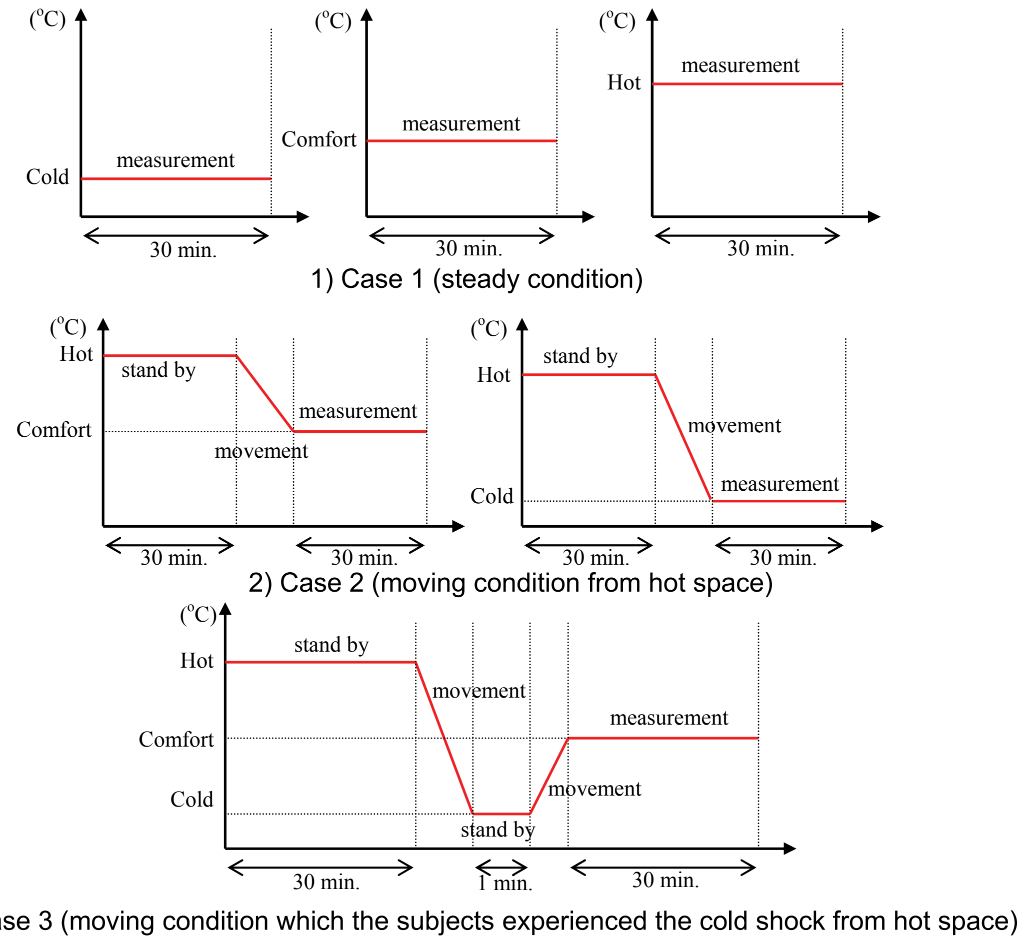

Figure 1 Cases analyzed

Cases analyzed are grouped into 3 according to the movement situation (see Figure 1).

1) Case 1

Measurement was conducted at each space, cold space (Cold), comfortable space (Comfort) and hot space (Hot).

2) Case 2

Measurement was conducted after the subjects moved to Comfort or Cold from Hot.

3) Case 3

Cold shock case. Measurement was conducted at Comfort after the subjects experienced the cold condition.

2.3 Results

1) Case 1 (steady condition)

The result of thermal comfort is shown in Table 3, and the result of Tissue Oxygenation Index (TOI) is shown in Figure 2. A-E mean 5 subjects. The difference of each subject's thermal comfort was small.

Concerning the thermal sensation declaration, valid results were obtained at each condition. A high TOI value was indicated in order of temperature.

2) Case 2 (moving condition from hot space)

In the movement from Hot to Comfort, average value of comfort sensation was 1.8 and thermal sensation was 0.0. These values were similar to those of Comfort steady condition (Case 1). However, average value of TOI was 70%, which was smaller than that of Comfort steady condition, approaching the value of Cold steady condition. It means that the psychological reaction did not correspond with the physiological response.

In the movement from Hot to Cold, average value of comfort sensation was 0.0 and thermal sensation was -2.2. The subjects felt cold, however they did not feel discomfort even in cold condition. Average value of TOI was 71%, which was close to that of movement from Hot to Comfort and different from that of Cold steady condition.

3) Case 3 (moving condition which the subjects experienced the cold shock from hot space)

Average value of comfort sensation was 2.0 and thermal sensation was 0.0. These values were very similar to those for Comfort steady condition (Case 1). Average value of TOI was 71%, which was also very close to that of Comfort steady condition. In this case, the psychological reaction corresponded with the physiological response.

2.4 Conclusion of Evaluation of thermal comfort of human who moves from outdoor to indoor

Thermal environmental change in pass space, human experienced, affected his thermal comfort. Sometimes, the psychological reaction did not correspond with the physiological response.

However, the appropriate change, ex. cold shock, may lead to the coincidence of the psychological reaction and the physiological response. There are possibilities of using these effects for energy saving.

Table 3 Thermal comfort

Thermal comfort / Case	Case 1			Case 2		Case 3
	Cold	Comfort	Hot	to Comfort	to Cold	Cold shock
Comfort sensation	-1.4	2.2	-0.8	1.8	0.0	2.0
Thermal sensation	-2.2	0.0	1.2	0.0	-2.2	0.0

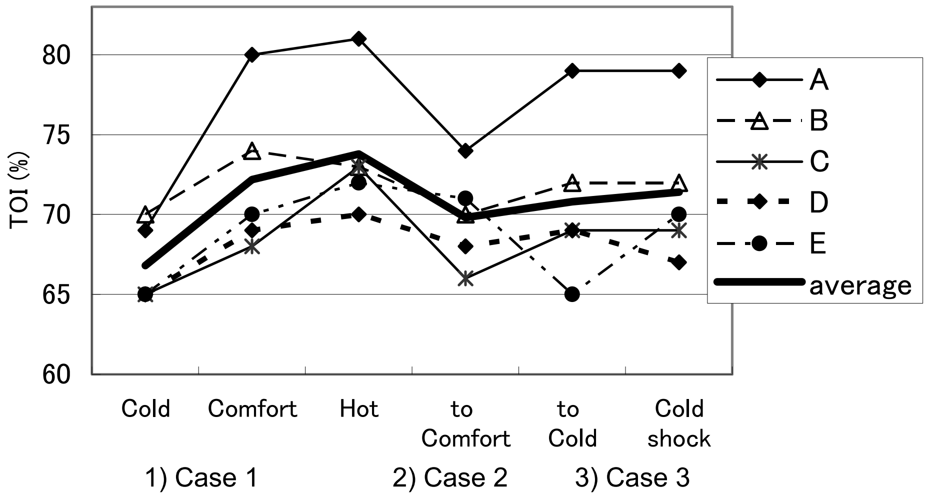

Figure 2 TOI values

3 Building example which makes positive use of environmental change to improve thermal comfort in destination, and its evaluation by field experiments

3.1 Outline

This performing arts center, which opened in 2005, has three state-of-the-art halls - the Grand Hall (2,001 seats), the Theater (800 seats), and the Recital Hall (417 seats) - capable of accommodating concerts, operas, ballets, plays and various other performing arts events (see Figure 3). Most visitors walk from the station on the Pedestrian Deck, then enter the Main Entrance, passing through the Piazza to reach the Grand Hall. The piazza has a light ceiling using natural sunlight like an atrium. It was designed for visitors to use as an intersection of the traffic line to three halls and as space in which to stay for a while, providing information of concerts, operas, ballets, plays and other performing arts.

Thermal sensations according to the movement were measured for the Grand Hall. While the room temperature, the illuminance, and residence time etc. of path space from outdoor to the hall were changed, a questionnaire survey was conducted and the influence of thermal sensation on the human body was investigated.

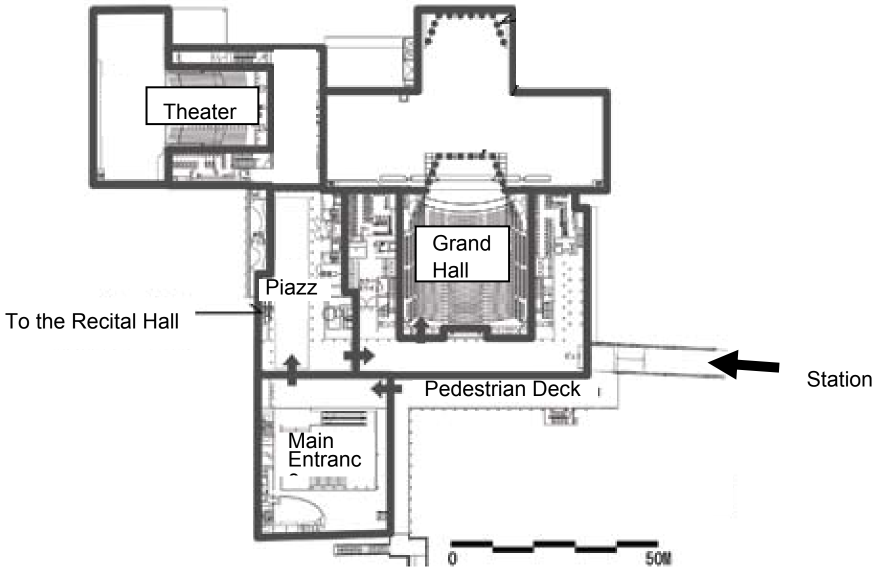

Figure 3 Plan of the performing arts center

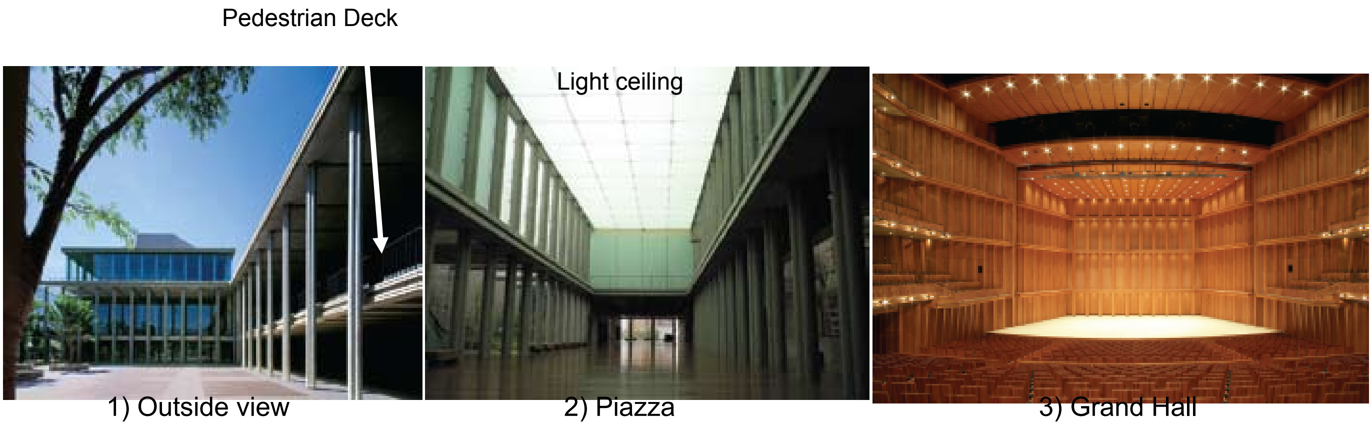

Figure 4 Picture of each area of the performing arts center

3.2 Method

Measurements were conducted on August 22-25, 2006. The change of the thermal environment and other factors from outdoors to the Grand Hall, and its influence on the human body were focused on in this study.

Measurement item and outline of measuring instrument are shown in Table 4.

Table 4 Measurement items

Thermal comfort	Comfort sensation : +3 (comfort) - -3 (discomfort) Thermal sensation : +3 (hot) - -3 (cold)	Questionnaire survey

Mobile measurement apparatus for measuring the environment around subjects was set up for this experiment. It consisted of a mobile measurement cart and the measurement items shown in Table 4 and Figure 5. Using this system, transient thermal environment and other factors around the subject walking to the Grand Hall were measured in summer. The questionnaire survey and the measurement of body and skin temperature were also conducted. Just after the subject reached the Grand Hall, the Tissue Oxygenation Index (TOI) etc. were measured by tissue oxygenation monitor using near infrared spectroscopy to assess the subject's physiological condition.

Figure 5 Picture of the mobile measurement apparatus

Measurement cases are shown in Table 5. Eight cases were conducted. In the adaptation group (Cases 1.1-1.3), whenever a subject passed through the room, the temperature gradually falls. In the cold shock group (Cases 2.1-2.3), subjects experienced the cold environment before entering the Grand Hall. In each group (Cases 1.1-2.3), staying time in passing through the room between outside and the Hall was set as the parameter of the experiment. We also set the luminance as a parameter. In low luminance case (Case 3.1), subjects experienced low luminance at the Main Entrance before entering the Grand Hall. In the high luminance case (Case 3.2), subjects experienced high luminance at the Piazza.

Firstly, subjects walked around at the Pedestrian Deck for 10 minutes to keep their metabolic rate at 1.4 met. Then they stayed in each area for the time shown in Table 4. Finally, they entered the Grand Hall.

The 5 subjects were healthy adult males, and wore clothing ensembles consisting of long-sleeved shirt, trousers and socks. All subjects wore their own underwear. The clo value was estimated to be 0.7.

Table 5 Measurement cases analyzed

		Pedestrian	Main Entrance	Piazza	Grand Hall
Case	Outline Parameter	32 °C	22 °C Case 4.2 :27 °C	28 °C Case 4.1 :25 °C	26 °C
Case 1.1	Adaptation	10 min	---	10 min	30 min
Case 1.2		10 min	---	30 min	30 min
Case 1.3		10 min	---	1 min	30 min
Case 2.1	Cold shock	10 min	10 min	---	30 min
Case 2.2		10 min	30 min	---	30 min
Case 2.3		10 min	1 min	---	30 min
Case 3.1	Low luminance	10 min	---	10 min	30 min
Case 3.2	High luminance	10 min	10 min	---	30 min

3.3 Results

Two kinds of comparisons which provided the clearest results are shown as follows.

One is the comparison between Case 1.2 (adaptation group, 30 minutes stay at the Piazza) and Case 2.2 (cold shock group, 30 minutes stay at the Main Entrance).

Another is the comparison between Case 1.2 and Case 2.3 (cold shock group, 1 minute stay at the Piazza).

In the comparison of these cases, the difference between the adaptation and cold shock were evaluated.

Case 1.1 (adaptation group, 10 minutes stay at the Piazza) showed the tendency to look like Case 1.2. And Case 2.1 (cold shock group, 10 minutes stay at the Main Entrance) showed the tendency to look like Case 2.2. Therefore, in this paper, 30 minutes and 1 minute stimulation cases are presented.

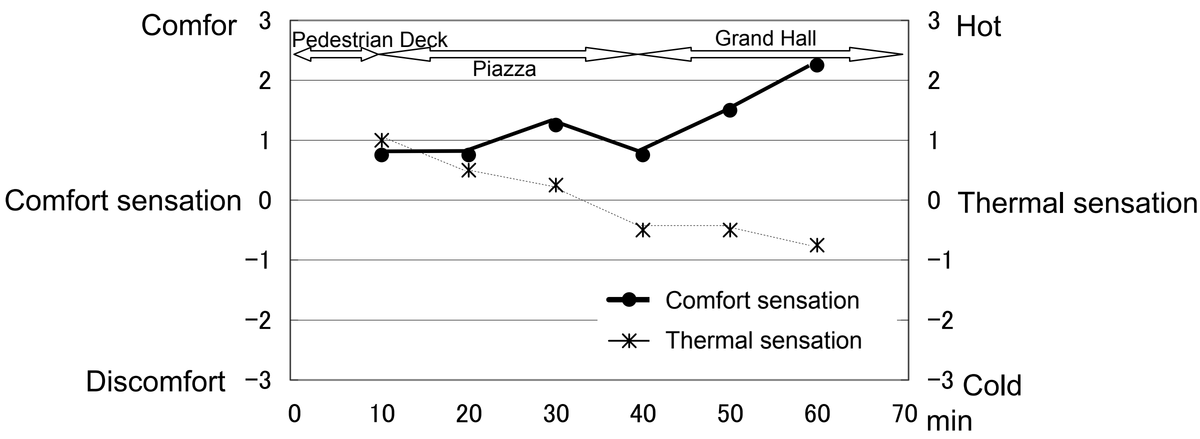
We have not yet obtained clear results in low and high luminance cases (Cases 3.1-3.2).

1) Comparison between Case 1.2 (adaptation group, 30 minutes stay) and Case2.2 (cold shock group, 30 minutes)

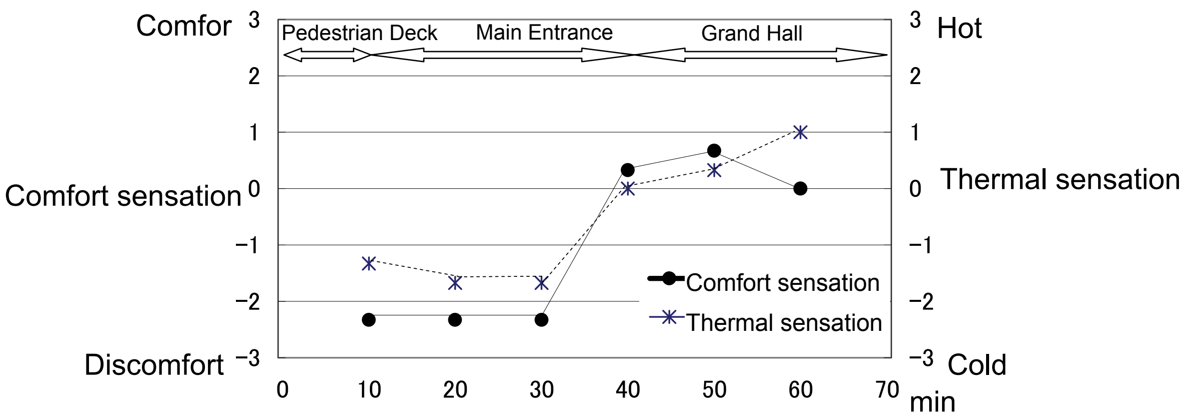
The results of thermal comfort in Case 1.2, 2.2 and 2.3 are shown in Figure 6.

In Case 1.2 (adaptation), thermal sensation was cool (changed to -0.8 from -0.5) in the Grand Hall (Figure 6 (1)). On the other hand, in Case 2.2 (cold shock), it approached to warmth (changed to 1.0 from 0.0) (Figure 6 (2)). Subject felt different thermal sensation in the same thermal condition between 2 cases.

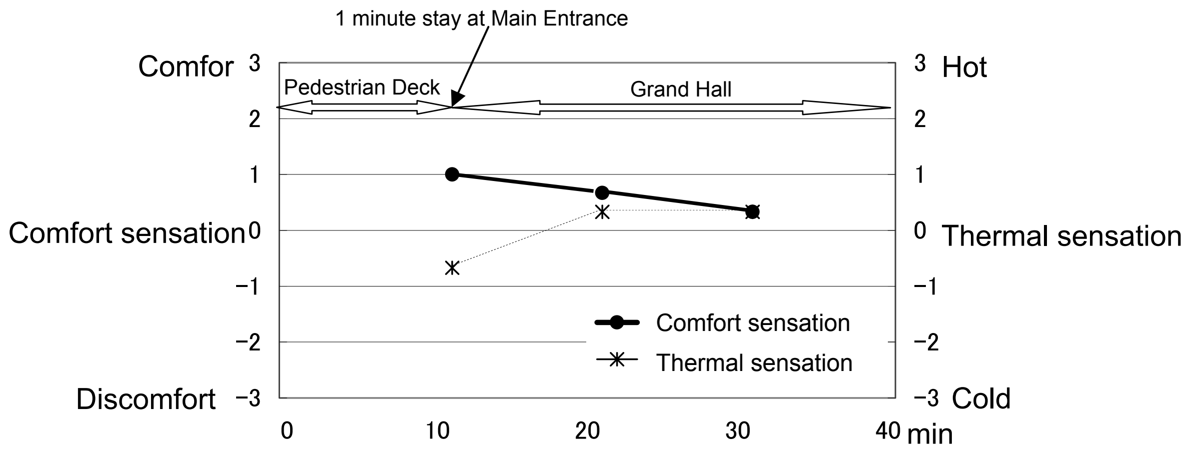
In Case 1.2, just after the subject entered the Grand Hall, comfort sensation approached to comfort from neutral (changed to 2.2 from 0.8) and even if time passed, this inclination still continued (Figure 6 (1)). On the other hand, in Case 2.2, there was not so much difference (changed to 0.0 from 0.3), even though he felt cold for long time before he entered the Grand Hall (Figure 6 (2)). It is assumed that the warm feeling while staying in the Grand Hall decreased the sensation of comfort.



(1) Case 1.2 (adaptation group, 30 minutes stay at Piazza)



(2) Case 2.2 (cold shock group, 30 minutes stay at Main Entrance)



(3) Case 2.3 (cold shock group, 1 minute stay at Main Entrance)

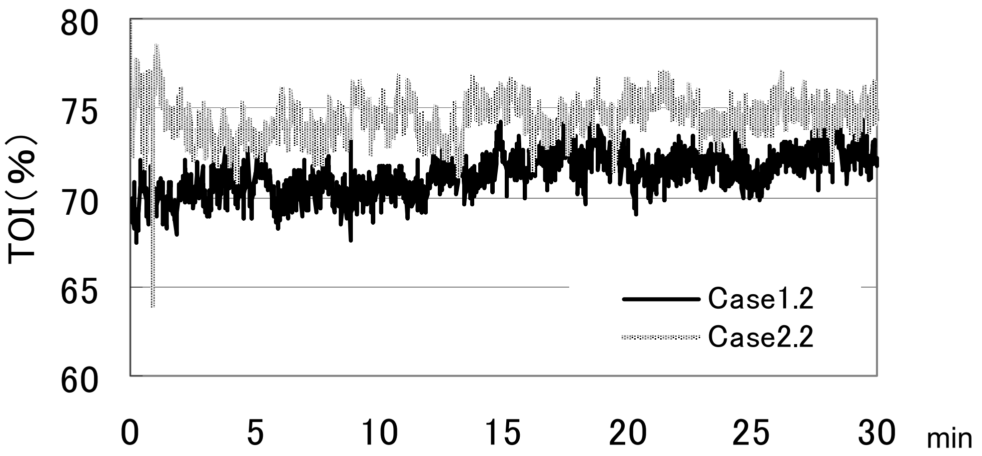
Figure 6 Results of thermal comfort

(Starting time of 10 minutes walk on Pedestrian deck was set as 0 minute in Figure 6)

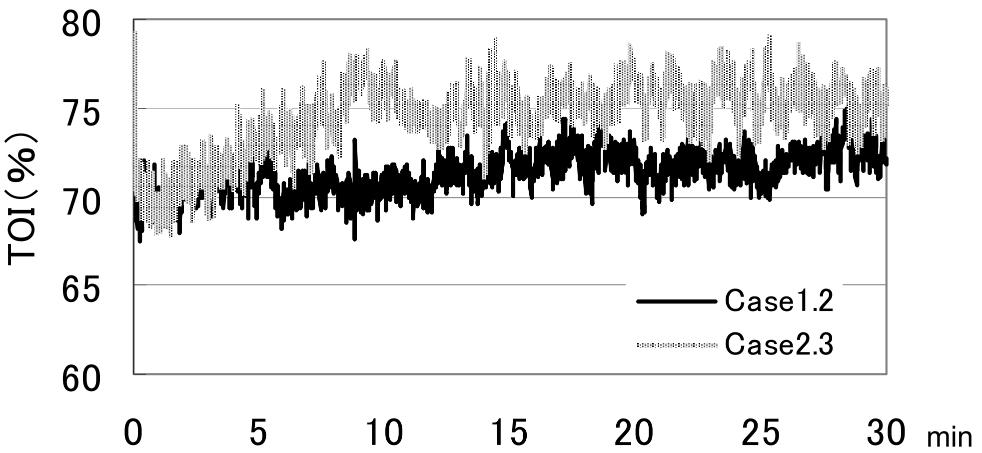
The results of TOI in comparison of Case 1.2 and 2.2, and 1.2 and 2.3 are shown in Figure 7.

In comparison of Case 1.2 and 2.2, TOI value of Case 2.2 was higher than that of Case 1.2 (see Figure 7 (1)). TOI value indicates the oxygen saturation of the hemoglobin. In Case 2.2, the subject was forced to be in a cold situation, and he felt the cold sensation, therefore it was assumed that the oxygen saturation of the hemoglobin rose to maintain the body temperature. Because of the high TOI value and high physiological activity, the subject felt warm after he entered the Grand Hall, then it was assumed that his comfort sensation was decreased.

30 minutes cold shock may be considered to be excessive stimulation.



(1) Comparison between Case 1.2 (adaptation group, 30 minutes stay at Piazza) and Case 2.2 (cold shock group, 30 minutes stay at Main Entrance)



(2) Comparison between Case 1.2 (adaptation group, 30 minutes stay at Piazza) and Case 2.3 (cold shock group, 1 minute stay at Main Entrance)

Figure 7 Results of TOI

(Starting time of measurement in the Grand Hall was set as 0 minute in Figure 7)

2) Comparison between Case 1.2 (adaptation group, 30 minutes stay) and Case 2.3 (cold shock group, 1 minute)

n Case 2.3 (cold shock, 1 minute), thermal sensation approached neutral closer than that of Case 2.2 (Figure 6 (2), (3)). However, it was also warmer than that of Case 2.1 (Figure 6 (1), (3)). Furthermore, the trend of thermal sensation of Case 3.2 after subjects entered the Grand Hall was similar to that of Case 2.2.

In Case 2.3, comfort sensation did not approach to comfort (changed to 0.3 from 1.0).

In comparison with Case 1.2 and 2.3, TOI value of Case 2.3 was also higher than that of Case 1.2 (see Figure 7 (2)). In this experiment, high TOI value and high physiological activity occurred with the stimulation of only 1 minute cold shock.

3.3 Conclusion of the building study which makes positive use of environmental change to improve the thermal comfort in destination, and its evaluation by field experiments

The influence of adaptation and cold shock on the way to the hall from outside was evaluated in the experiment. In this case, adaptation was more effective in the thermal comfort improvement than cold shock. However, there is a possibility that the effect changes depending on the amount and the time of stimulation. Therefore, it is thought that further quantification is necessary.

The Piazza in the performing arts center was designed with much sunshine from the light ceiling. Therefore indoor climate in the Piazza seems to be located in between uncontrolled outdoor climate and controlled indoor climate. By the experiment conducted in this study, the Piazza contributed to the thermal comfort of the visitors coming to the Grand Hall. Raising the preset temperature of the air-conditioning system in the Piazza would also lead to energy saving. In the Piazza, the preset temperature is 28 oC in summer, which is 2 degrees higher than in normal systems, and the measured temperature was almost 28 oC during summer. However, there were no complaints about thermal comfort from the visitors. In the Piazza, transmission heat has been reduced by at least 43 GJ/year in the cooling season.

4 Conclusions

This paper showed the experimental evaluation of thermal comfort of people moving from outdoors to indoors in summer. It also showed a building example which makes positive use of environmental change to improve thermal comfort in destination, and its evaluation by field experiments in summer.

Results of these experiments showed that actual thermal comfort was different from the stationary standard, and that it is important to know the history which the person experiences.

It is necessary for appropriate HVAC control and thermal comfort to understand the influence of thermal change on human perception both physiologically and psychologically.

Keywords: Indoor environment quality, occupant productivity, sustainable office buildings

Summary

This paper presents a summary of the results from a post-occupancy evaluation study on indoor environment quality (IEQ) and occupant health, wellbeing and productivity in the Council House 2 (CH2) building, which is owned and occupied by the City of Melbourne. This case study has highlighted that the productivity of office building occupants can potentially be enhanced through good building design, and provision of a high quality, healthy, comfortable and functional interior environment, that takes account of basic occupant needs.

1. CH2 Building

Council House 2 (CH2) is a 10-storey office building which houses around 500 City of Melbourne staff, and some ground-floor retail space. CH2 was officially opened in August 2006 and occupied by staff in October 2006.

CH2's gross floor area of 12,536m² comprises:

- Nine floors of office space (9,373m² total; 1,064m² per floor typically)
- 1,995m² of basement areas
- 500m² of ground floor retail

CH2 was conceived, designed and built with a substantial focus on setting a new standard for ecologically sustainable office buildings. It has a raft of sustainable technologies and design philosophies incorporated throughout the entire building, services and fit-out. Key sustainability-related features of CH2 include:

- Low energy, passive cooling systems
- Low energy, integrated electric lighting and daylighting systems
- Co-generation, photo-voltaic cells, and wind-driven turbines
- Active louvres on West facade and vertical garden on North facade
- Sewer mining, water recycling, rainwater collection
- Use of recycled materials
- Extensive facilities for cyclists

A key element of the business case for CH2 was that provision of high levels of IEQ, along with other design features, would result in significant benefits to City of Melbourne through improved health, wellbeing and productivity of staff in the building. Key IEQ features of CH2 include:

- 100% fresh air ventilation is introduced at floor level, and is then exhausted at ceiling height using natural convection.
- Radiant cooling is provided by the thermal mass of concrete ceiling panels, and also through chilled panels which use a mechanical chiller in combination with phase change material stored in the basement, to charge the coolant. Night purging of the building is used to store the night 'coolth' in the concrete ceiling which is then released during the day. Evaporative cooling through shower

towers on south face is used to cool the retail areas on the ground floor, and to remove some heat from the coolant used in the chilled ceiling panels.

- Lighting is provided through a mix of high-efficiency recessed luminaries in the ceiling, suspended strip lighting, daylight penetration, and extensive task lighting.
- Low toxicity materials used for all furnishings and finishes
- Extensive use of indoor plants

The Interior design was also intended to produce productivity benefits through increased communication and collaboration between staff. The fit-out of CH2 is based on a modern open-plan philosophy, with no enclosed offices and low adjustable partitions between workstations. There are relatively unobstructed lines of sight throughout each floor, with the only enclosed spaces being the formal meeting rooms. Informal meeting and social spaces are provided throughout the building. Occupants also have access to external balconies, a winter garden, a summer terrace and a rooftop garden. An external view of the CH2 building is shown in Figure 1, and some interior views are shown in Figure 2.

Figure 1 Exterior views of CH2

Figure 2 Interior views of CH2

1. Methodology

Evaluation of IEQ and productivity is based on a program of physical IEQ measurements, occupant questionnaires, focus group interviews, and sick leave and staff turnover data. A three page modified 'Building Use Studies' (BUS) occupant questionnaire was conducted in both CH2 and in a 'baseline' City of Melbourne building located next door (CH1). More than 260 responses were received in each building. Assessments for CH2 are compared against Australian and international benchmarks and against the CH1 baseline for productivity assessments. Physical measurements and spot health-symptom questionnaires were also conducted in summer and winter seasons. Measurements and occupant responses are averaged over spatial and organisational boundaries to allow overall assessments to be made.

The impact of the IEQ on occupant productivity is determined through a single question on the occupant questionnaire which uses a discrete nine-point scale, and asks the respondent to estimate how productivity at work is decreased or increased by the environmental conditions in the building. Although this may not necessarily translate directly to an equivalent increase in work output, it is the most appropriate way to measure the building's impact on productivity in a diverse organisation like City of Melbourne, which encompasses a wide range of job-types which have context-specific productivity dependencies that cannot be clearly defined or measured. The BUS self-assessment methodology has been widely used in Australia and internationally as it provides a consistent measure which enables comparison and benchmarking of productivity effects within and between buildings. Additional questions were added to the standard BUS questionnaire to obtain extra data on wellbeing, indoor plants, and other contextual factors which may impact on productivity assessments. Further details on the methodologies used are given in a separate report (Paevere & Brown, 2008)

2. Summary of Measurements and Questionnaire Findings

CH2 occupants are highly satisfied with the **building overall**, and its **facilities, furnishings and fit-out**. More than 80% of occupants prefer CH2 to their previous accommodation. A broad summary of the data collected is shown in Figure 3. Full details of the measurements and questionnaires used in the evaluation are given in a separate report (Paevere & Brown, 2008).

Thermal comfort is generally good in CH2 based on both physical measurements, and also occupant perceptions for all variables except ventilation, as a result of the airflow being perceived to be too still. The monitoring of center 'building core' comfort levels over the course of a three day period on three different floors of the building was extraordinary in terms of its consistency during both winter and summer periods. This indicates the building's capabilities to provide outstanding, continuous and a consistent level of thermal comfort. (see Figures 4 & 5). This is a good outcome given the relatively complex and inter-connected nature of the various cooling and ventilation systems, and the fact that the systems were being tuned during the period of the study. Further tuning may result in better performance in the future, but diligent management of the systems must be continued.

Air quality in CH2 is excellent in terms of measured pollutant levels, and is good based on occupant perceptions. Formaldehyde concentrations in CH2 were much lower than normally found in office buildings. This result can be primarily attributed to the use of 100% fresh air ventilation, and low emission furnishings and finishes throughout the building. Air quality was identified by many occupants as having a positive effect on their productivity.

Measurements of ambient **noise levels** and reverberation times were considered ideal in CH2, however occupant satisfaction ratings for noise are average to poor and are generally worse than benchmarks. The low satisfaction scores are primarily due to unwanted interruptions and distractions from other people in the building. The hindrance of noise from interruptions must be contrasted against the potential productivity enhancement due to the open plan layout, as improved communication has been reported by some occupants and managers. Satisfaction with speech privacy in CH2 may be improved through tuning of the white noise system installed in the building. Trials in which white noise levels were increased on one Level in the building resulted in better satisfaction scores for noise when compared to the rest of the building (10-18% better for relevant noise variables), however this result is not conclusive, given that satisfaction ratings for most other variables were also higher on this Level. Careful consideration of workgroup layout, circulation routes, and the separation of quiet and noisy activities may also lead to improvements in occupant satisfaction with noise.

Lighting is considered to be satisfactory in CH2 overall with some question marks against task lighting and satisfaction with daylight levels. The integration of task lighting into the overall lighting strategy, with lower general illuminance levels, as is the philosophy in CH2, is considered good practice from both a sustainability and user control perspective, however the initial configuration for the CH2 lighting resulted in some complaints about the building being too dark. Measurements shown in Figure 6 indicate that the lux levels for desktop illuminance often fall below the desired level. The background luminance (brightness) was thought to be problematic due to large variations between the electric light sources and the adjacent darker-toned ceiling surfaces, which results in a ‘starry-night’ effect where a dark surface background prevails against a bright source. These issues were addressed by building management during the study period by incorporation of additional direct/indirect lighting in several places, providing better light diffusion and reducing this problem, although the effect of the changes on occupant satisfaction are not clear. Grey concrete ceilings and darker-toned furnishings and plants are a part of the interior design of CH2 and these may have an impact on occupant perceptions of lighting. Given the improvements and adjustments made to the lighting systems during the study, further assessment of the lighting is warranted.

Perceived **user control** over IEQ was rated poorly by occupants in CH2, but only a small portion of occupants indicated this as important to them, and hence for this study, this is not considered as a major factor in assessment of the IEQ.

CH2 is rated very highly by it’s occupants for perceived **healthiness**, and is considered to have low levels of occupant-reported rates for building-related **health symptoms**, when compared to levels in the general population. **Absenteeism** and **staff turnover** have not changed significantly during the first 12 months of occupation of CH2, compared to previous years, however given the year-to-year variability, and the possibility that organisational restructuring may have had some impact, a longer period of monitoring is required before any solid conclusions can be made about the effects of the building on absenteeism and staff turnover.

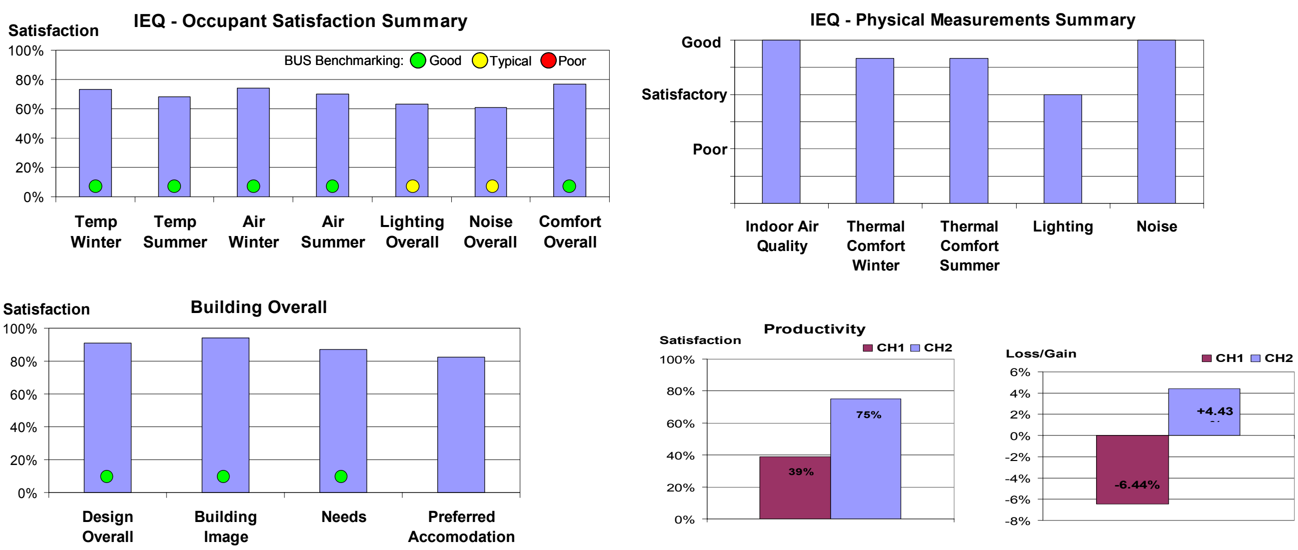

Figure 3 Summary of key findings on IEQ and Occupant Productivity

3. Impact of Building on Occupant Productivity

Based on the first 12 months of CH2 occupation, there has been a significant improvement in perceived health and productivity when compared against the CH1 baseline. Given the importance of health and productivity in the business case for sustainable buildings, it is useful to examine the differences between CH2 and CH1, as perceived by the occupants, to try and gain some insights into the impact that different aspects of the building have had on the positive productivity ratings for CH2. It must be noted however that it is not possible to make quantitative conclusions about the impact that any particular aspect of building design will have on health and productivity based on a study of only two buildings, in which many variables have been changed simultaneously. The results and analysis presented herein apply only to the context of CH2 compared to CH1.

The following categories have been adopted to represent the broad range of factors which could potentially have an impact on occupant productivity: Building Overall; Furnishings, Facilities, Fit-out & Equipment; IEQ (Thermal Comfort, Air Quality, Lighting, Noise); Health Symptoms; Other Factors

When the major variables from the occupant questionnaires are categorised in this manner, it can be seen which aspects of CH2 stand out as the biggest perceived improvement, relative to the CH1 baseline. Table 1 outlines the variables that are assigned to the different categories, the satisfaction differences between CH2 and CH1, and the correlation coefficient of each variable with Perceived Productivity in CH2. Figure 7 shows the averaged difference in satisfaction ratings between CH2 and CH1 for these different categories of variables.

The main conclusion that can be drawn from this analysis, is that in the case of CH2 compared to CH1, the 'Building Overall' category of variables is likely to be the most significant, in terms of impact on Perceived Productivity. All of the variables under this category correlate better with Perceived Productivity, in relative terms, than all of the other variables in all of the other categories (although it should be noted that the correlations are not very strong in absolute terms, with R in the range 0.5 to 0.6). This category also exhibits the largest difference in satisfaction ratings between CH2 and CH1. Other variables and categories in Table 1 which show a relatively stronger correlation with Perceived Productivity are Thermal Comfort (summer more than winter), Noise Overall, Air Quality, Space Layout, Workstation Usability and Privacy, although none of these are as strongly related to the Perceived Productivity rating as the 'Building Overall' variables.

Interestingly, if the averaged satisfaction differences for each category are summed together (they add to 36.5%), this value is very close to the difference in the Perceived Productivity satisfaction rating (which is 36%). Although this is most likely a coincidence, it demonstrates conceptually how different aspects of the building and its design may either enhance or hinder productivity depending on whether they are perceived as satisfactory, or not by occupants.

The analyses presented herein cannot be used to prescribe quantitative relative importance or weightings for the impact of individual variables (or categories of variables) on perceived productivity. However, they reinforce the notion that occupant productivity is likely to be dependant on a range of factors related to the overall building and it's fit-out, the different aspects of IEQ, and possibly other contextual factors which may not be related to the building itself, such as experiences in previous accommodation. In the case of CH2, it would seem that satisfaction with the 'building overall' is likely to have had a greater impact on occupants perceived productivity than any specific aspects of the IEQ. As far as the IEQ impact on perceived productivity is concerned, when the data is considered in light of occupant comments, it is likely that air quality and thermal comfort have enhanced productivity, whereas some issues with lighting and noise due to interruptions may have had a hindering effect

Assessment of various **contextual indicators** shows that there has been a reduction in perceived workgroup morale due to workplace restructuring, but there have not been any major contextual shifts in terms of happiness, autonomy and communication during the study period. It is therefore concluded that contextual changes are unlikely to have resulted in any 'false-positive' effect on perceived productivity ratings.

Further analyses of the productivity findings are given in a separate report (Paevere & Brown, 2008)

4. Business Case for CH2

In setting up the original Business Case for CH2 and convincing the Council to provide the necessary finance for sustainability and productivity enhancing features, there were two distinct components: 1) The energy and water savings which were conservatively measured at $330,000 per annum and; 2) Productivity and wellbeing of staff again conservatively measured at 4.9% and valued at $1.12M per annum.

These components were significant for reasons beyond the simple financial model to prove to the wider industry, the viability of CH2. By placing the emphasis on sustainability and IEQ, the Council was strategically targeting the occupants of future buildings as the most important change agents. Developers would naturally argue to minimise costs, and given they had no long term stake in the completed building, its running costs and occupant conditions, it became evident that if the Council was to promote change it would need to be via an education process of future tenants. This strategy has proved to be effective in that high profile tenants like the National Australia Bank and the ANZ Bank are now insisting on 5 and 6 star buildings with an emphasis on good IEQ.

The conclusion of this study has indicated that the productivity and wellbeing in CH2 is in fact 10.9% higher than the baseline building CH1.This represents a $2.4M per annum benefit to Council and reduces the payback time of the sustainability and IEQ features of the building ($11M) to around 5 to 6 years. Given the life expectancy of the Building, 50-100 years, this study has demonstrated that the business case for incorporating these features is compelling.

Summary

A bio-inspired ventilating envelope is presented. The ventilating envelope consists of a distribution and arrangement of a basic component. In order to examine and optimize the performance of the ventilating envelope, we simulated the airflow inside two different rooms for different cases of component numbers, locations and distributions. For the simulations we used the computational fluid dynamics (CFD) solution tool, *Fluent*, with the re-normalization group (RNG) $k-\varepsilon$ and second order discretization schemes. Distribution of velocity profiles and mean age of air over various virtual planes for the different cases were analyzed and compared to the comfort level of a *standard* ventilation system. The analyzes show that, for specific cases, the fresh air is uniformly distributed due to a good mixing layer close to the inlet. Moreover, by choosing the right configuration of the components, it is possible to have either a diagonal or a vertical distribution of the mean age of air (MAA) in the middle of the room, thus, the ventilating envelope has the characteristics of two different standard systems being placed on the wall or at the ceiling.

1. Introduction

The primarily focus in current ventilation system developments is reducing indoor air quality problems with minimizing energy use (Addington 2000). Ventilation in buildings is provided either naturally or mechanically. In natural ventilation, the flow process is induces by wind and temperature (Liddament 1996), and the main negative aspect is the difficulty to control air flow. However, natural ventilation could be found in many buildings in order to provide fresh air. Mechanical ventilation controls air flow via systems that respond to the needs of the occupants. There are different ways to ventilate mechanically, such as extract-only, supply-only, supply and exhaust or balanced, and recirculation (Roulet 2008). Some of them have the risk of back draught from flues, and others require empty floor spaces in order to allow air flow from diffusers places in the floor (Liddament 1996). Mechanical ventilating systems include several components: fans, ducts, diffusers, air-intakes, air-inlets, air grilles, and silencers (Liddament 1996), where they have to be maintained from time to time (Roulet 2008).

The bio-inspired ventilating system acts as a breathing skin that has the ability to control the amount of intake and outlet of air through it (Badarnah et al 2007). The evaluated system in this paper could be considered as a combination of natural and mechanical ventilation, where the components create pressure differences in order to suck the air inside and the fresh air is moved from outside to inside through and via the skin. The integration of the system in the envelope creates a situation where the envelope is permeable, but still controlled.

The application of computational fluid dynamics (CFD) has been widely used in recent years with aiding in predicting ventilation strategies. One of the first studies using CFD methods for predicting air movement and heat transfer in buildings was done by Nielsen (1974).

In the present work, airflow simulations for rooms (3×3×3 m³ and 1×1×1 m³) with integrated ventilation system are presented. The 3×3×3 m³ room was chosen due to its minimal size as an occupied room, and the 1×1×1 m³ room was chosen for initial simulation tests that can be used later to compare with experiments in a similar room. The simulation tool, *Fluent*, was used with re-normalization group (RNG) $k-\varepsilon$ turbulence models. Details on the $k-\varepsilon$ model are given by Gatski et al (1996).

The tested ventilation system consists of components that suck air from outside to the interior spaces; these components are part of the building envelope. Section 2 presents the breathing skin with its components for ventilation, and it is based on the work done by Badarnah et al (2007). In the simulations section, different variation of intake and outlet distributions are shown, which resulted in determining the effective distributions of components for better air-flow circulation and lower mean-age of air (section 4). Finally, a discussion and the conclusions are presented in section 5.

2. Background

The bio-inspired ventilation system is part of the envelope and reacts to changing environmental conditions and influences the air pressure at the surface to perform a process of inhaling and exhaling, and it consist of a basic component with a special arrangement.

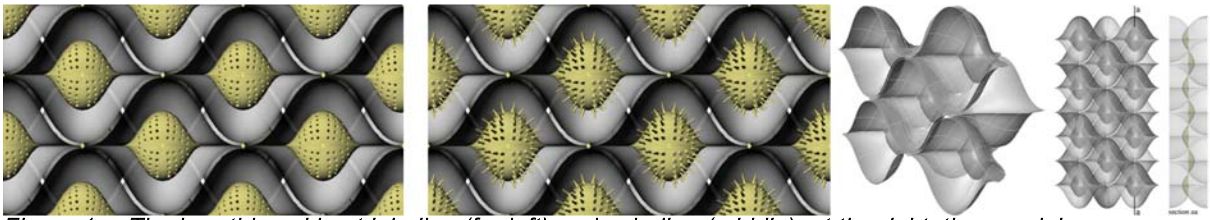

Figure 1 The breathing skin at inhaling (far left) and exhaling (middle); at the right: the special arrangement of the components and a cross section.

The *Lung-Like-Chamber* (LLC) consists of two surfaces attached to each other at their edges creating a specific volume in the basic component (Figure 2a). Piezoelectric wires are attached on the sucking surface of the lung like chamber. The sucking surface is controlled separately (Figure 2b&c). When a voltage is applied to the piezoelectric wires on the sucking surface, the lung expands and increases its volume and by that it increases the inner and outer surface area. A low pressure is created in the lung which results in sucking the air inside the lung (Figure 5b). The air flows into the lung through shafts on the surface of the lung. The shafts are designed in a way that allows the air to flow in one direction; valves are attached to the inner surface of the shafts, when the air pushes on the inner surface outwards, the valves are contracted and closed. Stopping the voltage from the surface results in contraction and creating over pressure (Figure 5c), which results in expelling the air out of the LLC through the other side, where the air pushes on the inner side of the expelling surface and results in opening the valves. By this action the air flow is controlled to flow through the lung in one direction.

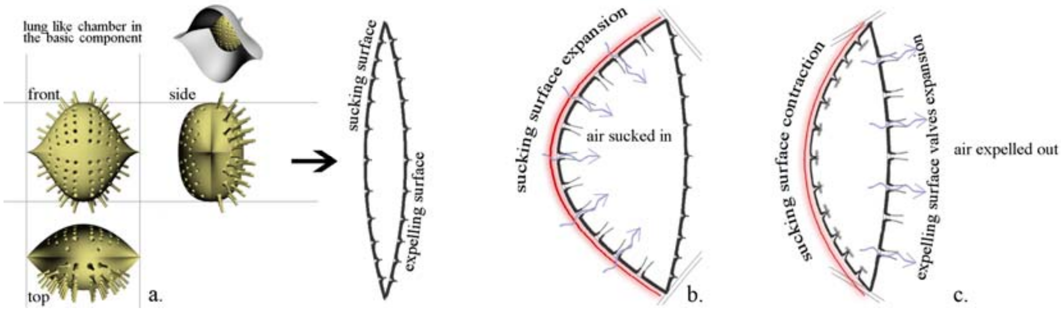

Figure 2 The expansion and contraction of the Lung-Like-Chamber (LLC).

The expansion and contraction of the LLC is combined with the movements of the basic component (Figure 3a-d). When the lung expands the basic component deforms and opens to create a bigger volume on that side where the lung had expanded (Figure 6b). Creating a bigger volume increases the low pressure and increases the air sucking from the surrounding environment. When the lung contracts and creates over pressure inside (Figure 3c), the basic component is deforming and closing the side where the air was sucked inside the lung, and opening the other side (Figure 3d). In this way the skin sucks air from one side and expels it to the other side. The skin consists of LLCs that take air from outside to inside, and LLC's that take air from inside to outside. In this way the air is exchanged continuously through the same system.

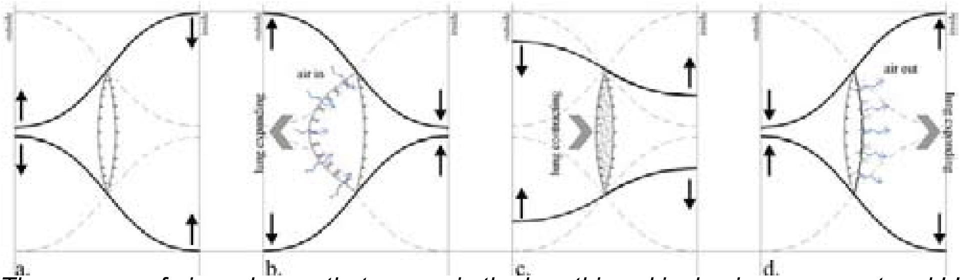

Figure 3 The process of air-exchange that occurs in the breathing skin, basic component and LLC combination.

The main advantages of this ventilation system are its direct contact with the fresh air, where the air doesn't have to flow through ducts and long distances to get to the occupied places, and the system has fewer components involved in the ventilation process than other standard systems. The system creates a controlled permeable envelope, where its porosity reacts to the interior needs and requirements of the occupants in terms of air quality.

3. Simulations

3.1 Geometry of Rooms

Two different rooms were considered in the simulations. The first room is a 1 m³ *testing room* with equal width (x -direction), length (z -direction) and height (y -direction). The second room is a *standard room* with width, length and height being all *3 m*. The origin (0,0,0) was placed on the right back bottom corner of the rooms. The components of the simulated ventilating systems, such as the LLC or the openings of a standard ventilating system, were placed on the front wall for both rooms, the xz plane.

3.2 Lung-Like-Chamber (LLC)

3.2.1 Geometry and Inlet Conditions

A schematic representation of LLC geometry is given in Figure 4. Each LLC consists of 17 openings with velocity vectors being inclined in x -, y - and z -axis as shown in the figure. Each opening has a velocity vector of 0.2 and 2 m/s in the case of the testing and standard room, respectively. It is notable that the simplified representation of the geometry of the LLC was considered. Thus, velocity vectors with different angles were considered expelling air in or out, while the original spherical shape of the component was neglected. It is also noticeable that there are two types of LLC's, the first expels air inside the room (LLC-in), and the second expels it outside (LLC-out). In principle the two types are identical, except that the direction of the velocity vectors is flipped. The airflow angles at the openings, as shown in Figure 4 for any axisymmetric line, relative to the axisymmetric line are 30^0, 60^0, 90^0, 120^0 and 150^0.

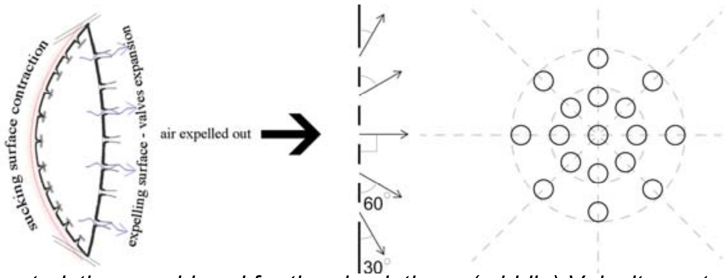

Figure 4 LLC characteristics considered for the simulations. (middle) Velocity vectors through the middle section. (right) LLC's holes distribution and amount.

3.2.2 Configuration

Equal numbers of LLC-in and LLC-out were considered in all of the simulations for each room. A summary of the different cases simulated is given in Table 1, and the configuration and number of the LLC's for the different cases is shown in Figure 5.

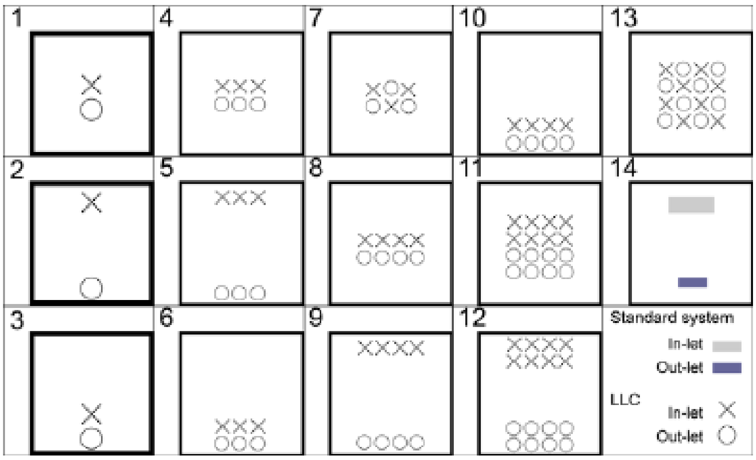

Figure 5 Numbers 1-13 present different cases of LLC configurations; Number 14 is a scheme of a standard ventilation system.

3.3 Standard Ventilating System

An additional simulation of the airflow in the standard room with a rectangular ventilating system was carried out for comparison matters. The height of the inlet and outlet is 0.2m and the width is 0.4m. The inlet has a flow rate of 0.0855 m³ (equal to the flow rate of cases 11-13). The inlet and outlet were placed in the middle of the front wall at distances 0.2m from the ceiling and floor, respectively (see Figure 5).

3.4 Solution Setup

3.4.1 Grid Spacing

A hexahedron cell has been chosen due to its homogeneity with the rooms. Different types of grid spacing were chosen: 0.01-0.05m for the testing room; and 0.1-0.3m for the standard room. The number of elements and nodes of the hexahedron cells are given in Table 1.

3.4.2 Approach

The approach that was used to treat turbulence in the rooms is the Reynolds averaged Navier-Stokes equations (RANS). The assumption in this approach is that flow quantities are averaged in time allowing fluctuating quantities from the mean term. These fluctuating terms produce additional turbulence terms that require closure models. Among these models, we chose the zero-equation model and the re-normalization group (RNG) $k-\varepsilon$ in order to treat turbulence near the openings.

Convergence was reached when the normalized residuals reached below 10^{-3}, and below 10^{-7} for temperature. Details on the computational time and number of iterations for the different cases are presented in Table 1.

Table1 A summary of the computational parameters of all cases.

Room (m³)	1×1×1			3×3×3										
Airflow rate (m³/s)	0.0011			0.032				0.0427			0.0855			
Configuration case (Figure @)	1	2	3	4	5	6	7	8	9	10	11	12	13	14
Maximum Grid spacing (m)	0.05	0.05	0.05	0.1	0.1	0.1	0.1	0.1	0.1	0.1	0.3	0.3	0.3	0.3
Number of elements (×10³)	141	162	146	653	739	661	653	817	951	885	835	932	835	470
Number of nodes (×10³)	153	174	157	685	775	694	685	857	996	927	894	996	893	527
Computational time (min)	20	10	10	90	60	60	30	100	120	80	45	45	30	30
Number of Iterations	85	70	80	520	125	120	50	185	160	120	85	135	45	245

4. Results

Results of the mean age of air (MAA) for the different cases of LLC configurations are presented in Figures 6 and 7. It is observed, in Figure 6, that the MAA is strongly related to the configuration of the LLC. Cases 3, 6 and 10, where the LLC's were placed at the bottom of the wall, have the highest MAA compared to the other cases with the same number of LLC's. However, larger number of LLC's, and thus higher flow rates, doesn't guaranty a lower MAA. As an example, in cases 4 and 8 the flow rates entering the room are, respectively, 0.032 and 0.0427 m³, even though, the MAA in case 4 is lower than in case 8. The circulation near the inlet, of case 8, causes the fresh air close to the front wall to be expelled through the outlet at higher flow rates than the rates at which air enters further inside the room.

Figure 7 compares between two different solutions for cases 11-13. In the first solution the zero equation with first order scheme was applied, and in the second the $k-\varepsilon$ solver was addressed with the following discretization schemes: standard pressure; first order momentum; second order temperature; and second order turbulent kinetic energy and turbulent dissipation rate. The zero equation can be used as an initial solution of the problem, then $k-\varepsilon$ with second order discretization schemes is used in order to account for convection and diffusion of turbulent energy in the solution. Nevertheless, it is possible to use the zero equation for case 12 if only the MAA over the total volume is of interest.

It is notable that the MAA of case 12 is the lowest among all other cases with LLC's. However, this doesn't necessarily mean that the distribution of the *comfort level* of case 12 is the best. In order to evaluate the comfort level of case 12, additional simulation for a standard ventilating system, such as case 14, was considered for comparison matters.

Results of the MAA and flow velocity profiles for cases 12 and 14 are presented in Figures 8 and 9. The values in Figures 8(A) and 9(A) were calculated on the central vertical line, and in Figures 8(B) and 9(B) on the central horizontal line in the z-direction. In Figure 8 it is shown that the MAA of case 12 is higher than case 14, along the chosen line, however, the distribution of the MAA of case 12 is uniform. This means that fresh air is more uniformly distributed in case 12 than in case 14. This can be explained by the better turbulent mixing produced in case 12 due to the distribution of the inlet openings over larger distances with varied angles of airflow inlet and outlet. As a result, a noticeably lower mean air speed is obtained in case 12 as shown in Figure 9.

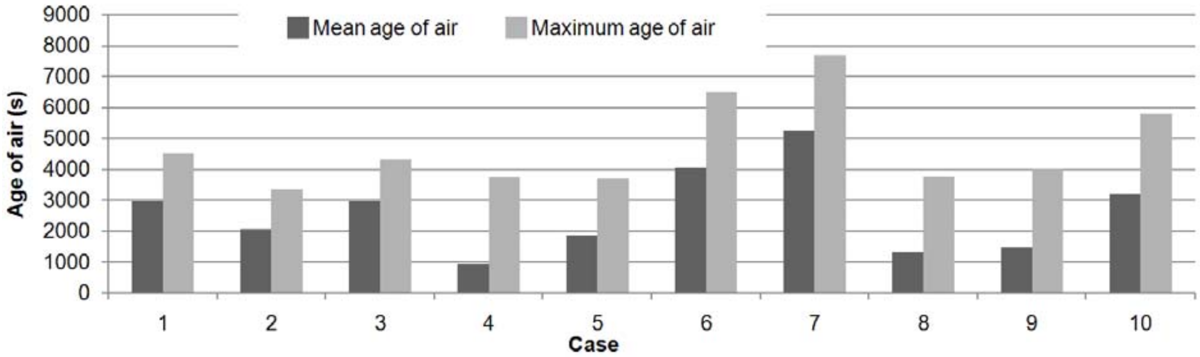

Figure 6 Mean and maximum age of air for cases 1-10.

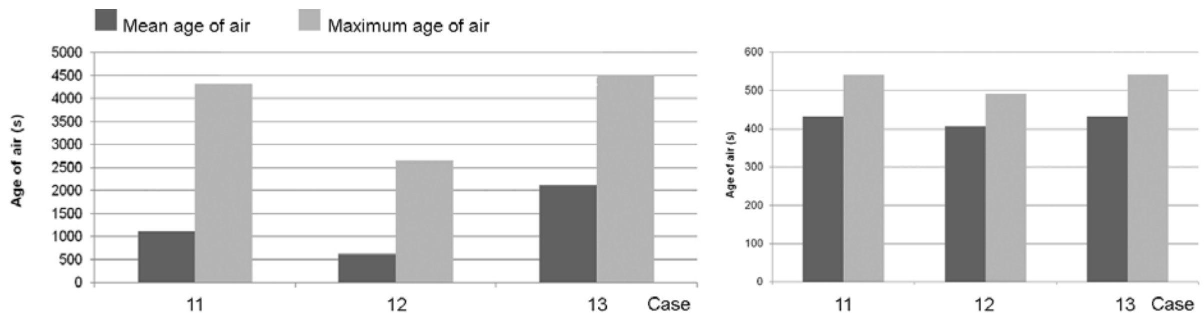

Figure 7 Mean and maximum age of air for cases 11-13; left: zero-equation; right: RNG with second order discretization schemes.

Figure 10 and 11 show isolines of the MAA in the $(-x)$ and $(-z)$ planes respectively. The figures compare isolines from case 12, on the right, with isolines from case 14, on the left. It is also notable, in Figure 10, that more isolines of the fresh air, in case 14, are located in the upper part of the room. Except this observation, the two plots in Figure 10 seem to have similar trend. However, a basic difference is noticed in Figure 11 between the isolines of cases 12 and 14. The change in the MAA isolines is diagonal in case 14 (left plot of Figure 11), whereas vertical in case 12 (right plot).

Figure 12 presents particle trace from the upper LLC plane (inlet) colored by MAA. The airflow enters at different angles and then, due to the LLC's that are situated at the bottom and expel air at different angles, the airflow moves almost vertically in the middle part of the room.

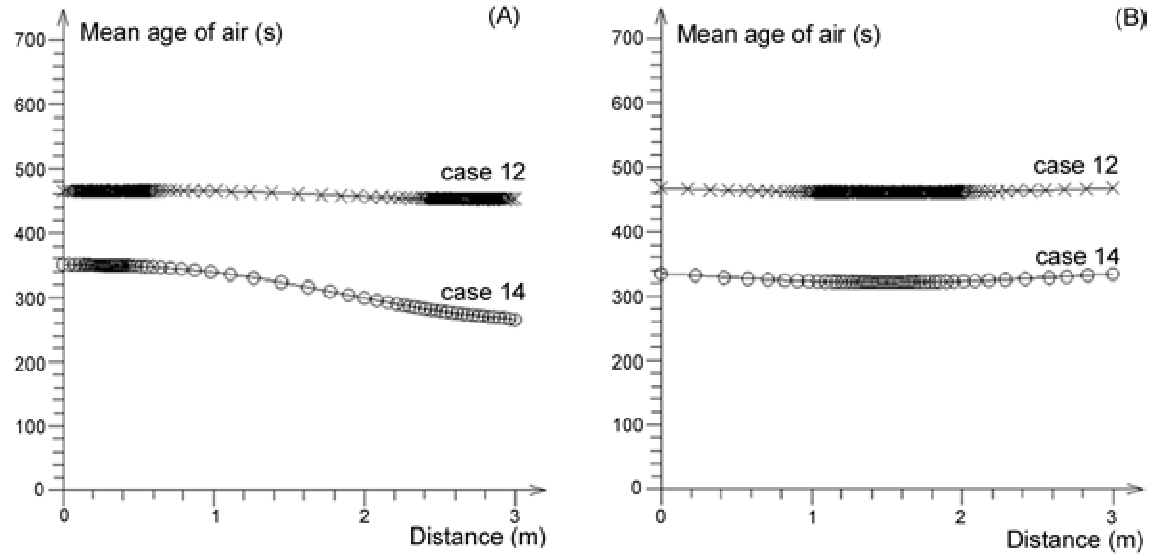

Figure 8 *Variation of the mean age of air (MAA): (A) along the central vertical line; (B) along the central horizontal line in the z -direction.*

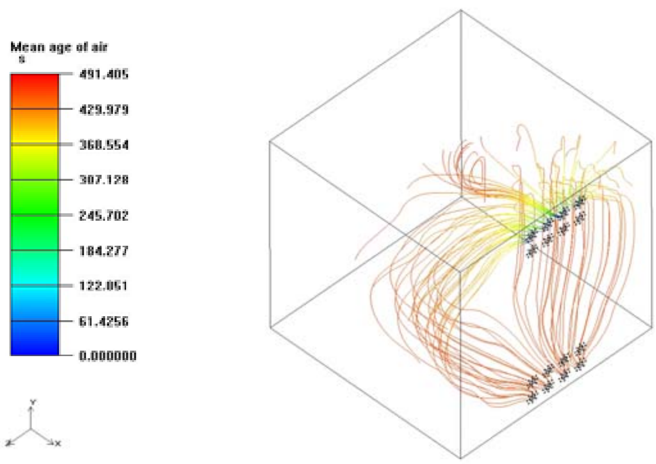

Figure 12 Particle trace from the upper LLC planes of case 12, coloured by mean age of air.

5. Discussion and Conclusions

Simulations of 13 cases of different configurations, locations and numbers of components in a bio-inspired ventilating envelope have been carried out. By analyzing the MAA, of the different cases, it has been observed that increasing the amount of LLC-in and LLC-out does not guarantee a better distribution of the fresh air. Thus, the location of the different components has a significant effect on the distribution of the fresh air. For example, in case 13 there are almost three times the amount of components found in case 4, however, the MAA of case 13 is only a factor of two times lower.

Among the simulated cases we found that by increasing the amount of components, a larger distance between the LLC-in and LLC-out is required for effective ventilating. At short distances between the LLC-in and LLC-out, increasing the number of components results in higher rate at which fresh air is being expelled outside before mixing, in this case the component special property of sucking and expelling air at varying angles might become a disadvantage. Whereas, given the 'right' balance between the number of components and the distance separating the inlets and outlets results in a turbulent mixing layer which distributes the fresh air almost homogenously at each constant horizontal line parallel to the inlet plane.

An interesting result is the fact that when the LLC-in and LLC-out are, respectively, situated at the top and bottom of the wall, the isolines of the MAA show vertical distribution, which is a characteristic property of ventilating systems located at the ceiling.

Furthermore, improving the fresh air quality inside the room could be achieved via standard sliding windows, but the bio-inspired ventilating system is considered as a ventilating wall, where there is no need to open windows and no requirements for temperature difference during its operation.

In order to further optimize the ventilating envelope for specific operating conditions, the effect of inlet-outlet distance, other configurations and possibly simulations of occupied rooms need to be investigated in more details. Moreover, in this paper we only considered the inlet and outlet being at the same wall, whereas it is possible to look at the effect of components distribution on multiple walls. This is left for future work.

Summary

A review is performed dealing with different driving forces and barriers related to implementation of a national classification system developed according to fit the scope of the classification system to be applied by the Building/Living dialogue project group. The result is based on an enquiry to the project group within the Building/Living dialogue. The enquiry is based on the experience from earlier interviews performed and was resulting in a number of key aspects found crucial for the implementation and establishment of the B/L classification system focusing on non-technical aspects. The following barriers and opportunities related to the B/ classification system are analyzed and evaluated in the paper:

- Classification and incitements
- Other classification, declaration and labeling systems
- Communication and organizational matters
- Legal aspects.

As a result of the enquiry the most important driving forces and barriers are identified. A discussion is conducted of how to handle these driving forces and barriers.

1. Introduction

The dialogue project Building/Living is a cooperation between companies, municipalities and the Government with a signed agreement and commitment to take the lead to achieve a development of a sustainable building and property sector in Sweden. This will be achieved by the means of introducing a classification system. Furthermore, the system will be supported by incitements from insurance companies, credit institutions, banks and the Government. Besides these originally incitements there are other types of incitements identified. The goal was that by the year 2009 all new buildings and thirty percent of existing buildings are voluntarily classified. This goal will not be possible to meet since the development of the classification system has been delayed.

A first draft classification system to be adopted by the Building/Living dialogue has now been launched (Glaumann et al 2008) and is here referred to as 'B/L classification system' version 2008:1: The dialogue project Building/Living set up three prioritized areas for the aimed classification system: Healthy indoor environment, Efficient use of energy and Environmental impact. The latter area has been redefined in the B/L classification system and is now divided into chemical substances and other environmental requirements that include aspects that are relevant only for certain buildings or buildings applications.

The B/L classification system can be utilized for existing and new buildings, where most of the requirements have to be verified by the existing building's performance, why a classification for not constructed building only can be an interim classification.

Four rating classes; A to D are defined in the system. Rating class C means that the building fulfills the current building code in force or current building practice if not regulated. From class C up to the best class A, the incitements are planned to increase. Consequently the cost to perform the classification might increase. The classification system up to class C is performed as a self-certification without external experts. However, for class A or B it may be required a third party expert to get the increased incitements.

Since the dialogue project Building/Living's scope is to establish a common building classification system that will be widely used by in the building and real estate sector by voluntary means, it is crucial to identify driving forces and barriers for implementation of the now launched B/L classification system. This implies that barriers can be found in the B/L classification system as such as well as organizational matter. This paper describes such early experiences from the Swedish Building/Living dialogue.

2. Key issues for implementation of the Building/living classification system

The current version of the B/L classification system is about to be launched on the Swedish market. Earlier versions of the system have been set up and validated (Carlson and Erlandsson 2006, Carlson et al 2007) mostly focusing on the indicators selected and classification requirements. A number of other more non technical barriers and driving forces can be found and handled in this paper. The methodology selected to investigate the opinion of different actors in the Building/Living dialogue about the classification system is examined by the use of a fixed enquiry in this paper. Earlier work within the developing work by Carlson and Erlandsson (2006) and Sundkvist et al (2006), has used interview technique. A number of crucial key aspects were selected for the enquiry, based on frequent issues appearing within the development of the classification system in relation the Swedish Building/Living dialogue group. These key aspects and the evaluation of the enquiry result are reported below.

2.1 Classification and incitements

A number of incitements may be found to conduct and assist an environmental classification system like the B/L classification system outlined by Miljövårdberedningen (2000). An increased knowledge of the own building as basis for improvement is fundamental but not enough to become a system that has a goal to be applied by a majority of the buildings in the stock. In the Building/Living dialogue project group on classification by Sjöberg et al (2003), different economical incitements were regarded as the most crucial as driving force for improved environmental performance. The importance of economical incitements for a market penetration is also confirmed by Sundkvist et al (2006).

The building classification shall in the Building/Living context be regarded as a voluntary tool for continuous monitoring of the building performance and not as a goal as such. Nevertheless, the costs to conduct the classification may not only be motivated by increased knowledge, but also the fact that high performance building should ideally receive economical incitements. The most important economical incitements that were defined by the Building/Living dialogue project report on classification are (Sjöberg et al 2003):

- Reduced building tax
- Less insurance fee
- Better loan conditions

An obvious economical incitement is the fact that that the classification – especially if it is accepted by both the government and market actors – could be a proof of an environmental high performance building and therefore as a better investment and market value. This incitement was not mentioned separately as a driving force in the Building/Living dialogue project report by Sjöberg et al (2003). This report had the scope to investigate the basis to establish a Building/Living unique building classification system. The fact that increased market value not was pointed out as a separately incitement can be explained by the building tax system valid at that time, where an increased market price/value would result in an increased building tax, since this was found on the market value (i.e. a counterproductive in an environmental view point). Since then, the building tax system has changed to a municipal tax with a limited fee per building. Therefore, an increased market value may now be essential for carrying out the classification.

On a general level it was asked in the enquiry to rank the most important barriers where the lack of incitements was pointed out together with the fact that the system is not well known on the market as the significantly most important barriers. This implies that there has to exist more incitements than increased knowledge of the building, if the market shall use the classification voluntary. A follow up question where the Building/Living dialogue group ranked the number one most important factors if the classification system should become a national de facto standard was not surprisingly that the system must have a function for increased market value when a building is for sale or to rent.

In the Swedish market only limited economical incitements are given by banks or insurance companies that are related to the environmental performance of a building. An indicator of an improved discount rate can be found by analyzing the situation for green cars. The bank SEB offer 7,18% as discount rate for a car loan and if it's a green car the rate will be 6,18% (April 2008), i.e. 1,0 % lower. Another Swedish bank Swedbank gives building owner a discount rate of 6,35% if the use of the money is used fore energy efficiency investments. This could be compared to a loan without any security of 7,76% that may indicate a reduced rate of at least 1%. However, an environmental classification is not needed for carrying out an energy efficiency investment and not for short loans with a pay back time of about 5 years. Experience from low energy concepts like Passive housing illustrates that part of the success for such buildings is that they were supported with better loans. For instance in the Swiss Miniergie system a reduced discount rate of 0,6% or up to 1 % is achieved by Zürcher Kantonalbank and Bank COOP (April 2008) respectively.

The insurance company Länsförsäkringar has indicated that they think that the insurance fee for a single family house could be reduced by a third for building that fulfills the requirement with the best performance class in the classification system. This means in actually figures about 150 € per year. If the cost to perform the classification for a single family house is about 1500 €, as given as an example in the Building/Living report 'B/L classification system version 2008', the pay pack time will be fifteen years and maybe not worthwhile. Nevertheless, if the result of the environmental classification qualify for an reduced discount rate of 0,5% this would result in a pay pack time less than years for a building with a loan about 200 000 €. The importance of cooperation and involvements by financial actors like banks is therefore crucial for economical motivation to conduct a classification on the Swedish market.

2.2 Other classification, declaration and labeling systems

In Sweden a number of classification and labeling systems for buildings are used. There are two systems that are more widely used than the others. One is Miljöstatus för byggnader/MFB, (Environmental Status of Buildings) which was developed by a group of companies representing building owners, developers and consulting companies. This system has been used for both commercial buildings and multifamily houses. More than 20 million m^2 of floor area have been classified. The interest for this system has drastically dropped the last years.

Other systems on the Swedish market is Miljöinventering i befintlig bebyggelse/MIBB, (Environmental investigation of existing buildings) which was developed by four organizations for multifamily houses. The only LCA based system that are used regularly on the Swedish market is Anavitor (Erlandsson et al 2007) that for instance is used by the construction company NCC to create climate declarations for all residential buildings. In this climate declarations from NCC there are also an energy classification reported that are based on the energy criteria for delivered energy defined by the B/L classification system. This actually makes NCC also as the first user that applies parts of the B/L classification system regular. Other examples of methods used are Miljöbedömning av fastigheter/MBF (Environmental appraisal of buildings), LEAD, BREEAM, Green Building, P-märkningen (the P-label) and Svanen (the Swan ecolabel).

At the moment there seems to be a growing interest for methods focusing on energy, i. e. the European Green Building, the Swiss Minergie, the German Passive house. All those energy systems will be covered by the B/L classification systems, which also encompass indoor environment and dangerous substances.

According to the result of our enquiry there was a great consensus that systems used in Sweden must be adapted to circumstances that are specific for Sweden building codes and practice. This result combined with the assumption that the foreign system also includes economical incitements pointed out by 67% by the responders as non-interesting. The same question but where the system was used an several countries was consider as non-interested by 73% There was also frequent given comments to these questions in the enquiry that it is one common system that is wanted for the building and real estate sector. Several of the notes given to this question in the enquiry pointed out that they were waiting for the B/L classification system to be launched and have been unwilling to introduce other methods for some time.

2.3 Communication and organizational matters

A number of practical issues such as how the classification body (or non) shall be found or how the result of the classification should be verified and communicated are all part of a classification system that makes it operational in reality. The enquiry points out that how the verification is carried out as the most important aspect to handle reliability, in favor to how the public communication is regulated or the organization structure behind the classification body.

When developing the system it has been discussed very much who shall be allowed to do the classification. One option was that the owner himself should do it as a kind of self-claim/-certification, here called *self-declaration* (see ISO 14021 and EN ISO/IEC 17050-1), like the declaration that is used for income tax (where the figures are given on our honour). Another one was to have a certified person to do this. A key problem was that the B/L classification system should according to the initial approach by Miljövårdberedningen (2000) be a voluntary one, and in order to get many owners to use it should not be too expensive as stressed by Sjöberg et al (2003).

Table 1 Enquiry alternatives on verification alternatives

Alternative verification of the classification result	Interesting alternative
Self-declaration, no requirements of public documentation	14%
Self-declaration, documentation available on request	21%
A third party verification performed by anyone	43%
An (by the org. body) authorised third part verifier	29%
Several alternatives parallel	36%

Note that more than one alternative may selected by the responder. If e.g. 14% pointed out an alternative as interesting, we have interpreted that 86% do not think this as a relevant alternative. The same structure is used for all query questions within this section.

The enquiry does not give any single solution on how the verification of the classification should be performed. An interpretation of the enquiry result (see Table 1) is that there is a greater consensus of what kind of verification system that is not generally accepted by the Building/Living group, namely a self-declaration system. The reverse result had been more beneficial. Nevertheless, a self-declaration may be acceptable if it is one option where also a third party classification is possible. The experience from the up to now carried out building classifications by professional real estate owner is that often a consultant or an internal expert does the classification work. Both of these persons may act as a third party, why this verification alternative seems as reasonable for a professional real estate owner. However for non professional owners of single family houses or multi dwellings a Self-declaration is preferable according to the organization Villaägarna (i.e. the home owners' organization). Comments in the enquiry also indicate that a self-declaration may be suitable for internal use within a company.

In the enquiry we asked; How do you want the classification system to be organized and further developed, and by whom? There was a strong majority (73% pointed out this alternative) for the Building/living secretariat to take this responsibility and to manage the system for the future. Other possibilities were to start an economical association (do. 27%) or to let Kretsloppsrådet,(The Swedish Ecocycle Council) (do. 33%) manage the system. The future organization of a classification system is on the top of the agenda in the Building/living secretariat and has to be handled in such why that a long term solution is found, where the problem is that the Building/living secretariat existence is limited in time. It is interesting to notice that Boverket (The National Board of Housing, Building and Planning) or any other governmental body is mentioned by 50% of the responders in the query when they have the possibility to select an alternative body not given in the fixed list. This actually makes Boverket a rookie.

The classification system is built up of four elements: Topic (Energy, Indoor Climate, Chemicals), Aspects, Indicators and Classification criteria, see Figure 1. The result from the classification can be presented on all these levels, but to streamline the interpretation of the classification result it may suitable to only communicate an agglomerated result per topic. An alternative to introduce a scoring system that includes weights between the topics would make it possible to condense the building classification result to one single figure.

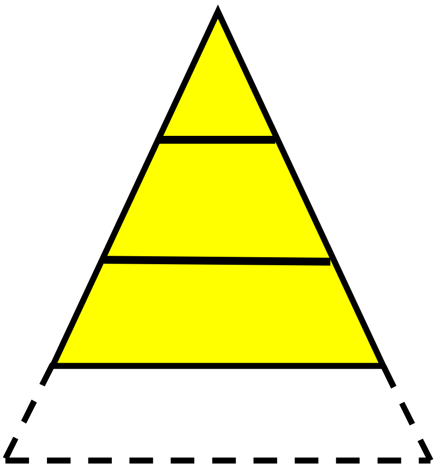

Figure 1 The structure of the classifications topics and the underlying aspect with indicators and the related classification criteria.

We asked in the enquiry how they wanted the classification result to be presented as a whole, from a single score and then following the structure in Figure 1 to the individual indicator result. A majority preferred to present the class for each topic (73 % pointed out this alternative, compare with the structure in Figure 1) and not to have one class for the whole building (do. 43%). Since more than one alternative was possible to point out in the enquiry also the possibility to introduce a single scoring system is not negligible. Especially some property owners (do. 60%) wanted to have one single class.

On the question how they wanted the classification to be designed and presented in a building, 71% preferred an A4, where the result was presented like a diploma or declaration, i.e. including the classification result. But also the alternative to design a label or similarly mark that indicate that the building was classified (but not the result of it) was pointed out by 64% as a good way to communicate to the visitors to an individual building. Regardless of how the result is shown in the building 57% think that the full classification result shall be available somehow to a document stored in the building.

Another aspect that was examined was how long time the classification should be valid. The majority, 85 %, meant that there must be a time limit. Some (do. 46%) argued that it should have the same time as the energy declarations, i.e. 10 years. Other (do. 38%) meant 5 years in a buying-selling situation.

2.4 Legal aspects

Since the system is voluntary the legal aspects of a classification is dependent on the status it has in the agreement between two parties. The classification could be seen as part of the information given in a situation of buying/selling or leasing a property according to the requirements in the Swedish legislation. However, the juridical importance according to the current legislation is limited for a declaration or classification like the B/L classification system. Such declaration or classification shall be regarded as a sort of risk warning (SOU 2004:109). The interpretation follows the interpretation of the classification result done by the Building/living group, where 67% of the responders in the enquiry didn't regard the classification result as a part of the juridical based information required in the buying/selling situation (mentioned above).

If the reverse appears that the classification results with high performance, i.e. class A for several topics. This can be seen as some kind of guarantee for the status of the building (SOU 2004:109) in the same situation. This will then have to be confirmed by the seller. The fact that the classification result was accepted as a guarantee was accepted by 75% of the responders in the enquiry. To be reliable in this kind of situation the classification should be done by a third party and not a self-declaration. There are special inspectors who investigate a building to be sold. They have technical and juridical education and are authorized by an organization (SBR). The inspectors have a responsibility insurance covering their business. The inspection follows a certain formula developed by SBR. So in this case the classification has a high degree of reliability. Though there is a disadvantage that these inspections is at the start focused only on an ocular inspection of the building itself and do not include water and electrical installations. If there are obvious risks the inspector can propose a deeper investigation.

In the situation of marketing and selling a house or apartment it has been pointed out that it could be a problem for the constructors to guarantee the highest, class A for indoor environment, since this class in the B/L classification system is dependant on the result from a questionnaire answered by the people living or working in the building (performed one year after they have moved in). They argue that the people can use this situation to their own advantage and affect the result of the classification by their answer to this enquiry. In the enquiry performed here a question asked if this indoor environmental declaration was a problem and therefore barrier for the use of the system, which resulted in a score of 3,5 where 1 is an important factor and 5 is a insignificant factor.

3. Conclusion and discussion

Based on the result of the enquiry it can be concluded that the significant identified non-technical barriers by the Building/Living group are as follows:

- The system is not well known
- The system is not yet related to any incitements
- The system is not reliable, since no organization is established
- The B/L classification system will not be applicable for all purpose why other (existing) environmental classification systems may be utilized parallel

Besides the non-technical barrier listed above, it is a frequent comment given in the enquiry that the system has to be simple to understand and to conduct. The Building/Living secretariat will start an information campaign about the B/L classification system during the spring 2008.

The lack of incitements and then for certain economical ones are a problem where no progress have been showed, even the fact that it has been part of the dialogue discussion at least since the first report on the aimed classification system (Sjöberg 2003). These kinds of incitement barriers can be handled by utilizing any governmental controlled system, as well as voluntary handled by commercial actors like the companies given in section 2.1. The problem in the latter case is if no win-win situation may occur. In the case of a bank it may be a case that the monetary risk is less for an environmental high performance building.

The discussion of the future origination of the project is now intensified by the Building/Living secretariat. The fact that Boverket was mentioned as a potential body to manage the system was surprising, since they have not so far been mentioned by this kind of people that take part actively in project meetings. Since the Building/Living secretariat is oriented as part of Boverket's organization and the mandate of the Building/Living secretariat is limited in time, this new information may be a door opener for new organizational solutions.

Other systems that may be used parallel to the B/L classification system (and therefore may not be regarded as competitors) are:

- Life cycle assessment (ISO 14040, -44)
- Building product declarations (type II/ISO 14021 or type III i.e. based on ISO 14025, ISO 21930)
- Climate declaration (a subset of product declarations type III given above)
- Energy declarations (following the EC building energy declaration directive)
- Other energy classification system that may be a subset of the best energy performance class A, such as Passive houses or Minimal energy houses that in Sweden are defined by FEBY (Erlandsson et al 2007, 2008)
- Due diligence
- Management systems like environmental systems like ISO 14001, or energy management systems like SS 627750.
- Different databases that give information like content declarations of building products.

Other systems with the same scope including all four classification topics that are part of the B/L system have more to be regarded as competitors to the B/L classification system. If a classification system (especially if it is non-mandatory like the energy declaration) it will always be a possibility for the B/L to adopt these kinds of specifications and/or give complementary classification criteria.

The following driving forces for the classification system are found on the enquiry answers:
- The system has to influence the market value of the building

- A class A building is related exclusively for (few) high performance buildings
- The system is adopted to/design for national conditions
- The national acceptance achieved is crucial (and much more important than a system based on international standards/work)

The added value for a building that has a B/L classification is not yet possible to evaluate, since no experience is available. Even if no precise figure can be established it seems quite reasonable that using the B/L classification system within our business will increase the good will of the origination as the value of the construction work where it is applied.

In the development work of the B/L classification system it was a common argument that class A should not be to tough (i.e. hard to achieve for all). So, we were a bit astonished when the enquiry indicated that a majority indicated that it has not to be a problem if class A is only reasonable to achieve expect for new or retrofitted buildings. However, this result seems to be sound and will support that the system is found pro-active supporting the “best in the class” and not a passive system only focusing on the opportunity to limit the worst ones.

Both the fact that the systems take national aspects into account and that it is part of a national dialogue project is a fact that supports the national acceptance of the system. The research team behind the classification system and their earlier experience from working in this field has hopefully also a positive impact of the acceptance of the system. However, even if the system is technically perfect concerning the definitions of classification criteria, it has also to be reasonable to conduct. This is an important aspect with the ongoing test of the B/L classification system 2008:1. If it is found as a problem to conduct the system it has to be improved by the project group behind the B/L classification system. Nevertheless, non-technical barriers included here have to be handled in a larger context and involves far more parties than the project group, and will be part for the future work to establish a classification tool that will contribute to a more sustainable future.

Keywords: construction materials, energy use, carbon dioxide emissions, life cycle, commercial buildings

Summary

This paper describes the influence of construction materials on the life cycle energy use and carbon dioxide emission of medium sized commercial buildings. When describing buildings by materials, there is a tendency to label according to the main material used, however, the vast majority of commercial buildings use a large number of materials. Hence it is not clear which materials or combinations of materials can achieve the best performance, in terms of life–cycle energy use and carbon dioxide emissions.

In order to develop a set of 'benchmarks', this research modelled the performance of three similar medium sized commercial buildings, located in the temperate climate of New Zealand, each designed using primarily concrete, steel or wood.

The model was based on an actual six-storey 4250 m^2 floor area building, with a mixed–mode ventilation system, currently under construction at University of Canterbury in Christchurch. While the actual building is being constructed in concrete, the authors have designed alternative versions in which the structures and finishes are predominantly steel and wood.

The analysis of each case study includes the calculation of embodied energy and embodied carbon dioxide. The whole life-cycle energy used and carbon dioxide emitted in the operation of the buildings was simulated using DesignBuilder software.

The results indicate that for an office building in which inside temperatures are controlled by an HVAC system, materials do not drive the life-cycle energy performance. The total operational energy over a 60 year life results in about 90% of the total lifetime CO_2 emissions, the same figures applying roughly for all three buildings. Of the remaining 10% of CO_2 emissions due to initial and recurrent embodied energy the largest difference between the three designs is in the embodied CO_2 emissions from manufacturing the building materials.

Introduction

Participants in this conference will need little reminding of the environmental impact of buildings. Events such as these serve to reinforce the message that in the developed world around 40% the energy use and 24% of carbon dioxide emissions can be directly associated with buildings – their construction, operation, maintenance, renovation, and so on (IEA, 2008).

Architects are being forced to radically re-appraise the nature of their role. Having traditionally thought of themselves as enhancing the environment, they must now consider seriously the potential environmental impacts of their activities and those of the building industry generally. There is an urgent need for information that will enable architects and the building industry generally to assess these environmental impacts, and for tools that will allow them to make an unbiased assessment of any negative effects of their activities on the wider environment; and thus fulfill their professional responsibilities to both their clients and to the wider community.

This paper will attempt to provide some of that information by exploring the influence of concrete, steel, or wood as the main construction material for the sub-structure, super-structure and finishes of a six-storey commercial building, on the potential environmental impacts over a nominal 60 year life-cycle.

Scope and Methodology

Energy use and construction materials for commercial buildings

Considerable effort has already gone into addressing these issues for domestic scale buildings (Mithraratne & Vale, 2004) which because of their greater numbers tend to be perceived as having the largest impact at a national scale. In addition, residential construction tends to be simpler than commercial construction, hence it is more readily classified and standardised, making analysis of energy and materials impacts relatively straightforward. Commercial-scale buildings on the other hand tend to be 'one-off' buildings with a wide range of functions, making them much more difficult to classify and analyse; and while their total numbers may be less than residential buildings, they consume a significant proportion of most western nations' energy and materials resources.

In terms of energy consumption, much of the existing commercial building stock is made up of multi-storey, highly-glazed, thermally-lightweight developments which are totally dependent on non-renewable energy for heating cooling and lighting.

In terms of materials, most commercial building tend to make extensive use of steel, glass, and concrete, all of which can be energy-intensive to produce via processes with the potential to have adverse environmental impacts, using resources that are in shortening supply. More recently, developments in wood technology have enabled timber to be utilised more extensively for the basic structure of medium-rise buildings, and this is investigated in this paper.

In this connection, it is worth noting the commercial rivalries that can exist between the purveyors of competing materials, each promoting the potential environmental advantages of their respective products – the thermal mass properties of concrete, the recycle-ability of steel, the renew-ability of wood, and so on – and the necessity for independent academic researcher to remain detached from these influences.

While there is a tendency for commercial buildings to be labelled according to the main material used for their sub- and super-structures, the vast majority of buildings use a large number of materials. Hence it is often not clear which materials or combinations of materials can achieve the best environmental performance (in terms of life–cycle energy use and carbon dioxide emissions, for example). Nevertheless we will retain this labelling system (while conscious of its limitations), as it is current practice. Studies have indicated that on average the structural components account for between 16 and 65 per cent of initial embodied energy (Aye, Bamford, Charters, & Robinson, 1999; Cole & Kernan, 1996; Oppenheim & Treloar, 1995; Treloar, Fay, Ilozor, & Love, 2001).

Typical building life cycle and key environmental indicators

Buildings go through many stages throughout their useful life, none of which are particularly simple to analyse from an environmental point of view. From initial conception to final recycling, re-use or demolition a whole range of processes must be taken into account. These include 'transportation to site, site erection and construction, life time use of building or structure, repairs, maintenance and refurbishment, demolition or dismantling at end of life, transportation for reuse, and recycling or disposal' (Cole & Kernan, 1996; Eaton & Amato, 1998). In short, a full Life Cycle Analysis (LCA) is required if one is to properly and thoroughly assess the environmental impact of a building.

As far as the selection of appropriate indicators of environmental impact is concerned, energy has long been the measurement of choice (Alcorn, 1998; Baird & Chan, 1983; Stein, Stein, Buckley, & Green, 1980). Operational energy use is relatively straightforward to assess. With international protocols (IFIAS, 1974) in place for the assessment of the embodied energy of materials (which tend to be country-specific), embodied energy calculations have been the subject of considerable study, particularly following the various 'energy crises' in the latter part of the twentieth century.

Energy has often been seen as a useful surrogate for overall environmental impact for many people, given the implied relationship between energy use and several other deleterious impacts, the multi-faceted nature of these impacts, and the absence of some other common factor or indicator.

More recently, it has been suggested that carbon dioxide emissions may be a more meaningful single indicator of overall global environmental impact. In many cases it is feasible to calculate carbon dioxide emissions from energy data, though again this tends to be country-specific, depending on the energy mix and industrial base of the region. In this study, both energy use and carbon dioxide emissions have been assessed using the following four main stages in the life (and potential environmental impact) of a building:

- Initial production of the building materials and construction of the building
- Operation of the building (mainly in terms of its energy use)
- Refurbishment and maintenance of the building materials over the building's effective life

- Demolition/disposal of the building materials

The focus of this paper will be on the first three stages. Research related to the final is ongoing at the time of writing and will be reported verbally during the conference.

Case study description

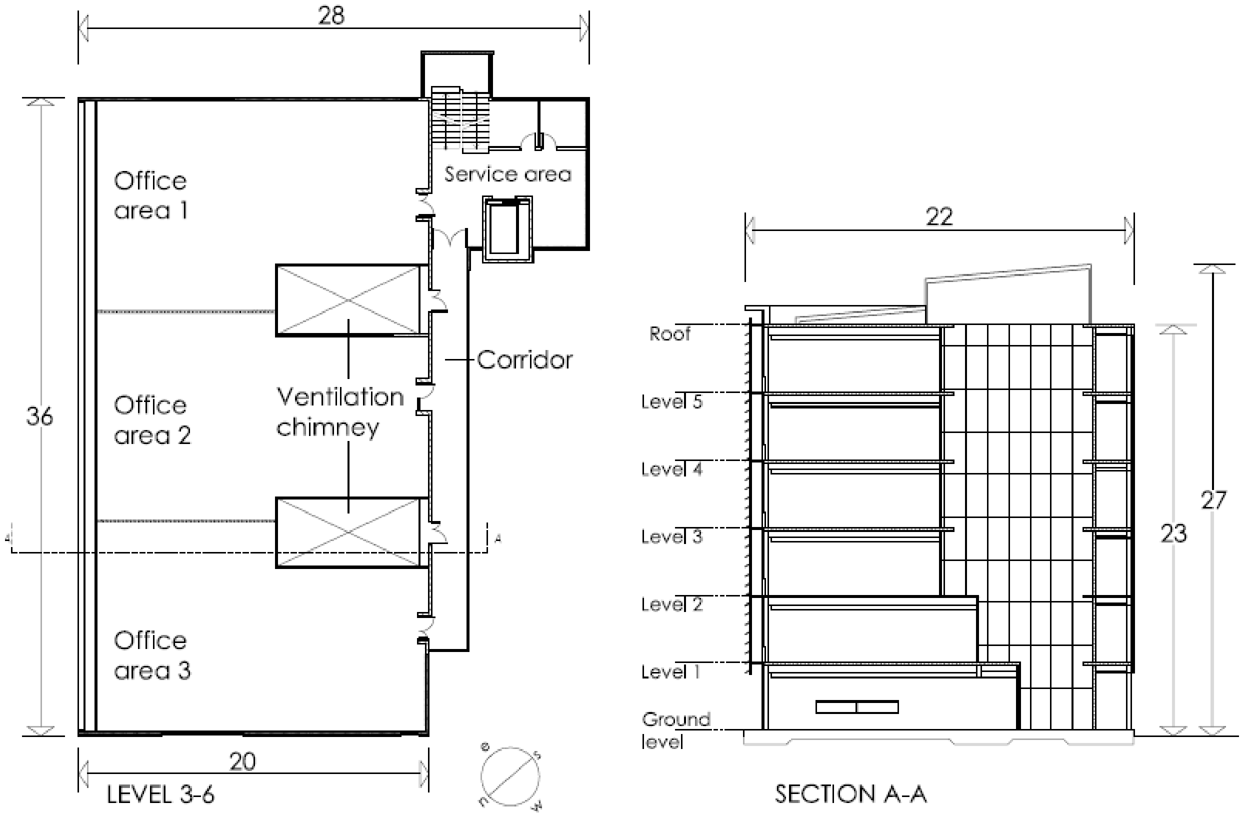

Figure 1: Plan of Timber building. This general plan is the same for all three buildings.

Building design

The buildings analysed in this research are based on an actual building, a new six-storey, 4250 m^2 floor area, laboratory for the School of Biological Sciences at the University of Canterbury in Christchurch. It was designed by local architects (Courtney Architects) with reinforced concrete as the main material for structure, envelope walls, floors and roof slabs.

The initial concrete building was used to produce architectural and structural drawings for three alternative buildings. The first alternative was a simplified reinforced concrete building, designed as a simple commercial building rather than a complex laboratory building. This building had the same structure and cladding as the real building, but open-plan commercial floor areas. The other two alternative buildings use steel and timber as the main materials for structure and many of the finishes.

For the steel and timber buildings, an objective was to use as much of the target material as reasonably possible, both in the structure and finishes. In order to maintain 'common practice', many interior and exterior finishes materials are common to all three designs. For example, most linings, ceilings, windows and other building components such as roof cladding and sun louvers are the same for all three case studies. External cladding on the timber building is fibre cement; a more detailed description is given below.

Design details

The building's envelope walls are the same at the east and west ends and different on the north and south faces. The north facade is a curtain wall made of double glass windows framed in aluminium mullions and transoms. The aluminium louvers outside the curtain wall cover all the façade from the ground floor up to the roof 'soffit'. North façade construction is the same for all three buildings in this research. The east and west façades are solid walls with only two narrow windows, one vertical (south corner) and one horizontal window centred in the façade.

The south side has an external corridor that connects the offices with the stairs, lift and toilets service area (see figure 1). Corridors are enclosed between a light wall (south façade of internal offices) and a single glass aluminium framed curtain wall. The south façade curtain wall is the same for all three designs.

Figure 1 shows the third floor plan of the timber building. This floor plan is the same for all three buildings. The floor is subdivided into four zones; three offices and one corridor and services area on the south side. Only the office zones have HVAC control. The corridors and service areas only have openable windows, set for natural ventilation. Two large ventilation chimneys were placed in the initial concrete design for the laboratory building, and these are retained in the three research designs. They continue through all floors from ground level up to the plant room on the roof slab. The ventilation chimneys are used for natural ventilation with automatic openable louvers set to be opened above 22℃ up to 26℃. When the louver openings are closed, the air conditioning keeps the temperature at 26℃ until 6pm.

Building description:

The following sections describe the components of the building that vary between each case. Components which do not change between buildings include the curtain walls and louvers in the north and south façades, as well as stairs, balustrades, and most of the internal finishes.

Concrete building:

The concrete building is a reinforced concrete column and beam structure. The floors are 300mm thick prestressed concrete hollow core slabs with 75mm reinforced concrete topping. The reinforced concrete roof slab supports a plant room for air conditioning equipment. The east wall, west wall and part of the south façade are a 310mm thick Thermomass wall which is a composite wall with 60mm concrete on the exterior, 50mm of extruded polyurethane insulation in the core, and 200mm of exposed reinforced concrete to the interior of the building. The service area walls are 200mm reinforced concrete walls. The light weight walls on the south face of the offices and the walls to the ventilation chimneys are timber framed walls containing 90 mm thick fibreglass insulation and a 25 mm air cavity for the exterior walls.

Steel building:

The steel building is a column and beam steel structure braced by eccentrically braced frames (EBFs) located beside the chimney voids. The floors and roof slab use the Comflor system, where a 0.9mm corrugated galvanized steel sheet supported by the structural beams, is topped by 150 mm of reinforced concrete. The roof slab has a 75mm thick fibreglass layer below the steel deck. The envelope walls on the east and south faces are supported between floors slabs, so that the heavy steel structure is exposed inside the building, and hence not able to act as a thermal bridge. The envelope and internal partitions are framed in lightweight galvanized steel studs and 90mm fibreglass insulation. The envelope walls have a 30mm air cavity for ventilation and the cladding is painted steel sheet profile.

Timber building:

The timber building is constructed from a new post tensioned structural timber system being developed at the University of Canterbury (Buchanan, Deam, Fragiacomo, Pampanin, & Palermo, 2008; Paleremo, Pampanin, Fragiacomo, Buchanan, & Deam, 2006; Smith, Pampanin, Fragiacomo, & Buchanan, 2008). The structural timber columns, beams and shear walls are prefabricated from laminated veneer lumber (LVL), and assembled on site with post-tensioned connections. The floors and the roof slabs are timber-concrete composite slabs build using prefabricated structural plywood and LVL decking supported on structural timber beams. The plywood decking supports a 60mm thick reinforced concrete composite topping, fixed to the LVL joists by embedded coach screws. The roof slab contain a 75 mm thick fibreglass layer. The structural LVL walls in this design are located within the east and west envelope walls, so must be considered as potential thermal bridges. The light weight envelope walls and the internal partitions are framed in timber studs with 90mm fibreglass insulation. The envelope walls have a 25mm air cavity for ventilation under fibre cement sheets.

Operational energy

Energy and CO_2 assessment:

An energy performance simulation was undertaken to assess the operational energy use of each building. The three buildings were designed to have similar operational energy consumption. This required different design of insulating materials, thermal mass, and heating and cooling equipment in each of the three buildings. With similar operational energy consumption, the final environmental performance of the three buildings was determined by the difference in the embodied and recurrent energy and CO_2 emissions in the materials used in each building.

The energy simulation was undertaken for the original concrete building using Design Builder software. That energy consumption was then used as a benchmark energy target for the steel and timber buildings. Subsequent energy simulations were undertaken with the alternative buildings, aiming to reach the benchmark set by the concrete building, with selection of improvement in insulation and some changes in finishes. Finally, once the benchmark was reached, simulations were carried out to assess the small differences between the energy performances of each of the three buildings.

Simulation method

The concrete building was designed initially to have low energy consumption, and perform better than the minimum requirements of New Zealand Standard NZS 4243 Energy Efficiency – large buildings (NZS, 1996). Subsequently all three buildings in this research had similar performance (85 kWh/m^2-year). This is particularly important because the aim of this project was to look at the influence of materials on the life cycle energy use and CO_2 emissions of the buildings. Several previous researchers have found that when the energy efficiency of building is code compliant, the effects of construction materials and embodied energy are negligible (Cole & Kernan, 1996; Page, 2006; Sartori & Hestnes, 2007; Suzuki & Oka, 1998).

For the simulation carried out in this study, many of the inputs are default data based on NZS 4243, but some data from the DesignBuilder software library database was also used as inputs (NZS, 1996).

An HVAC system operates when the inside temperature is below 22 °C and above 26°C. Between 22 °C and 26°C the buildings works under a natural ventilation mode with no heating or cooling. The buildings design includes two internal ventilation chimneys that under natural ventilation mode, are set in simulation to exhaust the air coming into the buildings through openable windows in the curtain wall of the north façade.

All three buildings were simulated as typical office buildings using schedules for simulation based on NZS 4243. Three schedules were developed to determine the percentage of loads for items such as occupancy, plugs, lighting and equipments and HVAC operation.

Buildings climate is controlled during week days from 8am until 6pm and on Saturdays from 8am until 11am with no occupancy during Sunday. HVAC runs from Monday until Saturday at 100% of the assigned load from 8am until 6pm, and for the rest of the time including all Sunday is set as 0% until Monday 8am.

Embodied energy

The drawings for the structure and architecture of the three buildings were submitted to a quantity surveyor (Davis Langdon) for measurement of material quantities, along with cost estimates. They were asked to measure the quantities of eleven construction materials, being: concrete, reinforcing steel, structural steel, other steel, glass, timber, aluminium, plasterboard, paint, particleboard/fibreboard and insulation. Subsequently each of these main materials was subdivided into specific items (eg timber was subdivided into plywood, LVL, sawn timber, MDF and imported cedar).

Once the quantities of materials for each building were calculated, the coefficients of embodied energy and embodied CO_2 of New Zealand buildings materials were assigned to each material for calculation of embodied energy and CO_2 emissions using data from (Alcorn, 2003). A schedule of material life spans, and resulting maintenance energy developed by SCION research (Love, personal communication, April 8, 2008) was used to estimate recurrent energy and CO_2 emissions of the buildings (involve the embodied energy and CO_2 emissions of all the materials used in the maintenance and refurbishment of buildings during its 60 years life-cycle).

Discussion of results:

Figures 2 and 3 respectively show the life-cycle energy consumption and the life-cycle CO_2 emissions for each building for a nominal life of 60 years. In all the cases the relative proportion of embodied, recurrent and operational energy are similar, except that the timber building has lower embodied and recurrent emissions than in the concrete and steel buildings.

Figure 2 shows that the total operational energy over a 60 year life accounts for about 75% of total lifetime energy use, most of the rest being embodied energy in the materials. It can be seen that the embodied energy in the timber and concrete buildings is only about 70% of the embodied energy in the steel building.

Figure 3 shows that for the concrete and steel buildings, the total operational energy over a 60 year life accounts for about 85% of total lifetime CO_2 emissions. For the timber building, the operational energy accounts for almost all of the lifetime CO_2 emissions because the emissions from embodied and recurrent energy are negligible. The recurrent energy is only about 3% of total lifetime energy use, representing less than 2% of total CO_2 emissions.

	Concrete	Steel	Timber
Embodied energy	17,369	25,969	18,376
Recurrent energy	2,399	3,198	3,164
Operation energy	64,138	65,310	67,255
Total life-cycle energy	83,906	94,478	88,795

Figure 2: Life cycle energy consumption for 60 year life, including embodied energy, operational energy, and recurrent energy (GJ).

	Concrete	Steel	Timber
Embodied CO2	1,129	1,325	176
Recurrent CO2	116	149	82
Operations CO2	7,239	7,377	7,654
Total life-cycle CO2	8,484	8,852	7,912

Figure 3: Life cycle CO_2 emissions for 60 year life, including manufacture of materials, operational energy, and recurrent energy (tonnes).

Figure 3 also shows that the largest difference between the three different buildings is in the CO_2 emissions from manufacturing the building materials. For the timber building, embodied CO_2 figure is very low so that the CO_2 emissions from manufacturing all of the materials in the building is almost completely offset by the carbon stored in the timber components of the building.

In order to justify this claim, it is necessary to consider the fate of the building materials at the end of the building's life. The carbon stored in the wood materials can only be used to offset other CO_2 emissions if we can be assured that the wooden demolition products will remain as solid wood, either re-used in another building or placed in a landfill (Micales & Skog, 1997) – in either case the carbon in the wood will not be returned to the atmosphere.

Another disposal option which can be considered for wood products is burning of waste wood in lieu of fossil fuel energy production. This bring even greater CO2 benefits than retaining the solid wood as a carbon sink (Gustavsson, Pingoud, & Sathre, 2006).

Figure 4 shows for the three cases in this research, the respective contribution of the building components (i.e. Windows and louvers, envelope walls and interior finishes, structure and foundations) to both, the initial embodied energy (EE) and the initial embodied CO_2 emissions (ECO2).

	Concrete EE (%)	Steel EE (%)	Timber EE (%)	Concrete ECO2 (%)	Steel ECO2 (%)	Timber ECO2 (%)
Windows and louvers	56	37	50	39	33	82
Envelope and Interiors finishes	10	9	9	0	6	0
Structure	30	51	36	53	54	0
Foundations	5	3	4	9	7	18

Figure 4: Percentage contribution of each of the five building components into the initial embodied energy and initial embodied CO_2 emissions of all three case studies

The energy figures in Figure 4 shows that the embodied energy in the structural materials ranges from 30% of total embodied energy in the concrete building to 51% in the steel building. The total embodied energy in the envelope, interior finishes and windows/louvers combined ranges from 46% of total embodied energy in the steel building to 66% in the concrete building.

The CO_2 figures in Figure 4 show that for the timber building, carbon is sequestered in the structural timber material, resulting in CO_2 absorption (hence the – negative value for emissions). For that building emissions are produced only in the finishing materials which are common to all designs.

For all three buildings, the structural materials (including foundations) account for roughly half of the initial embodied energy. Finishes all together account for the remaining half of initial embodied energy. This mean that embodied energy in the main structural materials accounts for only about 12% of the total lifetime energy use.

Conclusions

This paper describes the life-time energy and CO_2 analysis of a six-storey commercial office building designed in three alternative materials. The main conclusions are:

1. Regardless of whether the buildings are constructed mainly with concrete, steel or timber as the principal structural and non-structural materials, each building can be designed to have a similar indoor climate with roughly the same amount of operational energy for heating and cooling over the full life of the building.

2. When any of the three buildings are designed for low operational energy use (about 85 kWh/m^2-year), the total operational energy over a 60 year life accounts for about 75% of total lifetime energy use. This operational energy, results in about 85% of total lifetime CO_2 emissions for the concrete and steel buildings, and almost 100% of total lifetime CO_2 emissions for the timber building.

3. The embodied energy required for construction and maintaining the timber and concrete buildings is only about 70% of the embodied energy required for constructing and maintaining the steel building.

4. The largest difference between the three different buildings is in the CO_2 emissions from manufacturing the building materials. For the timber building, the CO_2 emissions from manufacturing all of the building materials is almost completely offset by the carbon stored in the timber components of the building.

CLIMATE CHANGE IMPACTS IN NEW ZEALAND: A CROSS-DISCIPLINARY ASSESSMENT OF THE NEED TO ADAPT BUILDINGS, WITH FOCUS ON HOUSING

BENGTSSON JONAS, BENNETT JESSICA, MCKERNON STEPHEN, MULLAN BRETT, PAGE IAN

BRANZ Ltd, Moonshine Road, Judgeford, Porirua City, New Zealand

ABSTRACT

The scientific evidence is very strong: climate change presents very serious global risks and it demands an urgent global response. This paper is part of the dissemination phase of a research project assessing the need to adapt buildings in New Zealand to climate change based on medium-low and medium-high climate change scenarios from research by the National Institute of Water and Atmospheric Research (NIWA). The overall purpose is to determine the impact of climate change on the built environment and to generate a set of options for adaptation. The building sector's vulnerability to climate change is assessed through:

- Topology and condition review of the national building stock;
- House overheating conditions and energy consumption simulations; and
- A scenario-based social impacts study.

Adaptation options and recommendations are presented for a broad range of building-related climate change impacts. Economic modelling and cost-benefit analyses are used to investigate the economic viability of thermal adaptation.

Although the effects of climate change are expected to be less severe in New Zealand than in many other parts of the world, the key message from this report is that the strong, early and coordinated action on climate change can limit potentially large social, cultural and economic costs in New Zealand.

KEYWORDS

Climate change, adaptation, buildings, cross-disciplinary, New Zealand.

INTRODUCTION

Climate change will have broad and far-reaching effects on New Zealand society and its lifestyles, economy and governance. Climate change is expected to impact buildings and the urban environment in a number of ways. These include: an increase in heavy rainfall leading to more flash flooding events and subsidence; and drier conditions leading to clay soil shrinkage and raised fire risk. Other expected effects are: a change in demand for space heating and summer cooling; increased immigration; regional redistribution of land and property values; reduced access to insurance; and higher cost of carbon-intensive goods and services.

This paper is a selection and summary of the results from a cross-disciplinary assessment of the need to adapt buildings to climate change. The overall purpose of the report is to determine the impact of climate change on the built environment and to generate a set of options for adaptation. The focus is on houses, and although non-residential buildings are not examined in-depth, many of the impacts that apply to housing will also affect non-residential buildings. Due to size restrictions for this document we refer to the complete report (Bengtsson et al 2007) for a full presentation of results and methodologies.

METHODOLOGY

Climate change scenario projections methodology

The climate change projections by the NIWA form the foundation for assessing the impacts of climate change on the New Zealand built environment (see Mullan et al 2006).

Climate scenarios are generated for a 50-year trend (2030s) and a 100-year trend (2080s). To represent uncertainties in future global socio-economic development two scalings – described as the 25th percentile (medium-low) and 75th percentile (medium-high) of the full IPCC temperature range – are simulated.[1] These

[1] The 25% and 75% limits were chosen to cover a reasonable range of possibilities while avoiding being alarmist by stressing extremes, in either direction, which some would view as unlikely.

scalings should not be considered extremes, but rather the lower and higher boundaries of probable developments. The climate scenarios in this report are based on two down-scaled global climate models: CSIRO and Hadley.

Social impacts scenario research methodology

This study used scenarios to construct strategically useful simulations of New Zealand's future housing system and its interactions with climate change. In common with other scenario methods, it seeks to initiate a *strategic conversation* (Van der Heijden 2005) about the future of housing by gaining input from experts in diverse sectors. Recent studies in New Zealand have explored the future of the housing sector with stakeholders (Saville-Smith 2000, Bates et al 2001, Bates and Kane 2006). This study employs a different approach to enrich the information available, but should be read in conjunction with these existing studies, especially the latter. The social part-study was carried out in four steps:

1. Key climate changes, potential social impacts and housing conditions were identified and projected for the years 2031 and 2081;
2. The projected changes were analysed and draft future scenarios were developed using qualitative/ soft systems analyses (Checkland 1981, Room and Britton 2006);
3. Draft future scenarios were explored with experts from diverse sectors to identify key impacts and adaptations, using one-hour phone or face-to-face interviews (sector experts) and a brainstorming group (householders). The experts explored the key influences that were identified in Steps 1 and 2. In total, 13 experts and eight householders provided strategic input into the development of this study. The total interview time was 17 hours.
4. Detail key social impacts and housing adaptations with respect to climate change.

The key changes in Step 1 above were the climate projections from NIWA, demographics, social variables, and wildcard variables. In summary, for the social scenarios we assumed an overall growth in the New Zealand population up to over five million people by the 2080s with larger Maori, Pacific Island and Asian ethnic proportions of the population and a decreased proportion of people with European ethnicity. The population was assumed to be ageing, with the median age rising from 35 years in 2001 to 55 years by 2081. An increase in single and couple households at the expense of two parent households was also expected.

Obesity and overweightness in the population were assumed to increase as a social problem, especially in the over 65 years age category. It was further assumed that there will be a rise in crime rate; immigration; percentage of the population working from home; development of telecommunication technologies; house mass production (with increasing imports lowering the price for householders and pressuring local manufacturers); the number and variety of sustainability initiatives (although they will be dependent for their success on the political, economical and social environment).

The wildcard variables used were: decline in global oil production (assuming virtually no production by the 2080s); percentage increase of the global population suffering from severe water stress (exceeding 75% by 2081); volcanic activity is assumed to remain significant enough to be included in civil defence and emergency management planning; and finally wars over access to natural resources and cultural/religious differences are assumed to continue to divert activity away from sustainability and quality of life which will engender economic hardship and shifts in migration patterns where New Zealand is typically viewed as an attractive alternative.

House thermal simulation and cost-benefit analysis methodology

A building stock analysis was used to identify two vulnerable and (for a large portion of existing buildings in New Zealand) representative building types.

For the identified house types the thermal performance and annual energy consumptions were simulated using the SunRel software modelling tool. These simulations were done for three locations (Auckland, Wellington, Christchurch) and five climate scenarios provided by NIWA (present day, and least change and most change for 2030s and 2080s respectively and abbreviated to PD06, C375, H325, H825 and C875 in the graphs). The simulations were performed for five insulation options per location. The base insulation assumed no wall, ceiling or floor insulation and single-glazed windows. The best insulation option assumed wall, ceiling or floor insulation (with R-values of at least 2.6 and up to 5.0 for the ceiling insulation in Christchurch) and with lowE argon-filled double-glazing. Exterior awning shades were placed just above all north-facing windows (and east and west-facing windows if they were in living areas or bedrooms) to reduce solar gains. Ventilation in the form of opening windows was incorporated to assist the heat pumps in cooling the house.

Each model used heat pumps to heat/cool the house, with the heating set at 16ºC from 11pm – 7am and 20ºC from 7am – 11pm. Cooling was set at 25ºC. The cost of a heat pump was $3,000 each (on average replaced every 10 years) and there was a coefficient of performance of 3. Windows were assumed to be replaced every 30 years and awnings every 10 years. Window prices[2] were obtained from the industry and window awning prices were obtained from Rawlinson's.[3]

Economic models were derived to analyse the effect of retrofitting these houses with different levels of insulation. A period of 55 years was used (2005–2060) for all models and it is assumed that it would take 10 years to retrofit all the existing houses with no or poor insulation. Three timeframes were modelled: start now; start in 2015, or start in 2025.

Using QVNZ data it was calculated that the Auckland model represents 54% of the existing stock, Wellington 21% and Christchurch 25%. The demolition model used assumes a 110 years average life for the existing house stock built prior to 1978 with little or no insulation. About 1,700 of these houses are currently being demolished per year now. This number is assumed to increase up to 5,000 demolitions per year until about 2075, after which it will start decreasing over the following years.

Health costs were based on research by Chapman *et al.* (2005) that found that a household would spend approximately $47 extra per year if they lived in an uninsulated house compared to in an insulated house.

Finally we used a 5% discount rate to get all figures into today's dollars, and we assumed an energy price escalation of 1% per year, with acknowledgement that the choice of discount rate for adaptations to climate change impacts is subject to debate and the development of energy prices is uncertain.

CLIMATE CHANGE SCENARIO PROJECTIONS FOR NEW ZEALAND

This section gives a summary of the climate change projections by NIWA (see *Table 1* below). The climate elements where we have the most confidence in expecting to see changes are: maximum and minimum temperatures; sea-level; drought and fire risk; and UV radiation. For a number of other elements, the future projections are either still uncertain (e.g. wind, storms, hail) or appear likely to be within the current range of inter-annual variability (e.g. solar radiation, relative humidity) at most sites. There is also a general expectation of increased rainfall extremes, but further research is required before we can be confident about differences between regions.

Table 1: Projected 50-year and 100-year climate change trends.

	2030s	2080s
Annual average temperature	+0.4°C to +0.8°C	+1.0 to +2.4°C
Mean sea-level rise	0.07 to 0.16 m	0.23 to 0.52 m
Frequency of days >25°C	Increase	Doubling or more (except Christchurch)
Drought (1-in-20 yr events)	More frequent (exc. Hokitika)	As frequent as every 5–10 years (exc. Hokitika)
Wildfire risk	Increase, especially eastern parts	>+50% near Christchurch and other eastern parts
Days with frosts	Decrease	Half as often in the South Island
Extreme rainfall events	Increase in frequency	Doubling in frequency
Average rainfall	Increase in autumn and winter, less over spring and summer	
Flood events	Increase in frequency	Doubling in frequency
Extra-tropical cyclones	Decrease in frequency and increase in intensity (still uncertain)	
Wind	Average westerly wind component +10% the next 50–100 years	

[2] Double-glazing prices have been reduced by 10% from current prices to reflect the expected economics of scale from the expanded market due to the proposed changes to the NZBC Clause H1 (energy efficiency) provisions, which will make double-glazing mandatory in climate zones 2 and 3 and possibly in zone 1. The use of double-glazing is widespread in the South Island, and the market size will more than double with the proposed changes.

[3] *NZ Construction Handbook* (Rawlinson, Auckland, 2005).

	2030s	2080s
Hail	Increase in hail occurrences (still uncertain)	
UV radiation (comp. to 1980)	2% higher	0% (i.e. recovered)

PHYSICAL VULNERABILITY ASSESSMENT OF THE BUILT ENVIRONMENT

The main identified physical vulnerabilities to climate change in the built environment are: indoor overheating; inland flooding; coastal hazards; droughts and fire. Projections for changes in intensity of ex-tropical cyclones and extreme wind conditions are also discussed in this section as they could have potentially catastrophic impacts, yet the climate science remain uncertain. Impacts and adaptations are largely based on research by Camilleri (2000).

Increased overheating risk

For the 2030s, annual-average temperature increases by about 0.4 to 0.8°C, depending on the scenario. By the end of the century (the 2080s), the temperature is projected to rise by 1.0 to 2.4°C. Projected temperatures increase everywhere, with the exception of Hokitika in summer for the 2030s Hadley scenarios.

High temperature extremes will increase in frequency and low temperature extremes (e.g. frost) will become less common. Extreme temperatures affect living comfort, and consequently the need for either space heating in winter or air-conditioning in summer. Table 2 below provides quantitative estimates of changes in temperature extremes calculated using *weather generators* (Mullan et al 2001).

Table 2: Number of days per year with daily maximum temperatures exceeding 25ºC in current climate, and changes for future scenarios.

Max. temp >25ºC	Present days	Additional days 2030s	Additional days 2080s
Auckland	21.3	6.9 to 14.6	25.9 to 52.6
Wellington	2.9	0.4 to 2.0	3.5 to 13.9
Christchurch	31.2	2.7 to 10.2	12.7 to 30.2

The future increases in Auckland and Christchurch would be enough to create a long summer *cooling season* lasting a month or more. Such prolonged discomfort is unlikely to be tolerated by many house-owners who would take adaptive measures, possibly by installing air-conditioning (and raising the greenhouse gas emissions from energy use). As will be discussed later in this paper, not all houses will be equally affected by overheating. Those houses with good solar design features such as properly shaded north and west-facing windows, minimal west-facing windows, or provision for effective ventilation should be least affected. Houses without such features, or poor solar design, could suffer severe overheating.

Increased rain and inland flooding

The amount of water held in the atmosphere increases with rises in temperature (about 8% more for every 1°C rise in temperature). What is an extreme rainfall in today's rainfall climate is projected to occur about twice as often by the end of the 21st century. Climate change is expected to reduce the Average Recurrence Interval (ARI) of high-intensity storms or, equivalently, for the same ARI and duration the rainfall amount increases. Rises in extreme rainfall are considered likely, even where the annual average rainfall changes little or even decreases.

In general, changes in frequency of flood events are expected to follow a similar pattern to extreme rainfall i.e. doubling by the end of the century. The relationship between flood events and extreme rainfall will vary with the characteristics of each catchment. For example, for small catchments or for the built environment with lots of paved surfaces run-off will be rapid, so fairly short accumulation periods of up to a few hours will be most relevant to local flooding. For more extensive flooding over large catchments, extreme rainfall totals of 2–3 days will be more important. Extra water can result in landslides which can directly undermine buildings or damage buildings.

The changes in heavy rainfall with climate change may result in more flooding with consequent water damage to houses, drain damage, erosion and slips, and damage to services such as roads, pipes, and cables. With climate change the historical flooding Annual Exceedence Probabilities (AEPs) are projected to increase, meaning a rise in the frequency of flooding and the incidence and extent of flood damage to houses. The actual cost of building damage is expected to equal or exceed the change in flooding AEP e.g. a 4-fold increase in the AEP could result in up to a 10-fold increase in the cost of building damage (Smith et al 1998). Even if the high end of these increases in flooding AEPs occur, it may take decades to determine if the AEPs have in fact changed. By this time it will be too late for changes in planning or Building Code requirements to reduce the impacts of climate change induced flooding on affected houses.[4]

Increased coastal flooding, erosion and rising water tables

Projected future global mean sea-level rises are consistent with the global mean temperature increases assumed in the scenarios of this report. Mean sea-level rises range between 0.07 and 0.16 m by the 2030s and between 0.23 and 0.52 m by the 2080s relative to sea-levels in 1990. In addition to mean sea-level rise due to global warming, the sea-level is determined by a number of components such as tides, storm surge and long period oscillations e.g. annual seasonal heating and cooling by the sun (±0.04 m to ±0.08 m), El Niño-Southern Oscillation cycles (±0.12 m), and Interdecadal Pacific Oscillation[5] (±0.05 m).

Coastal hazards tend to be a complex interaction of direct and indirect human impacts on the coastal zone and natural forcing processes, such as water levels, waves, currents and sediment supply and re-distribution. These interactions can operate over a range of different time and spatial scales, ranging from episodic storm events through to longer-term cyclic coastal change caused by seasonal, inter-annual and decadal variability (see MfE 2004a).

The increase in flooding risk with sea-level rise for a sheltered coast may be greater than for an exposed, stormy coast. Houses on a sheltered coast can be built closer to the sea-level than on an exposed coast as they do not need to have a large *safety margin* for storm surges and waves. As the likely sea-level rise is a large fraction of the safety margin for these houses, the risk of flooding could increase dramatically. For many exposed coasts, the rise in sea-level is much smaller than the storm waves, and so there would be less effects caused by changes in sea-level.

The water table is expected to increase in response to rising sea-levels. In areas with an existing high water table, surface flooding may become more frequent, leading to damage to foundations and walls. Unbalanced or changing ground-water pressure could damage foundations. Sewerage and stormwater systems may also be damaged or rendered inoperable by rising sea-levels (Mosley 1990), possibly causing flooding well inland in low-lying areas. Sea-level rise is potentially a big impact of climate change for vulnerable, low-lying areas of New Zealand.

Wind and ex-tropical cyclones

Recent work suggests a decrease in the frequency of *extra*-tropical (mid-latitude) storm centres passing over the North Island in winter, with a corresponding increase in frequency south of New Zealand. Under climate change arising from rising greenhouse gas concentrations, the change in *frequency* of occurrences of tropical cyclones is uncertain, but there is growing evidence that tropical cyclones will increase in *intensity*. On average a greater percentage of tropical cyclones will be in the higher strength category. It is likely that there will be some higher-intensity ex-tropical cyclones producing larger storm impacts as the 21st century progresses.

Changes in future storminess over New Zealand are still very difficult to quantify. The most robust feature is for poleward movement in storm tracks, which has its most marked effects in the winter season. On the other hand, in the current climate the westerly wind belt and embedded storms tend to move northwards to lie across New Zealand. There is currently low confidence in the projections for changes in strong winds (these vary between little change up to double the frequency of winds above 30 m/s by the 2080s – see MfE 2004b).

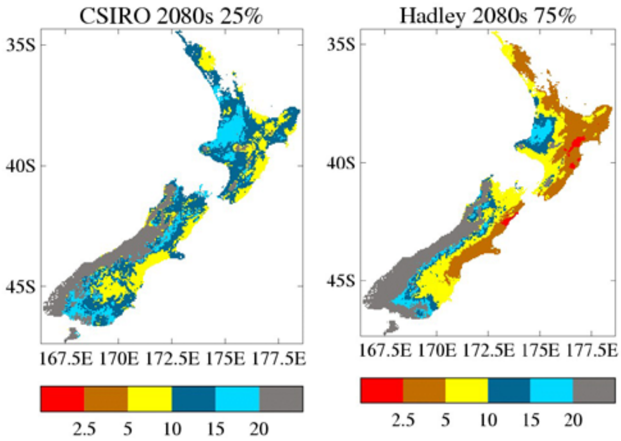
---

[4] See Camilleri (2000) section 6, page for a discussion.

[5] Longer "El-Niño–like" 20–30 year cycles of alternate positive and negative phases that effect the wider Pacific Ocean region, abbreviated as IPO. Since 1998 the IPO has been negative.

Drought and fire

Changes in drought risk are related to a combination of changes in evapo-transpiration and precipitation. Reduced rainfall is likely to increase the risk and severity of drought, particularly if the rain falls less evenly over time (i.e. falls on fewer days). Droughts are expected to become more frequent in all regions considered[6] except near the Hokitika site. A drought sufficiently severe to be ranked as a 1-in-20 year event under the present climate is likely to occur as frequently as every 5–10 years by the 2080s at all sites investigated in this study (except Hokitika).



Corresponding increases in fire risk are also considered likely over much of the country. Days per year of very high or extreme forest fire danger could rise by more than 50% by the end of the century around Christchurch and some other east coast locations.

The predicted increases in temperature, drought conditions and, in particular, wind have implications for the severity of exposure fires and external fire spread and the hazards of airborne embers and increased ember-strike in the urban environment (Bowditch 2006). The impact of climate change on the ignition of fire events that occur *within* occupied buildings may be more dependent on the changes in occupant behaviour (such as less use of active heating but greater use of active cooling) than directly relating to increases in climate conditions.

Recommendations, costs and benefits for physical adaptation

Regions with high climate change exposure from increased risk of bushfire, flood and coastal hazards should be avoided or developed with due consideration of future climate change impacts. Properties vulnerable to coastal erosion may need to be protected using measures to reduce wave energy or possibly move or abandon houses which cannot be economically protected. Territorial Authorities are usually in a better position than individual house owners to take preventative action to protect against flooding by using embankments, river straightening and similar measures. They should adopt a precautionary approach to coastal development and take increased vulnerability of coastal properties into account in modelling of flooding, coastal erosion and sea inundation. Territorial Authorities should also allow for possible sea-level rise in new drainage systems, coastal infrastructure and buffer zones.

The total climate change adaptation cost calculated for the existing housing stock in Bengtsson *et al*. (2007) is approximately $2.3 billion, which represents about 1.3% of the value of the housing stock. The expected benefit by the 2080s is estimated to at least $4 billion in present value dollars.

SOCIAL EFFECTS OF THE IMPACTS OF CLIMATE CHANGE

Background

From the previous section's review of projected climate changes and assessment of building-related impacts it is clear that New Zealand will experience significant changes and impacts. A part-study by Supplejack Ltd (McKernon 2006) was used to identify the social impacts of climate change in relation to housing. This social study was based on a background of local and international research into social change in relation to sustainability, global warming, climate change and a number of related topics such as energy use and waste management.

The social meanings and impacts of climate change can be expected to vary considerably, by community and over time. Empirical studies since the 1960s have detailed the dynamics of change in relation to the social impacts of industrialisation, and consumption in particular. One result is the often-observed tensions between communities that adopt new ways of living, or adapt to changed conditions, and those that do not.

While adaptation to climate change and sustainable behaviour change are increasingly understood through the social sciences, they occur for the public as loosely-framed media and interpersonal communications about,

[6] Auckland, Hamilton, Tauranga, Wellington, Nelson, Christchurch and Hokitika.

for example, bad weather and "being green". Further, they arise conversationally – as topics of discussion – and are not framed as calls to action. The systemic thinking required to grasp large-scale, diffuse, long-term issues such as climate change (or other social issues such as pollution, obesity, smoking-related cancer and drunk driving) is alien to everyday ways of accounting for personal, day-to-day experiences and activities. In recent years a range of international and local studies have shown awareness of climate change has grown rapidly, and with this has come an increase in attitudes favouring action and a concern to find solutions for living. A smaller set of studies have explored the specific meanings given to climate change and the specific behaviours that result: these show the well-known gaps between awareness, useful attitudes, and productive action.[7]

Social impacts on housing

Climate change is only one among a range of major future changes within the housing sector, be they political, social, cultural or economic. The social impacts study employed a scenario-building method to scope likely future societal and housing configurations in order to assess the range of likely social impacts of climate change. Some of the key impacts identified are:

- Social impacts result from climate and social interactions: in combination, house/household resilience and preparedness (including housing adaptations) reduce social impacts, while hazards and house/household vulnerabilities increase them. The interaction between these elements is an indicator of the relative social impact.
- Climate change promotes sector growth – and social tensions: external pressures could have a much greater effect on New Zealand society and its housing sector than anticipated local changes. The relatively benign impacts of climate change in New Zealand are likely to be a key driver of immigration with increasing ethnic diversity and social tensions. Climate and social adaptations are expected to co-evolve.
- An ageing population highlights key social impacts: this population increasingly remaining in their own homes could result in a rise in age-related vulnerabilities within housing. Research indicates other groups may be equally or more vulnerable such as: children; low income households; people with health problems or disabilities; and Maori or Pacific Island communities. Combinations of these variables with older age results in higher vulnerabilities.
- Key forms of resilience are psychological toughness and community cohesion: evidence available suggests older people, while physically more vulnerable, may also be psychologically stronger and more able to cope with crises. In addition, lower income neighbourhoods, immigrant groups and church communities, for example, may have levels of social cohesion that make them more resilient and speed their recovery.
- Social conflict is projected to be a major impact: climate change's social impacts are expected to include significant social disruption and conflict over changing patterns in the value of land in coastal areas, especially where wealthy enclaves suffer significant loss in value.
- Sector dynamics limit adaptation: housing as a business sector, as a householder investment, and as a key site for private consumption is highly vulnerable to external influences such as: global economic factors; the cost of capital; tax on capital gains; insurance sector policy in relation to housing; and local authority regulation. This means the sector's ability to develop a self-determined, coherent response to the social impacts of climate change may be limited.

Recommendations for social adaptation

In order to ameliorate the impacts from climate change housing it is recommended that, as a broader strategic platform, adaptations are oriented to the more vulnerable and socially-excluded groups. As climate change adaptation will progress in combination and in parallel with other social changes and drivers, behaviour change programmes need to make behaviour change easy, attractive, stylish and rewarding. Systemic programmes may need to span areas such as design, building, renovating, financing and insuring as well as ownership/dwelling.

[7] For example, research by EECA shows how difficult it is to get most people to do something as simple as turn out lights or close curtains to save energy – after decades of energy-related campaigns. It follows that adapting to climate change might be a slow process.

We recommend the development of a proactive approach that leverages research – such as this report – towards a coherent and effective sectoral response to climate change. Synergies may be achieved with initiatives that deal with health and other social issues. Housing adaptations can profitably be oriented to raise concern over storms/flooding/erosion/landslips as a threat to the New Zealand way of life, with particular impacts for coastal communities/houses. Loss of iconic housing locations, lifestyles and landscapes is a powerful motivator for public concern.

TOPOLOGY AND CONDITION REVIEW OF THE NATIONAL BUILDING STOCKS

This section summarises the building stock analysis which includes the typology describing the value of the segments, then details of the housing stock including numbers, location and other characteristics that are relevant to adaptation. The reviewed was in part done to identify building types in the building stock with specifically high vulnerability to climate change.

Capital value

Housing is a major capital asset with a replacement value of approximately $150 billion (in 2001 NZ dollars). The value of non-residential buildings is smaller but still significant at approximately $70 billion. This is followed by civil engineering structure (roads, bridges, other transport faculties, water/sewage/waste disposal, Telecom and energy infrastructure) at $50 billion. The focus of this assessment is on houses, and although non-residential buildings are not examined in depth, many of the impacts that apply to housing will also affect non-residential buildings. The inventory of non-residential buildings suggests that climate change adaptation should focus on institutional (hostel, health, education, social/cultural) and commercial (hotel, retail, office/administration) buildings. Industrial-type buildings (warehouse, factory and farm) can largely be ignored for climate change adaptation as they are usually fairly short-lived and simple buildings.

Housing overview

- Total number of dwellings were in 2001 approximately 1,435,000 units, of which stand-alone houses make up 80% and low-rise multi-units 18% of the stock.
- The largest proportions of houses are from the 1950s through to the 1970s and the most multi-unit dwellings are from the 1970s.
- Very few buildings (less than 10%) in New Zealand have more than two-storeys with the majority being single-storey buildings.
- Approximately 70% of houses are in the 100 to 200 m^2 floor area range.
- Concrete floor slab constructions are used in 92% of all new detached housings but only represent 27% of the total stock. Prior to the 1980s most (73%) new houses were constructed on a suspended timber floor.
- For all ages combined the predominant cladding is clay brick for walls, and sheet steel for roofs. Timber wall claddings are predominant for pre-1970 housings. Metal tiles and concrete tile are increasingly popular as roof cladding.
- Ceiling insulation data for Wellington, Auckland and Christchurch reveal that 45–65% of pre-1980 housings have 50 mm or less insulation.

A large number of houses constructed before the 1970s are in need of major maintenance within the next the next few years. Often the option is to replace the component rather than repair, in which case there is opportunity to provide wall insulation and double-glazed windows, provide stronger fixings for roof claddings, and install ceiling insulation for skillion roofs and other hard-to-access roof spaces.

From the analysis of the existing building stock it was noted that approximately 390,000 or 51%[8] of homes built prior to 1978 had not been fitted with any or sufficient insulation (this includes homes that have been retrofitted). Further, based on building stock analysis, we assumed that half of the existing pre-1980s stock can be represented by the small house and the other half by the medium house. The representative house types used are:

- small house – approximately 100 m^2, one-storey, timber weatherboard wall cladding, sheet metal roof cladding and timber floor

[8] Using QVNZ and HCS (Clark et al 2005) data.

- medium house – approximately 150 m^2, one-storey, masonry veneer wall cladding, sheet metal roof cladding and concrete floor.

HOUSE OVERHEATING AND ENERGY CONSUMPTION SIMULATION RESULTS

This section presents the results from thermal building simulations, primarily for the two representative existing building types as identified in the previous section. All of the explored building techniques outlined in the methodology section can provide energy savings and energy efficiency to reduce the risk of overheating.

The multi-variable thermal simulations, based on *medium-low* and *medium-high* climate change scenarios, show that all simulated types of housing in New Zealand will be negatively affected by climate change, in particular energy requirements for cooling (rather than heating as the climate is warming).

Without retrofit or new climate appropriate design, many New Zealand homeowners may find that temperatures during summer within their houses will be increasingly above the accepted comfort range (assumed 18–25ºC). However, the simulations showed that comfort temperatures can be achieved with significant energy savings through each or combinations of: window shading (particularly on the northern sides); upgrading to double-glazing or better; upgrading to base insulation or better; and use of natural ventilation rather than use of mechanical cooling i.e. air-conditioning.

Incorporating at least double-glazing into new housing and retrofitting into existing houses (with single-glazing) can significantly reduce energy consumption in New Zealand homes. The modelled step to lowE and argon-filled double-glazed windows does give additional energy savings, but of lower magnitude and at a higher material cost.

Window shadings can also play an important part in cooling interior spaces as the climate around New Zealand heats. Although on average this is expected to be only a few degrees, there will be a much higher demand for energy throughout the country. The use of window shadings on the sunnier sides especially will lower cooling loads.

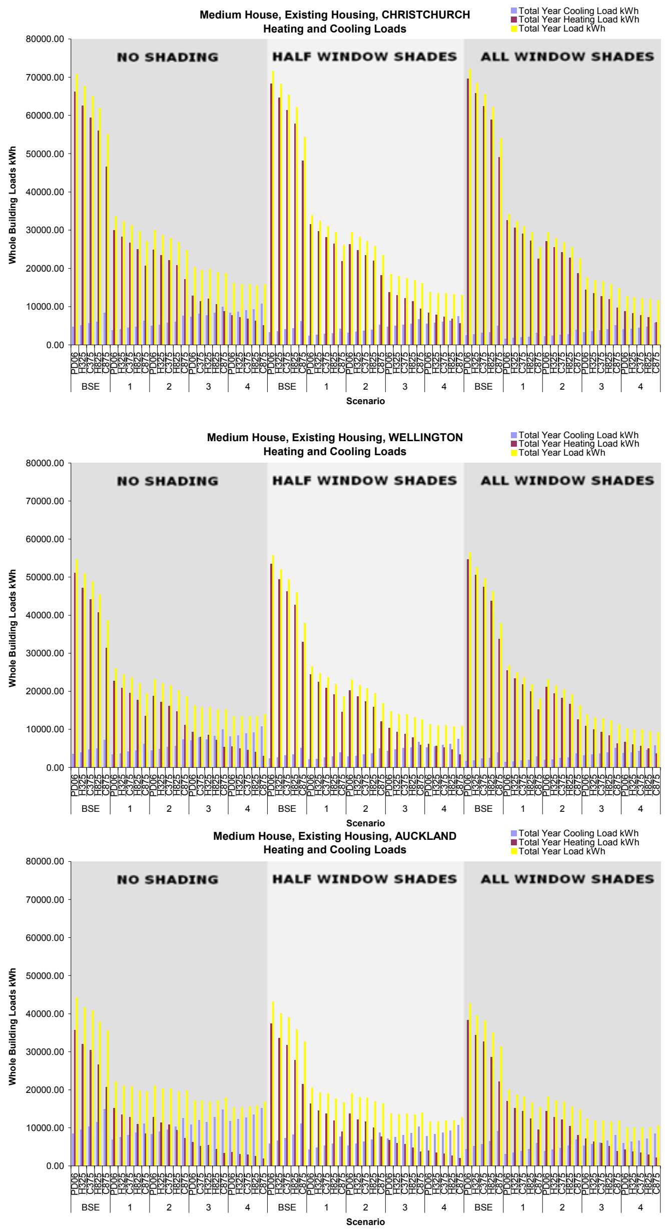


Figure 2: *Sample of simulation output for cooling and heating energy consumption for five climate scenarios, three shading options and five insulation levels (No insulation, single glazing = BSE; Ceiling Insulation only, Double Glazing = 1; Ceiling and Floor Insulation only, Double Glazing = 2; Ceiling, Wall, Floor Insulation, Double Glazing = 3; and Best Ceiling, Wall and Floor Insulation, Double glazing with LowE argon filled, thermal break aluminium frame = 4).*

Insulation has a significant impact on year-round energy consumption. The primary benefit is from reduced warming costs, and not so important for cooling energy demand.

Finally, homeowners benefit from maximising the use of natural ventilation before the use of mechanical cooling i.e. air-conditioning. This has been shown to keep average yearly temperatures within the acceptable comfort range and lower cooling energy requirements. Mechanical cooling would best be used as a fall-back in extreme temperatures.

In the following section the economic costs and benefits are analysed in order to explore economically optimal solutions for the two representative existing building types as identified in the previous section.

COSTS AND BENEFITS FROM ADAPTING TO TEMPERATURE INCREASE

The simulation results from the previous section were used to compare net benefits of selected adaptation option. The economic modelling suggests that insulation retrofitting of the existing housing stock should be done as soon as possible since the Net Present Values (NPVs) decrease over time, so the longer the delay in retrofitting, the lower the lifetime benefit (resulting in a lower NPV).

When retrofitting existing housing stock, if feasible, it is recommended that all homes have ceiling, wall and floor insulation with no awnings installed. None of the models indicate that it is best to install awnings. This is not because they do not provide significant energy savings, but because of the cost of installing them. While awnings provide good sun protection and energy savings they are quite expensive ($4,000 to $10,000 per house depending on size).

Double-glazing significantly reduces energy consumption, but in no situation modelled does it provide a greater NPV than single-glazing. Still, it is recommended that a double-glazing retrofit be considered in all regions due to superior energy performance and demonstrated strong positive NPVs. Overall it was shown that it is financially better to have single-glazing in the warmer climates if you have a small house, but if you live in a cooler climate or have a bigger house you should install double-glazing. Due to cost, in no case is it financially beneficial to install double-glazed argon-filled windows, even though these provide the greatest insulation and significant energy savings.

Due to resource constraints a wide range of situations or house types were not modelled, but rather typical house sizes by three locations to represent a sizable proportion of the stock. Ideally thousands of different homes should have been modelled and the results then averaged. Our analysis does not attempt to fine tune optimal levels of insulation; the goal is to indicate broad trends over time.

Different discount and energy price escalation rates were also modelled with the results as follows. As the discount rate increases the present values decrease, and the difference between the lowest and highest insulation present values gets smaller. The NPVs also decrease but the results (which insulation provides the highest NPV) are still the same. The opposite happens when the discount rate decreases. As the energy price escalation rises (energy prices increase at a higher rate), all the present values will go up. The present values of retrofitting the lower insulation houses increase by more than the higher insulation homes since lower insulated houses would use more electricity and therefore the present value of increased insulation goes up. With higher energy price rises the economics improve for better insulated houses. But the models still show that the economically optimal level of insulation remains the same.

CONCLUSION

Robust scientific projections show that climate change will significantly affect the New Zealand built environment. Major impacts are expected from inland and coastal flooding, building overheating, and increased occurrence of droughts and fire risk in the eastern parts of the country. It is essential that the climate-change planning process starts now, given the longevity of housing developments and infrastructure in increasingly at-risk communities. Costs to homeowners and the national economy, and social disruption and tension, can all be avoided by developing and retrofitting with consideration of increasing climate exposure and vulnerability.

The inventory of the building stock suggests that climate change adaptation should focus on residential, institutional and commercial buildings. Industrial-type buildings can largely be ignored for climate change adaptation as they are usually fairly short-lived and simple buildings.

Social impacts from climate change will be intertwined with other major social changes. A more detailed analysis of social impacts suggests these will be powerfully shaped by dynamics of social inclusion and exclusion. The prospect of increased damage means many communities may need to re-assess their futures. The social research, involving a broad range of experts from outside the building sector, warns that significant social disruption and conflict over changes in the value of land in coastal areas will occur, especially where wealthy enclaves suffer significant loss in value. The relatively mild impacts of climate change in New Zealand compared to other countries are likely to be a key driver of immigration. As climate change drives immigration, it also indirectly drives growth in the housing sector.

Building overheating from increase in frequency and severity of summer temperature extremes can be avoided by passive design and retrofit. Thermal simulations show that comfortable indoor summer temperatures can be maintained in all climate change scenarios explored by adapting to overheating with window shading and natural ventilation. The simulations also show significant year-round energy savings in all buildings using double-glazing or high-performance glazing, and improved ceiling and wall insulation.

To maximise economic benefits insulation retrofitting of the existing housing stock should be done as soon as possible. Thermal insulation comes out the most favourable as currently we under-insulate our homes by a huge amount. The second most favourable retrofit is upgrade from single-glazing to double-glazing. While awnings provide good sun protection, in no situation do they provide a greater NPV than having no awnings. It is therefore not recommended that awnings be installed if the primary objective is lower NPV.

Summary

In this study, the sustainability of office buildings in Japan is assessed via the indicator "environmental efficiency related to CO_2 reduction". First, the authors have developed a long-term prediction model for CO_2 emissions associated with office buildings from 1990 through 2050. The prediction via this model shows a potential 70% reduction of CO_2 emissions associated with office buildings from 1990 levels by 2050.In the second half of this report, the prediction model is extended to assess the environmental quality for office buildings by using CASBEE (Comprehensive Assessment System for Building Environmental Efficiency). As a result, it is possible to satisfy needs for both great reduction of CO_2 emissions and improvement of the level of environmental quality. The development of this model has meaning in post-Kyoto Protocol discussion.

1. Introduction

As an international trend regarding the issue of global warming, there is a high possibility that a 70% reduction of greenhouse gases from 1990 levels will be required in Japan by 2050. However the CO_2 emissions associated with office buildings have expanded rapidly in recent years in Japan, thus reduction of CO_2 emissions is an urgent issue. In this study, the authors have developed a long-term prediction model for CO_2 emissions associated with office buildings from 1990 through 2050.On the other hand, in considering sustainability, it is important to assess not only environmental load but also environmental quality. In the second half of this report, the prediction model is extended to assess the environmental quality for office buildings by using CASBEE. We report on the transition on "environmental efficiency related to CO_2 reduction" via the extended model.

2. Prediction model for environmental efficiency related to CO_2 reduction

Figure 1 shows the outline of the prediction model. The prediction model consists of three sub-models.

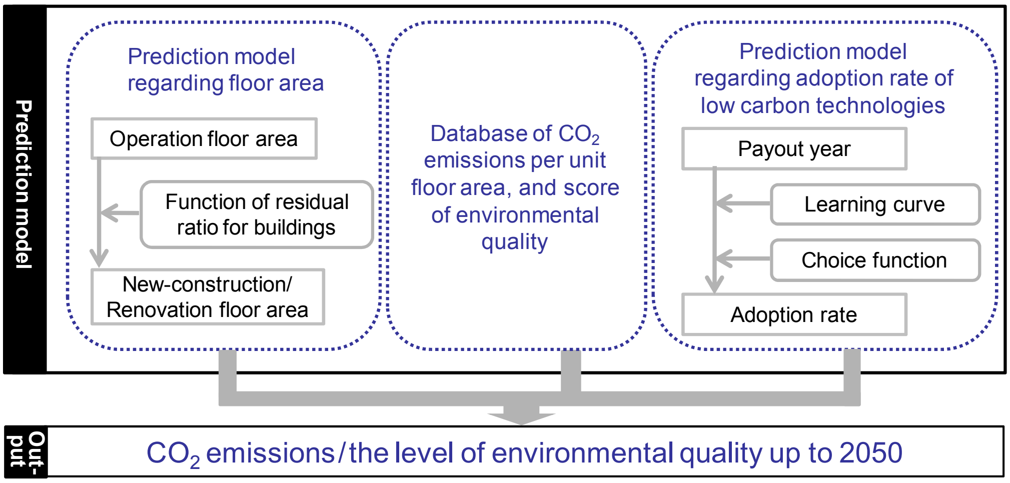

Figure 1 Prediction model for environmental efficiency related to CO_2 reduction

1) Prediction model regarding floor area: This model predicts each life stage floor area (operation/new-construction/renovation) of office buildings up to 2050.

2) Database of CO_2 emissions per unit floor, and score of environmental quality: This database concerns CO_2 emission per unit floor [kWh/m^2• year] and the environmental quality score assessed by CASBEE (Comprehensive Assessment System for Building Environmental Efficiency).

3) Prediction model regarding adoption rate of low carbon technologies: This model predicts the adoption rate of each low carbon technology, based on economic rationality.

2.1 Prediction model regarding floor area

2.1.1 Prediction of operating floor area up to 2050

In this study, operating floor area is predicted based on the estimation of future population and GDP data. Figure 2 shows the results predicted by each future scenario (urban centralization scenario: scenario A, regional dispersion scenario: scenario B).

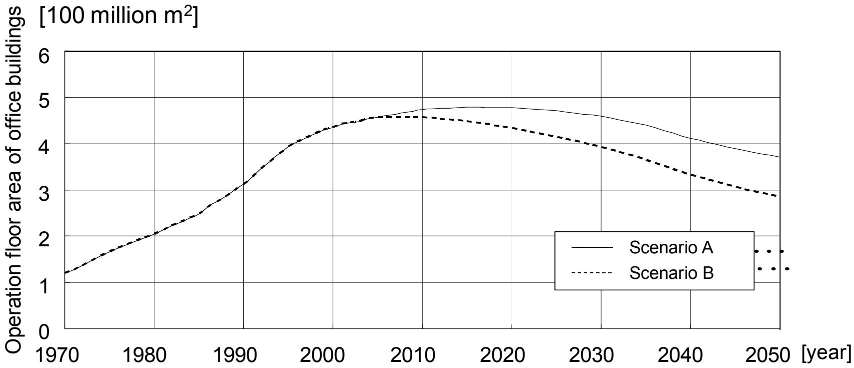

Figure 2 Prediction results of operating floor area

2.1.2 Prediction of new-construction/renovation floor area up to 2050

The new construction floor area is estimated based on the statistical data of construction up to 2005. Or later, new construction floor area is predicted that the attrition floor area which conform with residual ratio function and the demand floor area are balanced. The renovation floor area is predicted by assuming that renovation work is done in a 20-year cycle following construction.

2.2 Database of CO_2 emission per unit floor, and score of environmental quality

Figure 3 shows the flow of compiling the database of CO_2 emission per unit floor, and score of environmental quality.

a) Establishment of standard office building model

b) Selection of low carbon technologies

c) Selection of calculation/assessment tool

d) Calculation/Assessment on CO_2 emissions per unit floor area/environmental quality score

Figure 3 Flow of compiling the database

2.2.1 Calculation method for CO_2 emissions per unit floor area

a) Establishment of standard office building model
Different sized office buildings differ in energy consumption mechanisms or adopted low carbon technologies. In this study, three sizes of standard office building model are established.

b) Selection of low carbon technologies
Efficient low carbon technologies are selected based on “Guideline on environmental conservation for government offices” (table 1).

c) Selection of calculation tool for CO_2 emissions
CO_2 emissions associated with new construction or renovation are calculated by “The life cycle assessment tool for buildings”. “FACES” (Forecast of Air-conditioning System’s Energy, Environmental, and Economic Performance by Simulation) and “CEC (Co-efficient of Energy Consumption[*1]) Guideline” are used to calculate CO_2 emissions associated with operation.

d) Calculation results on CO_2 emissions per unit floor area
Calculation results are compiled in a discrete database by size, climate area, life stage, and low carbon technology. Figure 4 shows an example of calculation result in Tokyo.

Table 1 Low carbon technologies

Low carbon technologies		Building size	Performance		
			Standard	Provision when new constructed	Provision when renovated
Long-life	Leeway of story height	All	3.8m	4m	
	Leeway of ceiling height		2.6m	2.8m	
	Leeway of floor load		2900N/m^2	4500N/m^2	
Skin	Thermal insulation of	All	PAL*[1]: 300~320	PAL: 225~240	←
Heat source	High efficiency heat source	Small/ Medium	COP: 2.5	Electric engine heat pump (~2020) COP:4.5 (2021~) COP:6.0	←
		Large	COP: 0.9	Gas absorption refrigerator Replace to high performance heat	(~2020) COP:1.2 (2021~) COP:1.6
	Ice heat storage	Large	No	Yes	
	Total heat exchanger	All	No	Yes	←
Heat Fan	Control method	Large	Constant Air Volume	Variable Air Volume	←
Air conditioning	Control of outdoor air	All	No	Yes	←
	Air conditioning system	Large	Standard	Task & ambient	←
Light	High efficiency light	ALL	Standard	(~2020) Energy	←
			Standard	(2021~) Energy	
	Infant illuminance		No	Yes	←

Elevator	Control method	ALL	Alternate current	VVVF*[2]	←

2.2.2 Calculation method for environmental quality score

Flow a) and b) is same as the calculation method for CO_2 emissions per unit floor area.

c) The assessment tool of score of environmental quality

The environmental quality score is assessed by "CASBEE-New Construction". The CASBEE assessment items of environmental quality are categorized by three items, "Q-1: Indoor environmental quality", "Q-2: Service performance", "Q-3:Outdoor environment (inside the compound)". In this study, the assessment coverage is limited to Q-1 and Q-2 because they are related to CO_2 emissions, and Q-3 is not assessed because it is not related to CO_2 emissions.

d) Results of environmental quality score calculation

Figure 5 shows the results of environmental quality score calculation. The reasons for the improvement of the Q-1 score by the adoption of low carbon technologies are improvement of indoor thermal comfort by the thermal insulation of the skin and improvement of indoor air quality by the control of outdoor air installation. On the other hand, the reasons for the improvement of the Q-2 score by the adoption of low carbon technologies are improvement of modifiability by the securement ceiling leeway and improvement of earthquake protection by the securement of endurance. In this way, energy saving technologies are related to Q-1, and long-lived technologies are related to Q-2. In addition, Table2 shows the detailed relationship between Q-1, Q-2 and each low carbon technology.

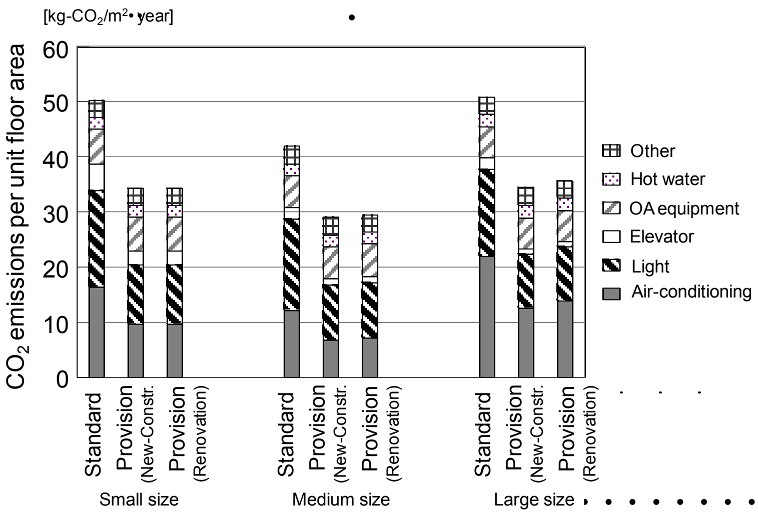

Figure 4 CO_2 emissions per unit floor area in Tokyo

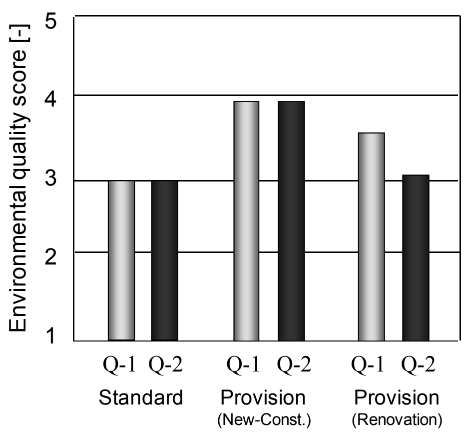

Figure 5 Environmental quality score

2.3 Prediction model regarding adoption rate of low carbon technologies

The adoption rate of each low carbon technology is predicted based on the payout year and the amount of cumulative production. Figure 6 shows the prediction results of the adoption rate.

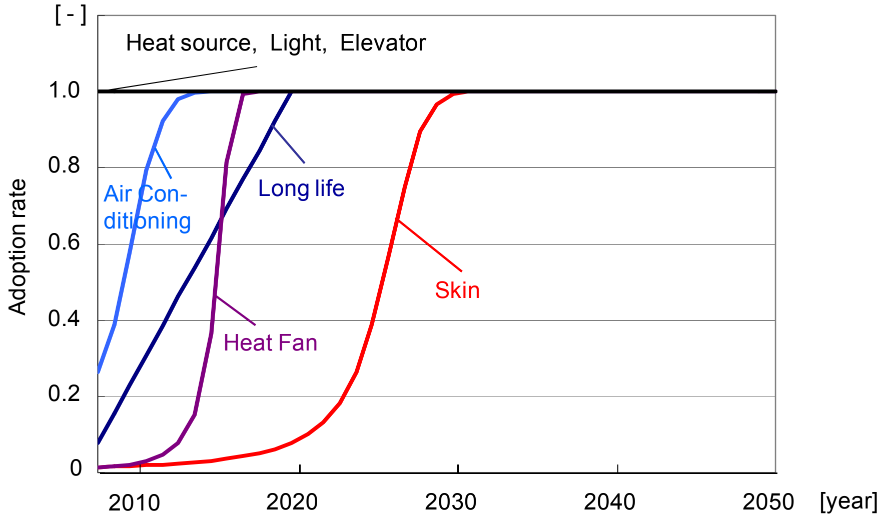

Figure 6 Prediction results of the adoption rate

3. Assumption for the prediction

3.1 Formula for the estimation of CO_2 emissions and the level of environmental quality

CO_2 emissions and the level of environmental quality are calculated with formulas (1), (2).

3.2 Definitional formula for environmental efficiency related to CO_2 reduction

In this study, environmental efficiency related to CO_2 reduction is defined with formula (3). This definitional formula is the indicator for assessing the improvement of environmental efficiency by the adoption of low carbon technologies.

CO_2 emissions associated with office buildings in Japan [kg-CO_2/year]

$$= \left\{ \sum_{size} \sum_{area} \sum_{performance} (CO_2 \text{ emissions per unit floor}_{(size,\ area,\ performance)}\ [\text{kg-}CO_2/\text{m}^2 \cdot \text{year}] \cdot \text{floor area}_{(size,\ area,\ performance)}\ [\text{m}^2]) \right\} \quad (1)$$

Level of environmental quality on office buildings in Japan [-]

$$= \left\{ \sum_{size} \sum_{performance} (\text{Environmental quality score}_{(size,\ performance)}\ [-] \cdot \text{floor area}_{(size,\ performance)}\ [\text{m}^2] \right\} / \text{Total floor area}\ [\text{m}^2] \quad (2)$$

Environmental efficiency related to CO_2 reduction [year/kg-CO_2]

$$= \frac{\text{Level of environmental efficiency on office buildings in Japan [-]}}{CO_2 \text{ emissions associated with office buildings in Japan [kg-}CO_2\text{/year]}} \quad (3)$$

3.3 Assumption for the prediction of operation floor area

For prediction of the operation floor area, adoption of the intermediate value between scenario A (urban centralization society) and scenario B (regional dispersion society) is assumed.

3.4 Assumption for the prediction of electricity CO_2 emission rate

Assumption for electricity CO_2 emission rate is estimated based on the actual achievement value up to 2005. For later dates, two scenarios are assumed for electricity CO_2 emission rate; one is to remain the same as 2005(0.425kg-CO_2/kWh), and the other is to conform to the "Ultralong-term energy technology roadmap" • 2030: 0.18kg-CO_2/kWh, 2050:0.12kg-CO_2/kWh• :

4. Results

"No provision case" means that no low carbon technologies are adopted, and "provision case" means that low carbon technologies are adopted in accordance with the adoption rate.

4.1 Prediction results for CO_2 emissions associated with office buildings

Figures 7 and 8 show the prediction results for CO_2 emissions. Assumption for the prediction of electricity CO_2 emission rate of Figure 7 is to remain the same as 2005, and Figure 8 is to conform to the "Ultralong-term energy technology roadmap". It is shown that CO_2 emissions in 2050 can be reduced by 65% in comparison to 1990 in the case of provision. On the other hand, in the case of no provision, CO_2 emissions in 2050 decreased by 42%. This is why mass construction in 1990 causes the decrement of new construction in following years. In addition, it is shown that CO_2 emissions in 2050 can be reduced by a maximum of 78% if the electricity CO_2 emission rate is improved (figure 8).

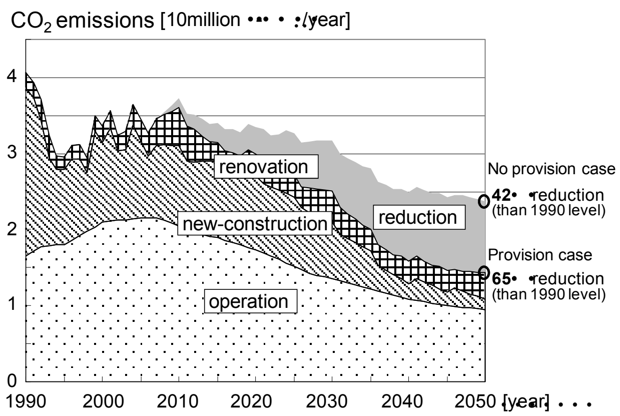

Figure 7 Results for CO_2 emissions (electricity CO_2 emission rate: fixed)

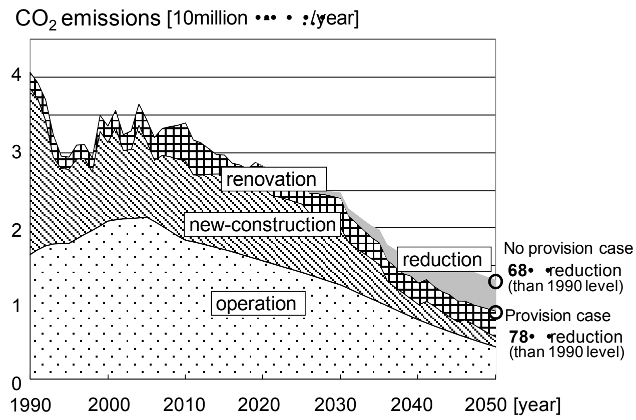

Figure 8 Results for CO_2 emissions (electricity CO_2 emission rate: improvement)

4.2 Prediction results for the level of environmental quality

Figure 9 shows the prediction results for the level of environmental quality*3. It is shown that the level of environmental quality in 2050 has improved 42% in comparison to 1990 in the provision case. Low carbon technologies are effective for not only CO_2 reduction, but also improvement of the level of environmental quality. On the other hand, the level of environmental quality has improved 4% in the no provision case. This is because the increment of floor area per capita causes the improvement of functionality.

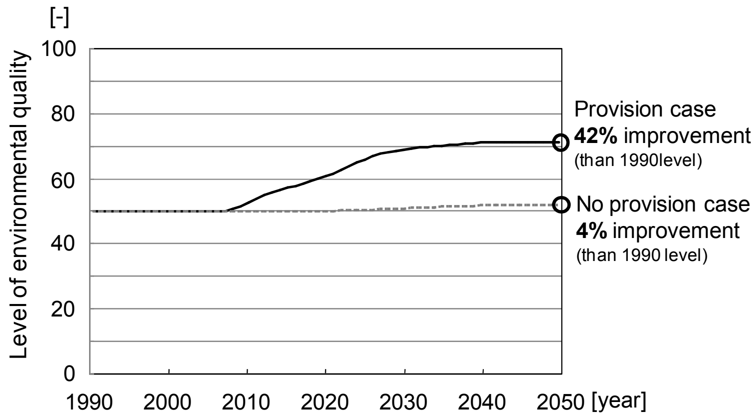

Figure 9 Result for the level of environmental quality

4.3 Transition on environmental efficiency related to CO_2 Reduction

Figure 10 shows the transition of environmental efficiency related to CO_2 Reduction. The vertical axis reflects the level of environmental quality, and the horizontal axis reflects CO_2 emissions. The Gray zone satisfies both CO_2 reduction target (70% reduction in 2050 in comparison to 1990) and improvement of the level of environmental quality. It is shown that it is possible to both achieve the CO_2 reduction target and improve the level of environmental quality by the adoption of low carbon technologies and improvement of the electricity CO_2 emission rate. In addition, the gradient of the graph depicts the environmental efficiency related to CO_2 reduction. It is shown that environmental efficiency improves 3.7~5.9 times in comparison to 1990 in the provision case.

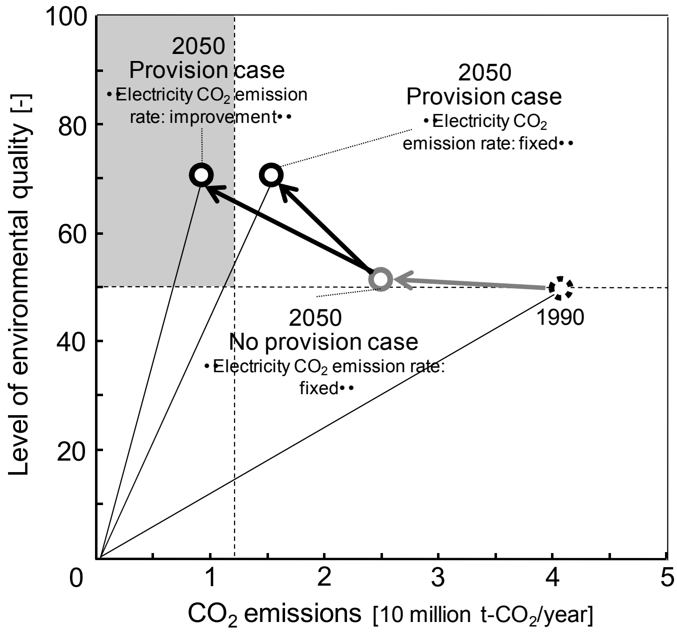

Figure 10 Transition on environmental efficiency related to CO_2 Reduction

5. Conclusion

1) We suggested a model of predicting environmental efficiency relates to CO_2 reduction for office buildings.

2) Adopting low carbon technologies are effective not only CO_2 reduction but also improvement of the environmental efficiency level.

3) It is shown that the possibility to satisfy both of, achievement of the CO_2 reduction target and improvement of the level of environmental quality.

6. Note

*1) PAL(Perimeter Annual Load) and CEC(Coefficient of energy conservation) are energy conservation standard of buildings in Japan. PAL is intended for building skin(wall, window, roof), and CEC is intended for air conditioning, ventilation, lighting, hot water supply, elevator.

*2) VVVF(Variable Voltage Variable Frequency) is a system for controlling the rotational speed of an alternating current (AC) electric motor by controlling the frequency of the electrical power supplied to the motor.

*3) The level of environmental quality is calculated following formula which is used in CASBEE.

$$\text{The level of environmental quality[-]} = \left\{ \left(\frac{S_{Q1} \times 0.4 + S_{Q2} \times 0.3}{0.7} \right) - 1 \right\} \times 25 \qquad S_{Q1} \text{ : Score of Q-1, } \; S_{Q2} \text{ : Score of Q-2}$$

RETROFITTING MELBOURNE'S OFFICE BUILDINGS – THE SZENCORP EXPERIENCE

Mark LISTER BEc GradCertBus MSocSci(EnvP)[1]

[1] Szencorp Sustainable Development – 40 Albert Road, South Melbourne 3205, Australia, mark.lister@szencorp.net

Keywords: retrofit, refurbishment, office, building tune-up, upgrade, performance, Tianjin, India

Summary

This presentation outlines the substantial work on sustainable buildings undertaken by Szencorp, an Australian company specialising in the upgrade of existing commercial building stock. Its core businesses sit across property development, energy and water efficiency and clean energy technologies.

During 2004 and 2005, Szencorp became well known in the sustainable property sector for its world-leading achievements at 40 Alert Road in South Melbourne. With the maximum ratings scores for both building design and audited performance, 40 Albert Road is among Australia's greenest office buildings, setting the standards for sustainability in Australian commercial buildings. 40 Albert Road is a renovation of a 20-year-old, low-performing building. The project experience is therefore useful for the vast majority of commercial properties, and sets an example to follow. Szencorp's commitment to sharing its knowledge has created enormous interest and growth in its business activities and efforts as a sustainability advocate.

Exciting new opportunities are now opening up for Szencorp to lead the way in the delivery of other world leading sustainability retrofits both overseas and more locally. For example Szencorp is in the process of retrofitting another commercial office building to achieve maximum ratings levels. Szen2, a 2400m2 building at 124 Camberwell Road East Hawthorn, is being retrofitted in conjunction with a range of partners and building on the successes, lessons and expertise gained on earlier projects. This and other landmark projects will not only add significantly to Melbourne's and Australia's sustainable building credentials, but will prove that building refurbishments to world-leading levels provide commercial returns worthy of attracting large scale investor interest.

1. Szencorp

Szencorp has built a strong reputation as a company that walks the talk of sustainability. From a history based in property development, lighting and electrical equipment, it has grown and expanded to become a full-service engineering and property company, with expertise in water and energy efficiency, bioenergy generation and sustainable buildings. Its activities are based on a business model of "what's good for the environment is good for both the economy and enterprise value". Employing approximately 80 staff, it has offices in all states of Australia and partners in Malaysia and Thailand.

Szencorp has undertaken a range of projects and initiatives in Australia, which have created both substantial greenhouse abatement and water savings, as well as engaging the community and contributing strongly to public awareness about the need for sustainable behaviour change. Its flagship headquarters at 40 Albert Road, South Melbourne is one of Australia's best known green buildings.

The company's philosophy holds that existing building retrofitting must be the clear focus of any mitigation efforts. New buildings make up a small percentage of overall building emissions and policies that target them such as incremental improvements to building codes and standards will not provide the scale of momentum required for implementation of energy efficiency.

2. The 40 Albert Road Project

2.1 Background

Group principal Peter Szental has been a long-time advocate of energy and water efficiency in commercial buildings. His passion and enthusiasm for demonstrating leadership by "walking the talk" underpins the vision for 40 Albert Road. Relocating Szencorp's headquarters was therefore an opportunity to demonstrate sustainable development principles and practices in action.

From the outset, the project aimed for the ambitious up-front goals of zero mains water usage, grid energy usage, waste and greenhouse emissions. A detailed design options matrix was developed to look at the many potential technologies which the building might employ to help achieve these goals and ensure economic, social and environmental outcomes were considered.

An innovative partnership was formed between Szencorp, engineers and ESD consultants Connell Wagner and SJB Architects to deliver the project. The project partnership was assisted by formal plans to ensure that sustainability principles and practices were fully integrated into project delivery.

2.2 Project parameters

2.2.1 Energy

The Managed Lighting System (MLS) control system is a network of motion sensors that control lighting in offices in response to occupancy and dims lighting to compensate for natural lighting levels or lamp degradation. Energy efficiency is achieved by maintaining lighting and mechanical heating and cooling only in zones that are occupied. Lighting will switch on automatically upon entering a zone and switch off when the zone is vacated (after a delay). This functionality is designed to be adjustable to support flexibility. Similarly, the zoning can be adjusted to suit the office environment. The ventilation system is mixed mode, with natural ventilation supplied by open windows and mechanical ventilation supplied by ceiling mounted fan coil units that have a damper to close off outside air. The roof-mounted gas engine driven air conditioning units use internal combustion engine technology, rather than electric motor conditioning units, which provides several benefits. First, avoiding grid electricity use results in a lower overall contribution to global climate change emissions. Secondly, it reduces demand on the electricity grid, which cuts down on the need to upgrade the infrastructure. Thirdly, it cuts electricity demand at peak periods, thus reducing peak tariff usage.

The building also trialled the first ceramic fuel cell in commercial operation in Australia. Fuel cells use chemical reactions rather than combustion reactions to provide electrical power. Reactants are continually fed into the process to provide ongoing power output. The waste heat generated during power production has also been used to provide the building with hot water. This hot water system is supplemented by a solar hot water panel with gas boost, resulting in the building saving an estimated 12 MWh per annum by utilising solar energy to produce the majority of the domestic hot water. A 1 MWh per annum amorphous PV array plus a 4.8 MWh per annum crystalline Origin PV array, both grid connected, provides additional electricity to the building.

2.2.2 Water

Water consumption is minimised at each end use point by using the latest in controlled flow showerheads and taps throughout, some of them sensor activated only. Toilets are an award winning dual flush design using only 4.5/3 litres per flush. Urinals are waterless.

Lightly polluted water gathered from hand basins and showers (greywater) is collected, treated and reused for toilet flushing. This is complemented with a rainwater harvesting system providing 4,400 litres of rainwater storage, estimated to be enough for 3 weeks of normal flushing.

2.2.3 Indoor Environment Quality

Thermal comfort is achieved by combining natural ventilation with mechanical cooling and heating. Mechanically operated opening windows and dampers allow fresh air in and expel used air out. Natural ventilation is automated and is optimised according to inside and outside environmental conditions. Mechanical cooling or heating is supplied by ceiling mounted fan coil units. A DryKor dry conditioning unit dries and cools the office space simultaneously, using a process of natural desiccant absorption of water vapour from the air. This technology is non-toxic and non-hazardous, and the humidity is ducted outdoors, eliminating the need for condensate pumps, pipes and drainage system. This addresses "Sick Building Syndrome" problems associated with poor indoor air quality as the process removes up to 94% of microorganisms, as well 77% of particles greater than 5 microns.

Natural light is maximised by floor-to-ceiling high-performance doubleglazing and is supplemented by the atrium and glass in the central stairwell. Further, there are skylights above the boardroom. Daylight modelling shows that there will be significant natural light at desk level across one third of the office space. This will also reduce energy use on artificial lighting, since the automated lighting system dims whenever and wherever daylight levels permit, to optimise overall light levels. For the majority of the time, artificial lighting is dimmed up to eight metres away from the windows.

2.2.4 Materials

All new materials introduced into the building have been chosen with office air quality in mind. Volatile organic compounds (VOCs) emission levels are minimised in the carpets, adhesives and sealants used, and 95% of painted surfaces use low VOC paints. All composite wood used in the furniture is low in formaldehyde emissions, and a dedicated exhaust riser is provided to remove emissions from printers and photocopiers.

Most of the reinforced concrete structure and 88% of the original façade has been retained. The additional concrete required uses recycled aggregate as well as incorporating industrial waste. The material specification for the refurbishment timber (using the good wood guide) and structural concrete incorporates strict sustainability criteria.

2.2.5 Waste

An environmental management plan ensures that at least 80% of the waste used in the construction of the building is collected and sorted for recycling. During operation, onsite recycling facilities are provided to recycle paper, co-mingled plastic and glass. There are recycling facilities for organic waste and toner cartridges.

2.2.6 Education and Information

The innovations at 40 Albert Road have been extensively demonstrated to the building development and management community, and the wider public. Controlled free access to the building and its systems have been provided for educational and commercial purposes. The roof layout provides access to the PV arrays, the gas engine AC units, the DryKor de-humidifier and the ceramic fuel cell. As well, there is a comprehensive weather station and 59 individual meters monitoring the various building systems.

As a live marketing demonstration of Szencorp's business capabilities to potential clients, the publicity and marketing boost to the company has been enormous. Substantial business opportunities continue to flow as a result. Commercialisation of a range of technologies has also provided Szencorp with a business advantage by securing rights to market these Australian and international technologies through its energy and water performance contracting businesses.

2.2.7 Measuring performance

As with any investment, it is returns generated and real results that drive investment in green buildings. Szencorp believes that credible, ongoing information performance results are essential to demonstrate which green building theories work in practice and what conditions are required to make them economically viable. This is especially so because there is a lot of green building 'hype' in the market – and unsubstantiated claims, rather than growing the industry, add caution to the market's embrace of green building practices.

Monitoring, verification and public reporting is the key to accountability. The Szencorp Building has one of the most advanced and transparent building performance monitoring systems in Australia, which is publicly available at www.ourgreenoffice.com, and enables any interested party to monitor real-time building performance. Company accountability is also the key principle behind the release of public reports on building performance.

Szencorp company Energy Conservation Systems have provided many of the energy conservation measures under an Energy Performance Contract which guarantees outcomes and eliminates technical and financial risks.

2.3 Results

Table 1 40 Albert Road performance results

		Design Expectations*	First Year Results	Second Year Results
Annual Electricity Consumption (MWh)		97	92	69
Annual Gas Consumption (GJ)		321	441	308
Annual Water Consumption (kL)		157	121	76
ABGR result	Stars	5.31	5.05	5.44
	kgCO2/m2/annum	153	167	146
NABERS Water result	Stars	5.61	5.15	5.71
	kL/m2/annunm	0.167	0.299	0.101

** Connell Wagner ABGR & Energy Report, 8th Reference 6103.01 Revision 5 - March 2005*

*** Based on energy data obtained from on-site metering system and retailer supplied data*

2.4 Lessons

Performance results overall have been excellent, although some areas require further focus to achieve the intended performance. Analysing what works and what needs attention has given Szencorp a number of fresh insights into building green.

It is relevant to note that, while much has been learnt about building performance, many lessons could not be extracted because the available data was not yet detailed enough, even with the enormous emphasis placed on metering and system performance. This points to the importance of further knowledge about building management systems, monitoring and verification.

Individual technologies can provide both positives and negatives for overall environmental performance. For example fresh air ventilation provides low-energy cooling but, as we have found, it also affects indoor air quality. Choosing the right balance between low energy and clean indoor air may be a decision that can only be made on case-by-case basis in close consultation with the building owner and intended occupants.

The Building relies on a chain of many mechanical systems for successful operation. Adding to this complexity are the many variables that affect how the mechanical systems should operate, including temperature (indoor and out), solar gains, wind speed and direction, occupancy, time of day, humidity. Even though systems and related controls were specified in detail, commissioned and then independently checked for correct operation, some sequences of operation through the year were less than optimal.

Green building projects generally pay more attention to occupants, so better productivity is often expected or assumed. However, occupants may also feel pressure from this expectation, at the same time experiencing changes to individual control that influence their satisfaction with a new office.

The balance between occupant comfort and systems efficiency needs careful management. On this point Szencorp Group staff had a relatively high “forgiveness level”, given that green buildings are part of the company’s core business. However adjustment and understanding on behalf of tenants is crucial for successful implementation and if this process is not handled effectively, tenants have long memories regarding instances where they experience discomfort in occupancy.

All of this points to the fact that a twelve month post-occupancy commissioning period, incorporating a rolling review of the performance of all major systems, is essential to ensuring a green building achieves its potential.

There were many alterations and adjustments made to the building management system from opening to fine-tune performance and improve operating characteristics. The Building won’t be a static facility - tenants may change and maintenance actions can introduce new characteristics, so the need for performance review is ongoing. Automating the process by building analytical “smarts” into the building management and metering systems will be a key strategy.

Without this commitment to ongoing monitoring and verification, it is unlikely that the Szencorp Building or any green building would perform, over time, to its design intent.

3. Szen2 at 124 Camberwell Road

Szencorp has purchased a two-storey 1342m2 office block at 124 Camberwell Road, East Hawthorn with the aim of turning it into another world leadership retrofit project. Re-design of the existing 1980s building will involve a range of energy, water and environmental design measures to substantially reduce the building’s environmental footprint and financial outgoings. This new project will put into practice all of the lessons learned by the team during the course of the successful 40 Albert Road project.

The application of this team’s proven experience will allow the project to deliver a commercial rate of return, proving conclusively that investments in sustainability do not need to come at the expense of good financial sense. This integration of financial viability and world-leading environmental standards is expected to create a new financial benchmark for sustainability in the built environment.

3.1 Building Elements

Atrium: an atrium is envisaged at the front of the building. It will create a new identity and provide the opportunity for the new office to be branded as a high end, environmentally sensitive workplace. A new café/restaurant is proposed to be located within the atrium to enliven both the entry and the street life.

Façade: a new façade will be ‘clipped’ onto existing northern building façade, and designed to reduce summer heat loads.

Tenancy Floors: floors will be redesigned to connect the existing toilets & stairs with the new lift, stair & services to create a single core. A central corridor spine is provided to accommodate a multiple tenancy size/type. There is an option to exhibit some tanks & services as feature for building users, and to provide a shared meeting room.

Basement: the basement will be reconfigured to relocate the existing stair from its current central location to the southern side of existing floor plate. New bicycle parking and showering facilities will be provided, and new areas set aside for grey water treatment, rain water storage and waste processing.

NLA Extension: an extension will be built at the rear of existing building, providing additional NLA of 355 m^2. A new outdoor deck area will be located on the same level as the Ground Floor offices to take advantage of view towards adjacent park.

3.2 Building Features recognised in achievement of 6-star Green Star

Indoor Environment Quality: increased air flow rates; carbon dioxide sensors, shading to reduce heat input in summer and glare year round, daylighting on top floor

Energy: Energy efficient VRV air conditioning system, energy efficient light fittings, integrated occupancy controls, solar hot water, appropriate zoning, extensive metering, peak energy reduction facility

Transport: provision of bike parking for staff and visitors with associated showers and lockers, spaces for energy efficient small cars

Water: High water efficiency fittings and fixtures, waterless urinals, grey water recycling, rain water storage and reuse, extensive metering, water efficient landscaping

Materials: a complete re-use of the existing building, low volatile organic compound (VOC) finishes and materials, minimal use of PVC and materials containing formaldehyde, areas set aside for recycling waste

Emissions: proper selection of refrigerants, minimization of outflow of sewer and stormwater

Innovation: The following innovative approaches will be explored within the commercial circumstance that surrounds this project: gas fired absorption chiller, fresh air ventilation.

4. “Tuning Up” Melbourne’s Buildings

4.1 Background

Government is interested to improve the uptake of energy and water efficiency practices in the built environment, and integrate with existing programs to deliver more sustainable buildings. Szencorp has developed a concept whereby commercial building owners within a precinct are selected to participate in a building refurbishment program, under which their building will be a) benchmarked according to accepted energy and water performance standards; and b) upgraded to a higher standard, with the costs of upgrade recovered through the energy and water savings generated.

A pilot Building Tune Up that was run by the Szencorp group in Adelaide upgraded ten buildings at a project capital cost of $449,300, which included the delivery of sustainability audits and reports. This cost was recouped through the energy and water savings generated **within twelve months**. The cost of capital upgrade work performed is paid for over time by the ongoing energy and water savings, after which time all savings accrue to building owners.

4.2 How the “Building Tune Up” concept might work in Melbourne

In the Victorian context, project steps might include:

1) Sustainability Victoria working with DSE’s Sustainable Futures team and local government representatives to establish the project as a joint state/local initiative, under the auspices of the Victorian Local Sustainability Accord.
2) Local governments interested in participating could run the project inception phase, that is, to identify willing “building tune up” participants/commercial building owners from their municipality, and to arrange performance benchmarking on their existing sites in conjunction with industry expertise.
3) Partnerships with energy services industry providers would deliver the building upgrades, according to the specified project outcomes. Capital cost of the upgrades would be financed using either private finance from the energy services industry or sourced from Victorian Government (in either case, likely to be at lower interest rates to what could be privately sourced by building owners). This funding would also allow provision of a monitoring and verification package for each site, which would prove the upgrade results.
4) SV would work to support local government in the provision of marketing exposure/publicity and community recognition for building participants. This could be delivered through Sustainability Victoria

awards programs, or in conjunction with other similar/associated efforts e.g. ICLEI's CCP campaign, the Clinton Climate Initiative, or the 'Grow Me The Money' initiative.

5) Commercial buildings upgraded and verified savings generated by this program could be deemed eligible abatement under the Victorian Energy Efficiency Target. This is appropriate given that the initiative overcomes the stated key disadvantage of including commercial energy savings under VEET in the first round, i.e. covering the administrative costs of measurement and verification of emissions reductions achieved through different types of energy savings.

6) To close the loop, Councils could also offer to purchase (perhaps at a rate discounted to the market price) and retire the VEET certificates generated by local building owners, thereby assisting the councils in their efforts to create "zero emission" commercial precincts.

This is represented schematically in Figure 1 below.

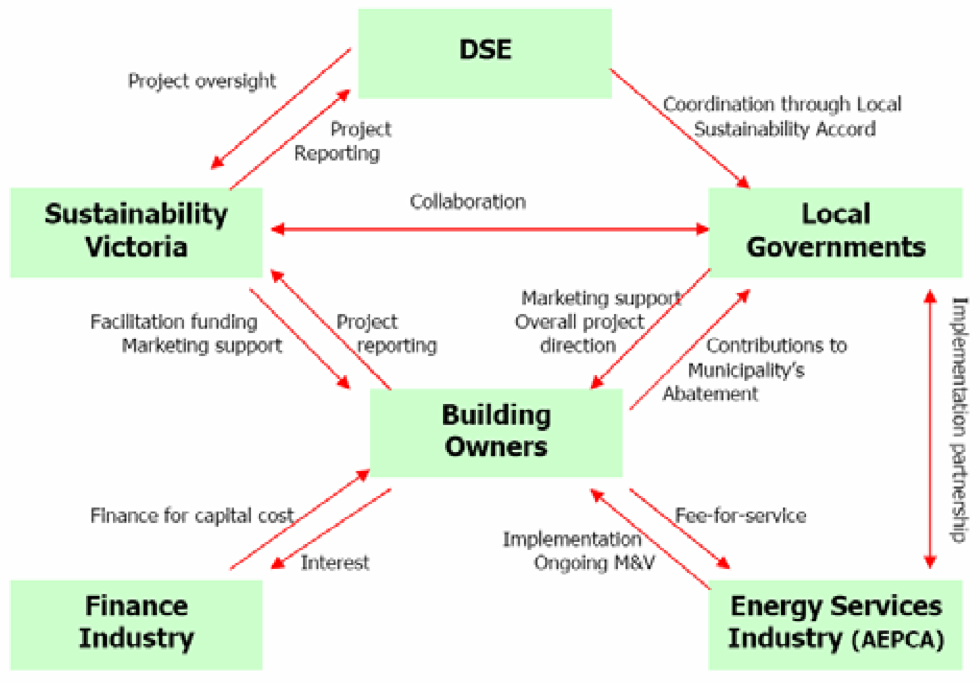

Figure 1 Project organisation – proposed Melbourne Building Tune Up

4.3 Incentives for participation

This program will encourage uptake of energy efficiency in the commercial buildings sector over and above current practice, because of incentives offered to a range of participants.

4.3.1 Building Owners

- Building owners will have part of their project involvement costs covered by Government funding.
- Building owners will have access to finance at reduced interest rates to what they may be able to attract privately
- Building owners will gain public exposure for improving the environmental performance of their assets
- Building owners will access additional income streams through VEET eligibility.

4.3.2 Local Governments

Local governments benefit from participation through

- Meeting CCP milestones (if members of the ICLEI CCP campaign)
- Extending efforts to make their municipality carbon neutral in a cost effective way
- State Government support to bolster existing programs to engage with the commercial sector on sustainability issues

4.3.3 State Government

State Government involvement is largely facilitative but, to create the appropriate incentives for participation, will involve providing funding for the project inception phase and to ensure that monitoring and verification meets requirements under the VEET scheme. It is possible that this funding be provided on a revolving basis; i.e. that it is recovered/repaid to State Government through the energy and water savings generated by the program. The extent to which this is done is proportional to the amount of incentive offered to building owners; i.e. if project inception costs are all to be recouped, then longer payback periods will result.

Amount of funding requirement varies depending on the size of each project and the difficulty of establishing benchmarks for participating buildings. A Melbourne Building Tune Up project proposal has been worked up in more detail that outlines a relatively ambitious project for Melbourne, under which a large percentage of buildings are upgraded (i.e. inception costs are high), and ongoing savings are very significant, as referred to in Table 2.

Table 2 Melbourne "Building Tune Up" Project Timeframe & Outcomes

YEAR	% of CBD Buildings Rated	% of CBD Buildings with improved to 5-Star ABGR & NABERS	Energy - reduction of existing consumption in CBD	Energy Savings (kWh)	Water - reduction of existing consumption in CBD	Water savings (kL)	Sewage discharge (kL)	GHG Emissions: reduction of total emissions*	CO2 Savings (Tonnes/CO2-e)	Predicted Cumulative Cost Savings ($)

5. Other Szencorp Projects

5.1 Tianjin Green Office Building, China

An Australian Consortium consisting of Maunsell, Design Inc, Bassett and Szencorp are pursuing high performance green buildings in China with the active support of the Melbourne City Council, the Victorian Government and the Federal Government. The consortium's credentials are based on Melbourne's two 6 star Green Star office buildings - CH2 and 40 Albert Rd. The Consortium has invested considerable resources in developing this opportunity and an MOU has been signed between Tianjin and the Consortium to renovate the existing Environment Protection Bureau (EPB) building with the view to expanding this throughout China and to develop a green precinct in Tianjin. The EPB have committed to a showcase leading edge building and the design team has finalised concepts. The objective of this project is to transform the existing Tianjin EPB building into a green building showcase, achieving significant energy use reduction outcomes and by ensuring that the project is delivered in a replicable manner, potentially for many other similar buildings throughout China. Expected outcomes of the project include:

- A replicable design and plan for retrofitting of similar buildings in China
- Increased comfort of occupants
- Energy and water savings and subsequent reductions in greenhouse gas emissions from the building upgrade
- Incorporation of renewable energy and embedded generation into building designs and retrofits
- Increased industry links with China

- Proof of concept that a more holistic approach to energy efficiency yields tangible results, i.e. that more sustainable buildings make economic sense
- Education and dissemination about this energy efficiency delivery model through industry and government networks and technology transfer.

The Tianjin EPB Green Office Building project will deliver the first ‘green’ retrofit of an existing building in China and will assist environmental improvements in China through design, technology, education and skills transfer. The project aligns well with the objectives of the Asia-Pacific Partnership on Clean Development and Climate and has attracted support from this initiative. It presents the capacity to act as a flagship for activities related to the Buildings and Appliances sector.

5.2 Indian Building Tune-Up

Since 1990, India has emerged as one of the fastest growing economies in the developing world. Consequently, the economic share of construction industry has grown significantly leading to increased demand of residential, commercial and institutional buildings. Building electricity consumption has more than doubled from 14% of the total electricity consumption in India in the 1970s to nearly 33% in 2005. However, the electricity supply has fallen way short of the growing demand with the peak and energy shortages in March 2007 estimated to be of the order of 14% and 9% respectively.

Recognising the demand supply mismatch, the Government of India enacted the Energy Conservation Act 2001 to promote energy efficiency and conservation in the country with an aim to reduce energy intensity of the economy. The intent of the Indian Government has yielded positive results with the energy intensity of the economy showing a downward trend for the last 3 years. The Bureau of Energy Efficiency (BEE) was created as the nodal agency to implement the Act along with its sister organisations in the states called the Designated Agencies.

Private ESCOs have recently set up the Indian Council for Energy Efficiency Business (ICPEEB), however, the ESCO industry is in infant stages. A recent report into energy efficiency improvements in India 11 concludes that a major barrier to energy efficiency uptake remains in “the absence of financial intermediation by banks and other lending institutions to promote and develop energy efficiency lending; the relative lack of private sector energy efficiency service delivery mechanisms such as ESCOs” and the fact that there is “insufficient understanding and assessment of the risks and benefits that accrue to the parties in an energy efficiency transaction. “ As a result of this lack of industry capacity, the large energy efficiency potential of India’s commercial buildings remains unrealised.

Szencorp aims to help address this barrier by working with the BEE and Indian building owners to take Australian energy efficiency service industry expertise to the Indian Commercial building market, setting up joint ventures to expand the ESCO offering in India, and delivering both know-how and tangible improvements for commercial building energy and water efficiency. The project is based on the Building Tune-Up Program delivery model, which holds that quite major improvements in energy and water efficiency can be achieved by implementing relatively straightforward and inexpensive initiatives that can also deliver excellent financial returns.

Work by Szencorp and the Indian Government has already identified a number of appropriate Indian commercial building sites for upgrade. Working in conjunction with the Indian and Australian Governments, the project proposes that Szencorp will joint venture with Indian energy service companies to upgrade the energy performance of 10 of these buildings. In the process, this will demonstrate the capacity of Energy Efficiency Audits and upgrades on Commercial Buildings to achieve significant energy savings where upgrades are paid for by future savings. The upgrades will draw on Australian ESCO Industry expertise and integrate renewable technology where applicable.

Once the buildings have been “tuned” the project will also demonstrate the Australian Government developed Green Lease Schedule’s capacity to lock in savings related to the ongoing management and maintenance of the building. As part of the Tune up, the project hopes to link in with the World Bank’s Global Environment Fund’s Chiller upgrade Program which seeks to address climate change and ozone concerns by providing financing support to upgrade the Chiller units on Commercial buildings in India.

It is hoped that this project will be able to demonstrate and document the additional major benefit of tune ups in that a tuned up building will not only use its Chiller unit more efficiently but may require a smaller chiller unit. The timing of the GEF project and ways that this project could link in are still to be finalised at the time of writing. Another major benefit could be realised through the use of solar air-conditioning units where possible. Solar is particularly suited to the Indian Climate and this would provide a demonstration of suitable renewable and embedded generation technologies within buildings.

COMPARATIVE ENVIRONMENTAL ASSESSMENT OF MASONRY WALL UNITS REGARDING MANUFACTURING PROCESS

Hülya KUS Dr.Eng.[1]

Keywords: masonry wall products, pumice, AAC, brick, sustainability, LCA, manufacture

Summary

Sustainable building and construction with respect to environmental and economic considerations are becoming more and more important because of high energy and resource consumption in the building and construction sector. In Turkey, residential buildings are mostly built with in-situ reinforced concrete structural frame and infill external walls made of lightweight masonry such as autoclaved aerated concrete (AAC), pumice aggregate concrete hollow blocks and fired clay hollow bricks. In the paper, information gathered through field investigations on extraction of natural resources, processing of raw materials and manufacturing processes are given for AAC, pumice concrete blocks and fired clay hollow bricks and the obtained data is evaluated comparatively in terms of environmental sustainability issues such as resource depletion, greenhouse gas emissions, water use and waste generation etc.

1. Introduction

Environmental sustainability of buildings is an important matter of concern towards sustainable development, since construction and operation of buildings consume high amounts of energy and natural resources, and also are responsible for large quantities of CO_2 emissions (UNEP 2007). Environmental performance of buildings during operation period are widely studied and known whereas knowledge about the environmental performance of building products are relatively limited and also information found is differing/conflicting. This is mostly due to the fact that conditions of use, technology of manufacture, preferences, etc. are specific to country or region and these affect the assessment results. Information on energy necessary to extract raw materials, manufacture and distribution of products, which is referred as embodied energy, needs to be carefully used and national life cycle assessment (LCA) studies need to be conducted to construct a building product database in terms of embodied energy (UNEP 2007; ARUP 2006).

LCA is a general environmental assessment technique that has been widely accepted and used as a base to compare alternative materials, components and services. In building research community, as well as the studies focusing on improving and adapting the LCA methodology, research studies using LCA as a tool to assess buildings, building services or building products are found. Recent studies indicate that, product manufacturing and construction phases have also important effects on the total environmental impact as well as the use phase of buildings (Nässén *et.al*. 2007, Gerilla *et.al*. 2007, Kibert 2005). A brief survey on LCA applications at building product level and on embodied energy of building products as well is presented as follows. Koroneos and Dompros (2007) present a cradle-to-gate LCA field survey conducted to assess the brick production in Greece, and discuss the emissions to environment and their impacts. Ardente *et. al.* (2006) present a cradle-to-gate LCA field survey on kenaf-fibres insulation board, and compares its environmental performance with other insulation products in terms of energy consumption and environmental impacts when used in residential buildings. Schmidt *et. al.* (2004a, 2004b) present a comparative LCA study on roof insulation products made of stone wool, paper wool and flux, based on the inventory data collected from literature, LCA databases and suppliers. The comparison presented considers emissions to environment, energy and resource depletion, solid wastes, and their impacts. Health aspects are taken into account in the comparison as well. Reddy and Jagadish (2003) discuss the embodied energy of different types of basic building materials, masonry wall units and mortar types. Results derived from the practices in India indicate that total embodied energy of load bearing masonry buildings can be reduced by 50% when energy efficient/alternative building materials are used. Alcorn and Wood (1998) outline the embodied energy research at University of Victoria and describe the embodied energy coefficients, their background and derivation. They discuss the process-based hybrid analysis including input-output analysis. Basic approach given in the existing manual system of analysis for collecting data includes steps as: definition of product/material; major and minor players in the field; constituent ingredients and composition of product; detailed manufacturing process; energy inputs; output of a particular processing plant; prices; source, age and confidentiality of data; and other comparative data. Alcorn (2001) applies CO_2 emission factors and derives embodied CO_2 coefficients for New Zealand building materials, based on the previous embodied energy work. An example of recycled steel is also presented.

Essential requirements for sustainable building products include more efficient use of inputs such as: reduction in consumptions of non-renewable raw materials; adoption of energy efficient and clean production methods and technologies; optimum use of water; increased recycling/reuse of waste in the production; shortened distances for transportation; and the outputs such as minimized associated environmental impacts. Hence, depending on the energy efficiency during building use phase, relatively higher environmental impact of embodied energies of the building products can be anticipated.

In Turkey, in-situ reinforced concrete structural frame with masonry infill walls is the most preferred construction system in buildings. External thermal insulation systems are also used lately. Widely used infill masonry products are fired clay hollow bricks and autoclaved aerated concrete (AAC) blocks, and use of pumice aggregate concrete hollow blocks has increased recently. Studies on LCA of fired clay bricks and AAC blocks can be found in literature, since these are global products. However, research on pumice aggregate concrete blocks is limited due to its relatively local character. Additionally, as aforementioned, in each country, specific investigations are required to be done for every product in order to obtain correct information about embodied energy, gas and particulate matter emissions.

In this paper, within this context, environmental assessment of the aforementioned masonry wall products regarding the manufacturing processes is considered. The aim is to gather inventory information about these products and to develop a local comparative model that is highlighting differing characteristics of each product in terms of environmental issues such as energy and resource use, CO_2 emissions etc.

2. Methodology

LCA is a tool designed to aid in environmental evaluation and decision making at various hierarchical levels and consists of; (i) goal and scope definition, (ii) inventory analysis, (iii) impact assessment, and (iv) interpretation phases. Inventory analysis, includes the identification and quantification of all inputs and outputs of the studied system. The inputs and outputs cover items such as natural resources; energy; releases to air, water and land; co-products, etc. (ASTM 1991).

The inventory investigation of building products usually covers five main life-cycle stages, i.e. material acquisition, manufacturing, construction, use and disposal/recycling. The scope of this study on masonry wall units is, however, limited with material acquisition and manufacturing stages. Data is collected through field investigations of plants manufacturing fired clay hollow bricks, AAC, and pumice aggregate concrete hollow blocks. Following topics are studied in details:

- Raw materials acquisition
  - extracting mineral resources from quarry
  - supplying materials in processed form
  - transportation.
- Product manufacturing
  - constituent ingredients and composition of products
  - manufacturing processes – technology
  - packaging, storage and delivery.

Plant facility characteristics unique for each investigated specific building product also have some effects on environment and therefore included in the study. Plant location, plant capacity, number of workers and their transportation, electricity and water use for domestic purposes, heating of office buildings and plants, etc are relevant information considered in the case studies.

Impact assessment phase of LCA aims to evaluate the significance of potential impacts of the investigated system using the inventory data. The level of detail, choice of impacts evaluated and methodologies used depends on the scope of the study (ISO, 1997). Within the scope of this study, the following criteria are adopted for the input-output analysis in order to assess the embodied energy and the environmental impact of the investigated masonry wall units:

- Resource consumption
  - mineral use
  - water use
- Land disturbance
- Energy consumption
  - mining
  - production processes
  - transportation

- Environmental impact
  - gas emissions
  - particulate matter
- Waste management.

The interpretation of inventory analysis and impact assessment results are made on a general basis due to the fact that the field investigations were executed in limited number of manufacturing plants and therefore will not be representative of the whole masonry wall product manufacturing industry.

3. Inventory Investigations of Masonry Wall Units

Inventory investigations of pumice concrete block and AAC block were presented in detail in Kus *et. al.* (2007). In this report, only the brief information for these products are given for comparison purposes, while fired clay brick production is thoroughly explained.

3.1 Plant Facility Characteristics

The investigated plants are all located nearby the raw material sources in order to shorten the transportation distance to manufacturing units. This preference helps to save energy and in turn reduces transportation costs and environmental impacts. Final distribution distances for the delivery of manufactured products to construction sites have also an effect on the selection of plant location and the possible shortest distances to target market areas are preferred. Specific information about the investigated plants are given in Table 1.

Table 1 Some facts and figures about the investigated plants

	Pumice Concrete Block	AAC Block	Fired Clay Brick
Plant Location	Nevsehir (mid-Anatolia)	Hereke-Kocaeli (Marmara)	Isiklar-Istanbul (Marmara)
Plant Capacity / year	30,000,000 blocks	100,000 m^3	~175,500,000 bricks
Plant Operation Duration/day	24 hours – 3 Shift	24 hours – 3 Shift	24 hours – 3 Shift
Number of Production Lines	2	1	3 (extrusion and drying)
Electricity – supplied from / annual consumption (if available)	City supply network 1.8 million kWh	Private power plant using natural gas	Private power plant using natural gas
Water – supplied from	Wells in plant area	Wells in plant area + city supply network	Two artificial lake on former clay pits
Energy used in space heating / annual consumption (if available)	Coal 250-300 tons	Natural gas	Natural gas
Number of Workers (Total)	148	31	270
Office / Other	15 / 49	11 / -	41 / -
Production / Loading	60 / 12	20	89 / 140
Raw Material Acquisition	12	Outsourced (from sister company)	Outsourced
Transportation of workers			
Shuttles (number and type / travel distance per day)	1 minibus / ~240 km 1 bus / ~80 km	1 minibus / ~270 km	1 minibus / ~180 km 1 bus / ~100 km
Number of Private Cars	8 (for office workers)	-	8-10 (for office workers)

3.2 Materials Acquisition

Material acquisition phase includes all activities and processes required for obtaining all raw materials, energies and other material requirements for the product system (ASTM 1991). In the investigated plants raw materials are supplied either by extracting from the quarry or by purchasing in the processed form.

3.2.1 Raw Materials Acquisition of Pumice Concrete Blocks

Pumice aggregate, cement, water and iron oxide are constituent materials of pumice concrete block production. Auxiliary materials required in association with block production are timber pallet, steel and plastic strip, and kraft paper protection corner pieces for packaging. Information relevant to inventory analysis is summarised in Table 2.

Pumice aggregate preparation for block production is consisted of (i) excavation and loading of pumice, (ii) transportation to cleaning/sorting bunker, (iii) cleaning and sorting of pumice, and (iv) transportation to production bunker processes. Pumice is excavated from three different areas, one located at the factory site and the others located 4 and 10 km far from the factory. Pumice is usually found close to the surface and as 4-5 metres thick bands (Figure 1). Cleaned and washed pumice aggregate is screened into 0-3 mm, 3-8 mm, 8-16 mm and over 16 mm. Aggregates in 3-8 mm and 8-16 mm sizes, used in the block manufacturing, are filled into bunkers through band conveyors and are ready to be used in the production mix. Water, in addition to block production, is used for cleaning and sorting of pumice aggregate (Figure 2), and after re-used.

Table 2 Figures for Material Acquisition in Pumice Concrete Block Production (after Kus *et. al.* 2007)

Purchased basic materials	Annual consumption*	Supplied from (distance)	Transportation method/capacity	Transportation energy
Cement	30,000 t	65 km	Truck / 40 t	Diesel fuel
Iron oxide	84 t	797 km	Truck / Vary	Diesel fuel
		~8000 km	Ship / Vary	Diesel fuel
Timber pallet	150,000 pieces	70 km	Truck/ 40 t	Diesel fuel
Steel strip	150 t	797 km	Truck / 40 t	Diesel fuel
Plastic strip	70 t	797 km	Truck / 40 t	Diesel fuel
Kraft protection	35 t	Vary	Vary	Vary
Extracted material	**Annual consumption***	**Extraction processes**	**Machine used in processes**	**Energy input**
Pumice	300,000 t	Excavation	Wheel loader	Diesel fuel
		Transportation (~4.5 km)	Truck / 32 m^3	Diesel fuel
		Cleaning / Sorting	Sieve	Electricity
		Loading	Wheel loader	Diesel fuel
		Transportation (~0.5 km)	Truck	Diesel fuel
Water for block production	95,000 t	Pumping	Water pump	Diesel fuel

* Consumption amounts are based on annual production of 30 million blocks having dimensions 19 x 33 x 24 cm and weight 7346 g/block.

Figure 1 Pumice excavation in the main quarry

Figure 2 Cleaning / sorting machine

3.2.2 Raw Materials Acquisition of AAC Blocks

Sand (quartz), cement, lime, gypsum, water and aluminium powder are constituents of AAC block production. Timber pallets and polyethylene wraps for packaging are the other materials used in the investigated plant in association with the block production. All materials required for production are purchased from outside sources. However lime and cement are supplied from sister companies located at the same site, therefore classified as in-house supplied material. Lime plant employs two 250 tonnes/day Maerz type parallel flow regenerative (PFR) shaft lime kilns. Information relevant to inventory analysis is summarised in Table 3.

Table 3 Figures for Material Acquisition in AAC Block Production (after Kus *et. al.* 2007)

Purchased Material	Annual Consumption	Supplied from (distance)	Transportation Method /Capacity	Transportation Energy
Sand	35,000 t **	~100 km	Truck / 16 t	Diesel fuel
Gypsum	1,500 t **	453 km	Truck / 16 t	Diesel fuel
		250 km	Truck / 16 t	Diesel fuel
Aluminium powder	400 t **	~2,000 km	Long vehicle / 20 t	Diesel fuel
			Ship / vary	Diesel fuel
Water*	25,000 m^3 **	-	-	-
Timber pallet	92,600 pieces	~30 km	Truck / 16 t	Diesel fuel
Polyethylene wrap	92,600 pieces	~80	Truck / 16 t	Diesel fuel
In-house Supplied Material	**Annual Consumption**	**Supplied from (distance)**	**Machine used in processes**	**Energy input**
Lime	7,000 t **	0 km	Air compressor	Electricity
Cement	7,000 t **	3 km	Truck / 16 t	Diesel fuel

* includes water supplied from wells at the factory site.
** Calculated consumptions based on annual production of the factory (100,000 m^3) and AAC recipe obtained from product literature (Masa-Henke, 2003). Aerated concrete paste recipe is for a density of 500 kg/m^3.

3.2.3 Raw Materials Acquisition of Fired Clay Bricks

Inner materials used in fired clay brick production are clay and water. In the investigated factory three different types of clay are used in the brick recipe. Clay pits of type 1 and 2 are about 1.5 km, and type 3 is about 2 km far from manufacturing facilities, and all pits are factory's own property.

In clay extraction excavators, front-end or backhoe wheel loaders, and in transporting clay to brick manufacturing storage area trucks are used. Trucks operating between pits and manufacturing plant are returning back to pit empty, and this situation doubles the energy consumption per a truck of clay.

Water required for brick production is supplied from in-house sources, i.e. two artificial lakes. One lake is about 0.5 km and the other is about 1 km far from the brick production facilities and water is transported to production area through pipelines.

Information relevant for inventory analysis of the investigated factory's material acquisition phase is summarised in Table 4.

Table 4 Figures for Material Acquisition in Fired Clay Brick Production

Extracted / In-house Material	Annual consumption	Extraction / Supply processes	Machine used in Processes / Capacity	Energy input
Clay	~381,489 t*	Excavation / Loading	Excavator	Diesel fuel
		Front-end of backhoe loader		Diesel fuel
		Transportation (~1.5 km)	Truck / 25 t	Diesel fuel
Water for block production	~15,895 t	Piping (~0.5-1 km)	Water pump	Electricity

* Calculated consumption figures based on annual production of 175,348,800 bricks (19 x 19 x 8.5 cm and weight 1850 g/brick) and assuming that moisture content of extracted clay is 20 % during whole year.

3.3 Manufacturing of Masonry Wall Units

Product fabrication, intermediate manufacture, raw material conversions excluded in material acquisition stage, packaging, storing and internal transportations either outdoors or indoors are processes included in the inventory investigations of the plants.

3.3.1 Pumice Concrete Block Manufacture

Pumice concrete block manufacturing processes in the investigated factory are mainly (i) mixing, (ii) moulding, (iii) drying, (iv) packaging, and (v) storing. Sometimes an additional crushing process prior to mixing process is included when pumice aggregates are stored in production bunker without a sorting process. Blocks are formed by injection and pressing through steel mould and subsequent vibration processes. Wet blocks are air-dried in a chamber for 72 hours. During production process, handling, placing and transport of pumice concrete blocks are made by the help of a robot arm and automatic controlled transport tower while the removal of faulty blocks and packaging are made only manually. In this respect, it can be said that highly mechanised technology is adopted by the plant. Information about sub processes of main phases, and machines and equipments used in these processes are summarised in Figure 3.

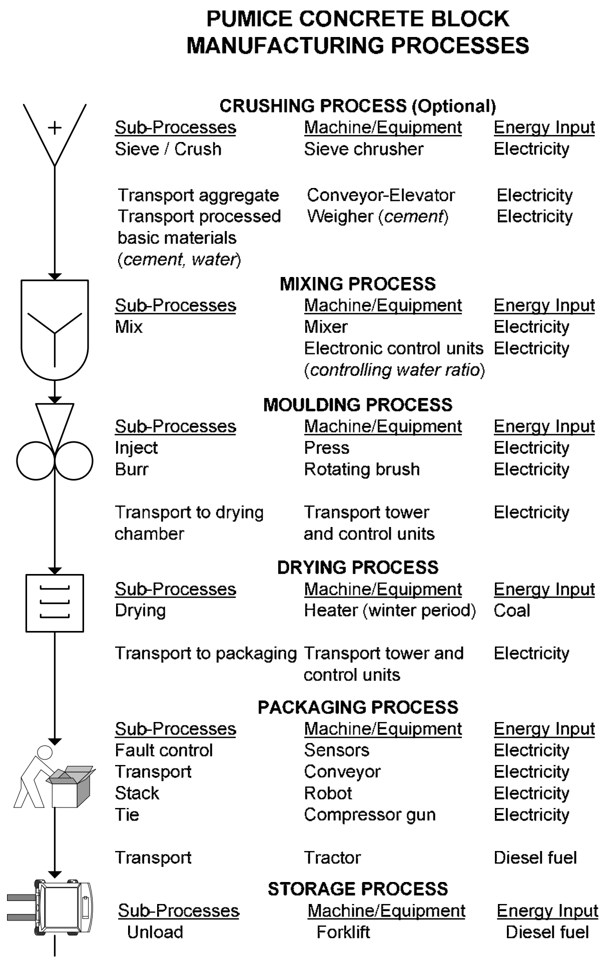
3.3.2 AAC Block Manufacture

AAC block manufacturing processes in the investigated factory are mainly (i) crushing, (ii) mixing, (iii) moulding, (iv) cutting, (v) steam curing, (vi) packaging and (vii) storing.

After crushing of silica sand with gypsum and then mixing all materials, aluminium powder is added and the paste is poured into the moulds. The expanded and hardened green cake is then wire-cut to desired size and steam-cured at 200 °C and 12 bar for about 10 hours for gaining its final strength and stiffness. The finished product is packaged and is usually delivered directly to the construction site.

The chemical reaction caused by addition of aluminium makes the mixture expand to about twice its volume, resulting in a highly porous structure. Approximately 80% of the volume of the hardened material is made up of pores, 50% being air pores and 30% being micropores. The microstructure of the solid matrix is mainly made up of microcrystalline platelets of tobermorite, calcium silicate hydrate, forming the pore walls (Aroni et.al. 1993). The quality of end product is highly influenced by the quality and mix design of raw materials, and the design of production technique among the other factors.

Information about sub processes of main phases, and machines and equipments used in these processes are summarised in Figure 4.



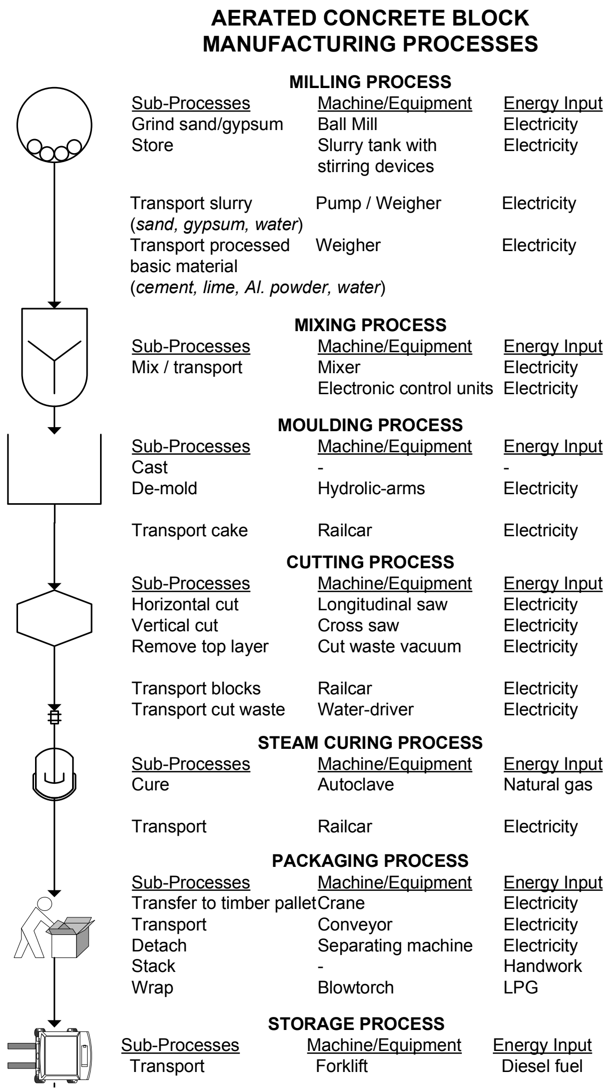


Figure 3 Pumice concrete block manufacturing processes   *Figure 4 AAC block manufacturing processes*

3.3.3 Fired Clay Brick Manufacture

Fired clay brick manufacturing processes in the investigated factory are mainly (i) clay / mud preparation, (ii) forming, (iii) drying, (iv) firing and (v) storing.

In the clay / mud preparation process, clay mixture of three different clay types taken from storage area is crushed and watered in the edge mil. Clay mud then transported to Vals machine for being compacted to eliminate air pockets. Later, it is transported to double shafts mixer for proper mixing and watering if moisture content is not adequate. For a proper forming, moisture content of clay needs to be 23-25 % by weight. During winter time, moisture content of extracted clay is about 18 % and less watering is required. However in summer time additional watering to obtain adequate moisture content is always required. Finally clay mud is transported to interim silos for resting.

In the forming process, clay mud taken from silos are compacted in the Vals machine and then transported to extrusion press. A long piece of paste is extruded through the die and is cut into smaller pieces with an initial cut and then into individual brick size with a second cut by means of a wired saw. The cut waste of the second cut is transferred back to extruder. Formed bricks are either transferred to pallettes for being transported to tunnel or chamber drying units, or directly transported to rapid drying unit by roller conveyor.

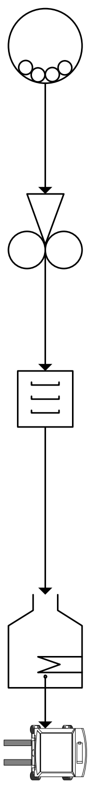
In the drying process, three different types of drying techniques are used. The first one is “chamber drying technique” in which shelved pallettes are filled into the chamber and the temperature of the chamber is increased to about 200 ℃ and left for a certain time, then the temperature is slowly decreased and the shelved pallettes are taken out. The drying continues approximately for 17 hours. The second one is “tunnel drying technique”, in which shelved pallettes move in the tunnel where the temperature increases slowly and remains in about 200 ℃ for 8 hours then slowly decreases. It takes approximately 10 hours for drying. The last one is “rapid drying technique” in which bricks move on conveyors and the air temperature in rapid drying unit gradually increased up to 200 °C and remains for certain time then decreased along the unit. It takes ~4 hours to complete drying. Following the drying, dry bricks are transferred to and loaded on trams by the help of conveyors and robot arms. Moisture content of dried bricks is about 1-2 % in summer time and 3-5 % in winter time.

In the firing process, trams move in the kiln having a length of 187 metres and the air temperature is gradually increasing and then decreasing along the length of the kiln. The maximum air temperature in the kiln is about 900 °C and it takes about 20 hours to complete the firing of a brick loaded tram. The temperature in the kiln is continuously monitored at several places.

Finally, the trams are transported to the outside of the manufacturing building for either being transported to storage area or for being directly distributed to construction sites.

The machines and equipments, and energy used in the manufacturing of fired clay bricks are summarised in *Figures* 5-7.

FIRED CLAY BRICK MANUFACTURING PROCESSES



CLAY / MUD PREPARATION PROCESS

Sub-Processes	Machine/Equipment	Energy Input
Grinding/watering clay	Edge Mill	Electricity
Compress/empty air	Vals	Electricity
Watering / Mixing	Double shafts mixer	Electricity
Interim storing	Silo	-
Internal transportations	Strip conveyors	Electricity

FORMING PROCESS

Sub-Processes	Machine/Equipment	Energy Input
Extruding	Extrusion press	Electricity
Initial cut	Wired saw	Electricity
Brick size cut	Wired saw	Electricity
Internal transportations	Roller conveyor	Electricity
Transport cut waste	Strip conveyor	Electricity

DRYING PROCESS

Sub-Processes	Machine/Equipment	Energy Input
Drying	Chamber dryer	Vary
	Rapid dryer	Vary
	Tunnel dryer	Vary
Internal transportations	Roller conveyor	Electricity
	Strip conveyor	Electricity
	Robot arm	Electricity
	Forklift	Diesel fuel
	Tramway	Electricity

BAKING PROCESS

Sub-Processes	Machine/Equipment	Energy Input
Baking	Kiln	Natural gas
Internal transportations	Tramway	Electricity

STORAGE PROCESS

Sub-Processes	Machine/Equipment	Energy Input
Unloading/loading	-	Manpower
Transportations	Tram	Electricity
	Truck	Diesel Fuel

4. Environmental Assessment

Resource and energy consumption, green house gas emissions and land use issues are thoroughly discussed for environmental assessment of masonry wall units regarding manufacturing phase.

4.1 Resource Consumption

Depletable resources consumed as raw materials in the manufacturing processes of clay bricks and concrete blocks can be classified as minerals and water. Considering sustainability, the amount of available reserves and the materials extracted in a year come into question. Low density of building products means lower consumption of raw materials contributing to their conservation. This is also beneficial during the use phase of the building, either by reducing the total loads of the building or providing better thermal insulating properties achieving greater energy efficiency. Despite their contribution to energy efficiency (with their low thermal conductivity) during the operation (use) phase of buildings, extended durability and service life of these products gain importance in reducing the depletion of natural resources by decreasing the need for new building construction.

Non-renewable energy resources like natural gas, fuel oil and coal are considered under the energy consumption sub-heading. Less-used raw materials and auxiliary materials used for packaging are left out of the scope of the present study.

4.1.1 Mineral Use

Pumice, quartz sand and clay are the main minerals needed to produce concrete blocks and clay bricks. In addition, limestone is used for cement and lime production. All these minerals are often obtained by surface quarrying. Use of recycled materials in the production is regarded as very important for decreasing the amount of extracted materials and thus protecting the finite mineral resources. In Table 5, annual mineral consumption amounts are given for all three plants. In cement manufacture, in average, 1.27 tonnes of limestone and 0.05 tonne gypsum are consumed per 1 tonne of cement (IPPC 2001). Regarding lime production, 1.78 tonnes of limestone is consumed to produce 1 tonne of quicklime (Hill and Mason 1997).

Table 5 Annual Mineral Consumption of the Visited Plants Manufacturing AAC, Pumice Concrete and Brick

	Density (kg/m^3)	Annual consumption	Pumice (tonne)	Clay (tonne)	Sand (tonne)	Gypsum (tonne)	Limestone (tonne)
AAC Block	500 (bulk)	100,000 m^3	-	-	35,000	1,850	21,350
Pumice Concrete Block (Hollow) 7.346 kg/block	488 (bulk)	30,000,000 block 451,598 m^3	300,000	-	-	1,500	38,100
Fired Clay Brick (Hollow) 1.85 kg/brick	602 (bulk)	175,500,000 brick 539,327 m^3	-	381,489	-	-	-

4.1.2 Water Use

Water needed for the production of block and brick is obtained in three ways: (i) by pumping underground water from the wells opened in the plant area; (ii) utilizing rainwater collected in the artificial lakes; and (iii) city water supply network. Total amount of water required for the processes and used for domestic purposes gains importance. Climate change is the biggest threat for the sustainability of water resources thus minimizing water use and recycling of waste water is important for efficient use and conservation of water.

4.2 Land Disturbance

From a sustainability point of view, the world reserves including non-renewable mineral resources are increasingly consumed in construction sector and the natural state of the landscape is destroyed leaving back a permanent change. After surface mining of minerals like pumice, clay, sand and limestone, disturbed land, i.e. the quarry and the surrounding land, needs rehabilitation. Land reclamation can be determined according to the specific characteristics of the open pits and the site. Agriculture and forestry are generally preferred land cover types.

In our case, depleted pumice pits are used as cultivation substrate to potato field. Clay extraction pits are rehabilitated as artificial lakes from which the water needed for the production is transported by pipes to the plant.

4.3 Energy Consumption

Natural gas, fuel oil and coal are the main energy resources for space heating in Turkey. These are depletable energy resources therefore need to be conserved and replaced by recycled or renewable ones as much as possible. On the other hand, energy for drilling of oil, gas and coal is indirectly covered by the embodied energy of the masonry wall units as for all other construction products. Electricity needed for space lighting and operating the machines is provided from city supply network and is mainly generated either from hydro-electric power stations or thermal power stations using natural gas. Besides, industry can also generate its own electricity using natural gas, as in our case, brick and AAC plants do. Vehicles used for transportation of either goods or people of industry mostly have diesel engine with manual gear type.

In addition, there is indirect embodied energy required for the investments like the machines, tools and all equipments used for extraction, production and transportation of construction products as well as infrastructure needed for generating electricity. Indirect energy for the production and maintenance of vehicles used in transportation can also be mentioned.

4.3.1 Energy Consumption in Mining

Equipment required for performing this process comprises front-end or backhoe wheel loaders. To power these work machines, diesel engine is used. Energy consumption greatly depends on the properties and efficiency of machines used as well as the amount (in weight and volume) of raw materials extracted and the depth of the excavation. Density of the material extracted thus play important role.

4.3.2 Energy Consumption in Production Processes

In the production process of masonry wall products, in general, (grinding, mixing and forming) machines work with electricity.

Heating and firing processes account for the highest energy use than any other processes; therefore temperature/time relationship is significant in determining energy consumption. For autoclaving and brick firing processes in the investigated plants, the required energy is supplied by natural gas. The autoclaving temperature of AAC is about 200 °C at 12 bar for about 10 hours. Waste steam generated at the power plant owned by the manufacturer is used in this process, thus no extra energy is required. Electricity is also supplied by this gas turbine and combined-cycle power plant. For brick, drying temperature is about 200 °C for about 4-17 hours depending on the type of the technique used, and the firing temperature is about 900°C for 20 hours. In the visited plant, the waste heat from the cooling zone of brick kiln is utilized in the drying process. In pumice concrete block manufacturing; on the other hand, there is no need for high temperatures in the process. The only heating needed is, in winter, for keeping the drying chamber air temperature around 15 °C. However, the production process of raw materials like cement and lime is highly energy intensive. High temperatures (about 1500 °C) are required in the cement clinker production phase. For the production of cement and lime, shaft kilns are generally used. Cement content in pumice concrete mix design, and cement and lime contents in AAC mix design constitute the total energy intensity together with the energy required for the other manufacturing processes. Indeed, embodied energies based on volumetric bulk densities of the wall units yield more practical values. Shape and hollow design of pumice concrete blocks and bricks are thus taken into account in terms of their contribution to energy efficiency and/or saving.

In Table 6, embodied energies, as found in literature are given (Elliott 2007, Hendriks *et.al.* 2004, NRC-OEE).

Table 6 Embodied Energy of Masonry Wall Products Manufacturing (excluding transportation)

	Mining & Hauling (MJ/m^3)	Screening & Sorting (MJ/m^3)	Cement production (MJ/kg)	Lime production (MJ/kg)	Embodied Energy (MJ/kg)	Embodied Energy (MJ/m^3)
AAC Block	Sand/limestone 78.79 / 78.79	Sand/limestone 78.79 / 78.79	3.5 – 5.5 (dry process)	5.0 – 7.0 (vertical kiln)	2.1 - 3.6	1050-1800*
Pumice Concrete Block	Pumice/limestone 48.14 / 78.79	Pumice/limestone 78.79 / 78.79	3.5 – 5.5 (dry process)	-	0.94 - 1.5	459-732*
Fired Clay Brick	Clay 78.79	Clay 78.79	-	-	1.2 - 2.5	722-1505*

* Calculated values in terms of bulk densities of the investigated plants' products.

4.3.3 Transportation

Internal (short distance) transportation within the plants, either indoors or outdoors, is generally provided by (horizontal, inclined or vertical) belt, roller conveyors and bucket elevators, 1-rail and/or 2-rail carriage systems, robot arm systems, crane, fluid transfer (slurry or watering) pumps and pipelines. All these transport equipments work with electricity. Furthermore, diesel tractor and forklifts are employed in moving and transporting final products within plant area. Between the quarry and the plant, diesel engine trucks are used. For the delivery of final products, dominating means of transport is road truck. Depending on the weight (and volume) of carried products (raw materials, auxiliary materials or masonry wall units) and the type/properties of vehicle, diesel consumption of rigid trucks varies between 30-45 litre/100 km. Shuttle bus or minibus, on the other hand, consumes diesel between 15-30 litre/100 km depending on the model (age) and type of engine.

In the investigated plants, annual total diesel consumption amounts needed for transportation of raw materials including transportation of plant workers and excluding final distribution of products are given in Table 7. Assumptions were made as all three plants work 330 days and offices 300 days a year. Trucks operating between pits and manufacturing plants are returning back to pit empty. This situation doubles the energy consumption per a truck of raw material transported but transportation of aluminium powder from abroad is exception. It is clearly seen that, transportation of AAC raw materials consumes significantly high energy and transportation of brick raw materials significantly less. This is probably not associated with the capacities of the plants. It is most likely related to the distances and the capacities of the vehicles employed.

Table 7 Annual Diesel/Gasoline Consumption from Transportation including Transportation of Plant Workers

	Raw Materials Truck (diesel)	Shuttle (diesel)	Car (gasoline)	Total Diesel consumption	Total Gasoline Consumption	CO_2* (Materials)	CO_2* (Workers)
AAC	174,640 l	17,820 l	-	192,460 l	-	501,216 kg	51,143 kg
Pumice concrete	71,200 l	21,120 l	6,000 l	92,320 l	6,000 l	204,344 kg	76,154 kg
Brick	14,650 l	18,480 l	7,200 l	33,130 l	7,200 l	42,045 kg	71,685 kg

*1 litre of diesel = 2.87 kg of CO_2 equivalence and 1 litre of gasoline = 2.59 kg of CO_2 equivalence (Jaques et.al. 1997).

4.4 Environmental impact

In order to provide a basis for a comparative environmental assessment of masonry wall units, it is necessary to identify the processes which require higher energy, and consequently, to determine the approximate embodied energies. Environmental impact depends principally on the amount and type of energy used in:

- extraction and processing of raw or primary materials
- manufacturing of products
- operation and maintenance of plant facilities including offices
- transportation of raw and auxiliary materials, manufactured products (delivery), and industry workers involved in the manufacturing processes.

Gas emissions and particulate matters are considered as the environmental impacts associated with the embodied energies of masonry wall units.

4.4.1 Gas Emissions

The main source of CO_2 emissions is burning fossil fuels like coal, oil and natural gas, and can be attributed to the high temperatures required in cement, lime, brick and AAC block production. In cement and lime production, the calcination process also gives out CO_2, which makes up about 50 % of the total CO_2 emission. In Table 8, gas emission factors are given as found in literature (EPA, ETS, GBC).

Table 8 Emission Factors

	SO_X kg/Mg	CO_2 kg/Mg	C_2H_4 Kg/Mg
Brick	1.22	194 - 235.5	0.07
AAC block	2.23	265 – 448	0.175
Pumice concrete hollow block	0.172	106	0.0229
Cement	0.56	710 – 970	0.0231
Lime	0.55	859 - 1210	0.0252

4.4.2 Particulate Matter

Particulate matters (PM), as coarse and fine particles, are emitted from power plants, industries, vehicles and buildings. PM quantities widely vary according to the plant characteristics and use of measures such as dry filter systems or electrostatic precipitators. Amount of PM emissions generated from cement, lime and brick production, depends mainly on the type of fuel, pre-heater, kiln (rotary, vertical shaft) and cooler used.

4.5 Waste Management

Minimizing waste generation and effective reuse/recycle through manufacturing processes are very important regarding reduced raw materials consumption and energy needed for post-processing of waste.

Waste material left over from the AAC manufacturing processes, prior to steam-curing process while it is still wet and unhydrated, are water-driven to auxiliary return tank for being used in the mix preparation. Faulty AAC blocks detected after curing process is stored in a waste area and sometimes used as pavement filler. Recycling of these blocks by grinding and adding to the mix production is planned for the near future.

In the pumice concrete block manufacturing processes, since the mixture is injected and pressed through moulds as individual units, there is no wet waste. Faulty or broken pumice concrete blocks which are already hardened after drying, are used as pavement filler material in the factory area to cover the pumice dust lying over the ground. Pumice aggregates left over after sorting and which are not used in the block manufacturing, having sizes over 16 mm, are used in the textile industry and in agriculture whereas sizes of 0-3 mm are used to produce plaster mortar.

Regarding the waste material from the brick manufacturing processes, the cut waste material is transferred back to the extruder. Faulty or broken bricks which are detected after firing, are stored at plant site for more than 30 years, and sometimes used as landfill when requested by neighbour factories. A research project is to be set up by the plant owner for utilizing this collected waste in the best way.

In all three plants, measures are taken to reduce the amount of faulty/broken products and the ratio of these remains between 1-2% of total production.

No wastewater is generated in any of the three plants except for the domestic water waste in the offices.

5. Conclusions

In this report, an attempt is made for understanding and comparatively assessing the manufacturing phase of masonry wall units regarding energy consumptions and environmental impacts. Comprehensive information on extraction of natural resources, processing of raw materials, manufacturing and transportation were collected from masonry wall products' manufacturing plants and data obtained was systematically organized. One plant for each masonry wall product, namely pumice concrete block, AAC and brick, was visited and their productions were investigated in detail. Plant facility characteristics were also considered as a factor affecting the environmental performance of factory-made building products. It should be noted that each plant has its own unique manufacturing characteristics and therefore it should not perceived as representing the general situation in Turkey. Other factories manufacturing masonry wall units may differ on certain measures. When assessing embodied energies according to the volume of the end-product the following conclusions can be drawn;

- AAC block manufacturing requires very low raw materials consumption due to the high porosity of the end-product. However, cement, lime and aluminium powder content in the production mixture are energy intensive processed materials although used in low quantities compared to the amount of end-product, and therefore product's embodied energy increases. Besides, autoclaving also requires relatively high energy.
- Fired clay brick manufacturing can be considered, relatively, energy intensive due to the high energy required for high temperatures in the kiln. However, its low bulk density (because of hollow design of brick) significantly reduces the embodied energy.
- Pumice concrete block manufacturing, although energy intensive cement is used, seems to be the most energy efficient among all, since no heating required in the processes, and because of its low bulk density due to porous structure of pumice aggregate and also hollow design of block.

Maximum efficiency is obtained in terms of consuming less depletable resources by either hollow design of bricks and blocks or porous material structure of the latter. In general, less use of raw materials according to the volume of the end-product contributes energy efficiency both in production and transportation. In addition, adopted efficient operation strategies in the investigated plants, such as use of waste heat in other energy consuming processes or reprocessing of cut wastes contributes energy and resource saving. From this point of view, all investigated products can be regarded as sustainable. Fuel consumption during transportation of raw materials and plant workers, on the other hand, seems to have considerable effects. Thus, strategies like decreasing the number of employed workers by changing and/or improving production systems and employing technology leading higher levels of automation rather than manual operations as well as shortening distances between quarries and plants would help to save energy and, in turn, minimize environmental impacts.

Briefly, profiling the environmental performance of building products in terms of aforementioned key issues according to sustainability approach, and bringing the assessment results in discussion may help;

- to encourage the use of energy efficient technologies in production,
- to develop methods for minimally processed materials,
- to recommend measures for reducing the impacts and costs,
- to select alternative products/materials on environmental performance,
- to plan production waste management,
- to rehabilitate quarry and the surrounding land.

Keywords: double skin facades, costs, payback, energy, construction, orientation, optimal, HVAC

Summary

This paper presents a dynamic thermal modeling study to show estimated energy savings and projected payback periods for various double façade construction systems in different climates and orientations. It concludes that although the economic case for a double façade is marginal when considering purely the simple payback calculation of additional capital cost divided by annual energy cost savings, a thorough and integrated consideration of many other factors can justify their construction. Climate, construction type, construction cost, and energy cost significantly contribute to the feasibility of each unique case and must be assessed for each building and costs and benefits vary widely.

1. Introduction

Double facades offer an effective means of buffering and controlling heat, light, air and noise through a building envelope. They do, however, carry a premium first cost compared to conventional facade systems. Justification of their inclusion in a building design, therefore is typically on the basis of energy efficiency and associated cost savings. Qualitative benefits of solar control, moderated surface temperatures, noise reduction, reduced glare, reduced heating/cooling demand, moderated access to fresh air, aesthetic purity and increased daylighting are generally seen only as intangible 'bonus' benefits.

The principle of a double skin façade is an additional layer of glass offset from the conventional curtain wall forming an interstitial space that acts as a thermal buffer. Blinds are typically incorporated into the void space to prevent solar heat gains from entering the occupied space (Figure 1). Blinds may be automatically or manually operated. On the outer surface of glazing, operable vents are located top and bottom to prevent the void from overheating in the summer. In the winter the vents are generally closed to trap heat in the void and reduce heat loss through the interior windows. In the mid-season condition, the inner curtain wall normally has operable windows for natural ventilation. An additional benefit is that modulating outer vents can be used to control the void temperature and thus extend the period suitable for natural ventilation.

Despite this sophistication, detailed energy savings analyses rarely conclude double skin facades have affordable paybacks at current energy prices although there is growing amount research that shows they provide better overall energy efficiency with proper controls. The aim of this paper is to investigate which scenarios may approach affordable payback periods and to what extent these are influenced by different factors.

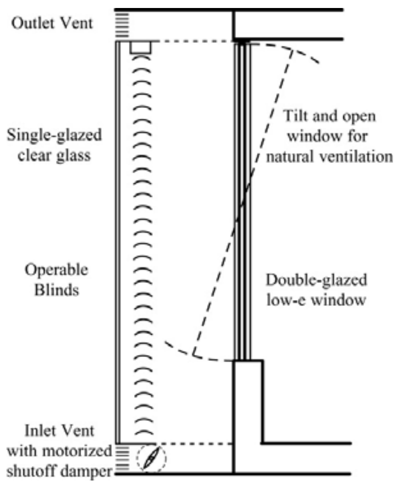

Figure 1 Typical double façade components

2. Thermal and Energy Analysis

To best understand climate conditions, dynamic thermal modeling (DTM) has been applied to the problem using the TAS software from Environmental Design Solutions Limited. DTM techniques employ a three dimensional virtual model of the building and calculate the time based thermal loads on a building based on its fabric, solar shading and historical weather data. It has been used previously in the application of double façade analysis and validated against detailed CFD analysis in this respect.

2.1 Orientation

A basic office building model was simulated with the intent of isolating the annual HVAC energy savings of a double façade over a conventional façade for various orientations. In order to do this a model of a four-storey office block was created with solid walls on three sides. The fourth side was a fully glazed façade which was rotated through eight different orientations with annual energy consumption calculated for each and for three different climates. London was selected as a mild, cloudy climate. Las Vegas was selected as a hot, dry sunny climate. Winnipeg, Canada was selected as a cold climate. Figures 2 illustrates the model geometry and the eight different orientations. Further modeling assumptions are detailed in Appendix A.

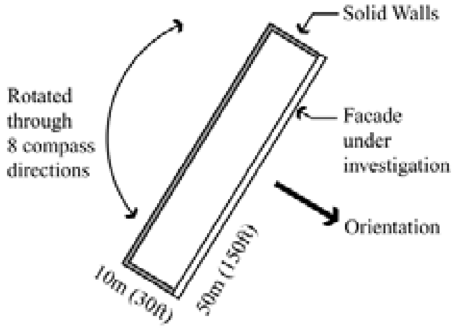

Figure 2 Plan Diagram of Simulation Model Investigating Effect of Orientation on Energy Savings of DSF

It should be noted that these results are not representative of actual office energy consumption figures due to the simplistic nature of the model. The results are intended purely as a comparison between the energy savings associated with each orientation for one design of double facade.

For London, the most significant savings in HVAC energy consumption are achieved with SW and S facades and are in the order of 23%. This is a result of the voids that are to capture solar gains in the winter providing an insulating layer and rejecting solar gain in the summer. Other orientations have less solar gain and thus heat up less in the winter and block less solar gain in the summer. Nevertheless, even the N façade shows 14% savings in energy consumption due to a greatly increased overall U-value.

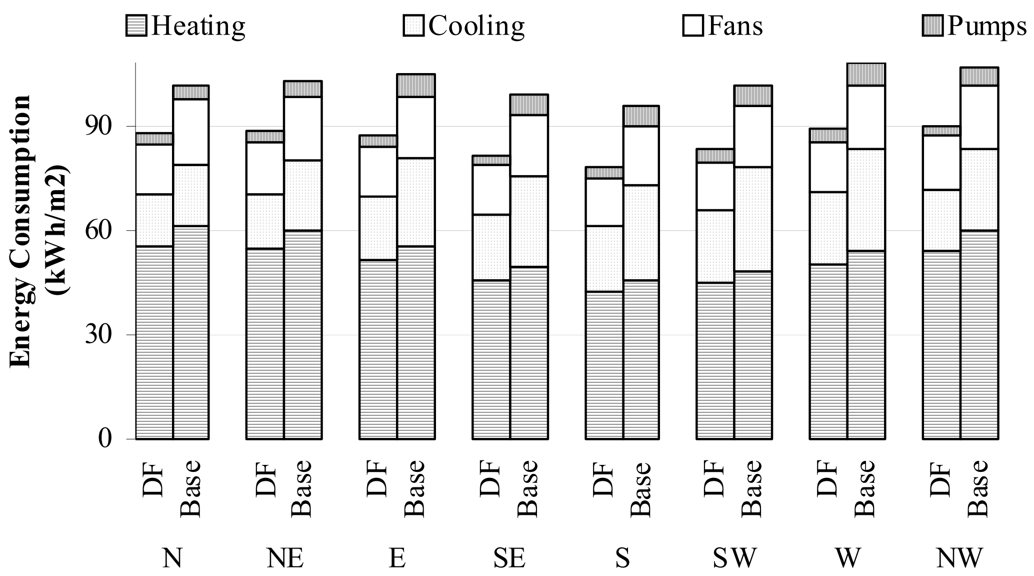

Figure 3 Energy consumption for a conventional façade and double façade (DF) for the London model

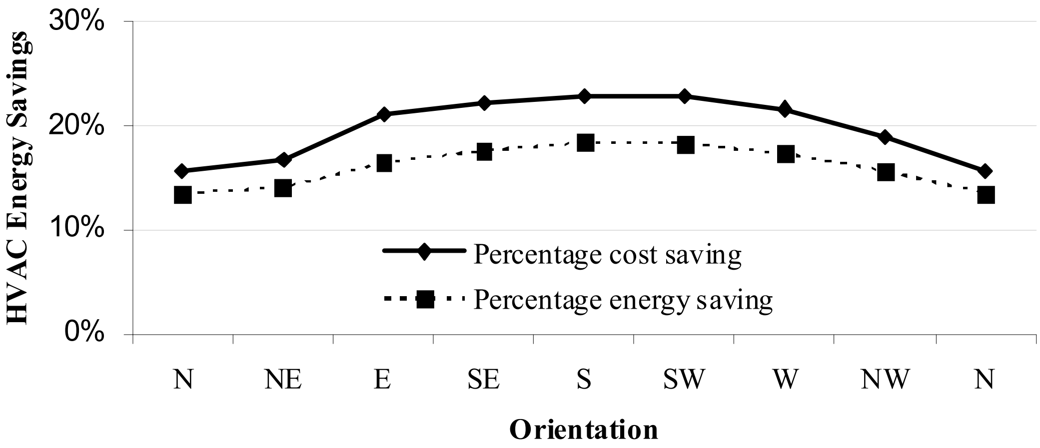

Figure 4 Percentage energy savings by orientation for the London DSF model

Las Vegas sees more energy savings from a double façade (in the region of 27%) because it is a sunny, hot climate and double facades do well to reduce cooling loads from solar gain. Other research supports the conclusion that warm climates are favorable for double facades (Cetiner and Ozkan 2005).

Winnipeg shows higher annual energy consumption than both London and Las Vegas with predominantly a heating load due to the cold climate. Energy savings shown are best on the southeastern side and are quite modest at 12%. This suggests that the design of façade selected in this analysis works more efficiently in a warm climate with high cooling load than it does in a cold climate. The solar heat gains are much less in this climate which suggests that the low-e single facade is already more efficient than it is in Las Vegas or London.

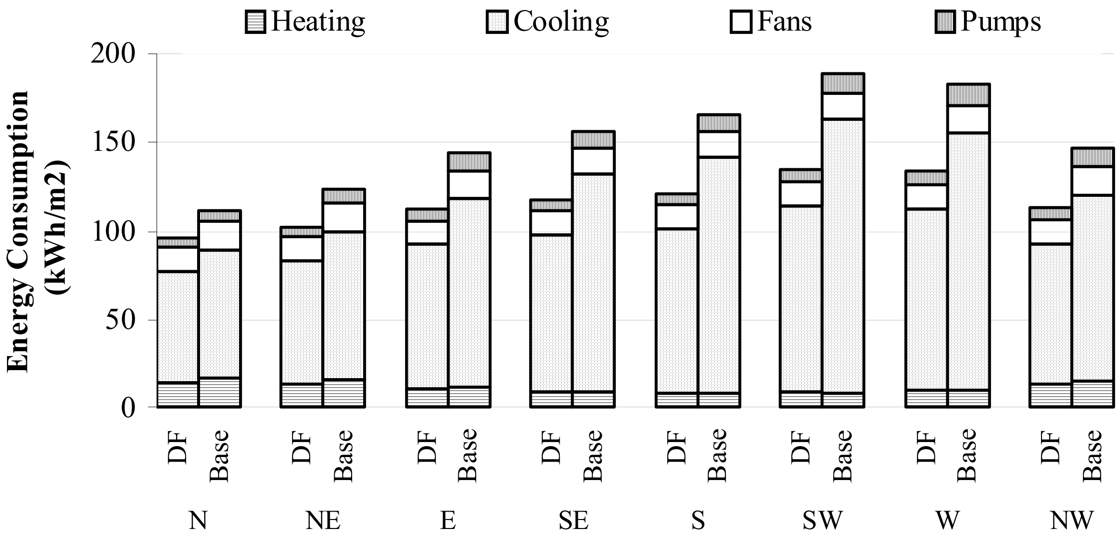

Figure 5 Energy consumption comparisons for conventional façade and double façades (DF) for Las Vegas model

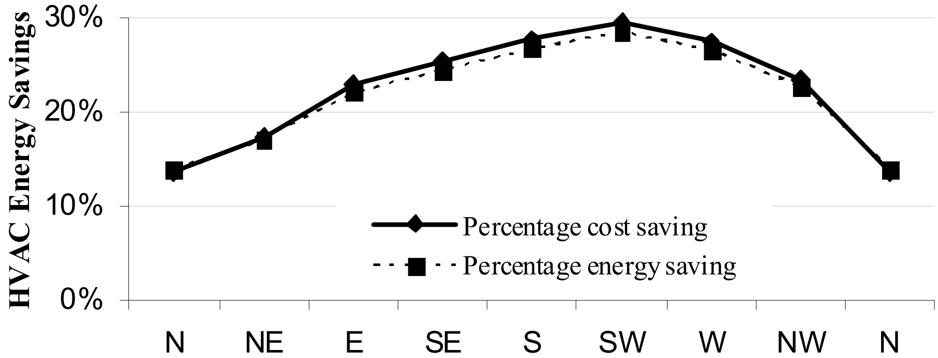

Figure 6 Percentage energy savings by orientation for the Las Vegas model

2.2 Optimal Climate

In order to determine what types of climate achieve the best energy savings through the use of double facades another model was simulated which was more representative of a typical office building. Using a southwest orientation, which was generally accepted as offering the most benefit from a double façade in the previous analysis, the building was simulated through 7 cities in different climate zones throughout the world.

The results of the analysis are shown in Figure 7 with an indication of the predicted energy consumption for the double façade versus a conventional double glazed façade for different global locations. Those generally with the greater energy consumption show the most potential for savings. It should also be noted that the same façade design has been used in all locations when in fact there may well be a different design for a warm climate as opposed to a cooler climate.

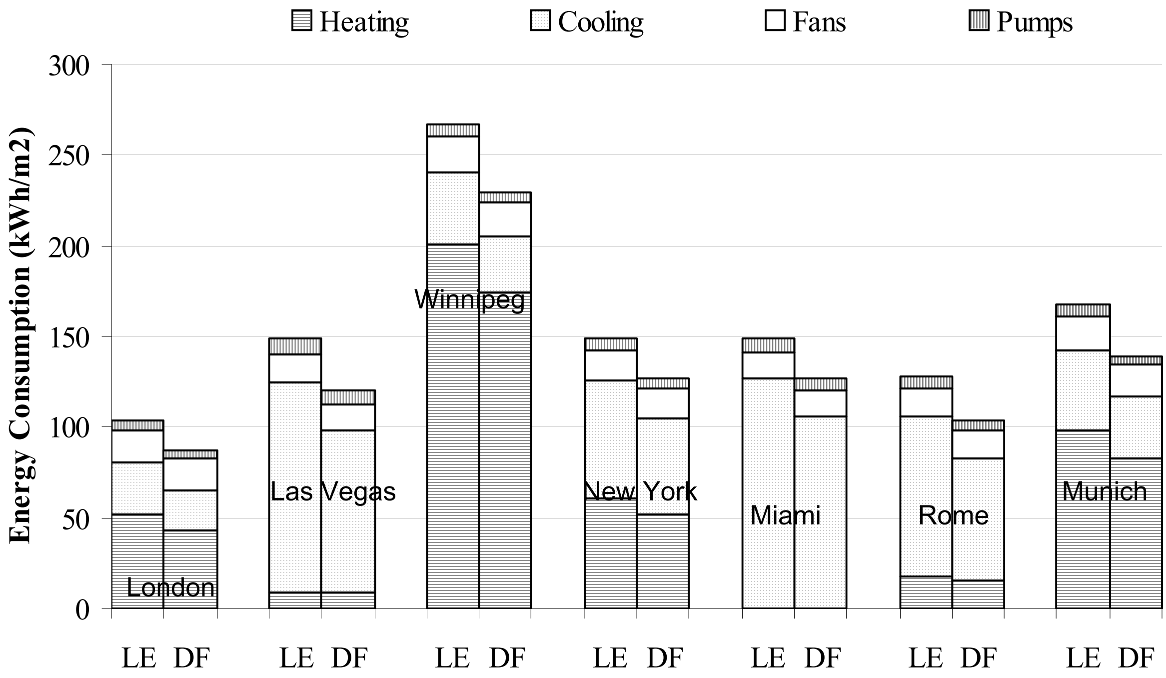

Figure 7 Energy consumption comparison for a conventional facade (LE) and double façade (DF) for different locations and climates

3.0 Economic Analysis

2.1 Façade Construction Costs

A double skin façade is a significant capital investment and an estimate of construction cost is necessary in order to make a calculation as to the likely payback period. There are wide variations depending on the level of sophistication of the façade, glass type, location, construction method and contractors experience. Many suppliers give ranges because of these factors but the figures assumed for the Las Vegas, USA analysis have been $65/ft2 for a conventional curtain wall façade with low-e glass and $180/ft2 for a simple, flat, double façade with operable vents, blinds and windows for a large building and manufactured in a factory. Europe has a wide variance of costs depending on the region. These figures are estimates rather than quotes and are based on experience and conversations with suppliers for the Europe and the US. There is some literature that has cost estimates but prices fluctuates radily and therefore much of this information is unreliable. However for comparison in 1999, double façade were approximately $585/m2 (Lee et al. 2002). The Kista Science Center in Sweden installed a double façade with venetian blinds and was estimated to cost €1000/m2 for the double façade (Streicher 2007). Table 1 lists the construction costs of facades for different locations used in this study.

Table 1 Construction Costs Assumed in Payback Analysis

	Typical Low-e	Double Facade
United kingdom	$38	$122
USA (Nevada)	$65	$180
USA (New York)	$80	$220
USA (Florida)	$65	$180
Canada	$65	$180
Italy	$145	$291
Germany	$53	$145

2.2 Energy Prices

Although double facades are meant to save energy and hence be more environmentally friendly, it usually is the payback period that determines if it is economically viable. Energy prices have an impact on the payback period. For this study, it was necessary to make assumptions on the prices of gas and electricity for each of the locations considered. Most all historical energy prices are available at the US Energy Information Administration (2008) or from the EU's Eurostat (2008).The figures used in the analysis are given in Table 2.

Table 2 Energy Prices Assumed in Payback Analysis ($/kWh)

	Electricity	Gas
United Kingdom	$0.11	$0.060
USA (Nevada)	$0.10	$0.040
USA (New York)	$0.15	$0.041
USA (Florida)	$0.10	$0.044
Canada	$0.10	$0.023
Italy	$0.16	$0.044
Germany	$0.15	$0.056

2.3 Simple Payback

The simple payback calculations in this paper are based on HVAC energy saving cost savings assuming the same type of air conditioning system for the typical and double façade.

Table 3 summarizes the energy cost payback for the 7 cities modeled and shows that the ultimate feasibility is largely dependent on energy price. The more expensive energy locations such as New York, Rome and Munich show the best paybacks with the lower energy prices of Canada extending the payback period significantly. London shows a longer payback period partly due to a lower energy price, partly due to a less extreme climate and partly due to more expensive construction costs

Table 3 Comparison of payback periods and costs for double facades

	London	Las Vegas	Winnipeg	New York	Miami	Rome	Munich
Façade area	1040m^2	1040m^2	1040m^2	1040m^2	1040m^2	1040m^2	1040m^2
Add. façade costs	$1300/m^2	$1200/m^2	$1200/m^2	$1500/m^2	$1200/m^2	$1570/m^2	$990/m^2
Add. capital investment	$1.4M	$1.3M	$1.3M	$1.6M	$1.3M	$1.6M	$1.0M
Energy cost saving	$2.46/m^2	$3.01/m^2	$2.56/m^2	$6.12/m^2	$5.41/m^2	$3.18/m^2	$5.11/m^2
Roof area	3000m^2	3000m^2	3000m^2	3000m^2	3000m^2	3000m^2	3000m^2
Annual cost saving	$7,387	$9,033	$7,688	$18,350	$9,547	$16,219	$15,319
Payback period	**185 Yrs**	**142 Yrs**	**167 Yrs**	**85 Yrs**	**135 Yrs**	**101 Yrs**	**67 Yrs**

From the results, it is possible to concluded that applies to all locations is HVAC running costs are very low compared to the capital cost of the double facade. With an expected building life of 50 to 70 years these projected paybacks would make double facades seem to be a financially poor decision. There are three things that control this, the cost of construction, the energy savings, and the energy price. The first two of these can be considered in the design and although the third is largely a factor of market forces. In the following section an analysis is carried out for double façades located in Las Vegas and London taking these factors into consideration.

2.4 Optimal Façade Design & Cost

Previous analysis has shown that the projected payback period for the considered design in Las Vegas is of the order of 142 years. Through simulation however, the baseline double façade design has been optimized to achieve 95 years. This has been achieved through optimizing the solar shading properties and control of the blinds and the temperature setpoints of the automatically opening vents and windows. The next challenge, therefore, is to reduce the construction cost of the façade and functionality to optimize the trade-off between energy savings and construction cost.

Additional features such as BMS controlled vents, BMS controlled blinds, daylight dimming, BMS controlled operable windows, shut-off dampers to air supply when windows are open, low-iron glass and an occupiable (wider) void all contribute to energy savings. However all of these additional features contribute to added construction costs. For a given climate and orientation a different set of these functionalities will produce an optimal payback period.

2.5 Payback Analysis

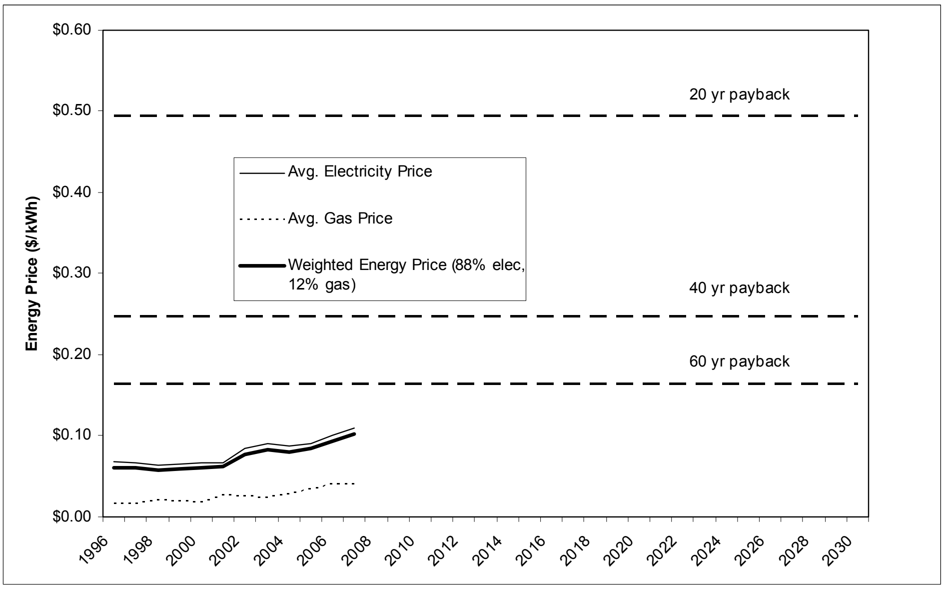

Figure 8 Energy cost for Nevada 1996-2007 (in constant 2007 dollars) compared to threshold values for target payback periods

For the optimum Las Vegas design (calculated above to have an 86 year payback at today's energy prices) the energy split is 12% gas, 88% electricity due to the predominance of cooling in this climate. A weighted average energy price for the model building has therefore been calculated and plotted on the graph in figure 19 together with threshold prices that would achieve 20, 40 and 60 year simple paybacks. This analysis shows that the historic gas and electricity prices for Las Vegas, Nevada in constant 2007 dollars would provide between 50 and 90 year simple paybacks.

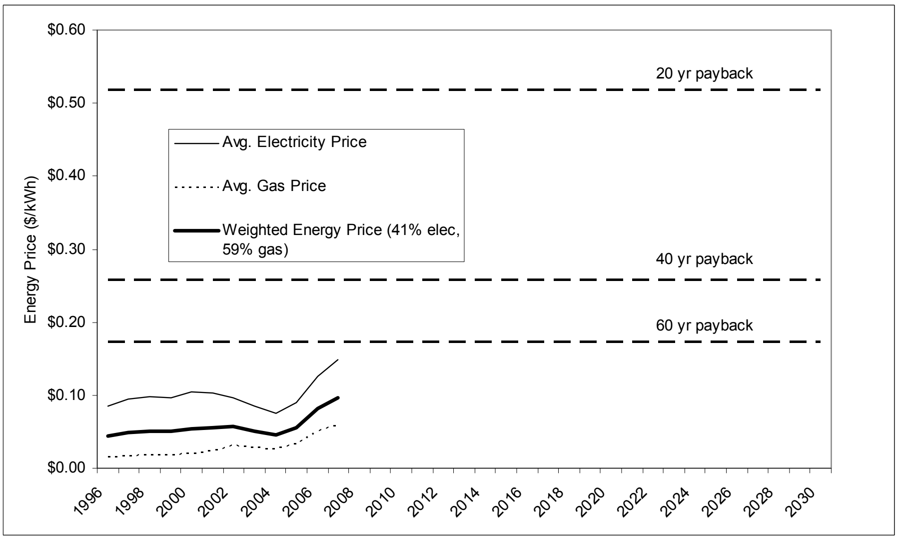

Figure 9 Energy cost for UK 1996-2007 (in constant 2007 dollars) compared to threshold values for target payback periods

If energy prices reach $0.90/kWh for electricity and $0.30/kWh for gas and the construction costs remain constant the payback would be 20 years. In the last five years energy prices have risen 20% to 75% depending on the location but are still well below a 60 year payback.

In a similar exercise, the façade design for London was optimized through simulation to give a 90 year payback at today's prices of $0.11/kWh for electricity and $.06/kWh for gas. The energy split for the modeled building in London is 59% gas, 41% electricity resulting in a weighted, current energy price of $0.096/kWh. Figure 9 shows the trend of the energy price for the UK normalised to real 2007 prices together with the thresholds for 20, 40 & 60 year paybacks.

4. Other Important Influences on Cost Payback

Other issues aside from strict energy savings and construction cost influence design decision, and a number of important factors for DSF are listed below. Many are soft issues which improve worker productivity, by far the largest portion of an office building's life-cycle cost. Little quantifiable research has been done on these topics and this is an area in great need for future research.

Additional Maintenance Costs – 4 window surfaces to clean instead of 2, motor replacement, louvre maintenance, etc.

Perimeter Zone Cooling Compared to Overall Energy – some studies have shown a significant reduction in cooling airflow but a minimum increase in the overall energy savings for a building (Doebber and McClintock 2006).

Glare Control – operable blinds block direct solar glare and accept diffuse light

Moderated Glass Surface Temperatures – blinds block direct solar rays from striking the inner glass preventing it from heating to upwards of 60°C (140°F). In the winter, the warm void heats the inner glass reducing drafts and cold radiant exchange.

Operable Windows in High-Rise Buildings –the void buffers wind pressures which otherwise make operable windows very gusty and disruptive in tall buildings.

Acoustical Buffering – the vents and void dampen noise improving acoustics near noisy roads, airports, factories or rail lines.

Increased Daylighting – operable blinds actively bounce light deeper into occupied space. Improved U-value allows larger windows.

Reduced Emissions – greenhouse gases, SOx, NOx and other particulates are reduced as energy consumption is reduced.

Aesthetic Purity – the exterior rain-screen requires no thermal breaks, structural mullions or spandrel glass providing a visually simple façade. Blocked UV, wind and rain allow a wood framed interior curtain wall. External blinds provide shading, so clear glass is acceptable.

The Air Cavity Use – it is very rare to reduce both annual cooling and heating demand. The width, type of vents, integration with mechanical systems and use of the air cavity has a significant impact on energy savings (Saelens et al. 2003).

Reduction of Rentable Square Footage – Rentable square feet (RSF) is the area for which rent is typically charged to the tenant. In major cities, the commercial office space is at a premium and a double façade reduces the RSF.

5. Conclusions

An analytical investigation has been carried out into the cost versus payback benefits of double skin facades with respect to their energy saving potential. From this work the following conclusions can be drawn.

A double façade offers the most energy saving potential on the south and south-west orientations.

Extreme climates offer more opportunity for energy savings as they require more HVAC energy and thus have greater potential for savings through improved building envelope.

Energy savings can range from 10% to 50% of HVAC energy, and cost payback can range from 30 to 200 years based on today's local energy prices. Double facades must be assessed specifically on their individual merit considering climate, orientation, detailing, construction cost and energy price.

The economic viability of double façades in a location is not only a result of the climate. Construction costs and energy price play an even more significant role in the results as there is a large global variation.

Although energy prices have risen significantly in the last five years, construction costs and material costs have also increased. Energy prices and construction costs are directly correlated and usually have the same trends. Therefore rising energy prices alone will not reduce the amount of time on return in investment for double facades.

The additional benefits of double facades have not been fully explored in this paper. Many of these attributes are unquantified. Considering their importance in making a financial case for double facades, further research is recommended in this area.

Appendix A. Modeling Assumptions

Orientation Model:

This model was 10m (30ft) deep and 50m (150ft) wide, four stories tall with solid walls and no glazing on three faces. On the fourth face, the façade was applied as described below.

The baseline building has 70% glazing on facade side (U-value = 1.8 W/m^{2}K, R-3).

The double façade building had a double façade on the glazed side with a 1m (3ft) wide void, motorized blinds with total solar transmittance of 0.6, operable lower and upper vents 300mm (1ft) high which are open in the summer months when the void temperature reaches 24ºC (75ºF), clear 10mm single glazing on the outer facade, and insulated low-e inner glass (U-value = 1.8 W/m^{2}K, R-3) on the inner facade. The double façade model had operable windows and are open for natural ventilation when the void is between 16-22ºC (61-72ºF).

Internal Heat Gains:

Occupancy - 10W/m^2 (sensible), 6W/m^2 (latent) between 8am to 6pm, 7 days per week

Lighting – 15W/m^2

Equipment – 8W/m^2

Plant switched on 8am to 6pm heating 20ºC, cooling to 24ºC

Night setback heated to 18ºC in winter

Optimal Climate Model:

This model was 15m (45ft) deep and 50m (150ft) wide, four stories tall at the optimal orientation of SW. The baseline building has 40% glazing on all four sides (U-value = 1.8 W/m^{2}K, R-3) which does not have operable windows. The double façade building has a double façade on the southwest and southeast facades. The double façade has a 1m (3ft) wide void, motorized blinds, motorized vents at 500mm width inlet and outlet (0.5ft^2/ft), clear single glazed outer glass, and insulated low-e inner glass (U-value = 1.8 W/m^{2}K, R-3) and operable windows. All internal heat gains and plant times were the same as described above for the orientation model.

ENVIRONMENTAL CONSIDERATIONS IN CONSTRUCTION IN JAPAN, BY OBAYASHI CORPORATION

Keywords: global warming, carbon dioxide, construction, fuel saving, industrial waste, zero emission

Summary

This paper investigates how a Japanese construction company, Obayashi Corporation, has worked to reduce environmental loads during construction.

The issue of global warming is important in the construction industry, which is responsible for 40% of total carbon dioxide emissions in Japan. During construction, diesel fuel consumption and industrial waste disposal are two major causes of carbon dioxide emissions.

Two thirds of the carbon dioxide emissions from Obayashi's construction sites are linked to diesel fuel, and more than half of these are emitted by dump trucks and construction machines. A 'fuel saving drive' method was introduced in 1999 to reduce fuel consumption.

Another factor in carbon dioxide emissions in the construction stage is the volume of industrial waste that must be disposed of. Industrial waste hauling vehicles, recycling facilities and incinerating facilities emit carbon dioxide, and about 20% of total industrial waste disposal in Japan is derived from the construction industry. A 'zero emission' method was adopted at construction sites in 1999 to reduce the volume of industrial waste.

Obayashi Corporation estimates that, as a result of various environmental actions, carbon dioxide emissions during construction in 2006 were reduced to 264,000 tons which is 30% less than those in 1990.

1. Introduction

The activities of the construction industry, from material production, material processing, and transportation to the building site, have a close relationship with environmental issues. Research on environmental loads from construction industry has shown that approximately 40% of carbon dioxide emissions in Japan are related to construction activities (Figure 1).

Although the construction industry has a potential impact on carbon dioxide emissions, carbon dioxide emissions in the transportation and building phases directly related to construction activities contributed only 6.4% of the total in 1995. However, unlike other phases such as material production, material processing and building operations, these two phases are manageable at construction sites.

In the transportation phase, the main activity relating to carbon dioxide emissions is haulage of building materials and industrial wastes. Thus, diesel fuel consumption by haulage vehicles has to be considered in reducing carbon dioxide emissions.

In the building phase, energy consumed at the construction site, such as electricity, diesel fuel and kerosene, and industrial waste disposal from the construction sites, are issues to be addressed. This paper focuses on diesel fuel consumption and industrial waste disposal in finding ways to reduce carbon dioxides emissions.

Obayashi Corporation has dealt with diesel fuel consumption and industrial waste disposal as two major causes of carbon dioxide emissions in the construction stage and applied a 'fuel saving drive' method to reduce diesel fuel consumption and a 'zero emission' method to reduce industrial waste disposal.

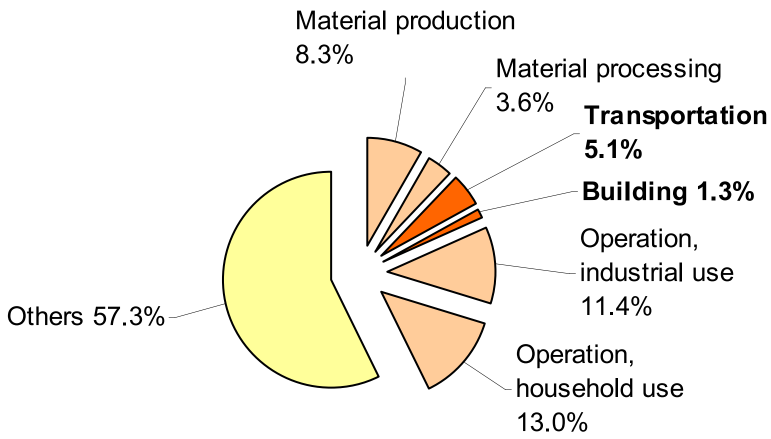

Figure 1 Carbon dioxide emissions related to construction activities estimated form inter-industry relationship table in Japan in 1995.

2. Carbon Dioxide Emissions related to Diesel Fuel Consumption

2.1 Diesel Fuel Consumption in the Construction Stage

Diesel fuel is consumed mainly by haulage vehicles in the transportation phase and by dump trucks / construction machines in the building phase.

In the transportation phase, haulage vehicles carry in building materials and carry out industrial wastes. Energy used to haul other things, like temporary materials and surplus soil, is counted in the building phase.

The main consumers of diesel fuel in the building phase are dump trucks / construction machines. Obayashi Corporation surveyed energy sources at 106 construction sites in 2006 and the results indicate that diesel fuel produces 61% of the total carbon dioxide emissions in the building phase. Dump trucks and construction machines have virtually the same impact, each consuming about 30% of the total carbon dioxide emissions. (Figure 2).

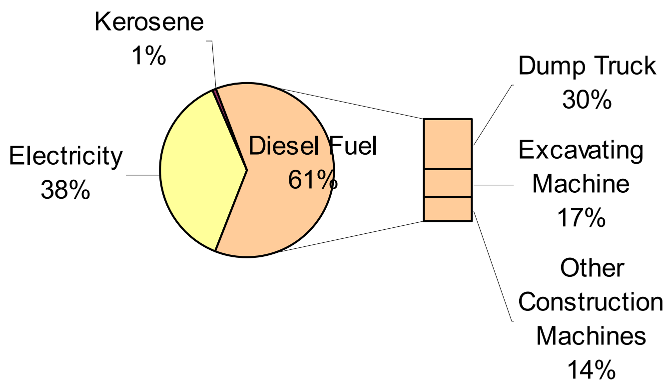

Figure 2 Carbon dioxide emissions in construction stage by energy sources at Obayashi Corporation construction sites in 2006.

2.2 Fuel Saving Drive Method

To reduce diesel fuel consumption in the construction stage, Obayashi Corporation introduced a fuel saving drive method to its construction sites in 1999.

This method, originally developed to save fuel consumption at the time of the oil shocks in the 1970s, was refined by Obayashi Corporation as a solution to reducing carbon dioxide emissions in the construction stage. Five clauses of the fuel saving drive for hauling vehicles / dump trucks are shown (Table 1). This method is more effective in city areas than in rural areas. By adapting these clauses, fuel consumption can be reduced without any initial cost.

To demonstrate the effect of the method, fuel saving drive workshops were organized with the support of haulage vehicle / dump truck / construction machine manufacturing companies. By installing precise fuel gauges to haulage vehicles / dump trucks / construction machines and driving the same route / performing the same operation, fuel consumption differences could be measured at the workshop (Figure 3 and 4).

More than 1,000 people had attended the Obayashi Corporation's fuel saving drive workshops by the end of March 2008.

To maximize the effect of the activity, Obayashi Corporation opened the fuel saving drive method to the public in 2001.

The fuel saving drive method is applicable to various haulage vehicles, dump trucks and construction machines. As shown in Table 2, since the workshops were held, fuel consumption has improved by 10 to 40% on average.

In terms of continued efficiency, the average fuel consumption of drivers who attended the workshop did not decline after they attended the workshop. The company conducted the workshop using the dump truck and started to record the fuel consumption after that. The average fuel consumption of 5 drivers who attended the workshop was nearly constant; 0.40liters/km in the next month and an average of 0.41liters/km over the following 9 months (Figure 5).

The advantages of the fuel saving drive method are not only reduction of carbon dioxide emissions but also saving of fuel cost, maintenance cost and insurance cost.

3. Carbon Dioxide Emissions related to Industrial Waste Disposal

3.1 Industrial Waste Disposal in Construction Stage

Industrial waste relates not only to transportation but to disposal. Carbon dioxide is emitted when industrial waste is reused, recycled, incinerated and landfilled, as well as transported.

According to the white paper put out by the Ministry of the Environment of Japan et al. in 2002, approximately 20% of both waste disposal and final landfill disposal are derived from industrial waste from the construction industry. Likewise, the construction industry produces 19% of all general and industrial wastes (Figure 6). This is because the volume of industrial waste is several times that of general waste. In 2002, the volume of general waste was 51,450,000 tons and the final landfill volume was 10,870,000.

This result shows that industrial waste produced by the construction industry must be reduced in considering carbon dioxide emissions.

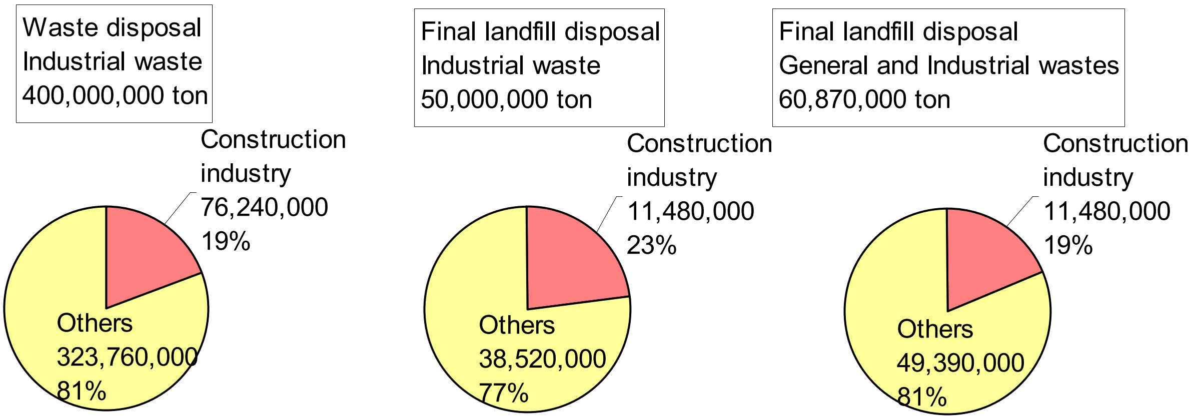

Figure 6 Proportion of waste disposal of construction industry to total waste in Japan in 2002.

3.2 Zero Emission Method

The zero emission method, originally designed to eliminate industrial waste disposal from a soap factory in Belgium, is also effective in the construction industry.

Keeping the concept of initial zero emission activity, Obayashi Corporation adapted the method and applied it to two construction sites in 1999. Successful results were achieved, and the method was then applied to all its other construction sites.

The zero emission method consists of four steps (Table 3). Firstly common awareness is shared among people involved. Then, efforts are made to produce as little waste as possible. However, some wastes are produced and they are classified to reduce the volume (Figure 7). Finally, classified wastes are recycled.

While the zero emission method is efficient in reducing industrial waste from construction site, it is impossible to achieve literally 'zero' emission in the construction industry. Obayashi Corporation set up in-house targets for zero emission; not over 5kg per unit floor area final landfill volume or not over 5% final landfill ratio.

As a result of these environmental activities, 76% of total Obayashi Corporation construction sites achieved the in-house zero emission targets, an increase of 8% from the previous year (Figure 8), and the final disposal ratio has been decreasing since 2001 and was 4.2% in 2006 (Figure 9).

Table 3 Four steps of zero emission method at construction sites

Step 1	**Common Awareness** Partnership for Zero Emission realization · Establishment of promotion body · Increase of educational activity · Organization of environmental events · Classification and reduction of general waste
Step 2	**Emission Control** Attempt to reduce emission in both design and construction stages · Improvement of construction method · Reuse of temporary materials · Reduce extra materials · Reduce packaged materials
Step 3	**Efficient Classification** Ultimate classified collection for easy recycling · Preparation of Recycle Palette and Recycle Station · Introduction of Logistic Center
Step 4	**Resource Recycling** Recycle classified waste · Establishment of resource recycling route · Positive usage of recycled materials

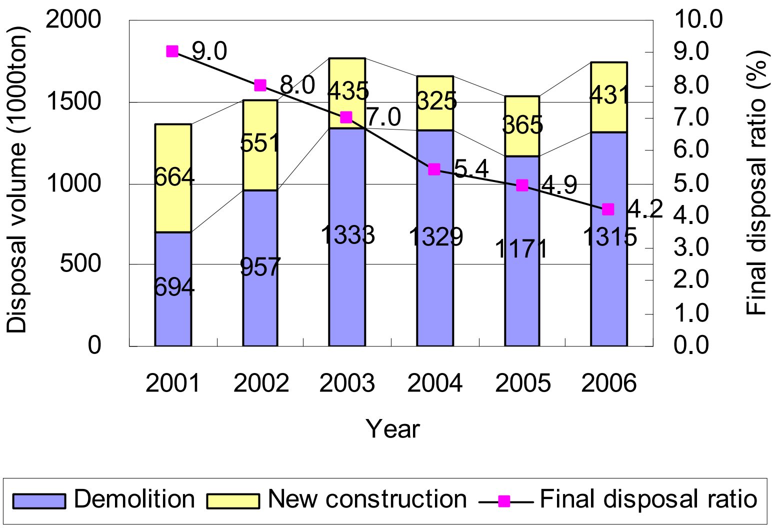

Figure 9 Industrial waste volume and final disposal ratio for Obayashi Corporation.

4. Carbon Dioxide Emissions during Building Phase

Obayashi Corporation has been surveying carbon dioxide emissions during building phase from energy consumption at its construction sites. Several construction sites of varied building types were selected and energy consumption was measured. Total carbon dioxide emissions were estimated after carbon dioxide emissions per unit sales were calculated. Measured energy consumption included electricity, kerosene and diesel fuel (Figure 10).

As a result of various environmental actions, carbon dioxide emissions during the building phase in 2006 were decreased to 264,000 tons which was 30% less than the emissions in 1990 (Figure 11).

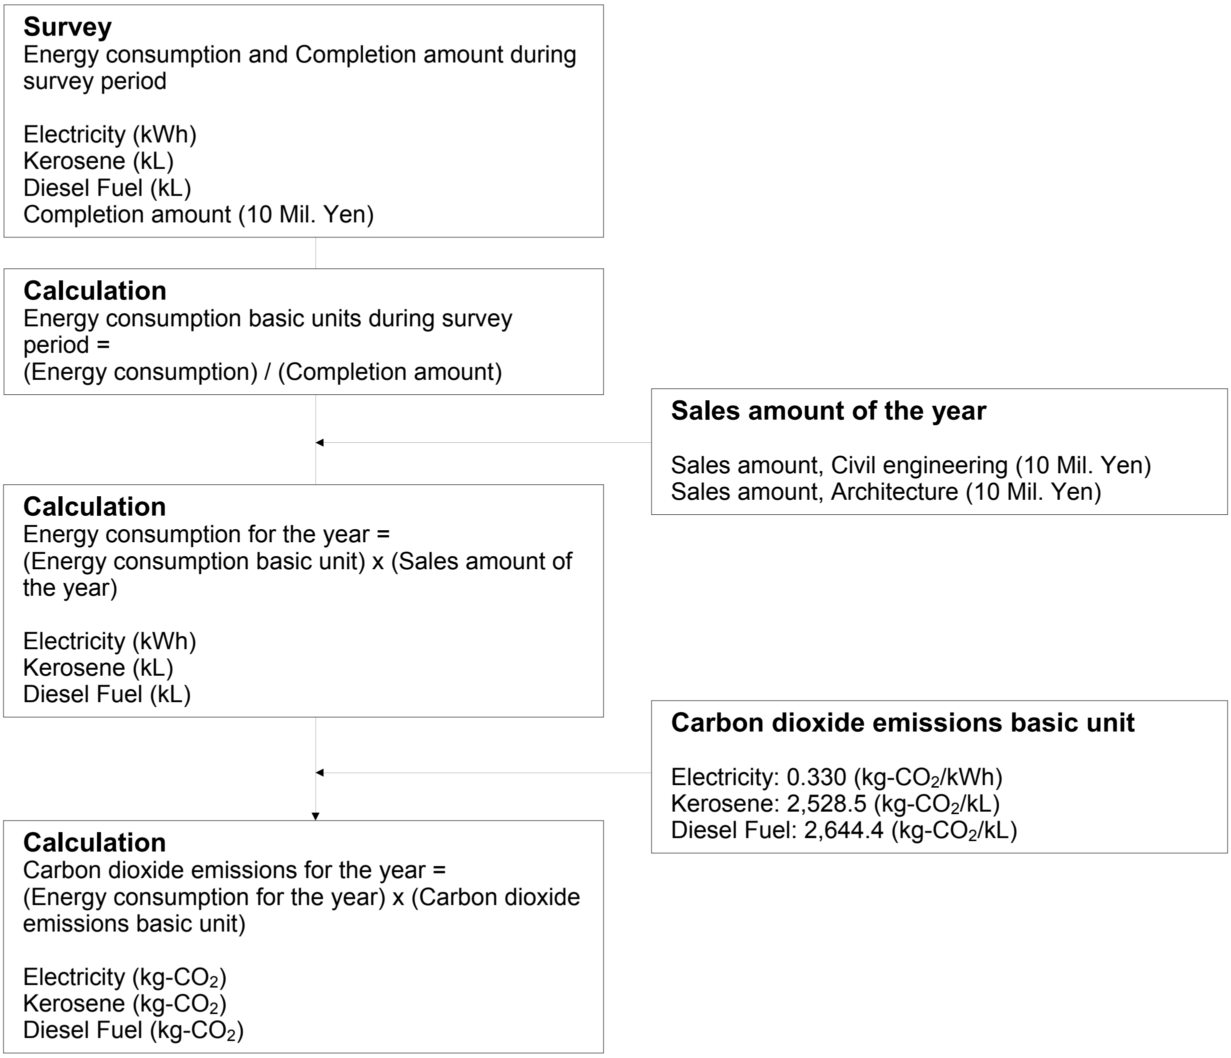

Figure 10 Estimation of carbon dioxide emissions at construction sites from energy consumption.

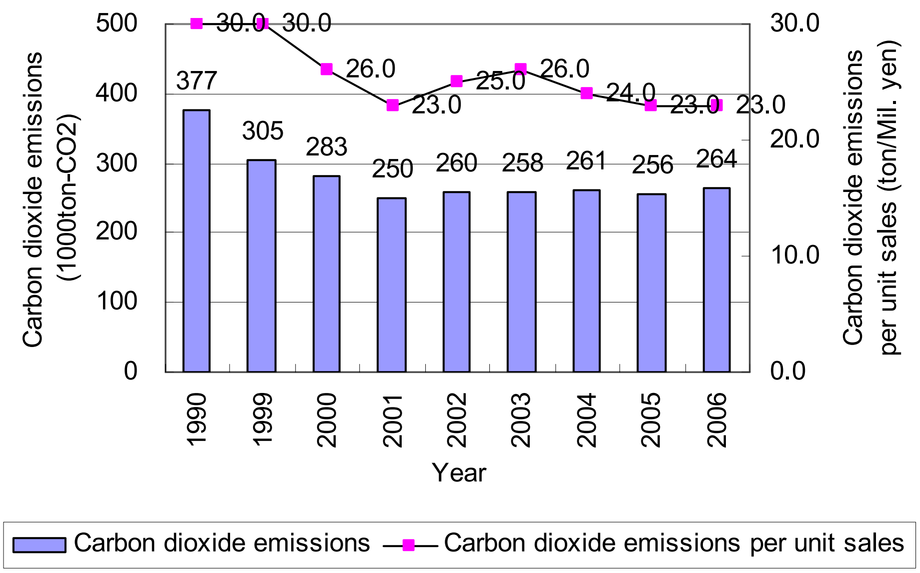

Figure 11 Carbon dioxide emissions in the building phase for Obayashi Corporation.

5. Conclusions

Although carbon dioxide emissions produced by the construction industry are more than 40% of the total in Japan, emissions during the construction stage, transportation phase and building phase, are only 6.4%. Because its environmental impact cannot be ignored and these emissions are manageable by construction companies, Obayashi Corporation started environmental activities to reduce carbon dioxide emissions from its construction sites in 1999.

There are two sources of carbon dioxide emissions in the construction stage: diesel fuel consumption and industrial waste disposal. Diesel fuel is consumed not only by haulage vehicles / dump trucks / construction machines in both the transportation and building phases, but also by industrial waste haulage vehicles. The construction industry produces about 20% of both total disposal and final landfill volume, and also relates to carbon dioxide emissions when wastes are reused, recycled, incinerated and landfilled as well as when they are transported. Obayashi Corporation introduced a fuel saving drive method and a zero emission method to mitigate this problem.

The fuel saving drive method was developed in 1999 and is used by more than 1,000 drivers / operators. Without investing any initial cost, a fuel saving ratio of 10-40% is expected for various vehicles and construction machines.

The zero emission method was also introduced to the Obayashi's construction sites in 1999. Approximately three fourths of sites cleared in-house zero emission targets in 2006. As a result of common awareness of the zero emission concept, the final disposal ratio was decreased to 4.2% in 2006, 0.7% less than the previous year.

To estimate carbon dioxide emissions in the building phase, a part of the construction stage, Obayashi Corporation surveyed electricity, kerosene and diesel fuel consumption at its construction sites. Because of the popularization of the two major methods, fuel saving drive and zero emission, carbon dioxide emissions in 2006 were estimated to be 264,000 tons-CO_2 which was decreased by 30% compared to the year 1990.

Summary

An adjustable shading system inspired by leaves is presented. Plants have developed unique mechanisms for specific climates and locations, where they can determine the amount of exposure for the efficient photosynthesis performance. Physiology and geometry are the most significant factors influencing light interception in plants, where leaf distribution, orientation and dynamics influence the exposure to sun radiation. Based on principles and methods extracted and abstracted from plants, a shading system was designed that has the ability to track the range of sun radiation throughout a day. Computer simulations checked the performance of the shading system through three critical days throughout the year, where azimuth and altitude angles were considered. The simulations resulted in showing different patterns of shading areas. The combination of azimuth and altitude angles determined the distribution of the shading system elements. Due to the flexibility of the system in orienting to different directions and repositioning through the day, it provides continuous shading all over the desired plane at the envelope. With the system it is possible to achieve maximum required shaded area with loose density of shade planes and avoiding self-shading, or shading with high density of shade planes for maximum energy gaining, due to their position normal to sun rays.

1. Introduction

Shading devices can be attached to building envelopes internally or externally, where they control the amount of light that permeates through the envelope. Adding shading devices to the envelope is important for reducing peak heat loads in the building, reducing cooling requirements, and improving natural lighting and more external visual contact than other standard shading devises. Energy-efficient building design is influenced significantly by the shading device. Current shading devices include solid shadings, canvas awning, roller shades, blinds and louvers. These shading technologies basically deal with extensions either vertically or horizontally, or by adding an extra cladding to protect against radiation from glazed openings, while leaving some amount of light to penetrate inside. These technologies have limited adjustability, while they are designed for the extreme situations of solar radiation and not for the whole range of solar radiation exposure (Badarnah et al. 2008).

Plants are organisms that have a significant relation with sun radiation. The relation between light and plant's leaves has been investigated and reported by numerous biologists (e.g. Ehleringer et al. 1980, Brunig 1976, and Loomis et al. 1971). Organizational features in plants offer various solutions for tracking sun radiation, either paraheliotropic or diaheliotropic. Plants have developed unique mechanics for specific climates and locations, where they can determine the amount of exposure for efficient performance. Physiology and geometry are the most important factors that influence light interception in plants (Badarnah et al. 2008). Therefore, looking at nature's solutions is a method for developing efficient technical systems for building envelopes. The structural geometry of the shade elements for *The Singapore Lyceum Theater* was inspired by nature, like sunflowers, fish scales etc. The intention of the architects (DP Architects) was, that the enveloping façade system changes pattern to suit the orientation of the sun, providing solar shading and controlling the internal environment of the pavilions (www.geocities.com). However, the individual shading devices are not adjusting themselves throughout the day or seasons according to sun-ray angles.

This paper introduces a shading system inspired by organizational features in leaves, where location and inclination were considered in the study and the developed system. The focus is on external shading elements, because of their effectiveness in blocking solar radiation before reaching the indoor environment (Olgyay 1992). Section 2 presents the background for leaves responding to sun radiation, and it is based on the work done by Badarnah et al. (2008). Based on this section, the main principles were transformed into technical solutions for a shading system (section 3). In order to evaluate the performance of the shading system throughout the day and seasons, computer simulations were carried out (section 4), and with these simulations, the different shading patterns of the same system where studied (section 5). Finally, a discussion and the conclusions are presented in section 6.

2. Background

From summarizing the techniques used in plants for reacting to sun radiation, three main categories were recognized for maximum and minimum light exposure. Leaf distribution, orientation and dynamics play a significant role in influencing the exposure to sun radiation. Principles from the different categories influence the plant to track the sun effectively. Morphological and physiological factors influence light interception in plants (Brunig 1976), where it affects photosynthesis and rate of plant productivity (Loomis et al. 1971).

2.1 Distribution

The combination of arrangement and density of leaves affects leaf distribution in plants for photosynthesis efficiency (Ehleringer et al. 1980). Therefore, there are two ways for photosynthesis efficiency: leaves distributed in a single-layer with high density or multi-layer distribution with loose density (Horn 1971). Leaf density of plants, influences the plant's projected area, which affects sunlight interception capability (Niklas 1988). Form and proportion are additional factors affecting photosynthesis efficiency (Kriegh 2003). Some plants have special arrangements that could be described mathematically, e.g. Fibonacci series, which are adopted for compact and dense packing of members.

2.2 Orientation

In plants, sun tracking is achieved in two ways: leaves move perpendicular to the direct sun rays, which are called diaheliotropic leaves, and leaves move parallel to the direct sun rays, called paraheliotropic (Ehleringer et al. 1980). Heat load, leaf temperature and transpiration rate are reduced with paraheliotropic movements (Forseth 1980). Diaheliotropic movements, fig. 1, allow a high solar irradiation and result in maximal rates of photosynthesis throughout the day (Mooney 1978). Regulation of leaf inclination is one of the mechanisms to avoid shading by neighbors (Mullen et al. 2006), fig. 1.

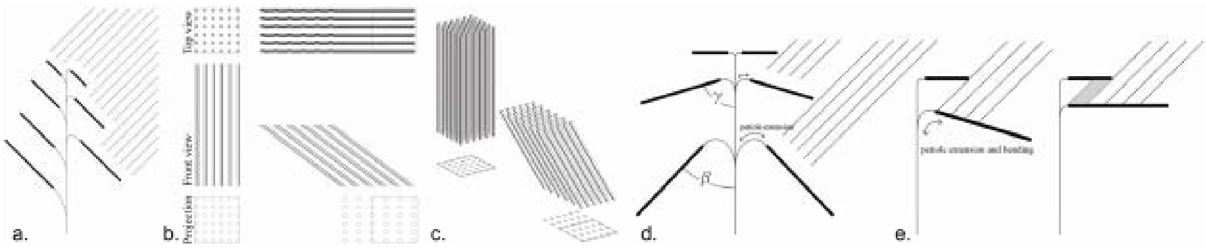

Figure 1 (a-c) The angle of incidence determines energy density.(a) leaves normal to sun rays for maximum energy gain. (b) the effect of different inclination on the projection. (c) top, front and projection view. (d,e) lower layers of leaves bend for maximum light perception. (d) lower leaves get bigger with smaller inclination (β<γ). (e) the effect of inclination, preventing self-shading.

2.3 Dynamics

Plasticity in response to sun light is one of the dominant aspects of plant architecture (Pearcy et al. 2005). This plasticity is recognized when leaflets shift from a vertical position to a horizontal position. In this process plants increase their internodes and petiole length, and leaves increase their area while reducing mass per unit area. Dynamics in plants are generated via their nastic structure (Bar-Cohen 2006); it has different functions, such as rapid bending, which is recognized at the *Venus flytrap*. Its closure is achieved through the property differences at the exterior and interior surface of the wing, fig. 2. The inner surface is able to extend 5%, while the outer surface extension is 20%. Another function is orienting horizontally or vertically, this property is adapted basically to track sun radiation. The centralization of vascular bundles in the leaf stalk allows the leaf to bend.

Figure 2 Venus flytrap. At right, a cross section showing different extensibilities for the inner and outer surfaces.

2.4 Summary of techniques used in light-responsive plants

Table 1 Summary of main organizational features in leaves for maximum light exposure.

	Distribution/position	Orientation/inclination	Dynamics
Maximum light exposure	• loose distribution at multi-layer • dense distribution at mono-layer • maximum projected area • Fibonacci series for compact pattern packing • extending stem • horizontal expansion	• perpendicular to sun-rays (Diaheliotropic) • facing east for maximum exposure at morning and afternoon • facing south/north for maximum exposure at winter noon's	• increasing internode and petiole length • increasing leaf area combined with reducing mass per unit • plasticity, nastic structure • different flexibilities of the sides of a blade • special surface properties-uncoated cell clusters (for flexibility) • convex surface shape

3. Principles Transformation

Leaves in plants have unique properties in order to track sun radiation. For maximum exposure, leaves tend to have a clear organization and distribution with an adaptive inclination and relatively high plasticity in the plant's body (Table 1). At minimum exposure, plants are less dynamic and reorient when having high exposure, e.g. at noon, also they tend to have low leaf inclinations, preventing conditions such as normal to rays. Furthermore, in order to achieve dynamics, the structural geometry is very significant. Geometry is a major aspect for determining the distribution, inclination and dynamics. Based on principles and methods extracted and abstracted from plants, a shading system was designed. For the design process we referred to the following (extracted from Table 1):

- Mono-layer at dense distribution for maximum light capture
- Plasticity, in order to adapt to different inclinations
- Different inclinations of leaves in relation to sun rays, the generated projected area could be maximized
- Leaves normal (perpendicular) to sun-rays
- Special surface properties, for flexibility
- Increasing leaf area combined with reducing mass per unit, for better photosynthesis process
- Petioles extension, in order to prevent self-shading
- Stem elongation for maximum light capture

These principles and methods are the base-line for the shading system development. The transformation of these principles and methods resulted in a shading system for building envelopes that has adjustability for different inclinations. In this complex transformation process, plant's mechanisms and building envelope's demands need to be integrated. Based on the unique shape and structure of plant's leaves, which provide them the desired flexibilities induced by sun light, it is possible to develop a system providing shading and also energy generation. The side of the sheets facing radiation has integrated cells for gaining energy and by that provides shade for underneath.

3.1 The shading system

The system consists of shading sheets, tubular members and profiles. The shading sheets are connected to the tubular supporting members via an elastic membrane for flexibility. The profiles create a grid, which allows the tubular members to roll over and control their position according to shading requirements. For sun radiation blocking, the shading sheets are flexible and can be adjusted to different inclinations, more explanation in the following sections.

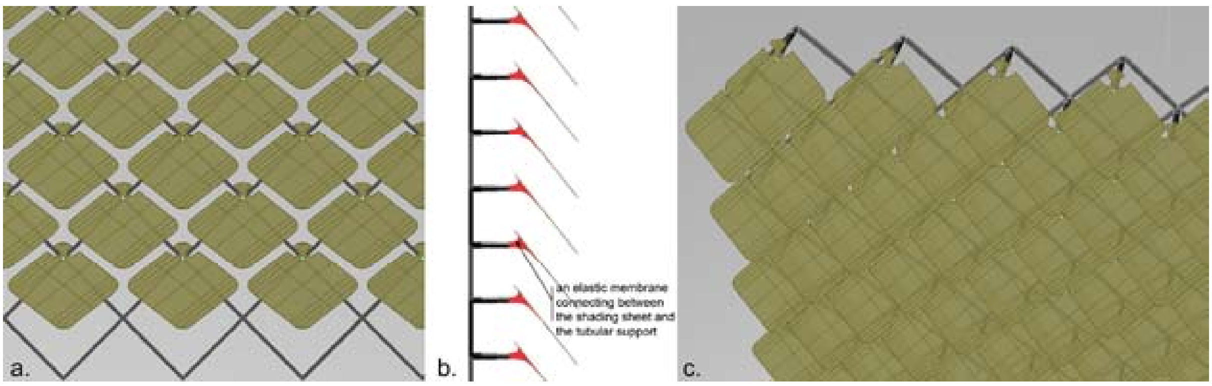

Figure 3 The shading system. (a) front view, shading sheets and profiles in the back. (b) side view, shading sheets connected to the tubular member via the elastic membrane. (c) perspective view.

This system is designed for the whole sun radiation path throughout all the days of the year, where azimuth and altitude angles are considered (Figure 4). The system blocks the sun radiation at a specific angle and allows the indirect light to penetrate between the sheets. When the sheets are normal to sun rays, their position in the depth could be different (Figure 5). In this case, indirect light reflected from the surrounding environment reaches behind the system and keeps the interior space with good quality of light. Additionally, shading sheets being normal to sun rays is the best orientation for radiation gaining, where photovoltaic cells are attached to the surface facing sun.

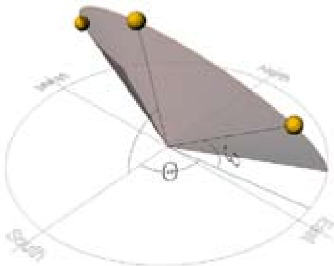

Figure 4 *Azimuth (θ) and Altitude (ω) angles determine the position of sun. The hatched surface presents the sun radiation path throughout a specific day.*

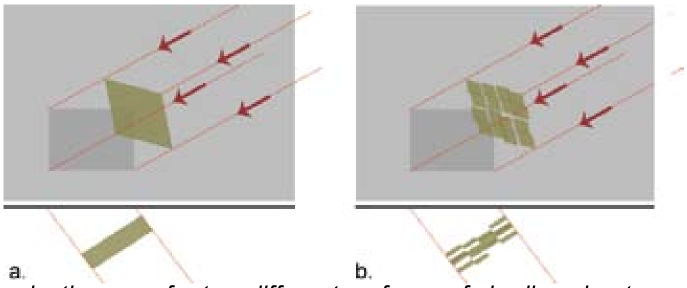

Figure 5 *The same projection area for two different surfaces of shading sheets normal to sun rays. (a) the shading sheet flat and normal to sun rays. (b) the shading sheet is divided to smaller pieces and positioned in different depths of ray direction.*

3.2 The shading component

The shading component consists of a sheet attached to a supporting tubular member with the property of elongation (Figure 6d). This elongation is important to avoid shading by neighbors. The sheet is able to have different inclinations as shown in Figure 6(a-c), where it covers and blocks the sun radiation path, which is determined by azimuth and altitude angles, throughout a day.

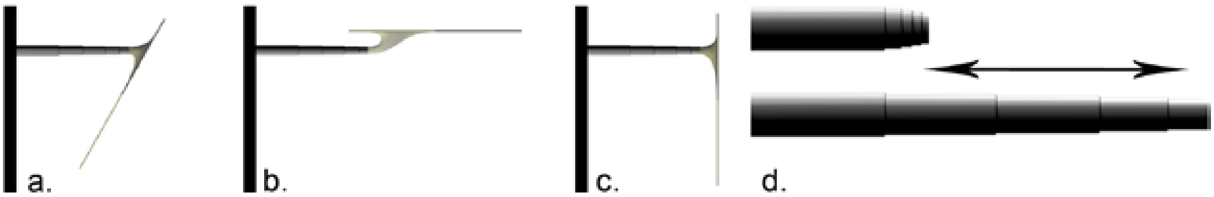

Figure 6 *The shading sheets inclination and their support elongation. (a.-c.) showing different inclinations of the sheet connected to the support member by an elastic membrane. (d) the support tubular member elongation.*

The shading component is connected to the grid of profiles allowing the components to move and change position according to users shading requirements. Four elastic wires are attached to each sheet at their corners, when one of the wires is stretched the sheet will rotate and change its inclination. The specific required inclination for a sheet is controlled via these four wires (Figure 7). The components are controlled separately with considering each other's position and inclination in order to have the maximum variation of shading patterns.

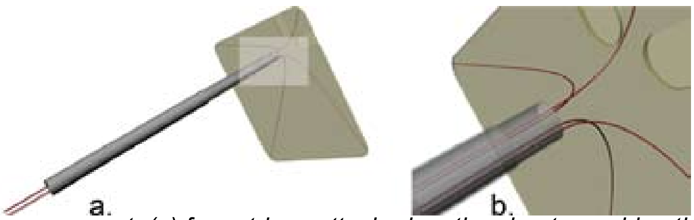

Figure 7 *The shading component. (a) four strings attached on the sheet, reaching the corners and inserted into the tubular member. (b) a close-up to the four strings interring the tubular member.*

3.3 The system implementation

The system could be applied on a flat envelope or on a freeform envelope due to its grid pattern. The scale and size of the gird depends on the specific envelope to be applied on. In cases where the envelope has a freeform layout, the grid has smaller dimensions than at a flat envelope. The shading components are controlled to move over the grid and pack under each other, in cases like cloudy days, where no shading is required and by that the visual contact to the outside is more open (Figure 8).

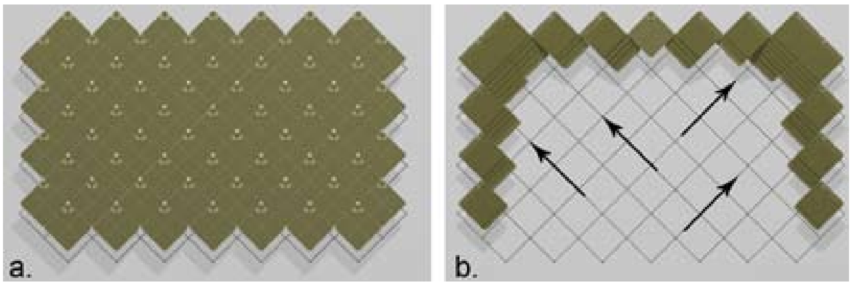

Figure 8 Shading components movement over the grid. (a) Shading components positioned to cover the radiation. (b) Shading components moved to the edges of the grid providing free visual contact and packing under each other.

4. Simulations

The main aim of the simulations is to check the ability of the shading system to track sun radiation throughout a day. These simulations refer to a specific location which is Delft at *52°0'54"N 4°21'24"E* (Figure 9), with considering three critical days throughout the year, where noon hour was determined (Table 1). The tested side of the envelope is south with 90° inclination.

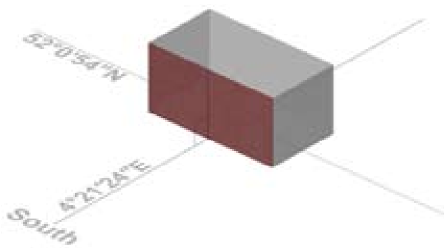

Figure 9 The shading system location, inclination and orientation.

In this paper, the focus is on the principle of the new shading system, where size of grid and amount of elements does not affect the way the shade is generated on the envelope. The dynamic projection of shading sheets, caused by sun radiation, on the envelope was studied. The values in table 1 and 2 are generated from an online calculator for sun angles (www.susdesign.com). The path of sun radiation is determined by altitude and azimuth angles. These angles change throughout the day and differ from day to day. In this paper we refer to morning and noon azimuth and altitude angles, since noon and afternoon need the same treatment but mirrored because of their similarity in relation to south (Table 2), more explanation will follow in results section.

For these simulations we refer to a system that has an initial status as in Figure 8a. It consists of 67 shading sheets distributed as a single layer all over the grid. The aim was to shade the grid with minimum shading sheets and preventing situations where two sheets shade the same spot (self-shading). In the results where sheets less than 67 are shown, means that the other sheets are moved over the rails and packed under the major shading generating sheets.

Table 2 Sun radiation period through three critical days throughout the year in Delft (day almost equal to night, shortest day and longest day).

Reference Date	Sun duration (hours)	Sunrise	Sunset	Noon
September 21	12:20	06:27	18:47	12:37

5. Results

In this section, shading simulations for three selected days (Table 3), introduced in the previous section, in Delft are presented. For each day two simulations were carried out, one at noon and the other one in the morning.

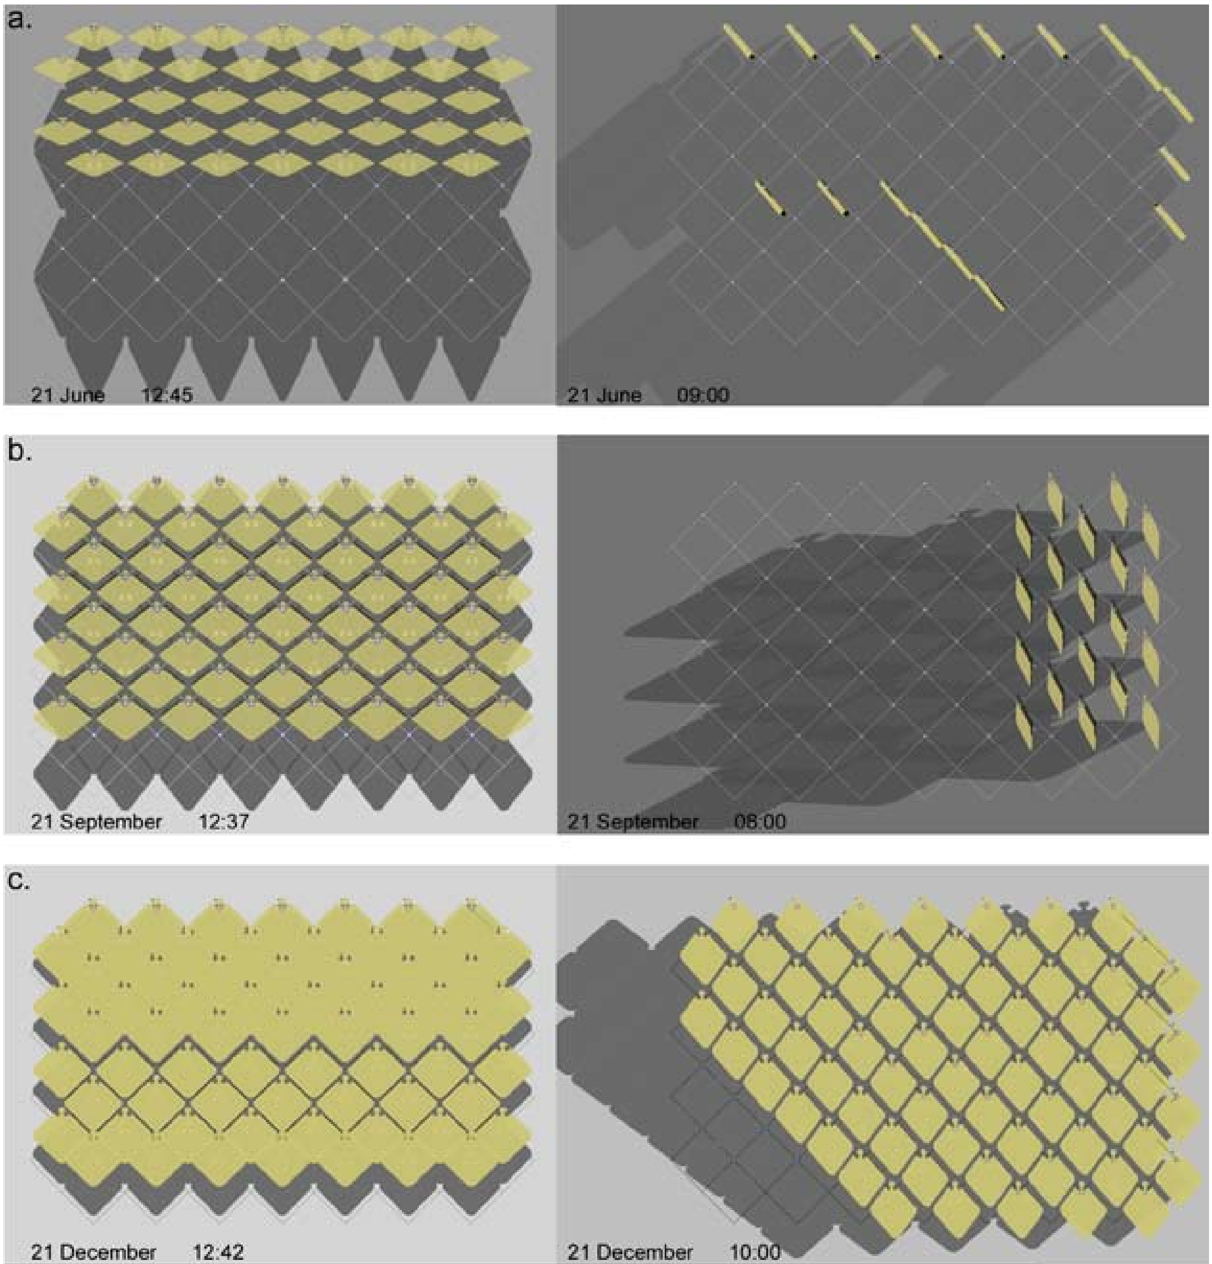

Figure 10 Shading results for the system located in Delft and facing south. (a) on the 21st of June at noon (left) and at morning (right). (b) on the 21st of September at noon (left) and at morning (right). (c) on the 21st of December at noon (left) and morning (right).

On the 21st of June, sun rays have high altitude angle at noon, which resulted in shading the surface with few shading sheets normal to sun rays (Figure 10a left). In this case the sheets have the same inclination, but the rows of shading sheets are not at the same distance from the shaded surface, this is important in order to avoid shading by neighbors. In the morning (Figure 10a right), when sun radiation reaches the southern façade then it will have already moderate altitude angle but with high azimuth, and resulted in shading with different organization and less sheets but with more surface area of shade.

On the 21st of September, sun rays have moderate altitude angle at noon, which needed more shading sheets to provide the required protection (Figure 10b left). In this case the sheets have the same inclination, but sheet rows are not at the same distance from the envelope, in order to avoid self-shading. In the morning, sun rays have high azimuth and low altitude which resulted in shading sheets concentration at east with relatively dense distribution (Figure 10b right).

And on the 21st of December, sun rays have low altitude angle at noon, where more dense distribution was needed to provide the required protection (Figure 10c left). In this case the sheets have the same inclination with different distances from the envelope, this was a way to provide a stronger visual contact with outside and lighten the perceived density of the shading system by creating the openings and division (the same principle as in Figure 5b). In the morning, sun rays have low altitude and moderate azimuth angles which resulted in having a large number of sheets, in order cover the required surface of the envelope, with high density (Figure 10c right). The same principle of distribution at noon was applied in the morning, where sheets have different distances from the envelope.

From these simulations, we notice that altitude angles, at envelopes facing south, affect significantly the density of shading sheets distribution. For low altitudes in the morning, sheets are more concentrated to the eastern side of the envelope with high or low density, depending on the azimuth angle. For different combinations of altitude and azimuth angles, different organizational patterns of the shading system are generated.

Figure 11 All shade blades have the same angle of inclination (α) when flipped. Light gray indicates the old position and dark gray the new position.

Current standard shading systems such as louver panels either vertical or horizontal, the sun radiation blocking is controlled by flipping the louvers to different angles. However, these louvers are not adapted, three-dimensionally, to track the exact sun radiation throughout the day. They tend to have the same angle of inclination when flipped, Figure 11. Venetian blinds, which consist of adjustable louvers, can be divided into separate parts, for controlling and adjusting them in different inclinations. This will control the sun radiation to get deeper in the room or reflecting it (Knaack et al. 2007). But still, this division has a limited adjustability, when the louvers are flipped they still have the same angle of inclination. The limited adjustability is due to their design principle, where louvers have their best performance at noon while facing south. This poor consideration results in cases where louvers are totally closed in order to block varied sun radiation, e.g. low altitude and high azimuth angles of radiations.

6. Conclusions

As a result of principles and methods transformation from leaves, a shading system was developed. This system is able to track sun radiation and provide shade for the desired plane of the envelope. It has flexible shading sheets that can rotate around their support. These supports are tubular members that can elongate and position the shading sheets in different distances from the envelope. The shading system is designed for the whole range of solar radiation throughout a day during the year. The simulations for performance testing refer to Delft at *52°0'54"N 4°21'24"E* (Figure 9), where different azimuth and altitude combinations influenced the shaded area on the envelope.

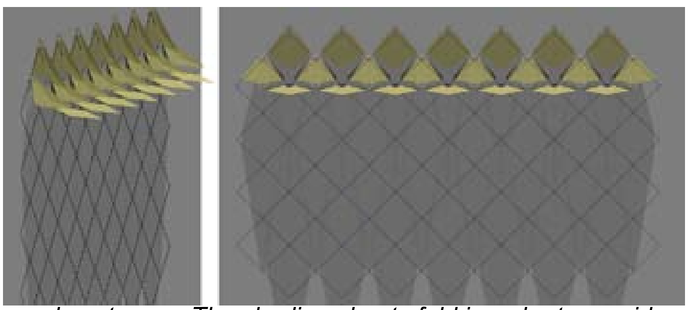

Figure 12 High altitude angles at noon. The shading sheets fold in order to provide more protection at the upper part.

From the results it is possible to conclude the high influence of altitude angles on sheets organization and their density, where azimuth angle has more influence at morning hours. The system is able to avoid self shading situation by elongating their support tubular members and by that they have different distances from the envelope, like leaves in plants elongate their petioles. If we compare it with existing shading systems, then we realize that current shading systems consider altitude angles or azimuth angles but not their combined influence (horizontal louvers for high Altitude angles or vertical louvers for low Altitudes in the morning or evening). This combination of altitude and azimuth is very important in order to cover the path radiation throughout the day, which is achieved in the designed system above. However, some improvements could be considered, the system was tested in one location for specific angles. Sometimes we have very high altitude angles and the system have some difficulties with shading the upper parts. A proper solution could be, allowing the sheets to fold and have better contact with the envelope (figure 12); in this case, the sheets don't have the same inclination, where their inclination gets higher at higher positions.

Due to the flexibility of the system in orienting to different directions and repositioning through the day, it provides continuous shading all over the desired plane at the envelope in Delft. With the system it is possible to achieve maximum required shaded area with loose density of shade planes and avoiding self-shading, or shading with high density of shade planes for maximum energy gaining, due to their position normal to sun rays. Further investigation on the flexibility possibilities of the sheets is needed in order to adopt the system to different locations with different altitude and azimuth angles.

Summary

Concrete is the dominant material used in the construction of many buildings, where it is used in various structural elements including external and internal walls. Depending on building type, up to 20% of the embodied energy of building materials may be attributed to the use of concrete. In the context of climate change impacts and the fact that concrete is the highest volume construction material used worldwide, there is a strong incentive to evaluate alternative technologies that may meaningfully reduce the environmental impacts of concrete use.

The use of lightweight technologies, such as precast cellular concrete wall panels, provides an opportunity to reduce the environmental footprint of construction materials, through the general reduction in materials usage, reduced transportation and lifting energy, potential improvements of in-service energy efficiency and improved recyclability.

This paper presents the results of an environmental analysis of a new load-bearing cellular concrete system and more traditional wall systems such as brick veneer, double brick and autoclaved aerated concrete. The results show that for residential buildings, the precast cellular concrete wall panel system has superior environmental performance in terms of reduced embodied energy, embodied water and greenhouse gas emissions when compared to traditional systems. This suggests that such building systems may play a crucial role in the future development of sustainable and environmentally friendly housing.

1. Introduction

Improving the energy efficiency of buildings could be a relatively effective and low-cost global greenhouse gas (GHG) abatement strategy (Enkvist et al. 2007). For instance, improving building insulation reduces the operational energy demands for heating and cooling, therefore building materials with good insulative properties will play an increasingly important role in assisting with global carbon abatement. One class of materials that may potentially play such a role is cellular concretes with densities ranging from 500 to 1500 kg/m^3. These materials may be manufactured in various elemental forms (from blocks to large precast panels) with compressive strengths of 3–25 MPa, providing a range of functional benefits, from non-load-bearing to fully structural load-bearing applications. Since the porosity of such materials increases when density decreases, low-density materials typically exhibit relatively lower thermal conductivity, and hence better insulative properties when compared to materials of relatively higher density. Therefore, products at the low-density end of the range may provide useful insulative properties in their own right, whereas materials at the higher density end need to be combined with other materials to provide adequate insulation.

Apart from the potential to provide improved building insulation, there may be a wider range of environmental benefits arising from the increased use of lightweight building materials such as cellular concrete. These may range from reduced materials usage to reduced transportation energy, both of which contribute directly to the embodied energy of a building. The lifecycle environmental impacts of using a particular material or design should not be overgeneralized on the basis of relatively rudimentary analyses of embodied energy. However, such analyses provide a useful starting point when considering alternative materials or building systems on the basis of environmental performance. In some office buildings, the embodied energy may be as high as 20 times the annual operational energy (Ballinger et al. 1995). Depending on the type of construction and design, various studies have shown that external walls contribute 10–20% of the total embodied energy of a building (Pullen 1995; Treloar 1996; Treloar & Fay 1998). Other studies have suggested that the embodied energy may be up to 60% of the overall lifecycle energy of buildings, and that materials substitution may provide up to 20% reduction in total energy over a 50-year lifecycle (Huberman & Pearlmutter 2008).

In recent years, there has been significant progress in the development of structural lightweight cellular materials for use in both commercial and residential construction. One such development is a load-bearing cellular mortar (LBCM) manufactured as large precast panels (Mak et al. 2005). Apart from direct weight reductions, which enables reduced structural member sizes and foundations, the LBCM panels may also provide further advantages in faster and cleaner construction with reduced on-site trades and waste generation. The proportional relationship between strength and density, in which strength decreases as density decreases, is well known. Therefore, the key challenge with lightweight cementitious products is to achieve the highest strength possible for a particular density. Strength not only provides load-bearing capability, but it also contributes to a wide range of other functions such as reducing breakage, and improving impact resistance and durability. Whilst strength is of primary importance, an effective lightweight technology also needs to fulfil a range of common functionalities and performance requirements. In the case of wall panel elements used in above-ground construction, these would include durability, shrinkage, impact resistance, thermal resistance and fire resistance. While the combination of a 40–50% weight reduction (compared to normal weight concrete) with structural load-bearing capacity is a compelling incentive to use such materials instead of traditional building materials, increasingly the reason for choosing them may hinge on environmental performance. This paper reports on an environmental analysis of an LBCM-based precast lightweight cellular concrete system in comparison with a conventional precast concrete and various wall systems commonly used for residential applications in Australia.

2. Defining Lightweight Cellular Concretes

Normal grade concretes typically have densities of 2300–2500 kg/m^3, while cementitious products termed ‘lightweight’ may have densities of 300–2000 kg/m^3. However, as there is no universally accepted definition of distinct classes of lightweight materials, it is important that the term ‘lightweight concrete’ is not overgeneralized, since there may by many very different materials with widely varying properties within a certain density range. Lower density products are typically used as insulation, toppings or non-load-bearing infills. Load-bearing lightweight concretes typically have densities of 1000–2000 kg/m^3. Many so-called ‘lightweight concretes’ are in fact not concrete in the traditional sense, since they do not contain aggregates, but are aerated mortars produced either by gassing reactions or the use of preformed foams. Alternatively, many such cellular concretes are cementitious mortars containing lightweight fillers such as polystyrene beads, vermiculite or pearlite, and these concretes typically have densities of 300–1200 kg/m^3. On the other hand, lightweight aggregate concretes (LWACs) normally incorporate either naturally occurring porous stones such as scoria, or artificial aggregates such as sintered fly ash or ceramics. LWACs typically have densities of 1500–2000 kg/m^3 and can be produced with compressive strength of 40–50 MPa.

3. Methodology

The use of lightweight building products has the potential to significantly reduce the environmental impacts of construction through reductions in, for example, bulk materials usage, and transportation and construction energy.

3.1 Analysis

The results discussed in this paper focus on the embodied energy, GHG emissions (in CO_2 equivalent) and embodied water in a range of commonly used wall systems compared to a new lightweight precast LBCM system. A ‘cradle-to-grave’ methodology was adopted, utilising embodied energy and GHG emission values through the Boustead modeling environment. In addition, a ‘gate-to-site’ transport value was also calculated to compare the transportation energy of different products over a distance of 40 km, based on a typical truckload of each product.

3.2 Wall Systems

The LBCM used in the analysis is a relatively high-strength cellular mortar manufactured as large precast structural panels in two density grades, i.e. 1000 kg/m^3 (H1000) and 1500 kg/m^3 (H1500). The cellular structure is created by gas aeration of a relatively high-strength cementitious mixture of Portland cement and various supplementary cementitious materials such as fly ash or silica fume. The product is precast in panel sizes up to 18 m^2 (e.g. 3 × 6 m) on steel formwork, then heat cured to achieve sufficient early-age strength before being demolded from the formwork. To improve handling, structural performance and shrinkage control, the panels are reinforced with various grades of steel mesh. The compressive strengths of the cellular material used for the H1000 and H1500 products are 8 and 20 MPa respectively. As walling systems, these cellular concrete panels can be installed with a thin concrete render, or they can be combined with insulative materials and linings to provide the required thermal insulation performance.

One of the key underlying environmental performance requirements for a wall system is its thermal rating, often expressed simply in terms of its thermal resistance or R-value. For residential construction, the recommended R-value for walls typically range between 1.5 and 2, depending on geographic location. This basic requirement provides guidance on the comparison of wall systems in this paper. The key property underpinning the R-value is the thermal conductivity of a material, which for concrete and many other materials is related to density, whereby as density reduces so does thermal conductivity. This is shown in Figure 1 where normal density concrete (NC) is compared with medium density LBCM and a relatively lower density autoclaved aerated concrete (AAC). In turn, this implies that the R-value will increase as density decreases, and thus lower density cellular concretes will exhibit relatively higher R-values compared to normal density concretes. However, when used in the normal thickness range of 100–150 mm, cellular concretes generally do not meet the thermal rating requirements for wall construction unless additional insulation is provided. For instance, the dry-state thermal conductivity of AAC ranges from 0.12–0.14 in the density range of 510–580 kg/m^3. The corresponding R-value of a 150 mm thick AAC element with a density of 550 kg/m^3 ranges 0.9–1.1, depending on the moisture content (CSR Hebel Technical Manual 2006). The dry-state thermal conductivity of the H1000 LBCM is 0.35, implying that the R-value of a 150 mm thick element is 0.45. For the same thickness of normal density concrete, the R-value would be only 0.12. However, when used as part of a wall system, the required R-value can be easily achieved by any of these concretes through, for instance, the addition or air gaps, fiberglass insulation batts, polystyrene sheets or reflective foil liners.

Therefore, it is important that environmental analyses of embodied energy be carried out for entire wall systems that meet a minimum performance requirement, rather than the primary wall material itself. From this perspective, the discussion in this paper is focused primarily on the H1000 LBCM used as 100 mm thick panels, this being the product intended for use in residential construction. Some reference will be made for comparative purposes to the H1500 LBCM and a range of wall systems commonly used in Australian residential construction. A description of the generic wall systems studied in this investigation is given in Table 1. These include brick veneer, double brick and concrete block walls, all rendered externally and lined internally with plasterboard.

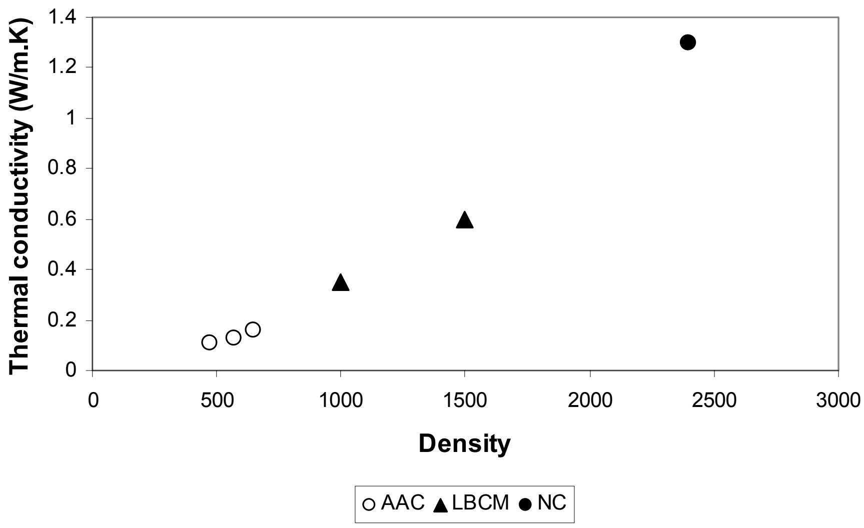

Figure 1 Thermal conductivity of normal and low-density concretes (source data for AAC, GFC Concrete Ltd *(2006)).*

Table 1 Wall systems investigated

Wall system identification	Primary material	Cladding and lining materials
PC40	40 MPa precast concrete	None
BV	Brick veneer	15 mm external concrete render, timber studs, R1.5 insulating batts and plasterboard lining
CB	Concrete block	15 mm external concrete render, timber studs, R1.5 insulating batts and plasterboard lining
DB	Double brick wall	15 mm external concrete render, timber battens and plasterboard lining
AAC	Autoclaved aerated concrete	15 mm external concrete render, timber studs and plasterboard lining
H1000/H1500	LBCM	5 mm external concrete render
H1000P/H1500P	LBCM	5 mm external concrete render, 65 mm polystyrene insulation and plasterboard lining
H1000B/H1500B	LBCM	5 mm external concrete render, timber battens, R1.5 insulating batts and plasterboard lining

4. Results and Discussion

4.1 Gross Embodied Energy

The direct relationship between bulk density and unit materials usage implies a potential to reduce embodied energy through the lower rate of materials usage in lightweight materials. However, normal density concrete is a composite material consisting of a cementitious binder and inert fillers such as sand or coarse aggregates. The relative unit contribution of these materials to the total embodied energy may vary greatly, with the gross unit energy of cement being 75–100 times higher than that of aggregates on a tonnage basis. The major volumetric constituents of cellular concrete are cement and sand, with coarse aggregates omitted. However, cellular concretes may contain more cement compared to normal grade concretes on a volumetric basis. Therefore, a lightweight cellular material may not always provide an obvious reduction in embodied energy when compared to a normal density concrete even though the amount of materials used is relatively lower. This is evident in Table 2 where two grades of LBCM (H1000 and H1500) are compared with a conventional 40 MPa precast concrete (PC40). On a volumetric basis, the gross energy of H1000 is 17% lower than that of PC40, but that of H1500 is 17% higher because of its relatively higher cement content. When the panel products are compared on a surface area basis, and including steel reinforcements, the gross energy of the 100 mm thick H1000 panel is 18% lower than for PC40. By contrast, the gross energy of the H1500 panel of similar thickness is 10% higher than that of the precast concrete. The gap in embodied energy between H1500 and PC40 has, in this case, narrowed due to the relatively lower quantity of steel mesh needed in the LBCM panel.

The results in Table 2 imply that the use of H1000 LBCM in residential construction, for example, may potentially reduce the gross energy content of a wall system by more than 15% when compared to precast concrete. However, the differences between LBCM and precast concrete are relative small, particularly when compared to other conventional wall systems. For instance, the results in Figure 2 show that the gross energy of the H1000B system is more than six times lower than that of the double brick wall and almost four times lower than that of either the brick veneer or concrete block walls. When compared to the particular AAC wall system analyzed here, the gross energy of the H1000B wall was 70% lower.

The addition of insulation to achieve the required R-values in the LBCM increases the gross embodied energy of the wall system. This is evident from Figure 2 where the addition of R1.5 insulating batts increased the gross energy from 328 to 531 MJ/m^2. However, the choice of insulation in this instance did not influence the gross embodied energy of the LBCM wall systems. The use of either R1.5 insulating batts or 65 mm polystyrene provided approximately the same amount of added insulation to the wall system, resulting in similar total R-values of about 2. However, there was very little difference in the gross energy of either wall system.

Table 2 Gross energy (MJ) of various normal and cellular concretes

Concrete	1 m^3 of product	1 m^2 of 150 mm thick panel incl. reo	1 m^2 of 100 mm thick panel incl. reo
PC40	3269	563	399
H1500 LBCM	3834	631	439
H1000 LBCM	2722	465	328

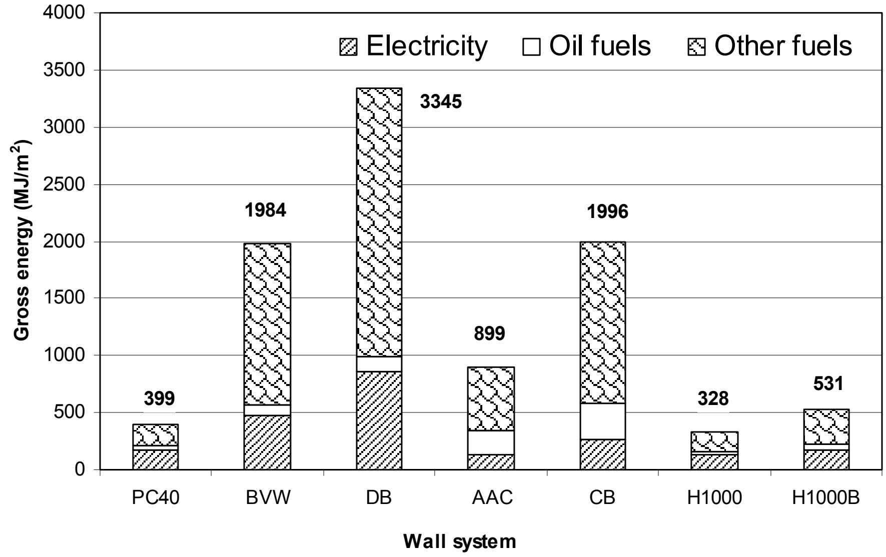

Figure 2 Gross embodied energy – comparison of 100 mm wall systems (see Table 1 for a description of wall systems).

4.2 Greenhouse gas emissions

In Australia, GHG emissions generally follow a similar profile to embodied energy values, due to the dominance of coal-fired power stations and the usually large flow of electricity use throughout manufacturing processes. However, concrete-based products can alter this profile due to the fact that CO_2 is released during the cement manufacturing process. It has been discussed previously that the cement content will dominate the gross energy of a product. This is even more so when it comes to GHG emissions.

As shown in Figure 3, in terms of GHG emissions, there was little difference between the H1000 LBCM and PC40. However, when compared to other conventional residential wall systems, the GHG emissions of the LBCM were significantly lower. Again, the double brick wall system produced the highest GHG emissions, being just under six times that of the H1000B wall system with batts. The brick veneer wall and the concrete block wall systems both benefit from a biomass credit in the GHG analysis, but still show higher GHG emissions compared to the LBCM system. The standard AAC block wall system also benefits from a biomass credit, which results in this system having the lowest GHG emissions of all systems analyzed.

4.3 Embodied Water

The consumption of water during product manufacturing processes has gained increasing interest in recent years in Australia, mainly as a result of the prolonged drought conditions being experienced here. Embodied water calculations are utilized to determine the total water consumption through a manufacturing process in much the same way as embodied energy tracks energy use through a manufacturing process.

An embodied water analysis (Figure 4) shows that the production of LBCM panels uses significantly less water than any other wall system investigated. The water consumption of a plain H1000 wall was only a quarter that of PC40, whilst that of the insulated H1000B wall system was over 60% lower than PC40, equating to a saving of more than 100 liters per square meter of panel. When compared to other wall systems such as concrete block, the use of the LBCM system produced savings of almost 160 L/m^2.

Previous discussion suggested that the choice of insulation to provide similar total R-values did not affect the gross embodied energy of the LBCM wall systems. By contrast, the embodied water content is significantly affected by the choice of added insulation material. Due to the relatively high embodied water content in manufacturing polystyrene sheets, the use of 65 mm polystyrene sheets as added insulation in the LBCM walls increased their embodied water content by more than three times when compared to a system that was insulated using fiberglass insulating batts.

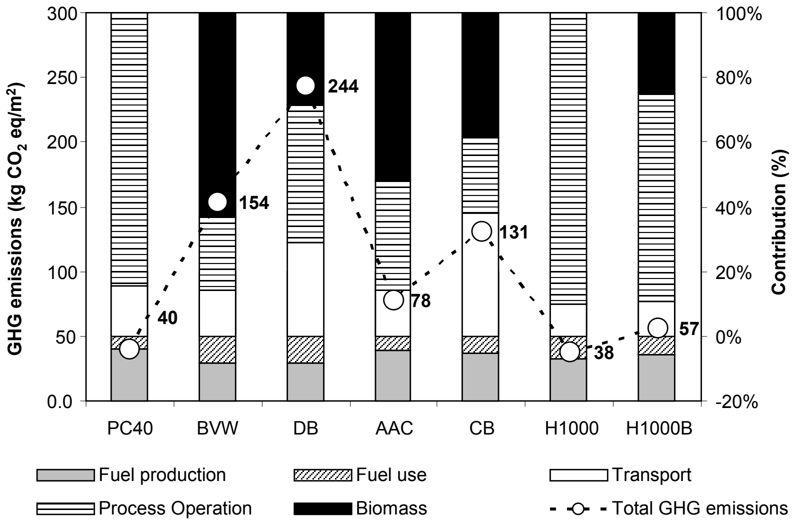

Figure 3 GHG emissions of various wall systems (see Table 1 for a description of wall systems).

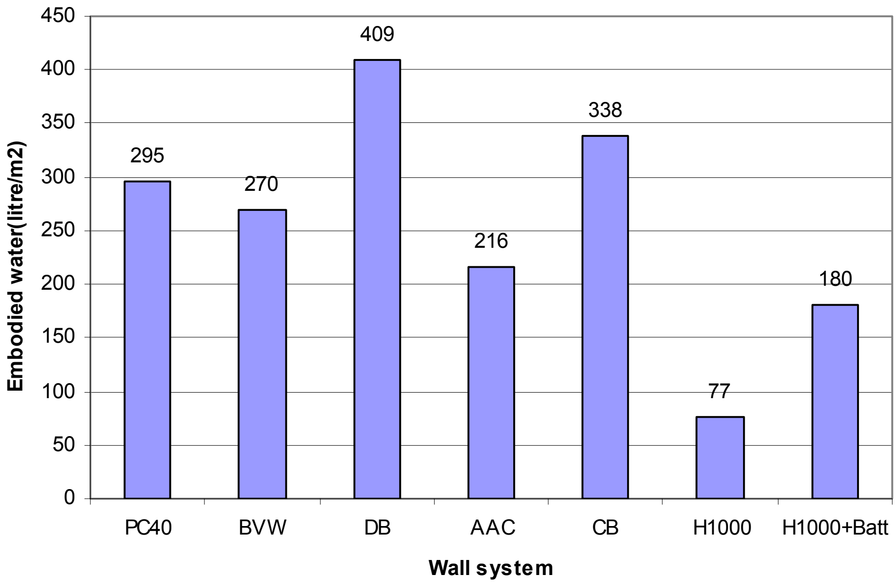

Figure 4 Embodied water used in manufacturing various wall systems (see Table 1 for a description of wall systems).

5. Implications for Sustainable Housing

This environmental analysis has shown that wall systems built with prefabricated cellular concretes have the potential to reduce the gross embodied energy, GHG emissions and embodied water content in residential construction. Based on comparisons with some conventional wall systems, the use of LBCM may result in a two- to six-fold reduction in both gross energy and GHG emissions. Adding further to potential improvements in sustainability is the reduction in embodied water used in manufacturing, and the feasibility of producing wall systems with the required thermal ratings by coupling LBCM with a range of insulation materials. However, it is important that environmental performance analyses of different wall systems be performed on the basis of some common functional requirements, such as equivalent thermal rating. Ultimately, it is necessary to obtain an objective comparison in whole building performance from either actual measurements or experimentally validated methods of calculating thermal performance (Heathcote 2008).

With Australia's housing stock increasing by an estimated 130,000 dwellings per year, the potential for reducing environmental impacts through the use of relatively low-emission materials to provide improved thermal performance, will add to the impact of other abatement strategies employed throughout the economy. The overall feasibility of using such new materials would obviously be based on a wide range of other considerations, such as unit product cost, cost of installation, fit with functional requirements, compliance with building regulations and supply chain issues associated with materials, manufacturing and transportation.

A single-storey model building with a floorspace of 25 m^2 was designed and constructed to demonstrate proof of concept for both the manufacturing process and the method of construction using LBCM panels. For construction of this demonstrator building, approximately thirty 100 mm thick panels with standard dimensions of 900 × 2700 mm were manufactured. All panels were reinforced with one layer of mesh placed centrally, and some panels included cast in conduits for electrical services. Figure 5 shows these precast panels being lifted into place and propped, as is normal practice for erecting precast concrete walls. The entire wall structure was completed in less than one working day. A number of joint preparation and surface finishing methods were used to assess the long-term weathering and shrinkage properties of the wall system. The completed building is shown in Figure 6. Further to this early demonstrator, larger precast panels of between 9 and 8 m^2 are currently being produced for application in housing.

Figure 5 Precast LBCM panels being lifted and propped.

Figure 6 The completed model building.

Abstract:

Bamboo plays a key role in the daily lives of 1/5 of the world population even today in many countries in Asia, Latin America and Africa. In many places expensive wood, steel, concrete, glass etc.and other such materials have replaced Bamboo- labeling it as a 'poor mans' timber' a 'poor man's building material' etc.

But of late Bamboo has liberated itself from this stigma and emerged as the **'Greenest of the Green Building Materials'**. It is the most fashionable building material in Vogue today and is in great demand across the World for buildings, Interiors, landscapes, bridges, etc.

- Any talk of Sustainable Buildings today is not complete without the mention of Bamboo.
- Bamboo was/is an essential building material in the specifications of the Topmost LEED Rated and other green buildings of the world!

Lots of people want to build Bamboo Houses want bamboo furniture, bridges etc., There is a lot of **Demand** for Bamboo! There is a great market awaiting this beautiful, highly sustainable, engineering material! But somehow the **Demand-Supply** chain of this building material is not getting established. Very few Bamboo buildings are getting constructed across the world. Number of Architects, Manufactures, Govts., Policy Makers etc taking this material seriously is very low .

WHERE AND WHAT IS THE MISSING LINK?

This paper is an account of our efforts to find this missing link!

Bamboo should find its rightful and respectful place with other modern Building Materials. This will also have tremendous impact on the carbon footprints of the Building Industry as well which is the Highest Polluter (+_50%) of the **Mother Earth!** (Whole Bamboo houses use 1/7 the energy required to construct a concrete house).

SUSTAINABLE DEVELOPMENT AND BAMBOO

"Sustainability" means development that meets the current generation without undermining the ability of the future generation to meet their own needs"
(def: as per agenda 21,world climate summit in Rio de Janeiro 1992)

Development and environment are inextricably linked and must be nourished by a change in the means, the contents and the uses of growth. Three criteria's to be necessarily retained are social justice, ecological prudence, and economic efficiency.

As the repercussions and downsides of the western culture and architecture are being discovered and as the world is turning towards regional sustainable technologies – Two definite categories in the development are emerging – one based on the principles of recycling and the other on the use of natural materials capable of being used without requiring Industrial processing – Raw earth and Bamboo figure prominently in the second category of Development.

This long organic stem (a grass) wide spread in many countries of the world grows very quickly (Often up to 1.5m in the first year and acquires its ultimate structural strength some three years later.

Like wood, recycled paper and clay, Bamboo is a premier building material in the new architectural movement. Sustainability and Integrative approach are two important characteristics of this new building trend. It is Bamboo which brings together representatives of the so called third – world countries as equal partners in a fruitful exchange of ideas with architects from the industrialized countries. Bamboo is probably an enriching contribution that countries in the Southern Hemisphere can make to the architecture of the Western World. More and more advantages of using Bamboo are being discovered and the importance of Bamboo is growing everyday. A Bamboo Renaissance is taking place.

As per the 27th principles of the "Rio Declaration" which states that – "Indigenous people and their communities have a vital role in environmental management and development because of their knowledge and traditional practices. States should recognize and duly support their identity culture and interest." In this context Bamboo rich areas and communities with traditional knowledge of bamboo construction and other applications have a very big role to play in mitigating Global warming

.

The technology of construction with Bamboo could be one of the greatest contributions that the South and the Eastern world can give to sustainable Development. Only North-South and East-West complementarity will be realistic to develop a fair and global practice of sustainable development and an apt and reasonable redefinition of our future.

This paper is based on a non- linear and associative thought. It discusses bamboo's emerging diversity and significance in the context of the emerging Sustainable and Green Building movement, and not attempting to give a conclusion.

BAMBOO- AS A BUILDING MATERIAL- PRESENT DEMAND SCENARIO

To know the future – Let's peep in the history of Bamboo and analyze its current trends. Bamboo plays a key role in the daily lives of more than 1/3rd of the world population even today in many countries in Asia, Latin America and Africa. It is used to make houses and bridges, used for various articles of daily usage and crafts, eaten as a food item, and many other such applications. In many places expensive wood, steel, glass, concrete and other materials etc have replaced Bamboo, labeling it as a 'poor man's timber', poor man's building materials etc. But of late, 'Bamboo has liberated itself from this stigma and emerged as a capable contender along with other modern materials.

1. In the search for more and more sustainable and low energy or zero energy building materials.–a lot of research is being done with Bamboo as it is a renewable material. And Bamboo has emerged as an excellent material on all counts. Standard Building codes for Bamboo have been formulated in many countries across the world. This has enabled many architects and engineers to start using it with much more confidence like any other building material.

A comparison of the energy requirement for production of various building materials confirms that Bamboo is a material with the lowest embedded, grey and induced energy requirement.

Table : 1

Materials	**Energy for Production MJ/Kg**	**Weight per Volume Kg/m3**	**Energy for Production Kg/m3**	**Stress When In use**	**Energy per Unit stress**
Concrete	**0.8**	**2400**	**1920**	**8**	**240**
Steel	**30**	**7800**	**234000**	**160**	**1500**
Wood	**1**	**600**	**600**	**7.5**	**80**
Bamboo	**0.5**	**600**	**300**	**10**	**30**

Source: Prof. J.A Janssen, Eindhoven University, The Netherlands

2. The tensile strength of bamboo fibers can be up to 12 kg/cum. almost twice that of steel. The weight to strength ratio of bamboo is far better that most modern material. It also makes for excellent support because of its inherent stiffness owing to the natural subdivisions. The engineering qualities of bamboo and its intrinsic structure anticipate the principle of many high-tech materials – making it an excellent value for money ,with its attractive appearance an added bonus. Utilization of bamboo for grid matrix structures because of its flexibilities or in high – tech composite materials with high tensile strength, is a trend which can completely wipe out all other so called energy intensive high tech materials from the construction market. Since tensegrity and synergetic structures require light and high tensile basic elements, Bamboo is ideally situated for such applications. Its suitability for such structures is another feather in its cap.

Table 2 : **Mechanical properties of various woods and bamboo**

Woods	*Strength [MPa]*	*Mod. Elasticity [GPa]*	*Density [g/cm3]*
Cader	29.3-48.5	4.4-9.8	0.29-0.46
Fir	30.7-33.8	5.9-6.7	0.31-0.34
Pine	34.0-41.6	6.5-8.8	0.36-0.42
Spruce	31.0-40.0	7.3-8.5	0.38
Hickory	62.5-81.0	8.9-11.4	0.56-0.67
Oak	47.7-74.9	7.9-12.4	0.53-0.61

3. Buildings of bamboo & bamboo elements can be easily recycled or dismantled and it is easy to replace individual elements. In the field of prefabricated construction elements, Bamboo will emerge as the most viable material in both the forms-whole Bamboo and Engineered bamboo as prefabrication is inherent to bamboo. Bamboo is stronger than wood in tension and compression.

4. Bamboo is replacing wood in all its applications from ply, doors and windows, shuttering ply,beams, pillars, flooring, roofing, sunshade blinds, interior furnishing, pergolas etc.All these factors will make Bamboo the most desirable building material in the 21st Century.

5. Because of the its high strength to weight ratio, bamboo has long been associated with aeronautics .Bamboo composites could become a major natural material for the Aviation industry.

6. World Green Building Council has recognized Bamboo as the most environment friendly and sustainable building material. And hence Bamboo finds a prominent place in the specifications of all the GBC-LEED rated buildings across the world as a building material and also in landscaping.

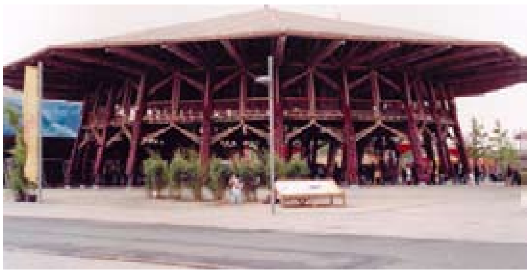
How sustainable is a Bamboo House?..

We have designed and executed a 1000 sft Bamboo House called “The Solar Hut” at the State Level Energy Park at Bangalore, India. It is a two-bedroom house with simple plan with bamboo columns, bamboo roofing understructure and bamboo composites boards for roofing, doors and interiors etc.A Comparison of the energy requirement [Embodied energy] [Ref.Table no.3,Page 4] of this building with a building with the same plan but built with conventional materials is given below.

Table 4: Bamboo House Conventional House

Materials	*Energy For production [Kg/cu.m]*	*Qty. of Material*	*Total energy requirement*	*Qty. of Materials*	*Total [Kg/cu.m]*
Concrete	1920	30	70080	175	864000
Steel	234000	0.6	140400	3	702000
Wood	600	2	1200	2	1200
Bamboo	300	30	9000	0	000
		Total	220680		1567200

The bamboo house needed 7.1.times less energy than a conventional house and hence is as many times more sustainable!



7. Simon Velez – An Architect from Columbia has designed and constructed all types of buildings from whole Bamboo- from low cost houses to high end exotic villas, large span bridges, industrial buildings, pavilions etc. He has set many precedents and his works done with Bamboo has encouraged many young Architects to experiment with this material. Simon Velez has been using bamboo since the mid 1980’s.

At the Expo 2000 at Hanover, Germany, the ZERI pavilion designed by Simon Velez made of Bamboo has proved to be a landmark in Bamboo based Architecture for its engineering qualities i.e.—strength, solidity, safety, fire-resistance, mold resistance, sustainability and aesthetics. This put into practice several principles of the "Rio Declaration" and was in perfect rhythm with the theme of the Hanover Expo –'Man, Nature and Technology'.

8. Several National and International Design Competitions have been organized for Building with Bamboo. In recent years buildings with bamboo have bagged several awards in various other Architectural Design competitions as well. This has sparked a lot of interest about this material in the architectural and engineering world - making it the most environment friendly, glamorous and fashionable building material across the world today.

Table 1.Indian Bamboo Market Potential

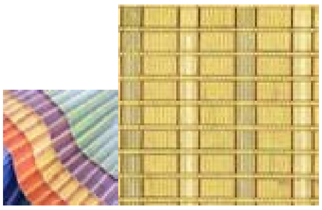
S.no	*Product/Application*	*Current Market(Rs.)*	*Expected Market(Rs.)*
1	Bamboo shoot	4.8 crores [2001]	300 crores [growing at 25]
2	Bamboo wood	10000 crores [import value]	30,000 crores [in next 20 years]
3	Bamboo plywood	200 crores	500 crores
4	Bamboo plyboard in Trucks & railways	1000 crores	3408 crores [in 2015]
5	Bamboo flooring	100 crores [Domestic]	1950 crores [2015]
		100 crores [Export]	
6	Bamboo pulp	100 crores	2088 crores [2015]
7	Bamboo furniture	380 crores	3265 crores [2015]
	Bamboo construction material		
8	Scaffolding	--	861 crores [2015]
9	Housing	--	1163 crores [2015]
10	Roads	--	274 crores
11	Bamboo grids	--	1000 crores [2015]
12	Agarbatti – Miscellaneous Industry, Pencil industry, Match-stick Industry	394 crores	600 crores [in 2004]

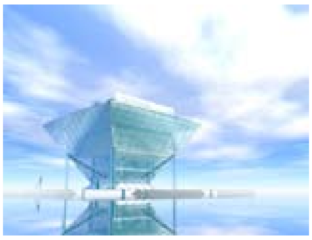
THE SUPPLY SCENARIO

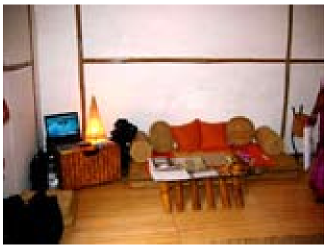
As is evident, tremendous demand for this material has been painstakingly created by several pioneers in the last several decades. A booming world market is awaiting prospective entrepreneurs and suppliers.

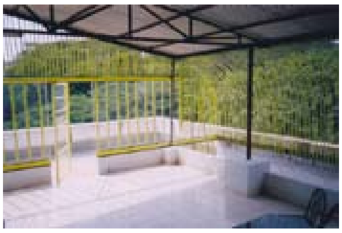
1. Bamboo is sustainable with respect to both the plant and the building material. Hence several bamboo missions have been taken up across the world to encourage bamboo plantations. Lots of farmers, horticulturists, environmentalists, architects, entrepreneur's etc. are taking up huge plantations all over the world. This will make available large quantities of this material for use in the future. And simultaneously, these plantations would mitigate the harmful effects of a global warming as Bamboo is a natural environment cleanser.
There is infact a severe shortage of quality bamboo materials. Hence, new bamboo plantations should be taken up to raise special purpose /species needed by the industry. Regulated plantation of selected species, sound management practices, proper harvest, post harvest treatments and new usages are essential for value added products.

2. Again as part of these Missions, states and countries are encouraging entrepreneurs to set up Industries for engineered bamboo product like bamboo ply, flooring, bamboo boards, roofing, wood etc. Venture capital finances and soft loans with tax incentives are being offered to prospective entrepreneurs and to number of industries have been set up. However these industries have failed to meet the growing demands of the market due to various reasons like lack of raw material availability, work force, appropriate marketing strategies etc.









Bamboo Based Products

3. All this popularity of bamboo is making it more expensive and less available for the common man. Hence, except in countries where the local labor wages are low, the cost of bamboo has gone through the roof, and lots of people have started to resorting to Imitations or plastic bamboo.

4. Architects & Engineers are slowly starting to use this material but their number is very small. Hence the number of buildings with bamboo as a building material is very very low.
Also the quality & design details and execution of these projects is very crude and amateurish. And this is hampering the propagation and popularity of the material.

5. Since the technology is new, there is a serious dearth of middle level workers like supervisors, carpenters, masons, etc absolutly essential for execution. Because of this the Architects & Contractors face lot of trouble in the execution of the projects and find it very difficult to maintain high quality standards and time schedules.

6. For the industries of engineered bamboo products, backhand industries linkages to produce the raw materials are not fully developed .This sometime cripples these industries, creating sever shortage of products in the market. The states and the countries are trying to take care of this problem but the process is very slow.

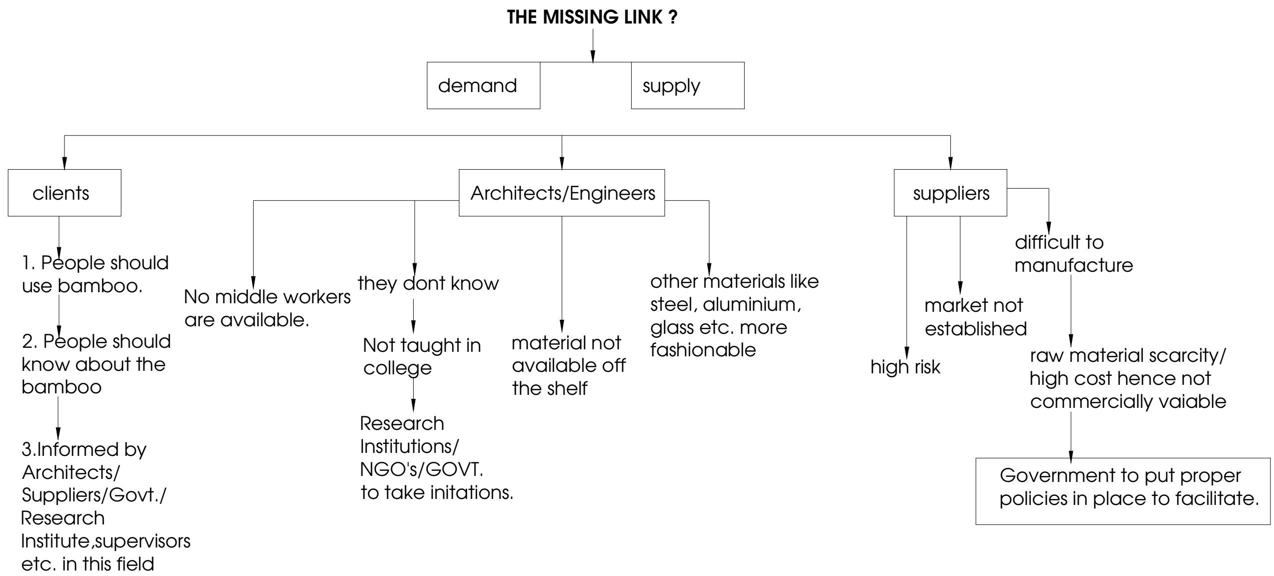
7. Since the material is unavailable all over the world, lot of export of raw bamboo and finished bamboo product is taking place, killing the very “spirit of sustainability” (by adding the energy for the transportation).On the other hand export-import of these item is making them exhorbtitantly expensive.

8. In India, National Mission for Bamboo Applications, NMBA and National Bamboo Mission,NBM is promoting the use of bamboo ply and other engineered products for disaster housing programmes. These houses provide a good solution as long as they are used as interim shelters only. But they are using it for permanent housing as well. Because of this the involvement oflocals in the reconstruction process is completely eliminated which otherwise could also provide Livilihood security to the victims. Bamboo is the most appropriate material to the used for the construction in disaster prone areas and also during disaster, only if it is used sensitively and sensibly.

9. In the mass housing sector, Bamboo is yet to make its foray as the mainstream building material. This is solely due to a seer lack of Architects and engineers with expertise in bamboo utilization and dearth of quality and quantity materials in the market.

10. Tourism sector also started with lot of enthusiasm in utilizing Bamboo in all its forms. A number of resorts has been done across the world. But since the expertise in protection of bamboo form biological hazards has not been completely standardized and generally taken very lightly, the usage is limited due to fast biological degradation of untreated Bamboo in exotic locales. And this probably further worsens the stigma attached to Bamboo as a material for Temporary structures.

11. There is no college, university or Institution as on date offering a structured course in Bamboo Technology for Building construction and Industrial Applications. Because of this the evolution, enhancement and absorption of the technicalities of Bamboo construction is not happening. There are no specialized Architects, engineers to adopt this material fully.



7

WHAT ARE WE DOING? OUR EFFORTS TO FIND SOLUTIONS.

We have been working with bamboo for several years now. This paper is the result of design, experimental works and their results by myself, proprietor Manasaram Architects, Centre for green building materials and technologies,CGBMT, and Guru Dayal, Propritor, Aditi constructions in association with various NGOs, Government, Research Institutions and Bodies and enthusiastic clients of various projects across India and abroad. We have been trying to find the panaceas for these problems- trying to establish THE MISSING LINK.

OUR ACTIONS:

• We have formed a team of Architects, contractors and R & D groups to tackle the problems of supply from every front.

• Each project that we undertake is done as a research based project with practical solutions for execution. And we always try new methods and technologies in each project to create precedents and create case studies.

• We monitor all our projects regularly and keep in touch with the clients to develop confidence. The monitoring has also resulted in a database of the performance of the material under different situations.

• We always try to use it in combination with other building materials and technologies so That it increases its workability and popularity.

• We have been conducting seminars, lectures, workshops, exhibitions etc and have also been speaking at National and International forums to spread awareness about this wonderful building material.

• We are starting a Distance Education course on 'Bamboo Technology for Building construction and Industrial Applications' in collaboration with Dayalbagh University Agra, India. It will have short term and long terms courses for Architects, Engineers, policy makers and other mid-level workers.

Epilogue

Bamboo will continue to form part of a trend in Sustainable Architecture– The return to local traditions with their enormous wealth of intelligent sustainable solutions which have stood the test of time. And man will hardly be able to survive without it in the 21stCentury.

The Recycling of Used Tyres as an Insulation Material in Cavity Walls in a Mediterranean Climate

Vincent BUHAGIAR, Dr. Arch.[1]
Annmarie MIFSUD, B.E.& A.(Hons.)[2]

Keywords: rubber tyres, recycling, insulation, cavity walls, thermal performance, building envelope, carbon emissions, sustainability.

Summary

This paper evaluates the potential of recycling used tyres in three different states: whole, shredded & pulverised. The study looks into the best use of the material as a form of insulation in cavity walls in Malta, with a typical Mediterranean marine (island) climate, where a greater concern for cooling has always exceeded that for heating - albeit until recently. The Maltese building industry still depends on a robust building technology, relying heavily on traditional quarried stone for load-bearing cavity walls.

An energy-awareness is also maturing towards curtailing carbon emissions, even if initially dominated by cost concerns, especially in view of the ever-soaring price of crude oil on international markets. Malta has also adopted the EU Directive on energy performance in buildings, thus making energy efficiency governed by national law.

In consideration of today's large amount of tyres being used and disposed of, the purpose of this study is to investigate the possibility of utilising recycled rubber as a building material, namely as insulation in cavity walls. This could replace new insulating materials, typically having a higher embodied energy content. The study evaluates the success/failure of such passive design strategies.

1. Introduction

Typical insulation-related measures in a building affect the energy consumption some 50-100 years into the future, and it is either very expensive or practically impossible to modify an existing non-optimal construction. Logically, it is still important for new buildings to be as energy-efficient as possible, since in the long term, they may become decisive for the energy consumption and possibly constitute a benchmark for what is obtainable when renovating the existing building stock of the day, whenever this materialises in future.

Innovative insulation materials are perhaps at the forefront of developments in building technology worldwide. Gaining particular attention are recycled or recyclable materials, particularly those that apart from their energy-saving measure, have an eco-friendly contribution to the environment. Given its high embodied energy and end of life disposal issues, rubber is but one of them. Rubber has aroused particular interest in its potential for recycling and re-use in different forms as safety floors, acoustic panels and thermal insulation among others. This paper focuses on thermal insulation in three forms, namely pulverised, shredded and solid sheets of opened out tyres.

2.0 Present Situation

Three problem scenarios are envisaged for Malta in the imminent future. Before presenting these an overview of the present situation is given, here outlined under traditional building technology, energy legislation and waste disposal, respectively mapping out the three scenarios.

2.1 Building Technology in Malta

The construction industry in Malta has always been heavily dependent on the local quarried material, namely globigerina limestone. This indigenous quarried material has its own unique properties perhaps giving it its almost unbeatable popularity among local folk as a standard building material used for over 5,000 years.[1] Its structural integrity, durability, weathering and thermal properties as well as its ease and low cost of quarrying combined with today's technology for cutting, planning and hoisting have all contributed greatly to its quasi-perpetual use in the construction industry in Malta.

Today, at the threshold of the 21st century, trends indicate that imported modern materials have superseded vernacular construction methods, where frame structures now replace block-on-block structural load-bearing walls, especially with an increasing demand towards high-rise development. Quarrying has also been limited both due to its exhaustion as a quality source and new quarries or extensions being curtailed by stricter environmental and land use control. The demand for quarried solid blocks of *Franka* stone (soft, lower coralline globigerina limestone) has dwindled, yet somehow complementary to this, the demand has increased for *Tal-Qawwi* (hard, upper coralline globigerina limestone) for hardcore aggregate in concrete casts and hollow core concrete blockwork, the latter now gradually replacing the quarried *Franka* stone, particularly in façades.

2.2 Energy Legislation and the EPBD

Thermal considerations have also been raised to a higher importance in view of a greater sensitivity to carbon emissions and EU legislation. The EU Directive 2002/91/EC, better known as the EPBD (Energy Performance of Buildings Directive) promotes energy efficiency in buildings both in construction and at operational stages. Conceptually a building is perceived to be energy conscious from the onset with a view to minimising energy losses through the envelope, particularly through heating and cooling, yet maintaining adequate thermal comfort standards for its occupants all year round.

In Malta this Directive was transposed to local legislation through LN 238/2006, where reference is made to the latest revised building regulations, particularly part F, where the technical guidance document sets minimum requirements for energy performance of new buildings. Although not yet enforced, it is intended to guide architects in their design schemes with appropriate construction detailing and design when applying for a building permit as from 02 January 2007. Perhaps foremost in controlling heat transfer through the building envelope is the type and thickness of insulation. Naturally this has its own energy implications. Ideally one should compare its embodied energy with the actual operational energy savings made and the pay back periods envisaged at today's energy costs. One strong potential for cutting back this embodied energy is the use of recycled materials for cavity insulation. Rubber is but one of them.

2.3 Waste Disposal & Land Use

Waste management has always posed an environmental problem worldwide. Malta is no exception. Considering a small Island State of 216sq.km, with a population in excess of 400,000 leading a more western lifestyle, waste disposal may be deemed as a very acute problem. A decision was taken some fifty year ago to collect all municipal and building industry waste in one national rubbish dump, close to a small rural community, *Maghtab*, today more known for its dump than for the original indigenous village.

In fact the problem became greater over the last two decades as the land take-up for waste disposal was having serious implications on the local residents, neighbouring towns and the tourist industry at large. Today waste management and the associated land use have gained more importance, where professionally managed engineered landfills are being meticulously planned and set up. A proper nation-wide waste separation educational programme is in place, identifying organic form inert waste, also separately collected at source. A greater emphasis on re-use and recycling is also made with a view to increasing longevity of materials and products ("cradle to the grave" life cycle) thus logically reducing disposal volumes and land-use demand. Apart from all other inert (possibly compacted) waste tyre disposal poses a serious concern, as its disposal takes up precious stockpile volume, considering a tyre's low mass per unit volume.It also poses a high helath risk when deteriorating or burnt, emitting toxic fumes.

Tyre recycling is typically considered when vehicles' tyres are beyond repair or rethreading. This is particularly the case with larger vehicles, especially when severely damaged or punctured. All but more particularly larger tyres present the most problematic sources of waste, due to the large volume required and their durability, thus having a slow rate of decay, if at all. These same characteristics that make disposed tyres generate such a waste problem can also be viewed positively, as it makes them one of the most re-used waste materials. Since rubber is very resilient it can also be reused in other forms and products. Examples include shoe soles, shock absorbers, road surfaces, noise absorption and thermal insulation.

In the U.S., approximately one tyre per person is discarded annually. In 2003 alone 290 million scrap tyres were generated, of which 45 million of these were re-used through re-threading.[2] With most landfills worldwide minimising their acceptance of whole tyres due to the health and environmental risks associated with stockpiling tyres, many new markets have emerged for recycling such a heavily disposed-of waste material. Established growing markets exist for a majority of scrap tyres produced every year; across Europe some of these plants are also being supported (or owned) by national authorities or local governments.

It is particularly worth investigating the LCA (Life Cycle Analysis) associated with the disposal of scrap tyres or their export out of Malta, as compared to the importation of synthetic rubber for use in various products such as road surfacing, safety mats for children's play areas and thermal insulation among others. The latter needs further investigation against other forms of insulation typically the more popular EPS (expanded polystyrene) or EPU (extruded polyurethane), both having a high embodied energy content.

Increase in public pressure in the field of waste management, deposition and internalization of environmental cost factors, has led to legislative measures, both National and European, which have resulted in a new scenery in the construction sector. The influence of an LCA approach is evident, when considering the environmental impact phase model of the entire building process.[3]

This paper however investigates the potential energy savings associated with achieving comfort standards through the use of three different types of rubber. These, in themselves, also encompass a different amount of embodied energy to produce; for example flattened tyres require less energy than machine-shredded crumbs, while the latter then demand less energy than pulverised rubber.

3.0 Experiment Methodology

3.1 Thermal Conductivity Theory and Codes of Practice

The ultimate aim of this paper was to determine and compare the U-values for two double skin cavity wall systems, one made of GLS (globigerina limestone) and another in HCB (hollow core concrete blockwork), both tested for three different types of rubber as cavity infill, compared to air. Independent of heating or cooling, the composite U-value is calculated theoretically assuming linear heat flow perpendicular to plane, parallel layers or skins of wall of uniform thicknesses. However in reality, all building components have irregularities, such as mortar joints, lateral cold bridges through corner bond stones, etc. These result in non-uniform transverse heat transfer, thus affecting the aggregate heat transfer through the element. Therefore this needs to be allowed for when determining the U-value of the composite element.

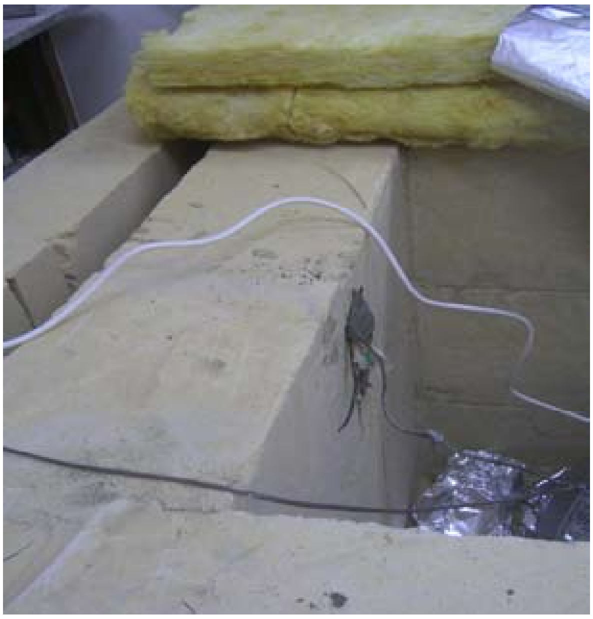
In general for such U-value calculations simplified methods are used where they are deemed appropriate for the element concerned. British Standards (BS) and other calculation methods define the scope of validity of the methods they describe. The method defined in BS EN ISO 6946 is often acceptable. This is known as the *Combined Method* since it involves the calculation of the upper and lower limits of thermal resistance of the element. Any non-uniform layer is to be treated as a bridged layer when using this method. The Standard calculates the U-value of the component from the arithmetic mean of these two limits. Hence its name, the *Combined Method*. However Anderson[4] points out that equal weighting can be an imperfect approximation when the difference is large, even though the true result always lies within the same upper and lower limits.

Finite element analysis is typically used for an accurate calculation of the thermal resistance of an element or single material in a composite part of the building envelope (wall or roof system). For routine calculations the Parallel Heat flow or Parallel Isotherm Method is used. The former overestimates the thermal resistance while the latter underestimates it hence it is for these reasons that the Combined Method takes their average. Based on empirical calculations of thermal conductivity of materials, the U-values were worked out for the different composite elements, representing wall construction in Malta, as per current practice in the building industry. These are later compared to physical testing out of similar test cells, as per current standards, namely BS EN ISO 6946. On the other hand EN ISO 8990:2003 uses the calibrated hot-box to find the steady state thermal transmission properties. This suggests using Q=UADS, but taking into account the emissivity factor, mean radiant temperature, radiant and convection coefficients.[5]

3.2 Test Cell set-up and Methodology

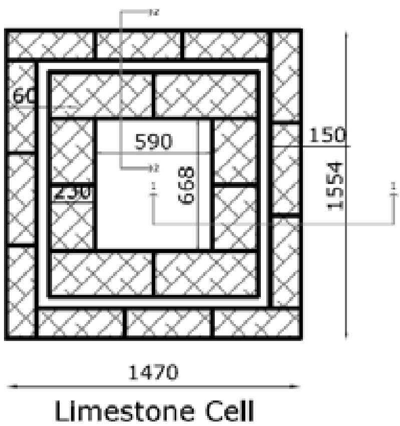
The experimental procedure involved the setting up of two test cells, as per EN ISO 8990:2000.[6] The principal difference between the cells was in their construction system. One was built using the local quarried material, *globigerina limestone*, composed of two skins of 230mm and 180mm, while the second test cell was similarly composed of two skins of 230mm and 180mm, but in HCB (hollow concrete blockwork). In both instances the thicker skin was deemed to be more effective for its thermal mass when placed on the inside.[7] A consistent cavity of 60mm was ensured throughout. The blockwork cell was plastered up to 5mm both sides, while the limestone walls were pointed both sides, both as per standard local building practice. Such cells were placed on an isolating pallet, to minimise ground cooling, yet built directly on glass wool as an insulating material. Top level capping was achieved with a similar layer of insulation, both 100mm thick; both floor and ceiling of insulation panels of the cells were lined up with aluminium foil for maximum reflectivity.

Pictures 1, 2 illustrate the experimental set up while drawings 1, 2 show the corresponding test cell dimensions and thermocouple set-up. The data logging device (not shown here) connects all thermocouples to a special card inserted in a PC, carefully navigated by moving around altogether on a trolley on castors.

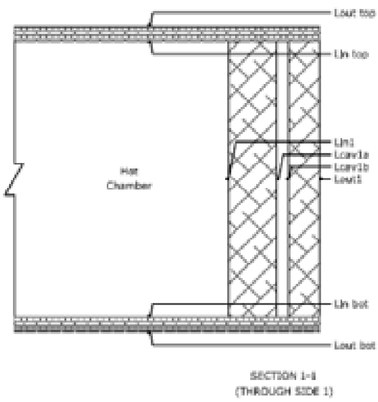


Picture 1 GLS cavity wall test cell

Picture 2 Insulation with aluminium foil lining



Drawing 1 Plan of test cell for GLS



Drawing 2 Section through test cell

Four rates of heat transfer were tested, namely with a void cavity, solid opened out tyres (sheets), shredded morsel (10-15mm) and pulverised rubber (1-3mm). The test cell facility was set up inside an environmental laboratory, behind a double door chamber to ensure a stable indoor environment. An electric heating element of a constant 1000W intensity was placed inside each test rig. A series of thermocouples were attached to the respective faces of the cell walls, interconnected to a robust data logger, previously calibrated, all set up as per MSA standards.[8] Although monitoring was initiated immediately, steady state conditions were allowed for until formal data logging was noted to be fairly stable, with a steady rate of heat transfer through the different test cells. Output results were charted and analysed for observations.

4.0 Results & Discussion

4.1 Charted Output: Building Materials comparison

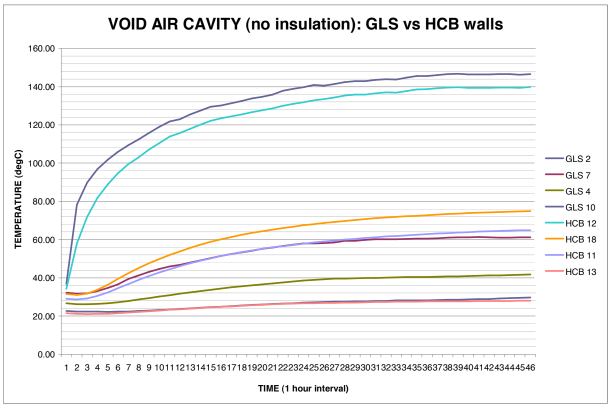


Figure 1 Void Air Cavity - GLS vs HCB

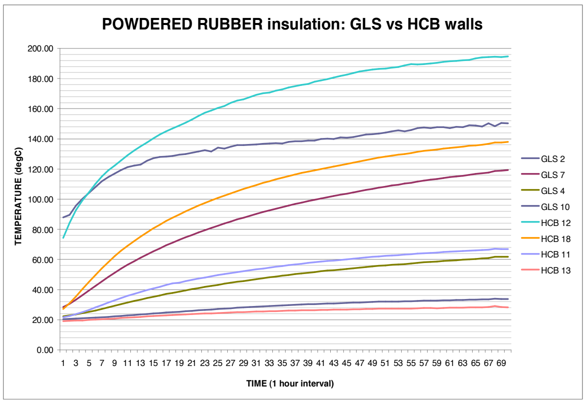

Figure 2 Powdered Rubber - GLS vs HCB

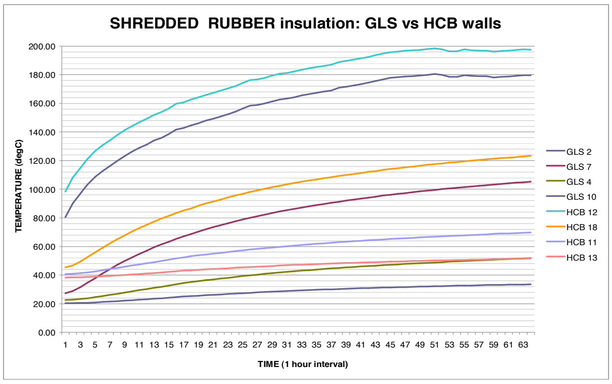

Figure 3 Shredded Rubber - GLS vs HCB

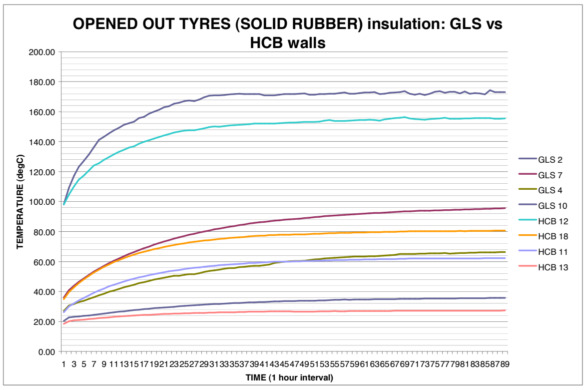

Figure 4 Solid Rubber Tyres - GLS vs HCB

From the above charts, figs 1,2,3,4 the four scenarios compare the different thermal performance of the two distinctly different building materials, GLS (Globigerina Limestone) and HCB (hollow core blockwork), the former naturally occurring and quarried, while the latter man-made, composed of hard-core aggregate, sand and cement. Both materials shave considerably high embodied energy, not calculated in this paper.

Fig.1: Void air cavity: It is noted that for both GLS & HCB heat transfer generally stabilises after 65 hourly readings. While GLS reaches 140℃ in 48 hours, HCB reaches the same temperature after 57 hours. The difference of 9 hours is attributed to the 100mm cast cavity within the HCB and possibly its lower porosity. Both GLS and HCB outer cell surface temperatures rose marginally from 26℃ to 28℃ over the same perio d.

Fig.2: Powdered rubber: Heat transfer stabilises after 60 hours for both cells. HCB inner surface temperature reaches 195℃ after 70 hours, while GLS reaches 150 ℃ over the same time frame. HCB cavity surface temperatures rose steeper than GLS from the onset. This may be due to the fact that GLS was probably still wet internally as typical for most freshly quarried stone. Although water is a better conductor of heat than air, the moisture content itself must have been cooler than capillary pores, thus lowering the kick-off temperatures. Hence the slow rise detected by the thermocouples on the GLS.

Fig.3: Shredded rubber: Both HCB and GLS rose steeply over the first 24 hours but rate of heat transfer slowed down to stabilise at 198℃ and 180℃ respect ively. Outer surface reached equilibrium after 63 hours with HCB rising to 52℃ and GLS lower by 17℃ at 35 ℃. It is also worth noting that cells' inner surfa ce temperatures experienced minor non-uniform fluctuations in temperature readings. This is possibly due to variations in the mains current supplied to the heaters since both HCB and GLS experienced consistent congruent dents in their temperature logging.

Fig.4: Solid Rubber: Inner surface temperature for both GLS and HCB rose steadily from around 96℃, possibly due to the thermal inertia of the stone from previous experiments. [This was the last test performed, and although a period of five days was allowed for cooling, the inner mass may have still been warm enough]. Its is also worth noting that both GLS and HCB temperature profiles are now experiencing more

erratic changes, yet retaining a steady flow overall. Both curves reach fairly stable values of 172℃ and 154℃ after only 33 hours of data logging. Cavity's inner surface inside the GLS cell stands at 96℃ w hile that for HCB is at 80℃. In this instance GLS cavit y temperatures are circa 14℃ warmer than the HCB c avity (unlike the former three scenarios). This is only attributed to the now dry globigerina limestone, after the earlier three experiments. Outermost surface temperatures are equally different by about 8℃ with GLS still the higher of the two cells. It is worth noting that while GLS was only pointed along its bedding joints, the HCB cell had a plastered surface composed of a sand+cement mortar of circa 5mm overall. This may have helped to dampen thermal losses overall, even if marginally. [Such surface finishes were applied to simulate current practice for typical Maltese building construction finishes].

4.2 Charted Output: Temperature Profile comparison

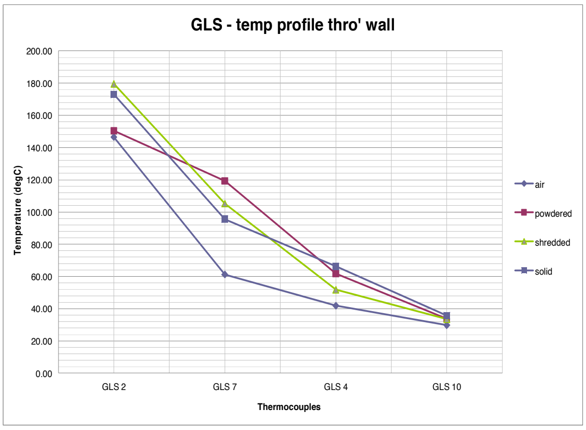

Figure 5 Temperature Profile for GLS

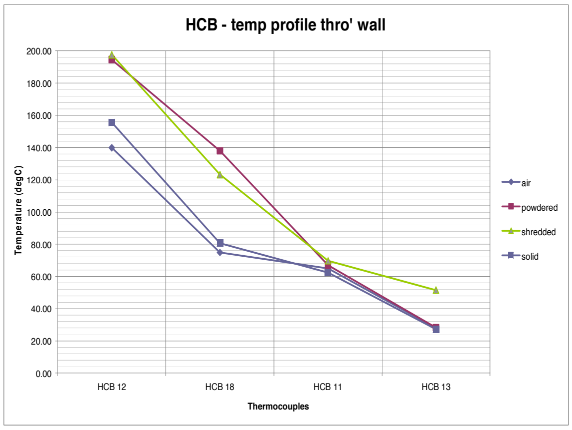

Figure 6 Temperature Profile for HCB

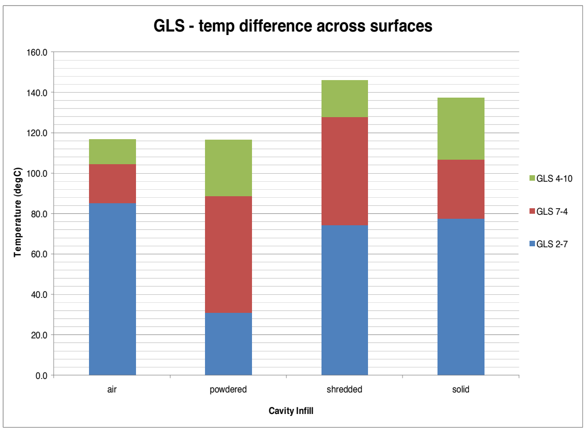

Figure 7 Four Insulation types for GLS

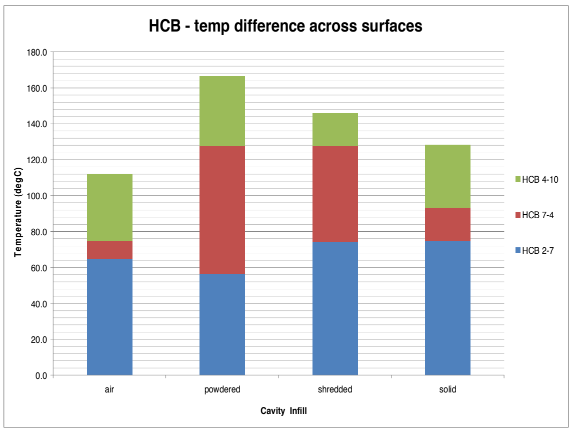

Figure 8 Four Insulation types for HCB

Figures 5 and 6 depict the 4 in 1 temperature profiles through the *two* different materials, while figures 7 and 8 represent the effect of each cavity infill (insulation type) for the same two materials, namely globigerina limestone (GLS) and hollow core blockwork (HCB).

Figures 5 and 6 indicate that while an empty (air) cavity and a solid rubber infill (opened out tyres) have a similar gradient of 72℃ and 40℃ across the inner skin and the cavity respectively, they converge to the same point at 28℃ externally. However, shredded an d pulverised rubber infill insulation behave quite differently: both GLS and HCB experience a greater resistance to heat losses through their inner skin wall of circa 30℃ and 70℃ respectively. The steeper gradi ent of the temperature profile for powdered rubber also indicates that it performs best of all three rubber types.

Figures 7 and 8 expresses temperature differences as bar charts. These further demonstrate that pulverised rubber offers the greatest resistance to the passage of heat, followed by shredded rubber.

4.2 Output Results and Discussion

After working through each cavity option case scenario for the two different materials, the following U-values were obtained, as summarised in table 1:

Table 1 U-values for different cavity insulation types

Cavity infill [60mm]	*U-value for GLS wall [w/m²K]*	*U-value for HCB wall [w/m²K]*
AIR	2.78	2.68
POWDERED rubber	2.21	1.65
SHEDDED rubber	1.91	1.77
SOLID rubber	2.03	2.19
*EPS	1.00	1.00
*EPU	0.76	0.78
*Glasswool	1.42	1.09
*Stonewool	**1.08**	**0.91**

**Note: These values were obtained through similar experiments carried out by Abela.[9]*

Comparing theoretical calculations with the experimental values inserted in Fourier's Law of thermodynamics U-values compared favourably. Table 1 illustrates all experimental values obtained. Once more it is evident that pulverised recycled rubber gives the optimum thermal performance out of the three types tested, followed by shredded rubber - both in hollow core blockwork.

However when compared with modern conventional purposely manufactured insulating materials, these performed marginally less. It is worth pointing out however that the embodied energy of both the new material, as well as the recycled rubber, did not feature in the overall energy balance equation.A holistic LCA would have been justified in this case for a true overall comparison, including embodied energy of both types.

4.3 Potential Shortcomings

To be precise, the solid rubber is actually an opened out tyre of circa 10-15mm thickness, including steel mesh. [Rim lining was deliberately stripped out to avoid steel conductivity]. The two factors that may have influenced readings are the percentage of steel content - albeit even if very low, as well as the remaining air void between the solid tyre and the cavity walls. These may have (marginally) distorted the readings for the opened out tyres. Naturally if the full 60mm cavity was packed with layers of solid tyres, the results would have been quite different for this case.

The heat source of a known intensity of 1000W was assumed to be divided between the four walls of the cell. Since the ceiling and floor of the two cells were heavily insulated with 150mm of glasswool internally lined with an aluminium foil, it was assumed that there was no absorbtion and no heat was conducted out of these two planes in theory. In reality however, the roof did warm up even if marginally. Ths may have contributed towards a margin of error when assuming the 1000W source to be divided into 250W for each side.

Initial kick-off of inner surface temperatures was slow, especially for 2nd, 3rd and 4th experiment set up with powdered, shredded and solid tyres respectively. Although a minimum period of five days in between was allowed, the thermal inertia of the GLS in particular could have remained relatively warm; this could have offset the readsings, especially when compared to the HCB, the latter having a greater porosity and a lower thermal inertia.

Globigerina limestone, when quarried is typically wet with a relatively high moisture content. Standard building practicve in Malta dictates (rule of thumb) that new buildings should be allowed to dry up for at leat one year before such walls are plasterd or decorated. In this instance, however, due to time constraints and availability of the builder, only two weeks were allowed. Hence the possibly high moisture content could have contributed to a small degree fo error, even if marginally, especially when compared with hollow core blockwork. With hindsight, this could have been measured and assessed against similar values for HCB.

5.0 Conclusions

Given that recycled tyres can be transformed into these three forms of opened out, shredded and grain size, it can be concluded that powdered rubber provides the best thermal performance of the four types tested, including an air cavity.

However it is worth noting that since the alternative four (and any other) materials compared with are purposely manufactured as insulating materials, therefore solid, shredded or pulverised rubber tyres present an added value ("win-win" situation), since they curtail waste both in terms of volume and in terms of their hazardous material decomposition.

Therefore such recycled rubber, an offshoot of used vehicle tyres, lareg or small, is here potentially put to good use. This points to the case that a full rigorous LCA (Life Cycle Analysis) needs to be worked out in order to compare the overall energy saving of the different systems against the deployment of various types of newly manufactured insulation. At this stage such a study was beyond the scope of this research paper.

5.1 Scope for Further Research

There is much potential for further research. As outlined earlier, one can focus more specifically on the embodied energy of each material in order to assess, compare and contrast different composite wall systems for their overall energy balance, including the insulating material's potential for recycling or in itself being a derivative of another material, possibly outside the building industry (e.g. tyres). This will ensure exhaustion for its embodied energy for a full LCA, with a thorough "cradle to the grave" sustainable approach.

There are numerous software packages on the market, most of which come with their own library of individual materials embodied energy.[10] Another area of research could be to compare these for similar external wall systems.

Such an approach will certainly minimise the impact of these three scenarios: the building industry's demand for new resources, reducing waste and health hazards and ultimately a reduction in carbon emissions and a lower carbon footprint of the building in question.

Keywords: Sustainability, FM, Recycling, Energy Management, Climate change

Summary

Facilities Managers are in the forefront for delivering sustainable assets management, and hence further the venture for mitigation and adaptation to climate change. This paper examines recent surveys conducting to establish the barriers and knowledge gap in applying sustainability principles and technologies in Facilities Management (FM). It describes the perceived barriers to the introduction of sustainable facilities management across the industry and reviews current analysis and understanding of sustainability and identifying the knowledge gap in its implementation. Majority of questionnaire respondents indicated the importance of sustainability to their organisation. Many of them stated that they reported on sustainability as part of their organisation annual reporting with energy efficiency, recycling, and waste reduction as the main concern to them. It is argued that the diversity of the FM role is challenging for incorporating sustainability agenda. The overwhelming barrier for implementing sound sustainable FM is the lack of consensual understanding and focus of individual and organisations for sustainability, hence appreciating the opportunities, threats and need for strategic leadership and direction in driving essential change. There is knowledge gap in having practical information on delivering sustainable FM. Skills and training provision traditionally offered to FM needs to be re-evaluated. Sustainability education and training should therefore be developed to provide effective structures and processes to apply sustainability coherently throughout FM organizations and as a common practice.

1. Introduction

Facilities managers have existed for as long as human activities have been carried out in designated buildings and sites. Wood (2006) highlights the need to address existing building stock in achieving sustainability goals and it is this emphasis on the operational phase of buildings that is indeed key to the role of FMs, since in the developed world the majority of buildings in current use will remain for the next fifty years, carrying their embodied energy and operational energy requirement into the future. Barbour (1998) identified a UK market for building maintenance and repair of £28 bn, and this easily exceeds the £10 bn new build market identified by Wood (1999). This puts into perspective our shared understanding that there has always been a need to manage the physical fabric of buildings, equipment and furniture within them, and the efficient supply of resources and removal of waste. These functions will have existed throughout history, but the complexity of modern society and its increased use of resources mean that there is now more than ever a need for facilities managers of high calibre to meet the needs of business, government and society in the 21st Century. The Barbour (2000) study indicated that over 75% of FMs had responsibility for both the routine upkeep of buildings as well as for their longer term repair and may operate at a strategic level in this activity.

According the BIFM (2007) Facilities Management is considered to be one of the fastest growing professions in the UK. The UK Facilities Management market is worth £106.3 billion Shah (2007) with an annual growth of between 2% and 3% anticipated up to 2012. The industry and its market are forecasted to develop to include non-core functions including payroll IT, activities traditionally not associated with this profession, but which are increasingly being addressed by FMs. Brown & Pitt (2001) highlight the anticipated growth in the airport sector for example, a traditionally poor performer in sustainability terms and the likely impact that sectoral growth will make in sustainability terms. The scale of growth in the built environment and the consequential growth of the FM sector is anticipated to be enormous and consequently the contribution to the environmental problems.

The concept of Sustainable Facilities Management has developed in parallel with the overarching concept of sustainable development and the growing appreciation of the scale of predicted climate change. Recent extreme weather events such as Hurricane Catrina, flooding in South East Asia and the 2005 record hurricane season in the Caribbean have illustrated the need to address the threat of global climate change. These experiences have been reinforced by scientific evidence of rising temperatures, the melting of the polar icecaps and glaciers and revised predictions of more rapid temperature increases and extreme weather conditions. The case for change has been successfully made and the need to balance the three strands of sustainable development - social, economic and environmental – is apparent. It is both fortuitous and timely that the facilities management profession has grasped the agenda for change and is aspiring to develop a practical sustainability goals within this rapidly evolving profession. Facilities managers are now at the forefront of organisational behavioural change and in a position to influence the behaviour of individuals working in business, government departments and public services within the facilities they manage. Governments at both national and international level are using regulation to bring reduce carbon emissions and manage demand. Much of the burden of regulation will need to be picked up by facilities managers at every level. Current examples of the impact of regulation are the Energy Performance Building Directive, now partly implemented, WEEE regulations from July 2007 and the changes to planning to move towards zero carbon construction.

Sustainability is becoming increasingly important for Governments, business organisations and community at large having experienced the consequences of the global warming. There is an urgent need to change the way people think and operate. The importance of sustainable development as a tool in the battle against the climate warming is well documented. The European Union as well as the UK government are designing and constantly introducing new pieces of legislation that are forcing the construction industry to achieve improved energy efficiency and to reduce the carbon emissions. Having said that, The built environment and the construction industry have a serious detrimental impact on the environment. The construction industry accounts for around 40% of all resources consumption and production of around 40% of waste including green house gases (Prasad and Hall, 2004). The built environment and especially buildings on their own use 45% of generated energy to power and maintain there in contrast only 5% is used to construct them (CIOB, 2004). The other problem of the present world is scarcity of resources and the situation is aggravating due to developing economies in China or India demanding large amounts of energy and materials. The situation is reflected through constantly rising price of energy, its limited and finite availability. The affordability and security of the supply is under a question mark. As Hodges (2004) says ‘All these lofty goals to reduce energy consumption and take better care of the environment are of clear benefit to the facility manager. Achieving these goals, however, is easier said than done’. This is due to a discrepancy between the abilities, knowledge, skills and willingness of the facilities manager to implement sustainability in their business and the fact that they are very often mandated to manage the facilities at the lowest possible present cost. The two desynchronised tendencies make another barrier that prevents the discipline of facilities management from becoming more sustainable.

In addition the social strand of sustainable development provides a focus on social justice and development, so ensuring community participation in decisions affecting wider site implications, participating in the sustainable development and possibly regeneration of the neighbourhood, embracing corporate social responsibility opportunities and possibly even buying fair trade catering supplies are all relevant. There is now an ever increasing focus on sustainable resource use as described by Barton, *et a*l (2002) advocated the concept of strategic asset management (SAM) as a guiding principle for strategic resource use that includes the principles of ecologically sustainable development for quality of life goals.

The need for sustainable facilities management, and for skilled facilities managers to carry out this function, is therefore growing and the need to develop new ways of working to meet sustainability criteria is of increasing importance. The drivers now are to meet the challenges of applying sustainable development criteria to the management of facilities. This encompasses the life cycle of facilities, from design and construction to disposal, but often with a strong focus on the operational phase. This phase provides a remit to factor sustainability into maintaining and repairing the physical fabric of the site, obtaining resources based on sustainability criteria and ensuring that this extends through the supply chain, minimising waste and disposing of it responsibly and reducing energy demand.

British Institute of Facilities Management (BIFM, 2007) reports on its website that 'although the FM profession has been presented with an opportunity to make a real and measurable difference by driving the sustainability agenda forward, it does not at present have easy access to the specialist knowledge, tools and supporting case study material necessary to make this a reality'.

The change in focus that this represents is supported by BIFM and partners in setting up a Knowledge Transfer Partnership to raise awareness of best practice in the industry and to provide an electronic knowledge portal to share information that will allow professionals to build on their skills in this area. In order to tackle the problem a project was developed. The University of Reading's School of Construction Management and Engineering in the partnership with the British Institute of Facilities Management is engaged in a project known as Knowledge Transfer Partnership (KTP). Its aim is to research the sustainability issues within the facilities management industry, design and develop investigative and diagnostic tools required to enable and facilitate the implementation of sustainability measures.

2. Complexity of the FM Industry: Definitions and Scope

The concept of Facilities Management is continuously developing. Lord et al (2002) claimed that the term 'originated in the late 1960's to describe the then growing practice of banks outsourcing responsibility for processing of credit cards transactions to specialist providers.' The British Institute of Facilities Management (2007) claimed on its website that this is one of the fastest growing professions in the UK and describes the concept as 'the integration of processes within an organisation to maintain and develop the agreed services which support and improve the effectiveness of its primary activities'. This commonly used definition of Facilities Management has been formulated first by the European Committee for Standardisation (CEN) and latter on formally adopted by the British Institute of Facilities Management. Franklin Becker, one of the Facilities Management pioneer, defines the term in the following way: 'FM refers to buildings is use, to the planning, design and management of occupied buildings and their associated building systems, equipment, and furniture to enable and (one hopes) to enhance organizations' ability to meet its business or programmatic objectives. FM thus refers to organizational effectiveness" (Becker, 1991). Chalmers FM Initiative defines yet another definition of the term which is '*the design and change of facilities and the organisation of services related to facilities, based on requirements derived from user core activities.'*

Various institutions, professionals and organisations offer different definitions but the idea that they reflect is the strong relationship and interaction between buildings, services and organisations' core activities. Organisations use buildings, services and assets to create an environment that can enhance the performance of their primary business. The remit of Facilities Management industry is very broad and is constantly growing as more activities are tend to be regarded as non-core ones and included in the facilities management sector. BIFM (2007) created the following range of ancillary services that are incorporated in the FM sector:

- Security
- Cleaning
- Catering
- Building Fabric Maintenance
- Gardening and Landscaping
- Lift and Escalators Maintenance
- Lighting
- Building Design
- Plant Replacement

- Construction Management
- Energy Management
- Voice and Data Communication
- Disposal and Acquisition of Buildings
- Relocation
- Space Planning
- Postal Services
- Secretarial Services
- M & E engineering
- IT management

Facilities management used to be perceived in an old-fashioned way as to being concerned with caretaking, cleaning, repairs and maintenance (Atkin and Brooks, 2007). Recently this view is changing as facilities management now include also such issues as real estate, finance, human resource, health and safety, change and contract management. Atkin and Brooks (2007) highlighted that the issues such as domestic services or building and engineering services maintenance are simply the most visible ones and that neither of the FM responsibilities is more important that the other one.

Atkin and Brooks (2005) discussed the issue of a various background of the facilities mangers as many of them *'are not graduates from schools or departments of facilities management'*. They are often qualified as architects, surveyors, civil engineers or accountant and often perceive the role of a facility manager as a new opportunity. Atkin and Brooks (2005) emphasise the importance of possessing certain attributes such as integrity, organisational and communication skills as these are the key to become a successful facilities manager. It is imperative, the writers point out, to be able to understand organisations, people and processes, as opposed just to the background on its own stand. Atkin and Brooks (2005) justified and gave their support to the idea of introducing specialised training and education within the FM. The professionals' background and skills are necessary but they need to understand the way people operate in buildings, the way the use them and the ways in which their performance and productivity can be maximised to the benefit of the organisation and society at large. The broadening of the scope of the FM industry, constantly changing legislation and technology pose yet further requirements in regards to training and education.

In response to the demand of the rapidly growing FM profession, more universities and colleges are offering specialist undergraduate and postgraduate facilities management courses. For those who are already in the profession there is an opportunity to undertake courses on the part-time basis which one of the benefits is application the knowledge in practice.

3. The Sustainability Debate

The term 'sustainable development' has had many interpretations and there have been numerous attempts to define it. The most oft-cited definition of the notion is derived from the report of the World Commission on Environment and Development called 'Our Common Future'. The document, also known as Brutland Report, as the event was chaired by Bro Harlem Brutland – the Prime Minister of Norway, was published in 1987. The report described the sustainable development as *'development that meets the needs of the present without compromising the ability of future generations to meet their own needs'*.

The simplicity of the definition of such a complex issue raised an avalanche of criticism. As Manson (2008) and Norton (2003) say that the definition as lacking purpose and its meaning is empty, but on the other side, '*it can mean almost anything to almost anyone'* (Manson, 2008). The concept of sustainable development was generated over 20 years before the Brutland's Report was created. Rachel Carson in her book 'Silent Spring' (1962) brought to the international attention the devastating effects of human activity on the environment and in this way pioneered the environmental movement. The link between the economic development and environmental degradation was first expressed and put on international agenda in 1972 at the United Nations Conference on the Human Environment in Stockholm. Unfortunately, there were very little signs of implementation of the environmental concerns into practice and attempt to minimise the depletion of the ozone and natural resources or to slow down the process of global warming. In the result, the environmental situation continued to deteriorate despite the international awareness and cry out for change.

In 1992, a major success was achieved at the United Nations Conference on Environment and Development, also called Earth Summit, in Rio de Janeiro. It resulted in adoption by the Member States of the Agenda 21 which was a proposed blueprint of actions in social and economic area required to achieve sustainable development across the globe. '*Governments recognized the need to redirect international and national plans and policies to ensure that all economic decisions fully took into account any environmental impact'* where the energy efficiency had a major role to play (UN, 1992).

The UK continues to tackle the issue of sustainable development by publishing the Energy White Paper in February 2003. It puts the country on the path to reduction of the carbon dioxide emission by some 60 per cent by about 2050 with the real progress seen by 2020 (BREE, 2003; 2007). In addition, the other objectives include reliability of energy supply; promotion of competitive markets in the UK and beyond so that the rate of sustainable economic growth is rising together with productivity; and ensuring that every house is adequately and affordably heated. In March 2005 the UK Government launched a new strategy for sustainable development called 'Securing the Future'. The document presents a set of shared principles that will help to achieve the sustainable development. They were agreed by the UK Government, Scottish Executive, Welsh Assebly Government and the Northern Ireland Administration.

The publication also establishes the priority areas of action shared across the UK. These are:

Sustainable Consumption and Production

Climate Change and Energy

Natural Resources Protection and Environmental Enhancement

Sustainable Communities

3.1 Significance of Sustainable FM

The main aspect of the Sustainable Facilities Management is its contribution in the battle against climate change. It is estimated that only 5% of generated energy is used in the construction process and 45% is used in order to power and operate the buildings (CIOB, 2004). The Organisation for Economic Co-operation and Development (OECD, 2003) highlighted that buildings consume about 32% of the world's resources and that includes 12% consumption of water. The emission of CO_2 as a result of such large consumption is enormous and its contribution to the problem global warming is significant. In this respect, there is a great potential for substantial reductions of these patterns and following that, the substantial reduction of the detrimental effect that it exerts on the environment.

The other aspect of introduction sustainable measures in FM industry is the problem of rising prices of fuel and insecurity of its supply as a result of intensive economic activities of two large developing countries – China and India. The increasing demand for the resources is feared to have aggravating effect on the climate change but also could generate the 'fuel poverty' and insecurity of supply and hence exacerbate social problems.

3.2 Consequences of not practicing sustainability – the Mayans

Certainly a lesson can be learnt from the mysterious collapse of the grand Maya civilisation that occupied the areas of present-day southern Mexico, Guatemala and parts of Belize, El Salvador and Honduras. The phenomenon is very complex and there is no single, universal theory explaining the demise of the great ancient culture. Many argue that it occurred as a result of overpopulation exceeding the capacity of the environment such as overhunting outbreaks of a disease, internal wars or dangerous dependence on monocropping (Peterson and Haug, 2005).

Many also believe in and support the idea of environmental degradation and climate change (e.g. Peterson and Haug, 2005). The latter led to an intense drought lasting over 200 years (Gill, 2000). Diamond (2005) also argues that climate change was one of the factors that contributed to the destabilisation of the Maya population. On the other side, he emphasises other influence factors which could also have contributed to the decline of the society and these are hillside erosion and deforestation as signs of environmental degradation, living close to the resource limits, poor leadership and concentration on short term benefits, and increased internal warfare.

The outcome of such a sudden collapse was not only a substantial decrease of the strength of their social, economical and political system. The lessons drawn from this civilisation can act as a warning as the problems that they were experiencing are very similar to those of the present world: wars, environmental degradation, overexploiting of natural resources, overpopulation and political instability. In this respect, immediate actions are required.

The social issues as well as those economic ones are also under the consideration of the Sustainable Facilities Management. The buildings are the environment in where people work and spend 90% of their time indoors according to the OECD (2003). Creating a healthy environment and good working conditions thus are crucial as they increase the level of the productivity of the employees and therefore benefit the employers and their businesses. Clements-Croome (2004) explains that it is more expensive to employ people who work rather than it is to maintain and operate the building and for this reason *'spending money on improving the work environment may be the most cost effective way of improving productivity'*.

4. Challenges and Barriers for Sustainability

The overall aim of this study is to investigate the nature of the sustainable facilities management and provide a benefit to the industry and community in the form of best practice guidance.

The objectives of this project are as the following:

- Establish the existing level of understanding and application of sustainable knowledge and practice within the facilities management profession
- Identify the key areas of Sustainable Facilities Management where clearer practical tools, information and industry best practice are required
- Identify the benefits of sustainable facilities management
- Determine and ascertain the existing drivers for implementation of sustainable practice in the facilities management industry
- Determine and ascertain the existing barriers for implementation of sustainable practice in the facilities management industry
- Produce a best practice guide comprising case studies for the facilities management practitioners and community

The data required establishing the level of sustainable knowledge and practice within the facilities management industry will be collected through an online survey in a form of self-administered questionnaires. The survey was accessed through the British Institute of Facilities Management website and made available to subscribing members. The received data will provide information on the current state of theoretical and practical knowledge among the professionals; it will identify areas in where there is a lack of practical tools, guidance and information.

The questionnaire consisted of a set of both closed and open questions. The pilot questionnaire was tested prior the commencement of the survey on a small number of potential respondents of the same sample as the final questionnaire. The aim of the questionnaire was to obtain data on the existing level of sustainable knowledge and practice within the facilities management industry. It also aims to establish the areas of the facilities management where it is believed that more information is required on the effective implementation of sustainability. The survey takes account of the type of the respondents and attempts to indentify their level of commitment or the commitment of the organisation they represent to the sustainability. The results presented in this paper are based on the views of 93 respondents.

What does sustainability mean to you?

Figure 1 shows the classification of respondents by sector. Almost 46% of all participants of the survey were facilities management service providers, while nearly 43% of all respondents were involved in the in-house facilities management. Only 3% were product suppliers and nearly 19% were from a different background. This of last group of respondents comprised property managers, FM consultants, building maintenance managers or company directors who cannot be readily categorised otherwise.

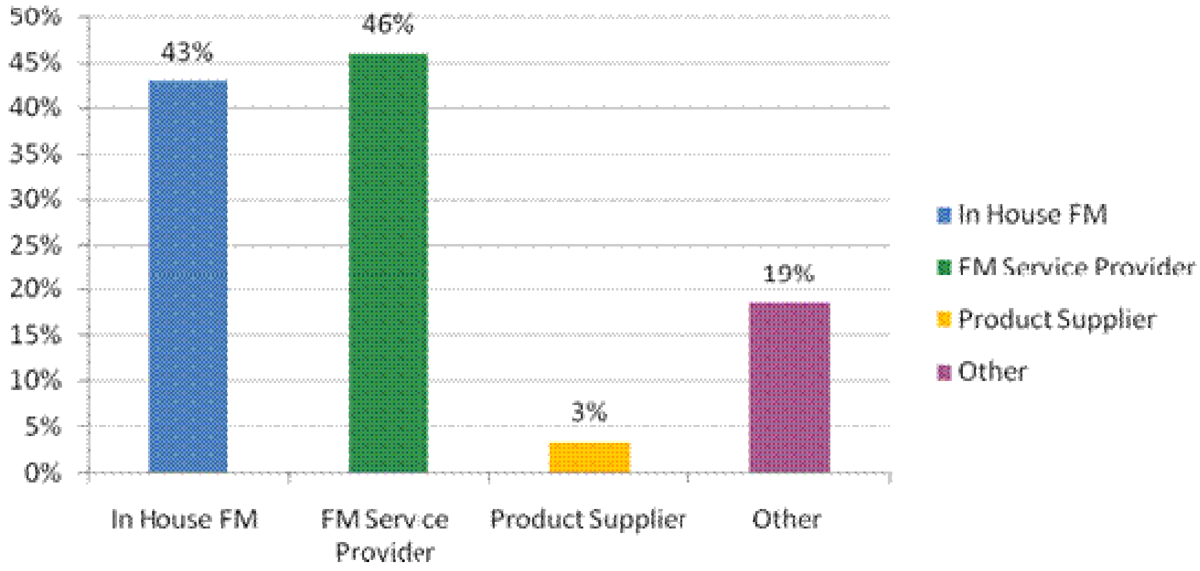

Figure 1: Respondents' classification by sector

Sustainability is characterised by three strands – environmental, economic and social and these were taken as the point of reference in assessing the level of theoretical knowledge, with respondents being required to indicate understanding in their answers. The responses were very varied as can be seen in Figure 2. Over 25% of the respondents have no understanding of the concept. 68% of the respondents recognise environmental aspects of the term (Figure 2). For instance, environmental concepts included 'protection of the environment', 'waste reduction', 'recycling' and 'limits of natural resources'. Key concepts for social issues included 'corporate social responsibility' and 'personal development'. For economic issues concepts such as 'business growth' or 'provision of goods and services' were used. Among the responses, only one individual quoted the Brutland definition of sustainable development.

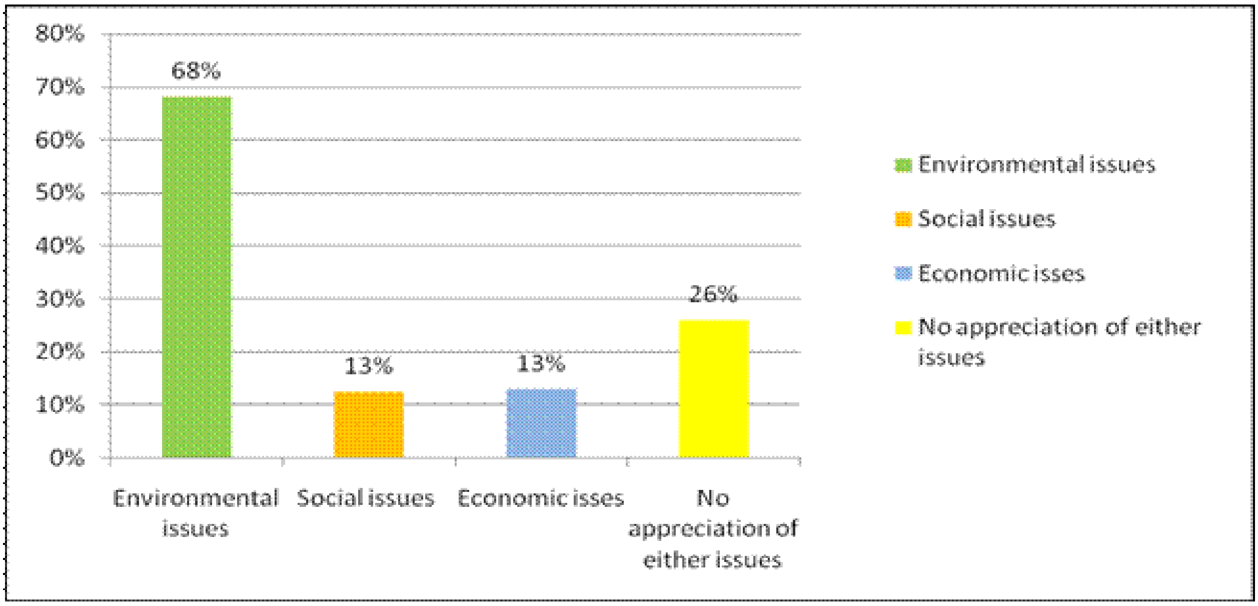

Figure 2: Breakdown of respondents' answers which encompassed the three strands of sustainability.

Below are some of the definitions of the concept provided by respondents:

"Minimising the impact of our lives on the planet and its resources. It also means a public corporate responsibility to protect the environment and its resources"

"The efficient use of finite resources involving waste minimisation, re-use, recycling and procurement"

"Sustainability is a holistic approach to development. Sustainability is about common sense in terms of the economy, environment and society, and acting responsibility"

"Acting responsibly in what we do so as to make a positive contribution to the communities in which we operate"

"To continuously provide the best services and levels of support with the minimum environmental impact"

"Providing commercial growth & business solutions, without leaving a legacy for future generations"

"Company mission and personal involvement on different levels"

Is making your organization more sustainable a key objective for you within the next 12 months?

The majority of the respondents, nearly 86%, indicated that it is important for them to make their organisation more sustainable within the next year.

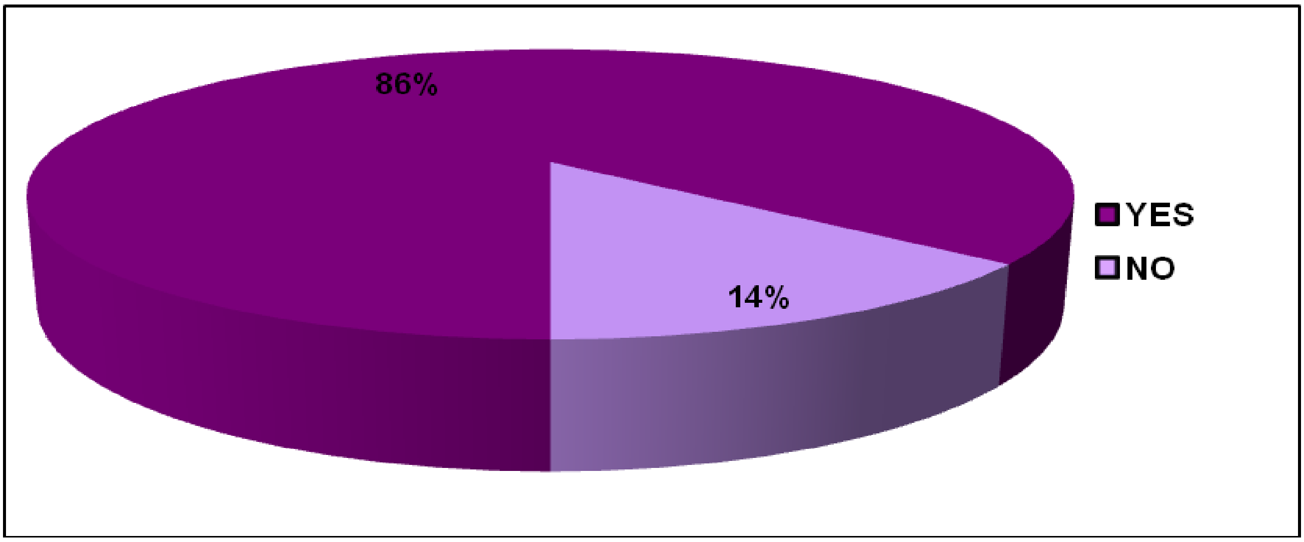

Figure 3: Proportion of respondents who indicated sustainability was a key objective for their organisations in the next 12 months.

How might you achieve this?

A wide range of responses were received in response to this question. Most of the respondents highlighted challenges such as energy efficiency, recycling, and waste reduction. These goals relate to the respondents' understanding of the environmental aspects as major part on their concept of the sustainability.

Below are some of the ideas mentioned by selected respondents to the questionnaire:

"More efficient use of energy, reduction in production of waste reviewing buying policies to ensure that we are using where possible products from renewable resources"

"Better utilities management (electric, water and gas), minimising waste and more recycling of waste, improvements in green travel alternatives"

"through the introduction of an Environmental Policy, the education of staff, focussed procurement processes and energy management"

"Selection of energy supplier with a green resource"

"We believe the best way to make our organisation sustainable is to increase our staff awareness of the issues and good practice"

"Develop travel plan
Reduce water consumption

Reduce energy consumption

Reduce-Reuse-Recycle

Raise awareness"

"There is a drive to pursue this approach to business from the main Board down to the lower grades of employee and corporate plans are in place to ensure we, and our third party service providers, do all we can to achieve both our corporate and legislative requirements"

Does sustainability feature as an objective within your organisation's corporate plan?

Nearly 80% reported that sustainability is incorporated as an objective within their organisation's corporate plan. For this reason sustainability can be assumed to be an important issue for the participating organisations and individuals within them

Was sustainability reported upon within your organisation's last annual report?

Just over 50% of all respondents confirmed that sustainability was reported as an item in the organisation's last annual report. Correspondingly, nearly 50% of the respondents confirmed that sustainability was not reported upon. When compared with responses to Question 7, it is clear that a discrepancy exists. This is discussed later in this report.

I/my organisation would find clearer, practical tools, information and industry best practice in the following areas:

- Developing a sustainability policy for my organisation
- Constructing a business proposal incorporating social, environmental and economic benefits
- Waste management and recycling
- Energy management
- Specification of sustainable products and services
- Ethical purchasing
- CO_2 footprinting
- Specification of sustainable M&E
- Occupancy satisfaction
- Biodiversity
- Community engagement
- Sustainable building and workplace design
- Sustainable travel
- Legal and statutory requirements
- Health and safety
- Flexible working
- Building disposal

5. Conclusions

Facilities Management (FM) is one of the fastet growing industry with almost 10% contribution to the UK economy. With the rising legislative requirements and targets to tackle global warming, FM are in the forefront in delivering the national and international sustainability targets.

There are challenges in the understanding and building a consensual definition of sustainability and The existence of such polarised understanding of the term together with materialised interests of various individuals and organisation is a main barrier for achieving sustainability. The lack or the limited understanding of the key concepts of sustainability and lack of practical knowledge contribute to the little implementation and effectiveness of the sustainable practice in the FM industry. The other primary problem preventing the FM sector from driving the sustainability agenda forward is the lack of expertise information and credible practical guidance. It was indicated that the energy management and the waste management and recycling were the primary areas where more information, practical tools and guidance is required. The reasons for demand of information in such areas are the result of the sustainability driving forces which the main ones are the extensive legislation, the various benefits of the sustainable solutions and their competitive advantage, the raising awareness of the global problems within the society and its demand and expectation for these practices to be implemented on a larger scale. The benefits of incorporation of sustainable practice are abundant. These comprise the economic benefits such lower energy bills or a positive revenue stream; the environmental – in the form of the reduction of the carbon emission and resources consumption and decreased amount of waste directed tot he landfill; the social benefits could be reflected in improved working conditions or a professional career training.

The questionnaire results indicated that the majority of respondents considering sustainability agenda as important to them and their organisations. Furthermore the majority stated that sustainability is incorporated as an objective within their organisation's corporate plan. Hence, sustainability is seen to be an important issue for the participating organisations and individuals within FM. The respondents indicated that information and practical guidance on wide ragne of issues will be helpful in contributing to implementing sustainable FM. Such wide range of issues included developing a sustainability policy for my organisation, constructing a business proposal incorporating social, environmental and economic benefits, waste management and recycling, energy management and specification of sustainable products and services, to mention a few.

There are numerous barriers, in addition to the lack of information and understanding of the key issue that prevents the implementation of sustainability in the FM industry. One of them is often the cost and the limited budget that the facilities management can spend on these solutions and initiatives. The other barrier is the lack of cost effectiveness of some of the technologies such as the photovoltaic systems where a large capital is to be invested and the very long payback time period is expected. Another problem is the lack of skills as well as knowledge among the professional to drive the sustainable practices. This has a great implication on education and training of FM professionals if sustainability discourse is to materialised.

DEVELOPING AN INTEGRATED DECISION MODEL FOR THE ENHANCEMENT OF SUSTAINABILITY DELIVERABLES FOR AUSTRALIAN ROAD INFRASTRUCTURE PROJECTS

Soon Kam Lim[1]
Jay Yang[2]

[1]PhD Candidate, Queensland University of Technology, Brisbane, Australia, sk.lim@qut.edu.au
[2]Associate Professor, Queensland University of Technology, Brisbane, Australia, j.yang@qut.edu.au

Keywords: Sustainable development, road infrastructure, construction management, project delivery, performance enhancement.

Abstract

Road and highway infrastructure provides the backbone for a nation's economic growth. The versatile dispersion of population in Australia, from sparsely settled communities in remote areas to regenerated inner city suburbs with high density living in metropolitans, calls for continuing development and improvement on roads infrastructure under the current federal government policies and state governments' strategic plans. As road infrastructure projects involve large resources and mechanism, achieving sustainability not only in economic scales but also through environmental and social responsibility becomes a crucial issue. Current efforts are often impeded by different interpretation on sustainability agenda by stakeholders involved in these types of projects. As a result, sustainability deliverables at the project level is not often as transparent and measurable, compared to promises in project briefs and designs.

This paper reviews the past studies on sustainable infrastructure construction, focusing on roads and highway projects. Through literature study and consultation with the industry, key sustainability indicators specific to road infrastructure projects have been identified. Based on these findings, this paper introduces an on-going research project aimed at identifying and integrating the different perceptions and priority needs of the stakeholders, and issues that impact on the gap between sustainability foci and its actual realization at project end level. The exploration helps generate an integrated decision-making model for sustainable road infrastructure projects. The research will promote to the industry more systematic and integrated approaches to decision-making on the implementation of sustainability strategies to achieve deliverable goals throughout the development and delivery process of road infrastructure projects in Australia.

1. Introduction

Sustainability challenges are becoming part of our daily lives. Broad media coverage and breakthroughs of scientific research is raising increasing levels of public awareness in recent years. Sustainability wake-up call has permeated into practically all strata of society across the globe. Mounting environmental concerns that include climate change, greenhouse emissions, changing rainfall patterns, carbon abatement, pollution and resource scarcity threaten biodiversity, human health and lifestyles. Given the unseemly scenario, 'business as usual' must needs reconsideration and more so, efforts must be taken to make good the situation.

For road infrastructure projects that involve huge resources, large scale of works and typically long periods of development, it may cause serious implications to the environment. While environmental issues are of great concerns, such development that underpins a nation's economy is equally important and necessary. To develop the road projects as well maintaining and preserving the environment, therefore requires the sustainability approach as the ideal way forward. In this regard, governments and project stakeholders alike are under pressure to look for economically feasible, socially viable and environmentally accountable project outcomes (Figure 1).

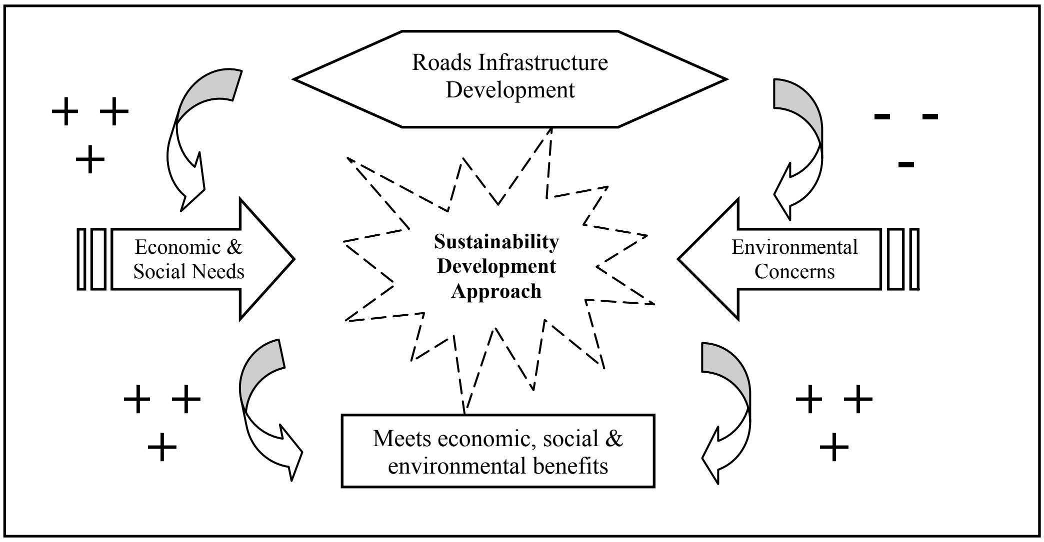

Figure 1: Sustainability Outcomes in Roads Infrastructure Development

Current efforts are often impeded by different interpretation on sustainability agenda by stakeholders involved in these types of projects. As a result, sustainability deliverables at the project level is not often as transparent and achievable, compared to promises in project briefs and designs. In the absence of common understanding among these stakeholders, achieving sustainability outcomes remains as a formidable task.

In the meantime, decision-making for sustainable development in the built environment requires new approaches that are able to integrate and synthesise all the dimensions and different point of views in a holistic matter (Mitchell, 1999; Deakin, et al., 2001). This process requires the application of a suitable operational framework, and an evaluation method or approach that is able to guide stakeholders through the decision-making. However, at the moment, such a structure for organizing the information required in decision-making is not yet available or agreed on among the different disciplines and fields of activities. The lack of an agreed structure that can help decision-making processes achieve greater sustainability is a major problem (Brandon and Lombardi, 2005).

2. A Buoyant Economy and Roads Infrastructure

Australia is currently experiencing an extraordinary economic growth and prosperity, following unprecedented resources boom. The political stability further spurs the confidence of foreign investors and thus, the economy by attracting substantial foreign investment. This has resulted ever-growing economic activities and accordingly, increased car travel and commercial vehicle movements that require greater supply of roads infrastructure. But the existing infrastructure, not only roads and highways, is well below the demand.

The Business Council of Australia has estimated the cost to the national economy due to infrastructure shortage to be about $100 billion, while the Committee for the Economic Development of Australia reported last year that the nation's economic worth could increase by 0.8% if unmet infrastructure needs were realized (Atkins, 2008). In response to the massive infrastructure needs, government has drawn up a priority list of infrastructure projects, worth billions of dollars, and regulatory reforms to speed up the planning, development and delivery of major works.

Roads and highways infrastructure that provides the backbone for Australia's economic growth is critical to this effect. Australia's roads infrastructure has been under constant scrutiny for not being able to sufficiently and efficiently cater for its rising demand. The land freight task is projected to double by 2020 and critical linkages such as the Pacific Highway between Sydney and Brisbane is under-developed, the Hume Highway in NSW is, in many sections, a two lane road (Infrastructure Partnerships Australia, 2007). Besides, Australia has a strong motorcar culture that is commonly believed to offer privacy, comfort and on-demand door to door transport. The geographical widespread and decentralized nature of development such as satellite cities, decentralized employment and housing mean more roads are needed to commute from one place to another. Additionally, many urban roads are old and in need of repair. The development bottle-necks are likely to continue until massive roads infrastructure is in place (Figure 2).

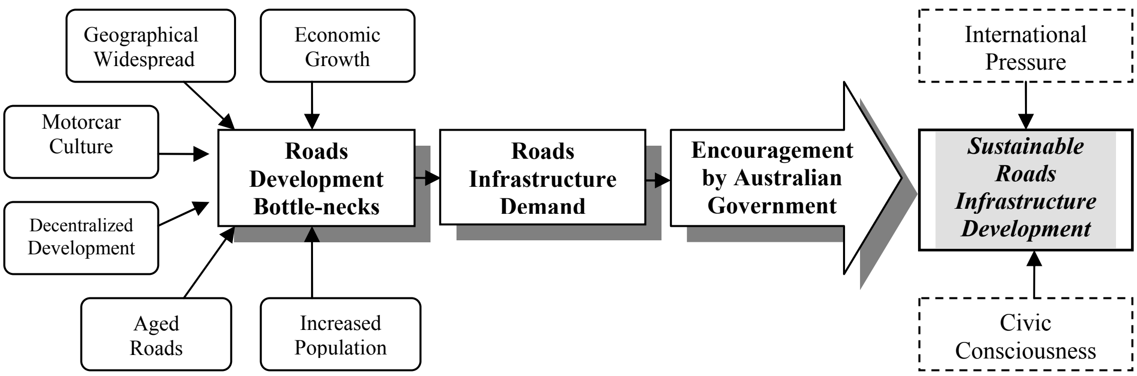

Figure 2: Roads Infrastructure Scenario in Australia

Though providing sufficient roads infrastructure will help ease the bottle-necks and bring about especially the economic benefits, this alone does not ensure a sustainable delivery. A wholesome roads infrastructure development means balance between economic, social and environmental considerations. While from time to time, one of these elements may require additional attention to ensure that balance is achieved; persistent favoring of one element over the others is not sustainable development (Engineers Australia, 2008).

3. Sustainable Road Infrastructure - The Way Forward

Indisputably, sound, well-functioning infrastructure in a country is essential for its sustained economic growth, international competitiveness, public health and overall quality of life (Mirza, 2006). No society has aspired to greatness and a capacity to endure without the ability to build, operate and maintain to a competitive standard of infrastructure required to drive its economy. However, the fact that infrastructure constitutes large built assets on earth and its demand is ever-increasing, the necessary involvement and impact towards global sustainable development efforts is critical and not to be overlooked.

Infrastructure is a key component of Australian nation's capital stock (Allen Consulting Group, 2003). The services from economic infrastructure account for more than 12% of GDP and employ 6.5% of the workforce. Infrastructure services are major intermediate inputs to Australian businesses. In turn, businesses represent some 70% of demand for power, sewerage and water, road and rail transport and postal and communication services. Economic infrastructure also accounts for some 5% of consumer expenditure.

Such facilities (eg. water supply, sanitation, urban roads) contribute to economic production and therefore are, not surprisingly, closely correlated with levels of development (Kessides, 1988). As such, the provision of physical infrastructure must be seen as a prerequisite for the achievement of sustainability of human settlements and of the meeting of basic human needs (Choguill, 1996). Roads and highways construction that often lead to other infrastructure development tops the priority list.

Though concerted efforts by Australian government in developing roads infrastructure, this crucial initiative will be more profitable and meaningful when the development is integrated with the concept of sustainable principles, since it will not only bring about economic gain, but also social and environmental benefits. This calls for a greater need of roads infrastructure sustainability in its overall delivery, especially for new projects.

Drawing from the understanding that sustainable construction can be defined as a construction process which incorporates the basic themes of sustainable development (Parkin, 2000; Chaharbaghi and Willis, 1999; Sage, 1998), sustainable roads infrastructure means the application of basic sustainable principles into roads infrastructure development. In a more concrete term, this means ensuring that our road projects are environmentally, socially and economically sustainable.

4. Sustainable Indicators and Road Infrastructure Development

To achieve sustainable roads infrastructure development, however, it is important to firstly understand how an infrastructure project relates to the principles of sustainability.

According to Dasgupta and Tam (2005), the life stages of any infrastructure project can be divided into (i) pre-project planning, which involves setting up designs, facilitating and mobilizing funds, preparing bills of materials, calculating costs and incorporating short-term and long-tem plans to implement the physical modification; (ii) project implementation, which incorporates the physical work of project implementation and could, for example, include refurbishing the existing structure wherever necessary; and (iii) ongoing operation, which includes the financial management, planning, accountability of responsible authorities, and maintenance of the structure during its design life after starting the intended operation.

Proper design, operation, and management of infrastructure must deal with every facet of its service life, ranging from conception, feasibility studies, design, construction, operation, maintenance, repair and rehabilitation, and finally decommissioning and disposal of the system after it has outlived its useful life (Mirza, 2006).

If an infrastructure project were to be sustainable, every phase of its development must be guided by the principles of sustainable development. A recent research of identifying Key Performance Indicators (KPI) for infrastructure in South Africa construction industry, Ugwu and Haupt (2005) have developed a comprehensive list of key sustainability items and its indicators. These constructs incorporate internationally accepted sustainability metrics, coupled with other performance-based indicators such as health and safety, resource utilization and aspects related to project management.

Based on Ugwu and Haupt's findings, coupled with consultation with the industry, key sustainability indicators specific to road infrastructure projects have been identified which embrace, among others, the issues of environmental concerns, social needs, and economic empowerment, along with health and safety, project management and relationship management (Figure 3). In addition, public governance and community engagement is becoming more appealing in the overall decision-making processes.

In this respect, the infrastructure development process should go through the various stages from conception, to feasibility studies, to design, to construction, to operation, to maintenance and disposal or decommissioning. These processes will be improved by the application of sustainable principles. Consideration must also be given to the differential needs of sub-criteria of each of these key sustainability items. By close monitoring of these processes and checking them against sustainable principles and its indicators, we can thereby ensure and enhance sustainability deliverables in the overall roads infrastructure development.

5. Developing Integrated Decision Model

So far, much of the focus on sustainability has concentrated on buildings and construction processes. Though there is an increased on the studies of urban sustainability in recent time, the methods and decision tools development have focused mainly on buildings; and there is noticeably poor coverage of construction and operation stages of project development (Deakin et al., 2001). Besides, less has been done on infrastructure systems, such as sanitation, transportation, and utilities, which may extend over large geographic spaces, have much wider and more varied potential impacts, and may be harder to understand from a sustainability perspective by multiple stakeholders (Dasgupta and Tam, 2005). To advance this thinking, due attention must also be given to the development of infrastructure sustainability in which this research is aspired to.

At one end, sustainable development efforts mainly remain ideological as seen in macro-level policies and broad-based concepts. They have not explained how they could be translated into practical decision-making during project delivery. The same observation holds for infrastructure projects where the current focus is largely on macro-level policy planning, with little research focusing on the micro level design and construction stage (Ugwu & Haupt, 2005). The situation exacerbates due to multiple stakeholders having different expectations and perceptions towards achieving sustainability in infrastructure projects. On the other end, there were many research initiatives attempting to develop sustainability assessment (Ugwu et al., 2006; Mirza, 2006; Sahely et al., 2005; Ugwu and Haupt, 2005; Dasgupta and Tam, 2005). In between the two, there is a perception-reality gap and mismatch, specifically on how to enhance sustainability deliverables during infrastructure project delivery.

As an exploration on ways of rectifying some of the problems discussed above, a research project is being undertaken at the Queensland University of Technology, Australia. It is aimed at identifying and integrating the different perceptions and priority needs of the stakeholders, along with identifying issues that impact on the gap between sustainability foci and its actual realization at project end level. Filling the niche found in previous studies, this research focuses on the practicality and real-world implementation of sustainability agenda in roads infrastructure projects delivery. This can be achieved based on the common understanding by various stakeholders, with individual view points shared, understood and mutual benefits supported.

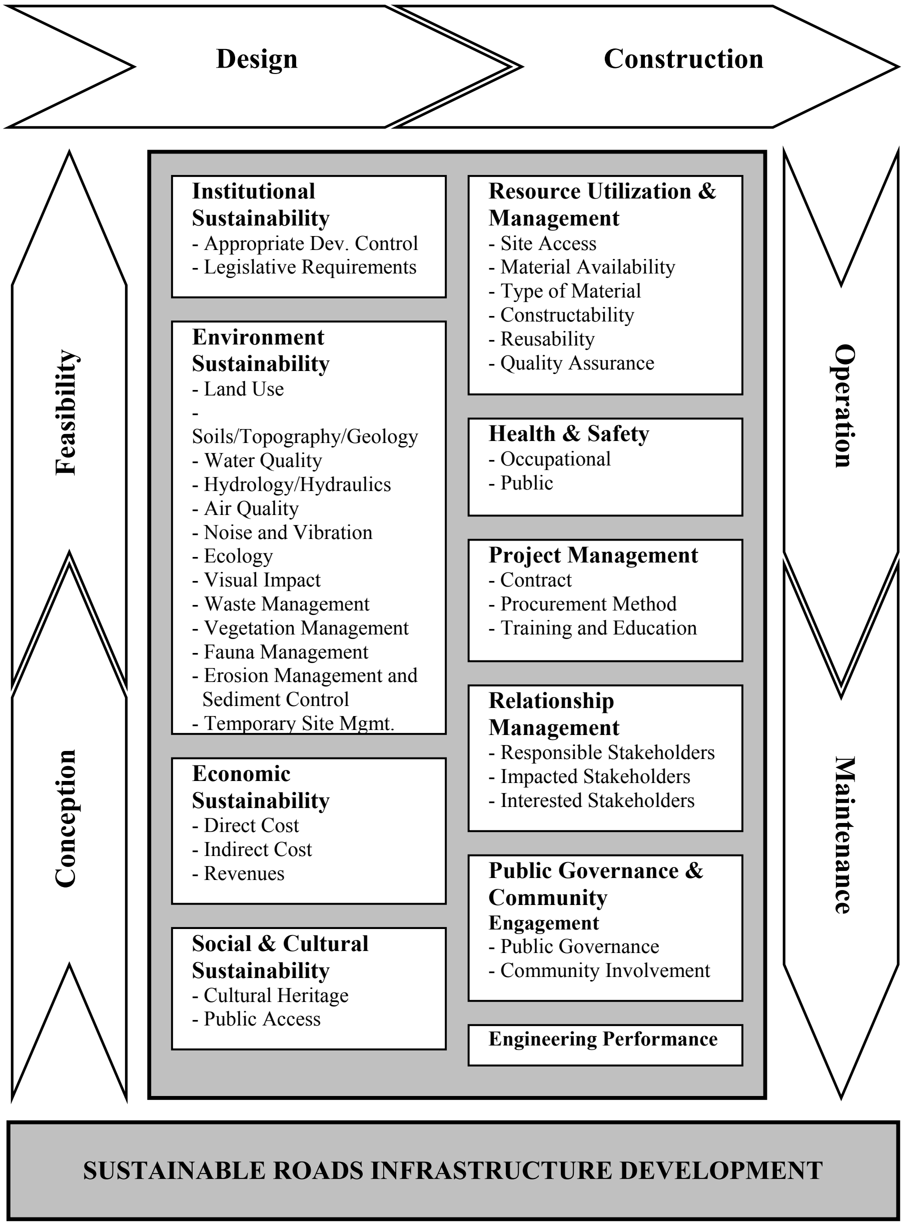

Figure 3: Sustainable Roads Infrastructure Development Processes

The on-going research project employs a combination of face-to-face interviews with industry professionals, a Delphi study among experienced practitioners and academics, and case study techniques to collect expert opinions as well as real-life project information. Figure 4 shows the overall developmental steps and information flow in this project. This acquired primary data acquired will be combined with secondary data from existing government guidelines on environment impact assessment and management, sustainable construction environment and literatures on sustainability research. Both the primary and secondary data will provide triangulation of results covering the perceptions of various stakeholders in infrastructure projects that shall underpin the basis for establishing decision-making process models for sustainable infrastructure projects.

While still at early stages of development, initial industry consultation and feedback has indicated strong interests in this research among stakeholders of road infrastructure projects. The guidelines to be formulated will help promote more integrated decision-making and actions on the implementation of sustainability strategies and foci during the construction project delivery processes. With the different perceptions and views shared, discussed, debated, and with common values and mutual benefits identified, fragmentation on the responsible roles of sustainability will be avoided. Accordingly, this helps facilitate collaboration, consultation and communication among all stakeholders involved in order to achieve consistent decision-making steps throughout roads infrastructure project development life span in Australia.

It is expected that the final framework will be formulated by October 2008 and the complete research results be disseminated to the industry by late 2009.

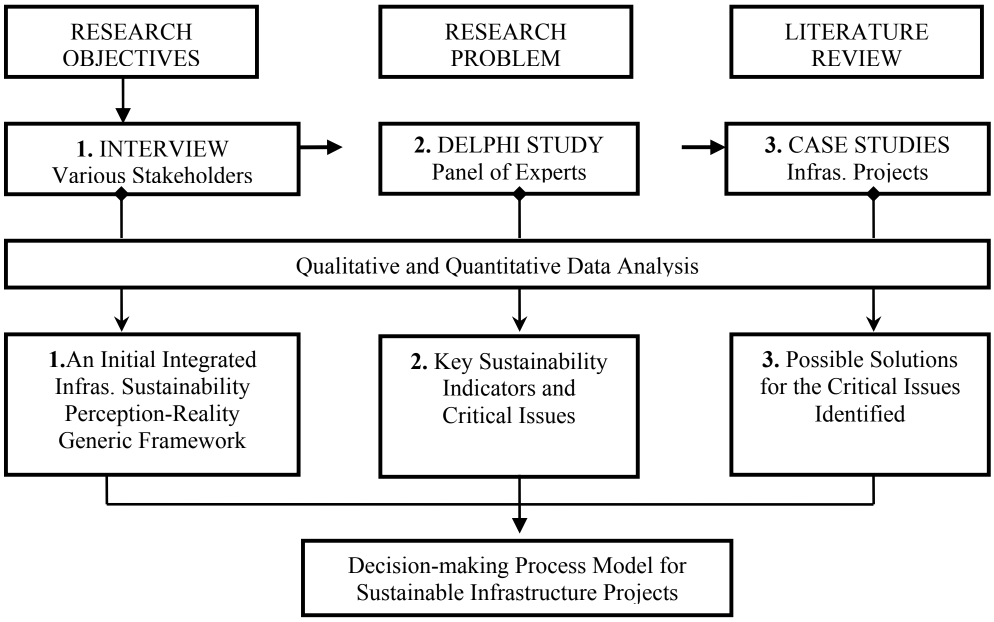

Figure 4: Research Methodology

6. Conclusion

The booming economy of Australia has caused massive bottle-necks in road infrastructure in many states over the recent years. Significant increase in infrastructure budget by three levels of governments indicates the urgency and resolve for Australia to alleviate the problems restricting its' continued growth. As road infrastructure projects requires large amount resources and can cause major environmental impact, achieving sustainability not only in terms of environment friendliness but also through economical and social responsibility becomes a crucial issue.

While sustainability is a logical link to infrastructure projects, past research for this industry sector mainly focused on policies, energy performance and overall assessment methods. As such, little has been done to promote specific applications at project implementation level which is the crux of sustainability initiatives. There is a need to find effective ways to enhance sustainability foci through project delivery, along with the development of policy and assessment methods. The gap must be filled between the industry wide recognition on the importance of sustainability and the lack of measurable sustainability deliverables and eventual realization at project ends. The on-going project, as discussed in this paper, is a positive step towards this direction by integrating different perceptions and priority needs of infrastructure stakeholders, and encapsulating critical issues affecting the sustainability delivery of road infrastructure projects through a framework of systematic approaches to decision-making on the implementation of sustainability strategies.

Keywords: contractor, organization, management, building, lifecycle, feedback, construction, operation

Summary

This paper investigates how a Japanese general contractor, Obayashi Corporation, has worked to reduce environmental loads during building lifecycles.

About 40% of total carbon dioxide emissions in Japan are produced by building-related activities. Reduction of environmental loads throughout a building's whole lifecycle is a challenge for the construction industry. Lifecycle management of a building is categorized into the following phases: Planning, Design, Material production, Construction, Operation, Repair/ Remodeling, and Demolition.

As design-phase measures, Obayashi has utilized its own integrated assessment system for energy saving, and has carried out environmentally conscious design, the results of which have been quantified as environmental protection effects. As construction-phase measures, decreases in both carbon-dioxide emission and waste generation has been achieved during construction. As operation-phase measures, a Building & Energy Management System and an Energy-Conservation Diagnosis have been introduced.

The key issue for total environmental management of buildings is to organically connect knowledge and information of the various phases of building lifecycle in order to achieve effective feedback. The organization of a Japanese general contractor is advantageous for this purpose, if information is exchanged effectively.

1. Introduction

About 40% of total carbon dioxide (CO2) emissions in Japan are produced by building-related activities including construction and operation (Figure 1). Thus, the challenge for the construction industry is to reduce environmental loads generated throughout a building's life. About half of building-related CO2 emissions occur during the building operation phase. Environmental measures taken during the design phase, such as design for energy-saving, are effective in reducing these emissions.

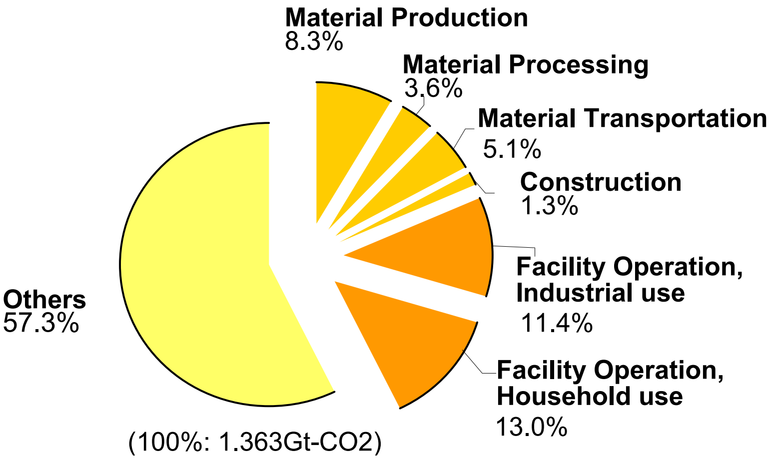

Figure 1 Carbon dioxide emissions related to construction activities estimated form inter-industry relationship in Japan in 1995.

Three organizations of construction industry in Japan, "Japan Federation of Construction Contractors", "Japan Civil Engineering Contractors' Association" and "Building Contractors Society" have established "Voluntary Action Plan on Environment" since 1996 to promote the initiative activities of the organizations' member companies. Periodically, the action plan has been revised and also its results are followed up.

The activities of Obayashi Corporation, a member company of the industry organizations, are introduced in this paper as example cases. Obayashi Corporation is one of the world's leading general contractors, being the 16th biggest global construction company in 2007 and one of the top five in Japan. Its revenue for FYE 2007/3 was ca. $132,282million. This corporation has expertise in carrying out every phase of any construction project and provides services as consultants, architects and engineers. 30% to 40% of buildings the corporation has constructed in the past 20 years or so have been designed by its in-house architects and engineers. This holistic organization is advantageous in achieving environmental goals, because, with effective feedback, lessons learnt from one phase of a building project can be easily utilized in other phases.

Since November 1997, Obayashi Corporation’s corporate activities have been based on the established “Environmental Policy” (Figure 2).

Principles

We at Obayashi Corporation regard our active involvement in environmental matters and continual improvement thereof as an integral part of our management and will take full account of the environmental impact of all our undertakings and activities, continually strive to preserve the environment and contribute to sustainable development of society.

Policies

1. We will fully observe all environmental statutes and ordinances.
2. We will reduce the burden on the environment by saving energy and resources, reducing CO2 emissions, promoting recycling, controlling the generation of waste and toxic chemicals, implementing green purchasing, and preserving natural ecosystems.
3. We will utilize environmental preservation technology and develop more effective forms of this technology.
4. Through our services, we will use our expertise, which has been acquired through our environmental preservation activities, for society.
5. We will make an effort to establish and maintain a rapport with local communities and protect the local environment.
6. Through training programs on environmental issues and publicity, we will fully inform all of our employees of this environmental policy and improve their awareness of environmental preservation.
7. We will encourage our affiliated companies, subcontractors and suppliers to take active steps toward environmental preservation and will support their efforts.

In order to promote our policy on an ongoing basis, we will establish, execute and maintain environmental preservation mechanisms.

Figure 2 “Environmental Policy” of Obayashi Corporation, 29th June, 2005

Lifecycle management of building is categorized into the following phases: Planning/Design, Construction, Operation, Repair/ Remodeling, and Demolition (Figure 3)

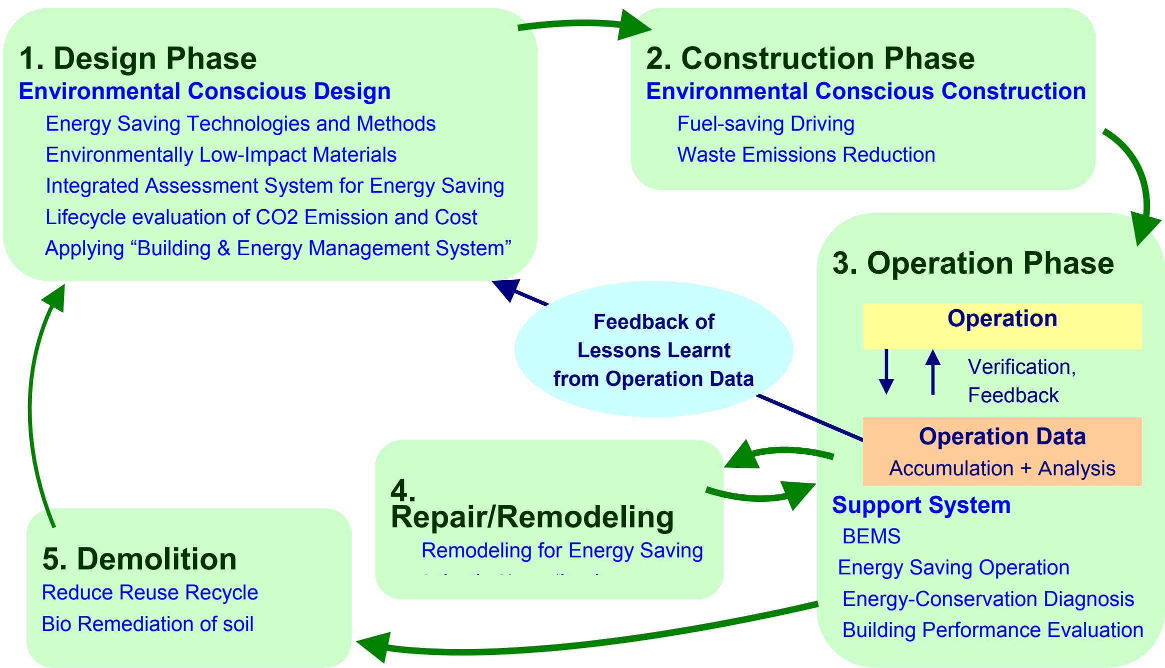

Figure 3 Measures for environmental load reduction throughout a building’s lifecycle

Some of the practices in the Design, Construction and Operation phases are introduced in the next part.

2. Countermeasures in Design Phase

A target in building design should be reduced loads and improved quality of the built-environment. For this purpose, Obayashi's design team makes its best endeavors to achieve environmental care over the building's whole lifecycle.

2.1 Integrated Assessment System for Energy Saving "Eco-navi"

Obayashi has developed and applied green technologies that are adaptable to the individual climates and characteristics of each project. Development and application of individual environmental technologies are important. However, economic and effective integration and application of those technologies are the key challenge in the design phase.

For this purpose, Obayashi utilizes its own integrated assessment system for energy saving in its decision making in the design phase. A computer program helps to check the priority of economical energy saving methods in the Pre-Design phase. Combined techniques or methods are effective in accomplishing significant energy reduction. An Integrated Vector Diagram helps architects and engineers to identify the most efficient combination of techniques and methods to satisfy clients' environmental and economical requirements. "Eco-navi" is a program that quickly shows a Vector Diagram (Figure 5). It also displays the energy saving effect as LCC (Life Cycle Cost) or LCCO2 (Life Cycle carbon-dioxide emission).

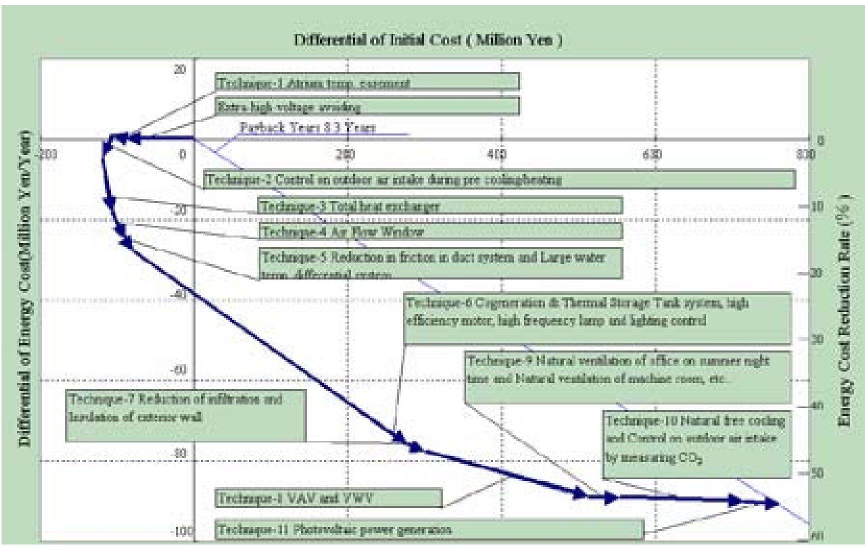

Figure 5 A Vector Diagram for Thermal Economics

2.2 Quantification of Effects by Environmentally Conscious Design

Obayashi's Design Division carries out environmentally conscious design. It also quantifies the environmental protection effects of resource-saving and energy-saving technologies. Such quantification includes low-environmental-impact materials used, energy savings, resource reduction, incremental green area, etc. For example, the amount of CO2 emissions reduced through energy saving during the operation of environmentally-conscious buildings was 19,268 t-CO2/year in 2006, down 10.2% in comparison with 1990's standard design for typical buildings. In the 2006 term, the LCCO2 reduction rate was 10.8%, assuming a 35-year lifespan for buildings utilizing environmentally-conscious-design.

Table 1 CO_2 Emission Reductions Achieved through Environmentally-Conscious Design (In comparison with 1990 standard design)

		2002	2003	2004	2005	2006
	Year	2002	2003	2004	2005	2006
Subject	No. of designs	105	111	131	127	122
	Total floor area (1,000m^2)	968	1,071	1,550	1,980	1,295
Environmental factors taken into account	**$LCCO_2$ reduction rate (%)**	**9.3**	**11.0**	**9.2**	**8.8**	**10.8**
	Reduction in CO_2 emissions achieved through					
	energy-conserving design (t-CO_2/yr)	11,314	14,808	18,493	23,178	19,268
	energy-conserving design per unit floor area (kg-CO_2/yr·m^2)	11.7	13.8	11.9	11.7	14.9
	green purchasing (t-CO_2)	10,340	26,054	38,840	29,100	31,588
	green purchasing per unit floor area (kg-CO_2/m^2)	10.7	24.3	25.1	14.7	24.4
	resource-conservation (t-CO_2)	8,267	22,939	14,028	26,654	11,000
	resource-conservation per unit floor area (kg-CO_2/m^2)	8.5	21.4	9.1	13.5	8.5

3. Countermeasures in Construction Phase

As construction-phase measures, Obayashi has been tackling the decrease in both carbon-dioxide emission and waste generation at its construction sites.

3.1 Reducing Carbon-Dioxide Emissions at Construction Sites

Obayashi successfully decreased carbon-dioxide emissions at its construction sites in 2006 by 30% compared with 1990, using fuel-saving driving techniques, etc. The main cause of carbon-dioxide emissions at construction sites is diesel fuel and electricity. The former is consumed by construction machinery and transport vehicles. The latter is for lifting materials and implementing interior work. Because the former makes up about 70% of the whole, a large part of the efforts to realize eco-friendly construction are directed towards promoting fuel saving for construction machinery/transport vehicles and stopping idling. The Carbon-Dioxide emitted in 2006 was 113,000t less than in 1990 (30% reduction). Within the next few years, Obayashi will have reached its 2010 target.

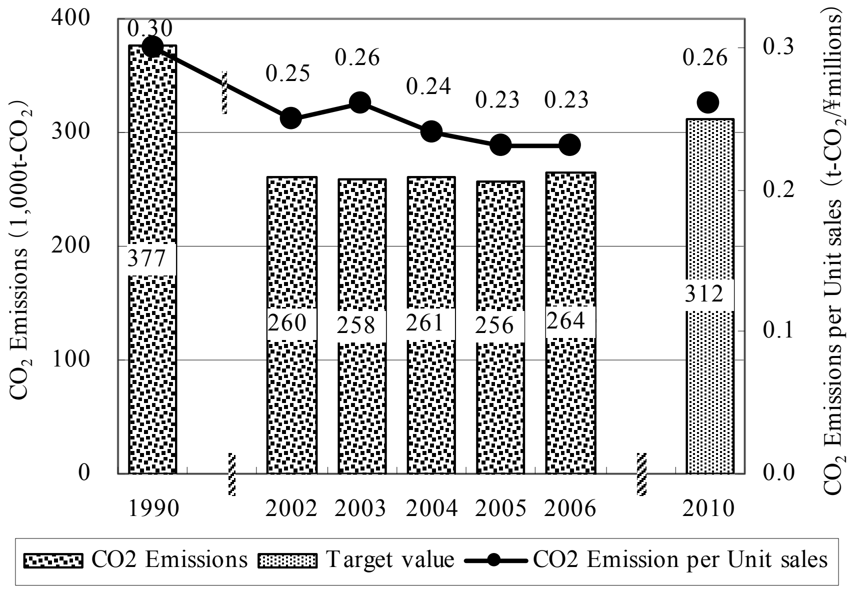

Figure 6 CO_2 Emission at Construction Site

3.2 Industrial Waste Disposal Emissions in Construction Phase

In Japan, 18% of all industrial wastes and 24% of the final disposal quantities are produced by construction activities. Since 2005, Obayashi has aimed for zero-emissions at all its construction sites by controlling waste and keeping the amount generated as close to zero as possible. Decrease in waste material and reuse of resources resulted in a reduction in the final disposal rate from 13.6% in 2000 to 4.2% in 2006.

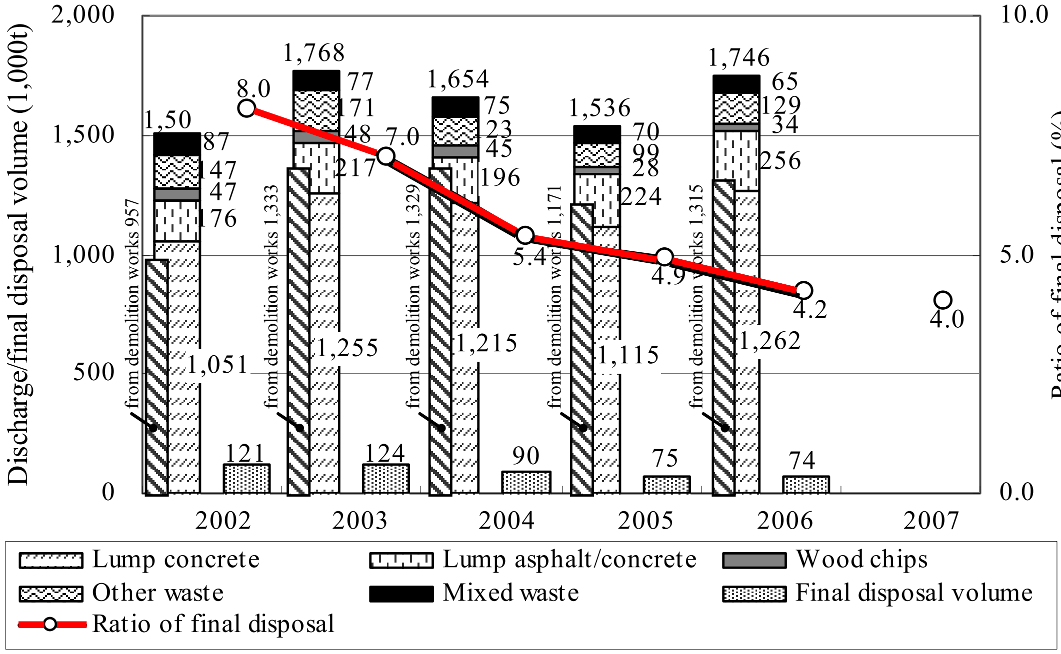

Figure 7 Changes in Construction Waste Discharge/ Final Disposal Amount (Excluding Sludge)

4. Countermeasures in Operation Phase

In the operation phase, it is important to achieve effective energy-saving performance. In addition, it is desirable that the knowledge obtained during operation is reflected in improvement of the particular building and improved design of future buildings. After delivering the building, in the building operation phase, Obayashi Corporation offers several services which are connected to environmental measures. For example, services for BEMS (Building & Energy Management System) and “Energy-saving diagnosis” are provided.

4.1 The Introduction and Application of BEMS (Building & Energy Management System)

Management for optimized building operation using only the BAS (Building Automation System) function is insufficient. Acquisition and various analyses of continuous energy data are necessary to optimize the building operation to realize effective energy-saving performance.

Obayashi Corporation has developed BEMS, named "BILCON- Σ", and has applied it to many projects. BILCON- Σ enables accumulation and analysis of operational data, in order to actualize comfort and energy conservation. “BILCON-Σ” consists of BMS (Building Management System) and CAFM (Computer Aided Facility Management). This BMS has a data acquisition system and a data analysis system. The BMS is connected directly with the BAS (Building Automation System). Using the BMS, operational data such as electricity consumption and interior temperature etc. are automatically collected over a long period from each mechanical &electrical system and accumulated in the database.

Several analysis programs calculate the collected data and evaluate the energy-saving management and efficient operation of the equipment. "BILCON-Σ" has been applied to 170 completed buildings designed by the Obayashi design division, and it is being applied to several selected projects. Obayashi not only delivers the system, but also provides building operation services using "BILCON-Σ" or operational consultancy services based on the data and analysis of "BILCON-Σ", at clients’ request. If Obayashi are entrusted with such management related services, feedback of useful information based on "BILCON-Σ" operation data can be executed effectively in its design division.

For improvement of environmental performance, the challenge is how to activate the feedback cycle from this operation phase to other building design phases.

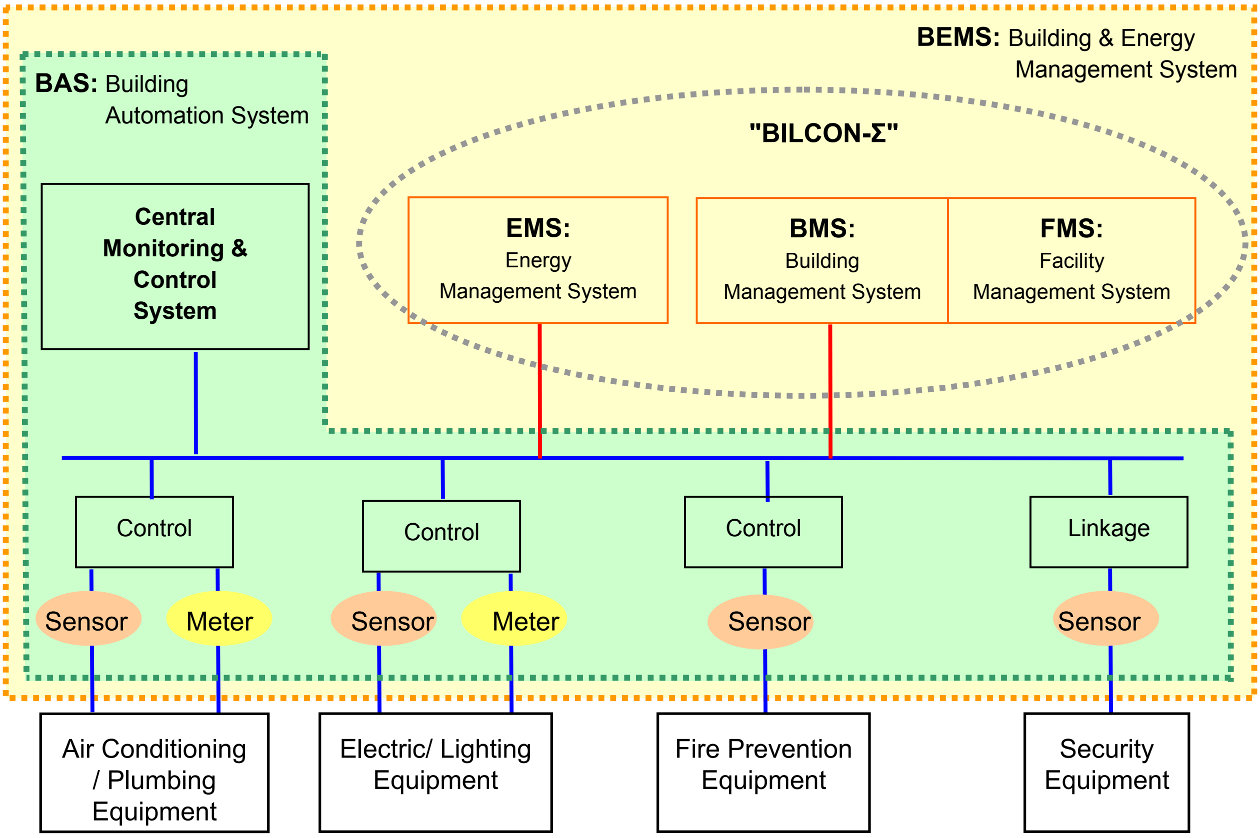

Figure 8 Diagram of BEMS (Building & Energy Management System)

4.2 Energy-Conservation Diagnosis

Obayashi has been executing services of "Energy-conservation diagnosis" and Repair/Remodeling for Energy conservation. "Energy-conservation diagnosis" enables verification and improvement of energy usage.

The service for "Energy conservation tuning," which is adjustment to the change of utilization conditions, is also provided to propel energy conservation.

5. Conclusion

Obayashi has expertise in carrying out every phase of a building project and develops feedback between phases. The most important issue at present is how to increase the acquisition of operational data for feedback to the design phase.

Because Sustainable Design is a holistic work, integrated and flexible organization is important to achieve it. Such organization can comprise not only a network of special companies or professionals, but also a single corporation. The key issue for total environmental management of buildings is that knowledge and information of the various phases of building lifecycle must be connected organically in order to execute the feedback effectively. For this purpose, an organization in which information can be exchanged easily is advantageous. Traditionally, it is characteristic of general contractors in Japan that they provide not only construction but also various building services for each phase of its lifecycle. The organization of such general contractors is advantageous in fulfilling environmental protection if the information and lessons learnt from the building phase can be utilized in other phases using effective feedback.
It is desirable for a general contractor that provides total services during building lifecycle to utilize its advantageous potential for environmental measures.

When services or works of each phase are executed by plural special companies, it is also desirable to have an organic network of environmental information exchange between professionals or companies for various phases of building lifecycle.

Keywords: cooperation, competition, increased sustainability, innovation, measurements, resilience

Summary

The notion that we are becoming more competitive and individualistic is diffused in today Sweden, argued to be a positive or negative outcome of the social, political and economical changes of the last decades. So is also in the construction sector. The call for competitive building outcomes has driven many technical innovations while the lack of cooperation is claimed to be the principal cause of non-sustainable development. Hence the dichotomy must be verified and our understanding of it must become sharper.

Challenged by the climate change societies may compete about sustainable results, but competing to be sustainable has a twofold outcome. We may compete in order to reach high performance measurable solutions in one building and we may compete to spread good enough sustainable integrated solutions throughout the environment. The both seem to be necessary, the first attracting the traditional innovation paradigm, measured in quantities, while the second risks staying in the shadow of technological progress. We have to worry about this and develop new integrated theories.

Emerging patterns of *competitive cooperation* are observed in evolving projects for sustainable buildings in a local Swedish reality, within a study (Demo-04) focused on giving guidelines for the implementation of sustainable building goals. A stakeholder participatory approach reinforces the need of a better understanding of the integrated sector-specific innovations as they all affect the design and construction processes. They are questioning the way people make decisions in everyday work and address a corporate integrated and shared responsibility. Innovations in building can be inconsistent with the concepts of sustainability when isolated from shared and clear sustainability goals. Still sustainable innovations emerge within a framework of coordinated design between stakeholders and new profiles of action in projects. Transparency is the common denominator of both cooperative and competitive behaviours and guarantees the possibility of resilience of the chosen social and technological paths.

1. Introduction

Construction work is collaborative. To undertake a construction work requires the collaboration of a number of different firms and a wide range of skills and specialists: architectural and design practices, general contractors, consultant engineers, subcontractors, fabricators, manufacturers, and suppliers. The challenges of the climate change and the global limitation of resources are changing the global rules on which modern construction work has been based, and at the same time call for increased corporate responsibility for managing the adaptive capacity of local built environments towards sustainable development.

The change emerges in Sweden as an increased awareness about the energy and matter flows in buildings and can be considered an evolution of three decades of implementation of energy efficiency in building following the ecological modernisation (Fudge et al 2002) implemented in the country during the same period. Sector-specific innovations are intertwined with sustainability goals.

1.1 Integrated sector-specific innovations towards sustainable energy efficiency

The overall technological innovation going on in Sweden is centred on energy concepts and seems to enter the sector of construction through approaching different types of innovations found within the different building activities. From the production of components to the systemic nature of the whole of the house, through the combined activities of designers, builders, construction firms, regulatory activity and construction-related research, a real technological change seems to be taking form.

For ten years ago Gann et al (1998), while addressing the impact of regulations on innovations, presented an analysis of the many factors which are influencing innovations which they noticed were becoming more and more performance-based so that regulations increasingly depended on what current practice was able to perform. Four integrated types of innovations were found in building activities: 1) *product 2) process 3) configurational and 4) system* innovations (Gann et al 1998). It is important to keep these aspects in mind when trying to understand the kind of change specifically going on in Sweden.

The *product innovation* came first, mostly conditioned by the push of the top-down managed ecological modernisation (Fudge et al, 2001; Jensen et al, 2008) which conditioned the R&D activities carried out by material and component producers. Many are the claims that these manufacturers carry out the majority of construction-related research. "They develop products aimed ultimately at improving the performance of buildings to the benefit of end-users" (Gann et al 1998). It is the case of the new window generations with low U-values, of solar heating- and energy technologies, of heat exchangers and heat pumps, of new insulating materials, just to name some.

A process innovation, such as the ways of assembling buildings or installing components, has resulted in an improvement of the way in which buildings are designed and constructed on the part of designers and builders. This may be the most diversified part of the innovation process because it is linked to local contexts of implementation. In the case of the new quite diffused performance-based requirements this is the activity which is mostly developing, as it causes an innovation of roles and responsibilities among the actors involved. As site monitoring of performances pose cost and time-limitations not affordable within current practice, pre-production energy simulation models are substituting more and more postproduction tests. The design process is very affected by this.

The configurational innovation surely depends on the abovementioned product and process innovations as it addresses the way in which "existing components are combined in new ways to provide improved performance characteristics" (Gann et al 1998). It can be observed in the long way towards healthier and more secure buildings which successfully has lead towards energy efficiency in building solutions and increased quality of requirements. The evolution from the solar house approaches of the 1970-80s to the low-energy-house concepts of the early 1990s constitutes the headlines of this configurational innovation.

Finally a *systemic innovation* is affecting the design and construction of buildings with the spreading of passive house concepts. "This occurs when change in one component or subsystem cannot be introduced without altering other parts because of the ways the whole is integrated and works together" (Gann et al 1998). The configurational and systemic aspects of the ongoing change are of interest for this study as they seem to give some guidelines about possible future directions. They affect not only the final product but also the process of becoming of the project.

1.2 What is sustainable?

We, a group of researchers from the Department of Architecture at Chalmers University of Technology in Göteborg, Sweden, have been working during the last three years on the research programme Demo-04, studying a group of six projects with declared environmental-friendly ambitions (Eden et al, 2005). All the projects were started in autumn 2004 and evolved differently in time while influencing each other (Rubino and Eden, 2007). Observing aspects of sustainable technological innovations in the specific dimension of experiences in the local context, the question about what is to be considered sustainable and what is not has often come to the fore. In the building community trust is traditionally given to studies which by means of measures are able to predict future behaviours. The belief that a unique solution will substitute all existing solutions is also rooted and the "best" solutions are experimental, demonstrative projects, driven by local "best practice" but developed independently of the normal context of current practice. The initial conditions of the projects are stated from an abstract set of ideal parameters and their results are stated from the set of these initial conditions and often self-referential.

We assume that sustainable building is a concern of the real world and that only when building projects are realized within current practice and meet the complexities of society will they be interesting as sustainable. Experimental projects are contexts for learning but become sustainable in the impact with real context. We have then been looking for a different kind of demonstration projects as contexts of change, able to implement the complex goals of sustainable building (Femenías, 2004; Eden et al 2005; Rubino and Eden, 2006; Rubino et al, 2007; Rubino, 2007). Furthermore, we are observing an unexpected innovation rate due to the new energy efficiency goals of this particular phase and wonder if the struggle for the best results constitutes a sustainable pathway. The closure around the solutions given by the *passive house* techniques seems to lock practitioners from different technical backgrounds by setting the issues of debate on sure measurable levels, in a moment of big uncertainty and disagreement. Measurements, true controllable solutions, profitability and a brave use of simulation-tools are paramount in the Swedish debate but risk to simplify the issues of a wider sustainable debate. As we are looking for sustainable pathways, we must be critical as to the sustainability of these solutions.

Are co-operational behaviours less important than optimized kWh for heating? Is the diversity of solutions not as much important for the transition to sustainable development as an isolated object with high energy efficiency performance?

1.3 Is there a measure for sustainability performance?

Long-term sustainability goals make the context of action of construction work much more complex than before. Consequently both research and practice easily renounce to follow these both qualitative and quantitative paths, and go back to the linear simplifications of predictable and measurable outcomes starting a battle of thresholds. The actual energy efficiency trends are often implementations of the energy efficiency debate from the 1970s. The same technical actors are working on them, sure of having known the true solutions leading to sustainable change. Focusing on the *environmental dimension* of sustainability the characteristics of sustainable building become an issue of *performance*. Hence, a methodological problem arises as we do not find any absolute or agreed upon measure of sustainability performance. This leads us automatically to work in the amorphous field of the many definitions of sustainability (Williams and Lindsay, 2007) forced to set up a measuring scale which goes from "slightly better than regular standards" over to "very sustainable". On this scale the "zero-emission" buildings are the "most sustainable" and the housing for, for example, climate-refugees are not regarded at all. Still the performance of the building stock has never been assessed.

In order to cope with these questions we propose an analytical framework resulting from the observations done in the Demo-04 study. It is important to underline that the many stakeholders involved are far from having reached any agreement about how the big global questions should be managed. Hence, the emerging issues of resources interdependencies lead the sustainability debate more and more towards cooperative societal problem solving mechanisms. Further, the traditional forms of the state being the sole regulator seem to be left behind. Making corporations answerable for their actions presents difficulties but networks of actors can accomplish consequences more than centralized authority. This does not mean to substitute directive-based regulations. Companies are more and more compelled to show verifiable accountability and enhanced transparency by a collective pressure and their management and performances must be evaluated within a long-term perspective. Simultaneous efforts are under way in multiple potential solutions, but the process is split among stakeholders and projects with heterogeneous background. Many current solutions have true sustainable ambitions but are not the most efficient: they are selected by small events, by the social settings of project-teams, by their access to components, and last but not least by the individual responsibility of each representative of the construction community, culturally representing the historical path taken by a local system. A feedback system for these efforts seems to be lacking.

Section 2 presents the proposed analytical and methodological framework. Section 3 addresses some inconsistencies of the traditional dichotomy between competition and cooperation. The findings of the study are presented as descriptions of emerging profiles of action along the design process in section 4 followed by a discussion about the consequences of these emerging patterns on the rationalities used in sustainable building environments.

2. The analytical framework

"We can no longer allow the attraction of having a simple, elegant, and, above all, understandable theory trump the attraction of having a theory that is difficult to understand in its entirety but better captures the workings of the real world" (Anderies et al, 2006).

The effort to be made in research is to rationalize the interplay between change and persistence, between the unpredictable and the predictable. It means that there is always an existing system where persistency is rooted but perturbed.

The adaptive capacity of a system is basically grounded on diversity, genetic diversity, biological diversity and heterogeneity of landscapes. In social systems "the existence of institutions and networks that learn and store knowledge and experience, create flexibility in problem solving and balance power among interest groups play an important role in adaptive capacity" (Walker et al 2006). Systems with high adaptive capacity are able to re-configure themselves without significant declines in crucial functions in relation to primary productivity cycles and social relations and economic prosperity.

Folke et al (2004) identify and expand on four critical factors that interact across temporal and spatial scales and that seams to be required for dealing with natural resource dynamics during periods of change and reorganisation:

1. learning to live with change and uncertainties;
2. nurturing diversity for resilience;
3. combining different types of knowledge for learning and
4. creating opportunities for self-organisation towards social-ecological sustainability.

2.1 A stakeholder approach

We assumed that the transformations of the built environment affect the resilience of the local living system as a whole in the same way that changes affect the resilience of all ecosystems (Folke et al 2004; Walker et al, 2006). The introduction of a resilience analysis of human built environments proposed a pragmatic perspective through which the wide definitions of sustainability could get meaning and gave sense to the methodological guidelines of the research study.

We proceeded then from the assumption that social and technological phenomena can be explained as the outcome of interactions among actors. Governing the built environment towards sustainability improvements is here seen as a collaborative process which involves all stakeholders, where "a stakeholder is any group or individual, who can affect or is affected by the achievements of the organization's objectives" (Kuhndt et al, 2004).

Stakeholders exist both internally and externally to the built environment. From the perspective of the building sector designers, builders, clients, employees and workers are the internal stakeholders, while end-users communities, public authorities, shareholders, financial institutions, the media can be counted among external stakeholders. The very peculiar fact in the building sector is that internal stakeholders at the same time can be external stakeholders belonging as individuals to different societal groups and networks.

2.2 Shaping a multi-actor arena for the heterogeneous engineering of SB

No study will ever be able to identify and intentionally influence the "painstaking arrangement of the myriad of human and non-human elements" interacting in technological change (Harty, 2005). Hence change is said to occur with intensification of interactions and links between elements. So we gathered a number of firms involved in six newly started projects and invited their representatives to participate in an "arena" in order to share experiences and difficulties when working with the resource and environmental performance of buildings.

A heterogeneous group of between 15 and 60 persons, representing both the "best" and the current practice of design, management, consulting and construction in town, was invited regularly, during two years, to focus-group meetings, seminars and smaller conferences. These internal stakeholders came together in order to meet academic researchers, experts, representatives from associations and stakeholder's organisations and end-users of previous completed demonstration projects. Mostly they met each other in unusual constellations and from a new perspective. During the same time the process of evolution of the projects was observed and totally 14 individuals were interviewed. It was important to know how different stakeholders use their resources and capabilities and what goals they pursue when a long-term sustainability perspective is introduced in their usual work.

3. Cooperation and competition

The chosen approach focused on human interactions and consequently on how these are affected by non-human elements (artefacts, skills, tools, pictures, measurements).

To begin with, many generalisations are in use concerning competition and cooperation. The notion that we are becoming more competitive and individualistic is diffused in today Sweden, argued to be a positive or negative outcome of the social, political and economical change of the last decades. So is the case also in the construction sector. The call for competitive building outcomes has driven management efforts at all levels and at the same time the lack of cooperation is claimed to be the principal cause of all non-sustainable development. Ideological divorces argue that competition might not admit cooperation and cooperation might not admit competition.

Hence, as sustainability is a concern for the real world, the understanding of this dichotomy must become sharper.

It can generally be assumed that the myths about competition are many and that we are not so aware of co-operative behaviours. Competition associates directly to outcomes, indeed both positive and negative as competition normally assumes winners and losers. Cooperation is a more delicate issue than competition. From the *competition point of view* cooperation is automatically interpreted as the weak characteristic of actions made by losers in order to survive. Ideologies play a fundamental role in these questions and ideological discussions often only results in sharpened initial convictions. They are usually not the way to get a better understanding of what is true and what is not.

The direct observation of ongoing change can help on the way to get a sharper picture of how competition and cooperation emerge in human action. The micro details of "human free interaction of an ordinary everyday kind" have been suspended, in terms of understanding, in order to conceptualise a macro system of generalizations approached as a natural phenomena in science. This move "encourages us to miss the essential feature of human action, namely its cooperative nature in the living present" (Shaw, 2000).

If the lack of cooperation seems to be the origin of so much non-sustainability, we have also been unused to focus on it at all. It can be difficult to accept its dynamic role showing up with thousand different faces. Project-teams are what we are interested of within a sector that has characterized its managerial trends by competitive attributes. Cooperation becomes competitive by its outcome for the local community and strengthens the bound in new contents and ever new sustainability solutions.

4. Pathways towards sustainable energy

Energy efficiency still must demonstrate its cost efficiency before it is implemented. This never happens to this level of precision for other innovations to be implemented in building enterprises. In fact while implementing innovative processes or innovative components do not require more than normal managerial spirit of competition parallel with normal paradoxes of presumed control over the predicted outcomes, resource and energy efficiency must demonstrate its profitability in detail. The complexity of the issues introduced in the projects goals cannot still be summarized in a few innovative moves easy to calculate in comparison with previous technologies. The issues introduced are concerned with a *systemic innovation* as well as a *design process innovation*, integrating a series of new components which substitute the core of the current technical support for heating/cooling and warm water supply as well as the traditional building materials used in the external walls and the type of windows used. A c*onfigurational innovation* follows and affects the process of shaping the building which is then more emerging from the interactions of the multitude of parameters involved than from "human intentionality".

4.1 Messages about new processes.

From the interviews we received messages about the elements of a new process:

- The awareness about energy and material flows in building activities give *legitimacy* for the overall sense of environmental and social responsibility of individuals.
- Working with energy efficiency goals is equal with working with environmental goals. "There is much *environment* in the *energy* we use today" (interview, march 2005)
- They adapt existing capabilities.
- The new projects present the necessity of new structures of co-operation
- Transparency during the whole design and construction process is fundamental.
- Competition is necessary, at a certain point, to spread and optimize the new solutions.

Energy efficiency has in Sweden continuity with the past. Many of the older informants talked about a change of perspective: *"There is much more environment in working with energy today. But it is easier to calculate on energy than on environment. You can both minimize it and directly control the results. All the rest, the choice of materials, upstream materials, emissions, the material-flows in future refurbishment as possibility to renew, recycle or deposit components are too difficult. A client assumes not to be able to calculate the costs for this over 40-50 years. So it is also more complex. When we began to work with energy efficiency during the 1970s (at the time of the first oil-crisis) it was very much a question of making existing technical services more efficient. We had under a period of ten years filled new buildings (think that one million apartments were built during that decade) with over-dimensioned installations. We were only looking at the service effect trusting in a never ending access to Swedish energy sources (water power plants, some new nuclear power plants)"* (Interview march 2005)

"Today we answer personally for the new we introduce in projects. At that time (1980s) research was financed directly from the BFR (Byggforsknings Rådet, i.e. the national building research trust) and the office received a 10-20 % research subvention only for the energy side of a project. Each project was later published into very simple reports which gave reference objects to be developed and knowledge transfer in the sector. Each report was further sent to all firms and consultants. Today we learn about the new only directly working in projects. In projects we meet lots of people; we get knowings about what and how others do, and what is going on even outside the local context. At least we engineers we work very locally. It is different for architects. They have the possibility to win a competition somewhere else. But then they have to trust a local consulting firm if they want the building to be built" (ibid 2005).

As a consultant you are alone in your choices. "We work with Environmental Control Program. We have to check all components as to project requirements. Then you access the homepage of the manufacturers and you control by yourself, but indeed you do not have the means to control these issues and you just follow some guidelines. At the end you just put together pieces, while you should work at least with assemblies of pieces, with connected solutions, where pieces are already put together" (interview 2005).

"When nobody knows better about how to solve the problem, you begin to play with open card and the goal is reached together, like sharing a cake which cannot be bigger than that and is made of each single kWh/m2 yr. We discovered lots of energy thieves we never thought about before. In large extreme low energy buildings, the part of energy going to the artificial lighting of the common vertical communication, elevators, common services and garages constitutes the largest part of the bought primary energy in the building. You suddenly realize that many efforts have been centred on heating and warm water production issues and that there is so much that can be done for reducing the need of primary energy" (interview 2005).

They also tell us about:

- a different co-operative behaviour searching for common solutions. A new stimulating sense of co-discovery and learning. The need of integrating specialists early in the design process
- the need of precision, exactness and correctness during the design of the details

- the need of follow-ups on the construction phase. Details are important on paper and in reality
- an unusual openness in spreading knowing of problems and practical solutions encountered already during the design process, diffusing temporary results and networking across specialist groups
- a competitive behaviour between companies increases after a first period of co-discovery. Each single organisation is maturing own internal demo-projects in order to learn, adapt the new to existing organizational capabilities and even in order to reach better solutions and stress the thresholds

4.2 Transformed energy balance calculation. Different energy efficiency solutions

The use of the energy-balance-calculation tool is finally diffused among Building Services Engineers. For just two years ago many told us about the requirement written in the project programme for the use of this tool but nobody saw the meaning of using it.

The projects object of this study where in almost all cases started with energy efficiency goals among other goals concerning the total environmental performance or a sustainable future vision.

Even if the process of innovation of buildings in Sweden shows a clear tendency to energy efficiency solutions, arrived at by the use of new materials and components, what is new in the new energy efficiency trend is a changed use of the energy balance calculation. 2005 some of the interviewees told about projects where they had been told to calculate the energy balance but they did not see any meaning in doing that. Currently three years later the energy balance calculation is paramount. The use of this tool showed a need for a clear definition of the energy goal of the project.

The EBC is the real interactive core of the new projects, able from a very beginning to connect most of the part of the building to each other towards a declared minimal amount of energy needed to heat interiors and to supply warm water. It integrates the U-values of different components of the climate shell with the degree of tightness and with the dimensions of the ventilation system along with the speed of the air exchange. The architect’s layout changes continuously, adjusting the size of windows, of balconies, of sunshades and also of solar heating or floor heating. A clear tendency to a paramount optimization of building functions has astonished more than one of the agents involved in the projects. Efficiency becomes more when it proposes a synergy of effects just within the single building.

4.3 LCC-calculations

Life Cycle Cost calculation tools have been basic in some of the first demonstration-projects of this kind. Taking the first steps inside the new energy efficiency concepts LCC-calculations have been used by some companies or consultants in order to control and compare investments with long-term costs and profitability. The difference they demonstrate is important for current practice. The LCC-calculations permit somehow current practice to look at different solutions at the same time and manage the change. This has been related to the necessity of adopting many innovations at once which has not been usual for clients and for specialists.

LCC-calculations have been used in the largest projects. The use of them is quite particular as they often are implemented in order to show long term profitability in comparison to one or two or, in one case, even six different more current solutions or even with more expensive/advanced solutions.

Optimal solutions are weight both against the prefixed energy goals and against the cost efficiency of the project. It is not unusual to state a goal (as a defined quantity of kWh/m2 yr) and an investment (as it uses to in all projects) and then state a limit as a percentage (6%, 10%) of possible overdue of costs. Moreover, many engaged practitioners have been publishing, both on the national and the international arena, detailed reports of LCC-calculations comparing costs and benefits in time for different scenarios in order to show the economical feasibility of extreme energy efficiency solutions in buildings of different kind.

4.4 End-users and current practice

Energy efficient buildings do not necessarily look different than old buildings. Walls may be thicker and windows are not cold during winter.

The optimal solutions of early demos are translated in current, context dependent, practice solutions. The “good enough” plays a usual role this time “optimized” in relation to the goals and to the quantities of innovations the cultural and social base of the project permit. It means the technological context in which the building is inserted (access to components, sub-components and so on; access to handcraft capability to support the precision needed; integration of the built solution in an existing built environment; just to name some). It also means the kind of end-user the building is built for. For just one year ago the building companies totally agreed about the opinion that consumers were not mature for energy buildings and less for eco-buildings, as they were called then. During the last few years eco-green-buildings have been transformed into a new but more current urban typology with embedded modern environmentally friendly and resource-efficient performances (Jensen et al, 2008).

The difference today may be described by the publicity campaign made by COOP in Norway: “Do it for your sake. Forget the old bad conscience”

Hence, solutions discard the expensive details offering some decimals of the average total U-value of the climate shell and of the final energy performance in change of some more freedom in shaping the building.

What is remarkable is the apparently overdue of learning in each project. The iterative process normal for a building project (Rubino, 2007) allows for the production of a redundancy of proposed solutions and continuous trade-offs until the final design is defined. Learning and practitioner-research are paramount within an environment of shared responsibility and competitive cooperation co-discovering the new possibilities lying within the new goals of energy and resource efficiency.

4.5 Responsible governance of the project

One more trend emerging from the investigation of these cases is the very common as well as unexpected need for a change of management of the design-process of the project. Generally it can be said that a tendency to “half-partnering” management solution are chosen. This means that in some way in all phases of the process agents share the responsibility for the outcomes and the transaction cost for the innovation. Learning seems at the same time to be spread on all levels.

Hence, in practice, the goal of for example 45 kWh/m2 yr can be reached in different ways. This may become possible by

- 1) using features of integrated design where the social and physical contexts determine the need of energy per person along with the amount of m2 each person has at disposal;
- 2) the design team sharing the limited quantity of kWh at disposal gives each consultant the responsibility of reducing as much as possible the quantities embedded in the functions and services s/he proposes, showing the capability of co-discovering alternative possibilities during the process;
- 3) changing the role of the architect’s pre-figurative layout which is adapting to new more dynamic rules at play;
- 4) as a consequence of the previous point, transforming the vision, that strong vision of modernity, into a dynamic, loose and adaptable “picture” (still clear and inspiring) into which the whole project team co-operates, adjusting needs, details, masses, flows. Not only functions and services for minimal costs and maximal yield are delivered but original solutions for high energy efficiency as the new competitive quality of buildings.

4.6 Profiles of action within a non-linear process/project.

A new awareness for processes which allows for the possibility of multiple outcomes is emerging. These processes are typically non-linear, path-depending and submitted to historical events.

What these projects are telling us is that small events can lock a project into different structures and that this happens at all scales.

The design-process emerges from these evolving projects for energy efficiency performances as in need of a redefinition. Open participative processes are aligned to cooperative behaviours within the boundaries of the project. Design is crossing the boundaries of different disciplines and the function of traditional actors and especially the function and responsibility of the architect is changing. The profiles of action are chosen along the process according to the specific character of the project and the agents involved, therefore allowing a wide platform for open cooperation. Different actors act next to each other in the design process, the architect’s pre-figurations being a hindrance as it wants to produce the entire process in detail and too early. The traditional total pre-figuration of the architect, responding to the linear project management, is experienced by many as a barrier. There is a general call for a figurative work able to evolve as a processing of the whole range of parameters, human and non human agents, changing economic conditions and required performances (Bono, 2007).

The process could be open-ended but it always comes to a point of return where the project begins to become a building. At that point when the general concept has been developed the design process does not stop. It is at this point that the enormous job of detailing and specialized engineering begins. Only if the expert actors have been present during all the precedent phases of the project and have been influencing the design process as to its choice of principles and temporary assembling, the continuity of processing into projecting will succeed. There will not be a break.

5. Conclusions

Emerging patterns of co-operational behaviours in a number of observed projects and in the spreading of information in this phase of change have highlighted the importance of the learning processes for sustainability, placing the evolution of knowledge and of novel solutions in the core of all building activity, i.e. the project. A new definition of the project is the ultimate context of the change caused by the integrated implementation of the four sector-specific innovations. In fact, the innovative components (*product innovation)*, the improved way in which they are assembled and installed (*process innovation)* in new combinations in order to achieve new performance-requirements (*configurational innovation*) result in a wide *systemic innovation* emerging and managed within the collaborative structure of the building sector. In everyday work thousands of people manage the transformations of the built environment often relying on individual responsibility continuously adapting solutions and sometimes inventing novel solutions (Arthur, 2004; Rubino, 2007). The freedom to choose among possible solutions is on play in this phase of change challenged by the societal goal about the management of a common good, the built environment, no longer envisioned by someone staying outside but emerging from an heterogeneous engineering (Harty, 2005). The goals of sustainability development for buildings have to be developed within new conceptual frameworks. Previously isolated dimensions (the social, economical and environmental) are intertwined and new kinds of arenas for the management of local resilience are needed to challenge the different goals and the diversity of views of the different stakeholders towards a common desirable sustainable future. The different stakeholders play different roles at different stages of the long decisional process that characterizes every building enterprise. Different visions and practices come to a confrontation and are challenged to cooperation. Building projects can no longer be isolated from the context of local sustainable goal settings for the environment as a whole. The contrary becomes obsolete and the action of isolated, uncoordinated loners is no longer competitive. Co-operative behaviour is in itself competitive as it is the sophisticated human base of learning. In further development of sustainability framework for building four concepts may resume the results emerging from this study: 1) coordinated design between stakeholders; 2) CTS (Certified Technology Specialist) action profile within projects; 3) transparency, through the whole of the building process from briefing to construction; 4) competitive cooperation, which gives feedback to cooperative behaviour and moves the limits of measurable performances within shared common visions.

Keywords: sustainability, retrofitting, housing, Tasmania, social and economic values, capacity building

Summary

Australian building legislation now incorporates significant environmental performance requirements for new housing and major housing renovations. These regulations are likely to be tightened over the coming decade, especially as policies for climate change mitigation and adaptation take effect. Yet most urban and suburban landscapes in Australia are dominated by existing housing which falls well short of current standards. This observation is particularly pertinent in Tasmania, the coldest, most economically marginal state in Australia, with one of the nation's highest proportions of old housing stock. This existing housing will deliver unacceptable environmental impacts and unsustainable living conditions for decades to come unless retrofitted or renovated to improve resource use efficiency, ecological appropriateness and liveability. In this paper, we describe and analyse a range of individual, institutional and organisational barriers to renovation for housing sustainability in Tasmania. We draw upon interviews and focus groups conducted in three interrelated studies, with stakeholders from all tiers of government, and from private and non-government sectors. Our analysis of the data suggests that a number of complex narratives exist to explain the barriers to sustainable retrofitting. These are related to social values, socio-economic forces, physical constraints, deficits in capacity and deficits in governance.

1. Introduction

During the winter of 2002, monitoring of the indoor climate of an 80 year old weatherboard house in a riverside suburb of Tasmania's capital city, Hobart, recorded unheated daytime temperatures as low as 6 degrees Celsius. At the start of the following winter, Hobart City Council, the owner of the property, made available $3000 in funds for researchers to purchase and have installed draft proofing, floor and ceiling insulation, and window pelmets and curtains. Within a week after the completion of that retrofit the unheated temperature, under equivalent conditions, was recorded at 18 degrees Celsius. More significantly, the low-income tenants reported that, for the first time in a year, their children seemed free of any cold symptoms (Weaver 2005).

This example hints at the potential to improve housing in Australia by renovating or retrofitting existing stock in ways specifically oriented to the principles of sustainability – now well-established as a conceptual framework for how to live. Among those principles are intra- and inter-generational equity of opportunity; environmental protection and management; economic resilience and effectiveness; and ethical governance. Typically, these principles are expected to be fulfilled via myriad tools and mechanisms of sustainable development, which Berke and Conroy (2000, p.23) define as 'a dynamic process in which communities anticipate and accommodate the needs of current generations in ways that reproduce and balance local social, economic, and ecological systems, and link local actions to global concerns'.

We note that sustainable development is meant (but often fails) to avoid resource, property and development conflicts in pursuit of green, profitable and fair outcomes (Campbell 1996/2003), and that is perhaps because it also remains embedded in particular understandings of human existence that are broadly neoliberal (York & Rosa 2003); in short, it is *'weakly'* defined. At the same time, while sympathetic to many critiques of sustainable development so conceived, we accept that all reasonable efforts to address current and anticipated socio-ecological problems merit consideration, including those 'inside' the paradigm of neoliberal sustainable development. Among such efforts, we count the current discourse of sustainable housing, and should make explicit a hope that the discourse will be more *'strongly'* defined in due course.

We acknowledge that discussions about how to encourage and entrench *sustainable* housing policies and practices proliferate in international research and policy circles (Alexander 1998, Bhatti 1993, 2001, Burton 2003, Goodchild 1994, Schulman 2000, Various authors 1996). However, it is the design and construction of *new* housing (Crabtree 2005, Itard & Klunder 2007, Scott et al. 2006, Tiwari 2004, Tosics 2004), rather than the sustainable *renovation* of existing stock, that has attracted most attention. Despite the existence of literature on its merits dating back 30 years (Antolini 1978, Crossley 1979, Robinson & Dubin 1978, Vale & Vale 1977), retrofitting or renovation for housing sustainability appears limited in uptake.

Our working definition of *renovation or retrofitting for housing sustainability* is the renewal and adjustment of the fabric, fixtures, fittings and landscape of any given residential dwelling in order to improve the dwelling's ability to sustain the occupants within the carrying capacity of the Earth. It may include, but is not confined to, insulating, sealing the building envelope, properly treating windows by the use of pelmets, curtains and appropriate glazing, fitting water tanks, solar panels, energy efficient light, heat and water systems, and planting native, productive and low-water gardens. Such renewal and adjustment avoids or minimises the depletion of natural, human, social, financial, physical and organisational capital, and is mindful of the scalar and temporal dimensions of our actions: it remains apposite rather than clichéd to think global, act local, and over the long-term. In an ideal world, it would also move beyond site specificity and integrate with abutting and adjacent sites to effect a 'rippling' out of transformation and change.

In this paper we document a range of barriers that limit sustainable renovation or retrofitting as we define it. We report on three interrelated studies which describe and analyse a range of individual, institutional and organisational barriers to the sustainable renovation of housing in Tasmania. In particular, we seek to understand various perceptions, attitudes and values shared with us by a number of participants who deliver or influence the delivery of housing and building services. We conclude by speculating about how the existence of these barriers is linked to limitations inherent in dominant understandings of (weak) sustainable development (Davison 2001, Davison 2008), particularly those related to the (rights of the) consumer-citizen and to notions of housing as a private rather than a public good.

2. Context and Research Design

Tasmania is reputed to be the coldest and most economically marginal state in Australia, with 40% of households on low incomes, and a quarter of those reported to be suffering housing stress outside of the social housing system; housing stress being defined by the Australian Bureau of Statistics as a condition induced by having mortgage or rental payments in excess of 30% of net household income (Housing Tasmania 2003, Tasmanian Council of Social Services 2007). Hobart also shares with Sydney the distinction of having the oldest housing stock in metropolitan Australia (Australian Bureau of Statistics 2003). This stock will provide shelter for a significant proportion of the (ageing) Tasmanian population for decades to come. Much housing is of poor quality when assessed against contemporary standards, and arguably contributes to unsustainable environmental impacts, and uncomfortable and unaffordable living conditions. Such is likely to remain the case without coordinated, broad-scale renovation such as we defined earlier. Such widespread action and innovation will need to encompass the entire socio-economic spectrum, and not just those people likely to be early adopters of 'green' housing techniques. Small-scale, relatively inexpensive and cost-recovering retrofits, such as that described in the Hobart City Council example above, will be vital in achieving significant transformation of existing stock.

The scope to encourage small-scale and inexpensive retrofits for sustainability outcomes would seem considerable, given that residential building renovation currently accounts for approximately 10% of total construction activity in Australia, or around AUD$5.7 billion per annum (Australian Bureau of Statistics 2007). Yet, while there are significant commitments to comprehensive performance requirements in construction (Australian Building Codes Board 2007), numerous barriers appear to limit renovation of existing stock for sustainability gains, despite its efficacy (Edwards & Turrent 2000, Nye & Rydin 2006, Priemus 2005). It is these barriers we have focused upon in the three interrelated studies reported here. Each study was presented to the Social Science Human Research Ethics Network (Tasmania), as required under the National Statement on Ethical Conduct in Human Research, and was approved.

The first study, whose findings form the foundation of this paper, was conducted in 2004[i] and addressed the following question: *What are the formal and informal institutional and organisational barriers to retrofitting existing public and private housing stock in Tasmania for affordable energy-efficient outcomes, and how might these barriers be overcome?* Semi-structured interviews were conducted with 24 individuals with prominent involvement in housing policy in Tasmania. Taped interviews undertaken by Stratford were transcribed and analysed using hermeneutic practices that involved the reading and rereading of interviews to distil themes according to what respondents said, a process followed by synthesis with the wider literature. Part of the study's impetus was the completion of the case study described in the introduction above (Weaver 2005) and a wider research interest in questions of sustainable development and Tasmanian settlements (Armstrong & Stratford 2004, Stratford *et al.* 2003, Stratford & Davidson 2002).

The second study was conducted in 2007[ii] and targeted Hobart-based builders in order to understand how they think existing housing might be renovated to meet the objectives of sustainable development as they understood these (Elliott 2007). A postal survey was sent to 28 builders who claimed membership of the Housing Industry Association or Master Builders' Association, and follow-up semi-structured interviews were conducted with 14 of them; these were taped, transcribed and analysed in the manner described for Study 1. Representatives of the two aforementioned industry organisations were also interviewed to gain further insights into the building industry in Tasmania.

The third study, ongoing to 2010, is informed by Studies 1 and 2, and seeks to uncover more about what drives and impedes renovation for housing sustainability in Tasmania, broadening the number and range of 'actors' participating in the study, and attempting to focus on policy innovations and solutions. Watson's project[iii] commenced in 2006 and has brought together four focus groups involving a total of 20 participants to construct a picture of current perceptions of barriers and drivers to sustainable renovation, and generate a discussion on sustainable (and especially energy efficient) renovation. Focus groups' participants were drawn from State and local governments, the private sector and peak body representatives, and non-government organisations, all recruited through purposive sampling. Four semi-structured sessions, each of two hours duration, were recorded, transcribed and analysed.

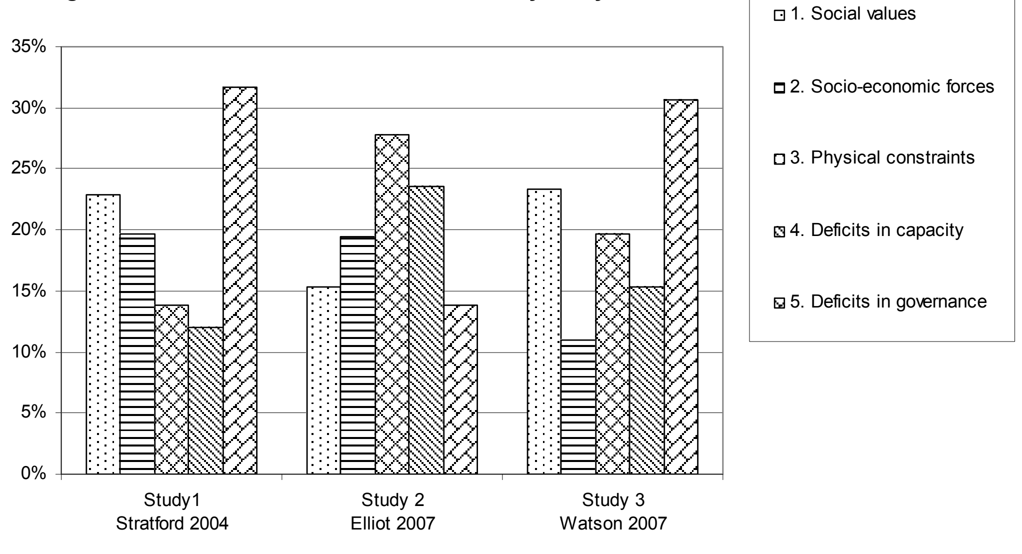
Taken together, the studies involved 72 conversations via questionnaires, interviews and focus groups. To ensure rigour (Janesick 2000), a joint thematic analysis of participants' stories describing the barriers to renovation for housing sustainability was conducted in early 2008, and was indebted to insights by Feldman *et al.* (2004) that story-lines share chronological and thematic ordering, they cement, and confine or bound.

Story-lines are sub-sets of larger narratives (for example, the narrative that retrofitting is too technically difficult or scientifically unproven). These narratives then constitute discursive orders (for example, retrofitting is too difficult, full stop, so let's not 'go there'). These orders then become routinized via our cognitive commitments to them (Hajer 1995) – in short, they become our understanding of the 'truth' and difficult to change.

3. Barriers to housing renovation for sustainability outcomes in Tasmania – key findings

In what follows, we draw on a range of participant narratives about the barriers to retrofitting existing housing for sustainability outcomes. These narratives are organised according to five categories of barriers: (a) social values; (b) socio-economic forces; (c) physical constraints; (d) deficits in capacity; and (e) deficits in governance. Figure 1 shows points of convergence and divergence among participants across the three studies in relation to these five themes. In what follows, we briefly address each in turn, focusing on one or two of the most frequently cited barriers to retrofitting.

Figure 1. Barriers to sustainable renovation by study



(a) Social values

Among the factors seen to impede renovation for housing sustainability were the following: (a) adherence to consumerist value systems; (b) inability or unwillingness of householders, industry players and governments to change behaviours, attitudes and practices; and (c) lack of motivation, apathy and/or fear of change.

Social values and practices were most frequently raised by participants from non-government organisations (NGOs) concerned to highlight intra-generational equity gaps in housing affordability, and underscore how these gaps mean that people in low income housing are often (or perceive themselves as) unable to engage in retrofitting, especially when renting. One social service provider, for example, noted that the '*primary concern for low income people is cost – most are in private rental, paying over 30% of their income but that income is in the bottom two quartiles. They have massive heating expenses and large upfront costs to get the power on … Landlords are reluctant to retrofit, for example by adding insulation, because they want a profit'.* NGO staff also tended to emphasise cognitive barriers to value-shifts such as people's lack of will to change, and the frustration of '*having the same converts around the table all the time, people without the real power to force change*'.

In marked contrast, some participants from the private sector cited the pressure they feel to respond to client demands that their renovations include 'the latest' fixtures and fitting. We were told that people in middle to upper income brackets prefer to prioritise the marble benchtop over the installation of appropriate R-rating insulation or energy efficient lighting and heating, for example. Yet, as one industry participant noted '*builders [also] have an aversion to providing too much advice to clients; it's not inside their comfort zone and they see it as a liability issue if they get it wrong – and there's not much training out there*'.

(b) Socio-economic forces

Among the socio-economic forces participants identified as barriers to retrofitting are: (a) cost as the primary basis of decision-making by householders; (b) pressures to meet client budgets; and (c) limited evidence of return on investment from retrofitting. We were also told that '*larger considerations*' beyond the socio-economics of individual households included (d) pricing, taxation and hidden subsidisation mechanisms that foster unsustainable practices and outcomes; (e) a widespread focus on economic growth and profit; (f) compliance costs; and (g) lack of market incentives for retrofitting innovations.

A number of builders informed us that their clients saw cost as the bottom line, but that this consideration was often muddied by other influences upon them, and especially by a desire to keep up with fashion trends in housing and interior decoration. In short, particular preference hierarchies influenced some people's choice of what was affordable [read desirable] – and we were told that clients would often privilege visible icons of affluence over less visible fixtures and fittings that are crucial to, for example, thermal comfort or energy efficiency.

The relationship between cost and the efficacy of any given renovation choice was a key issue for builders; most simply felt that they had insufficient information or expertise to tell clients that X action (for example, increasing the amount of insulation in a property) would result in Y savings or Y comfort gains over Z periods of time. Most also suggested that sustainable development was not a priority for many clients. One builder told us that at '*the lower end of the market … the customers I see don't even understand what sustainability is; [they] have no idea and just want to know "can I afford [the building work and] will the bank pay for it?" They're not interested in how much energy they can save as an end save; they're looking at the fixed costs of getting in.*' In passing we note that a participant from the scientific community working for an Australian Government organisation suggested that, apart from anecdotal information or one-off cases such as reported by Weaver (2005), there was insufficient data on the cumulative effects of retrofitting. He maintained that it was thus difficult to make a convincing *economic* case for retrofitting, since how much can be saved and at what cost has not been widely established (but see Howden-Chapman *et al.* 2007). We can only speculate here about whether recent changes in public perceptions of the need for climate change adaptation and mitigation may see householders come to grips with rising energy costs by taking the 'risk' to complete sustainable retrofits in any case.

In the public housing sector, Tasmanian Government stakeholders voiced an interest in the benefits of renovation for sustainability, yet highlighted the financial and policy difficulties they face. Economic pressures on their political masters have produced what one asset manager described as demand for increases in the number of dwellings rather than for quality dividends: he termed this getting '*bang for the buck*'. Given both the present extent of housing stress in Tasmania and highly publicised shortages in public housing (Flanagan 2007), this focus on the size of the public housing estate is not unreasonable in and of itself. Nevertheless, implementing well-established environmental design measures in public housing appears to have been secondary[iv]. As one government stakeholder noted, '*A significant number of properties are over 30 years old, located in broadacre housing areas, constructed mostly of concrete blocks with basic insulation and [are] not well aspected [positioned for passive solar advantage]. There has been no significant focus on energy efficiency in the construction or maintenance of these properties. This observation refers to a large amount of stock*'.

It is also noteworthy that recent intensification of action on climate change under the Rudd Australian Labor Government has also translated into – or at least coincided with – a shift in Tasmania in the *rhetoric* of sustainable and not just affordable housing (Lennon The Hon 2008). However, as one policy professional suggested, the move from rhetoric to practice is always challenging. '*Formal barriers to the uptake of retrofitting include shifting from current thoughts and operations to new ones; making energy efficiency and retrofitting emerge on the agenda as something possible to do; being able to do things cost-effectively and get a good return, capable of enhancing the asset; health and well-being not always linked to infrastructure; and change management process – it takes a while to get people to think differently*'.

(c) Physical constraints

Participants expressed a range of views on how the uptake of sustainable renovations is constrained by a range of physical conditions, most notably a sense of (a) the inappropriate planning, design and construction of housing and the perception of retrofitting as technically difficult, of limited benefit or unaffordable; (b) a settlement history based on northern hemisphere practices; (c) past investments in particular forms of subdivision and construction; (d) poor standards applied to retrofitting; (e) lack of skilled trades; (f) poor quality housing to work from; and (g) Tasmania's topography, climate, population, and isolation.

Many of those we spoke to across various sectors understood and emphasised the point that retrofitting means coming to terms with existing housing and subdivision or land-use arrangements, and revisiting and revaluing established knowledge about planning settlements and using quality building materials for thermal comfort, that we note have been in circulation, in one guise or another, for over a century (see, for example, Howard 1898/1998, Stevenson & Murray 1892). Participants thus acknowledged a need to come to grips with poor-quality housing that is inappropriately sited on individual parcels of land that are collectively unsuitably organised, the cumulative effects of which are unsustainable suburbs.

Many participants also saw retrofitting as technically difficult and, in this respect, insulation is an interesting case in point. In 2004, one industry representative told us that '*In Tasmania, 70% of all insulation sold goes to residential buildings. To fully insulate a standard new house ceiling (150-160 squares) would cost approximately $850 in materials, and approximately $300 in labour … and the payback is around 4 years … but we need people to move from R3.5 to R7 and R10*'[v]. A leader in insulation product supply noted that '*To insulate efficiently, material must be installed in a way to allow it to go back to full manufacturing thickness e.g. R3.5/185mm thick. It must be installed to fill all gaps and retains thickness or R rating drops. Batts are often manufactured to fit the spacing of traditional building frameworks. So 430mm of batts into frames of 450mm fits snug, but 600mm frames and 450mm batts equals gaps*'.

Study 2 work established that significant controversy surrounds the installation of wool, combination or fibreglass insulation and sisalation[vi] (Elliot 2007). We were told that to ensure that insulation is applied correctly for maximum energy efficiency gains, it is important that the insulation manufacturer has advised building professionals correctly; that insulation is reasonably affordable; that residential designers have properly detailed drawings; that builders store and install it correctly; that correctly sized timber is available to frame it; and that everyone has the information they need to complete their part of the task at hand. There is also the challenge of appropriate insulation being available from suppliers, which may serve to illustrate larger challenges related to supply chain management and Tasmania's isolation as an island – removed by 256km of the Bass Strait from the Victorian coast on the mainland of Australia, and thus from supplies more readily available there. In summary, unless clients have particular expectations that builders will provide constructions that have high levels of thermal comfort, these challenges are sometimes seen by builders as beyond their scope or domain.

Several builders were also concerned about the oversupply of materials – a particular problem on renovation work where only small quantities of materials are required. Some explained how they ordered more timber and other materials than necessary because the cost of transporting extra to a building site was more than the cost of 'wasted' materials and materials could only be purchased in standard bulk lots. Others explained how there was no way for them to recycle materials and said it was easier, cheaper and more time-effective to dump used materials into a rubbish skip or bin once a job had been completed. Tasmania's small industry and lack of entrepreneurial recyclers were also noted in interviews and focus groups in Study 3.

Representatives of the Master Plumbers Association who participated in our 2004 study were also keen to explain the range of difficulties facing them in doing retrofits. We were advised that plumbing and heating jobs were generally not done with a view to achieve energy gains and were often prohibitively expensive. In addition, few plumbers were familiar with workplace health and safety legislation that may pertain to retrofits, and were struggling with the enormity of detail in the Building Code of Australia (Australian Building Codes Board 2007). In the final analysis, plumbers may not be persuaded that X or Y new energy efficient option is the best for a client given cost, novelty of installation requirements and related higher labour costs or structural integrity issues. In study 3, however, we were told that there is now a water and energy efficient scheme for Tasmanian plumbers, which included an Association-backed training course on the subject.

(d) Deficits in capacity

A number of the issues raised thus far were associated by participants with (a) a lack of appropriate general education and training, and of specific skills training; and (b) a lack of good quality practice/demonstration projects. Less frequently cited but allied comments related to concerns about (c) the insufficient availability of good quality information and tools on retrofitting; (d) inability to upskill capacities; (e) limited capacity for quality assurance of skills in practice; (f) lack of access to facilities and products supportive of retrofitting; (g) lack of collaboration and integration among specialist and professionals; and (h) confusing or incomplete information on what 'sustainable' is in the context of building and renovation.

Solving these deficiencies requires significant investments in interdisciplinary and multilateral collaboration (see, for example, Després *et al.* 2004). Nevertheless, in a chicken-and-egg conundrum, such collaboration is unlikely to have effect without major investments in general and specific education and training to improve the capacity of professional to support sustainable change in existing housing.

It was generally believed that changes in education and training happen slower in Tasmania than on the mainland. Yet, Tasmania is also a source of significant innovation across a range of economic, social and environmental spheres and has been for well over a century (Green Sir 2003), and such patterns of conduct and behaviour exist now and are considered important by participants. For example, the Tasmanian Government's Building and Construction Industry Council's commitment to sustainability seems clear: an industry that (i) 'makes a genuine contribution to sustainable development by building or refurbishing facilities and infrastructure that make more efficient use of resources, protect ecological systems and account for community needs' (Tasmanian Department of Economic Development 2008), and (ii) makes available a $10,000 innovation award, including scholarship for education and training. But this initiative is itself relatively new, and its effects are yet to be fully tested.

Those most concerned with the need for training and skills-development in sustainable renovation techniques were builders, although we underscore the point that information, education and communication were universally noted as crucial in all three studies. Some had noticed improvements in the level of knowledge about sustainable renovations. Others indicated that lack of capacity and insufficient value-shifts arising from more general education about sustainable development are still barriers to the better uptake of retrofitting. One architectural professional suggested that the '*groundwork for such a shift in awareness may take many years. Education, policy and demonstration projects must be made more available. It's not so much genuine resistance but apathy*'.

Certainly, builders who participated in Study 2 were in agreement about the type of training and knowledge they would find beneficial: clear, unambiguous information both easy to access and affordable to implement. As one builder commented, as soon as information on a technique appears vague or unclear, builders and clients alike have a fear that it is too difficult to apply or could have unforeseen and risky effects. Builders also noted significant dissatisfaction with the Building Code of Australia (BCA), observing that it was financially and practically inaccessible. Although some understood why performance requirements are used in the BCA, they said that it takes them too long to find the relevant regulations and then the instructions are too ambiguous. Finally, builders also wanted to see significantly more invested by governments, Research and Development (R&D) groups, and the private sector in demonstration projects that would allow them to see, first hand, the effects of retrofits. Presently, such projects are largely oriented to new builds rather than retrofits[vii].

(e) Deficits in governance

Concerns about deficits in governance were pronounced in Study 1 and Study 3. Among these deficits, (a) lack of coherent and connected leadership and political will and example; and (b) non-aligned, complex and disjointed legislation were most often cited. But an extensive range of other interrelated observations were made about (c) the collective inability to manage or understand demand and need; (d) lack of rewards and incentives to encourage retrofitting; (e) a focus on managerialism and risk aversion; (f) ambiguous regulations and poor enforcement of same; (g) the proliferation (or lack) of performance benchmarks, standards and accreditation; (h) the lack of appropriate human resources; (i) non-aligned legislative tools; (j) tensions over mandatory and voluntary arrangements, and confusion over roles and responsibilities; and (k) capture of the State by private or union interests and a related short-term 'bang for the buck' mentality.

Lack of leadership and a deficit of political will and example were seen by participants to be evident across all tiers of government and all sectors of industry. For instance, we were told that there were significant opportunities for local government to be better involved in encouraging retrofitting in Tasmania. Two municipal officers informed us that, to '*purchase a 2,000L tank costs $600 on a small urban block. [Council X] provides the council plumbing permit ($120), and a further $170 rates rebate or $220 if the tank is connected to a toilet. This saves bulk water, especially through peak summer usage, and for water restrictions that affect gardens; and it reduces the volume and velocity of stormwater reaching waterways, thereby reducing pollution. But encouraging people [through leadership] to install water tanks is hard because they are more likely to spend money on improving the look of their house*'. Another participant, associated with local government, suggested that '*rebates may be useful but savings would need to be provided back to local governments whose rate bases are very low in many cases, particularly in Tasmania. Even sums of $5,000 or $10,000 are a significant impost'*.

Participants in local government recognise their capacity to effect change at that level via a range of voluntary activities, such as involvement in the Cities for Climate Protection protocol[viii], and regulatory mechanisms such as the BCA and planning schemes. But they also suggest the need for greater integration in policy, greater and more consistent leadership from State Government, and better (constitutional) recognition of local government. At the beginning of 2004, we were told that the '*State Greenhouse Strategy does not engage local government and it should do so – currently it impedes intergovernmental relations. Most effort now goes into dialogue about adaptation not reduction*'. In 2008, it is clear that the Tasmanian Government is now taking significant steps to address the impacts of climate change (Lennon The Hon 2008) but whether, how and to what extent that leadership gives effect to sustainable renovations is unclear. Certainly, a number of participants suggested there was a general reluctance on the part of governments to further regulate industries considered important to economic growth.

Participants also suggested that there were opportunities for all actors in the housing arena to show leadership: that householders could be more proactively engaged in adjusting their preferences; peak industry associations could better pressure their members to adopt and conform to best practice sustainability innovations in sustainable renovation; and housing professionals and trades people might be less risk averse and seek to provide well-rounded advice to clients and lobby suppliers to actively source and advertise the capacity to supply materials for sustainable housing outcomes.

4. Summary and conclusions

We now know with some confidence that, for the cases under study, there are numerous and complex narratives about the barriers impeding more widespread and effective uptake of retrofitting or renovation of housing for sustainability outcomes – narratives from which we have distilled five larger themes: social values, socio-economic forces, physical constraints, deficits in capacity and deficits in governance.

We also know that differences were evident in how stakeholder groups understood and gave relative importance to various barriers. For instance, participants from all tiers of government placed most stress on deficits in governance, while building professionals placed least emphasis on that theme and most weight on physical constraints to retrofitting for housing sustainability. In general, such differences reflect the area of focus or expertise of stakeholders, and suggest the existence of stable (even durable) discourses or 'truths' that are continuously reinscribed via particular narratives.

We have also established that there is, among different groups, some significant commonality and shared understanding of the underlying reasons for the barriers identified; that finding, too, bodes well for possible and productive collaboration for reforms to housing renovation for sustainability outcomes.

Furthermore, in general terms participants displayed well-developed appreciation of the long-term need for housing to be sustainable and, in itself, this finding is encouraging. However, it was also clear that many participants thought that this need would be met in practice *only* if renovation or retrofitting for sustainability outcomes was linked to fundamental and powerful agendas for change.

In light of the insights we have gained from working with participants, and from engaging in the analysis of the literature and its synthesis with the narratives we were provided, as a research team, we have also reflected upon what to distil – in preliminary fashion – from the three studies described here. A number of opportunities or potential drivers present themselves in the stories participants shared with us or are canvassed in scholarly and policy documents.

First among these potential drivers is the power of visionary political leadership; political in this sense including elected representatives of all three tiers of government as well as of peak professional organisations; leadership including both authoritative forms (given by constitutional or other formal fiat) and facilitative forms (charisma, influence, 'response-ability').

Second, such visionary political leadership is supported by – and in turn supports – the exercise of active citizenship. In other words, leaders will be empowered to lead to the extent that citizens question their own constitution as mere consumers, embrace their responsibilities as well as claim their rights, and have high expectations of those representing them.

Third, in terms of housing, leadership and active citizenship might mean prioritising renovation activities that extend consideration beyond individuals and their property rights to include (indeed mandate) actions that benefit non-human nature and the common good. A concrete example of that may be cited in relation to one of the authors of this paper, who has recently made a decision to sell an investment block and redirect the funds to the renovation of a main residence, prioritising over a remodelled kitchen and dining room the purchase and fitting of solar panels, solar hot water, rain water tanks, gas heating, energy efficient lighting, and an increase in insulation. Acknowledging that the author is in a position of privilege relative to many householders it remains the case that many gains appear to be possible from minor retrofits.

Fourth, opportunities for the better uptake of renovations of sustainability outcomes are likely to be enhanced by significant commitments to education and training such that innovations in retrofitting are shared across organisations and sectors and rapidly and effectively communicated and applied. In this sense, information flows need to be multidirectional: those in R&D learning as much from those in the trades as they disseminate to them.

Fifth, fiscal and financial incentives and attention to regulatory context are imperative and, at the same time, more modelling is needed to persuade householders, the building industries, housing professionals and allied groups of the effectiveness of retrofits across a range of price thresholds and in relation to a range of desired environmental, social and economic outcomes.

Finally, we are persuaded that significantly more research is needed to establish the determinants of what drives – rather than what impedes – the uptake of renovations for sustainability outcomes, but caution that such research might be most productively advanced by stakeholders having significant and joint say in its design, conduct, dissemination and implementation. The collaborative learning experiences that we think would flow from such collectively agreed investigations could be substantial and may also serve to enhance a robustly integrative approach to a common challenge.

"A house is a machine for living." - *Le Corbusier.*

Summary

Information and trends across many aspects relate to housing sustainability. The ability to implement sustainability into housing forms goes beyond the physical environmental properties of water, energy, waste, materials and indoor environmental quality. Sustainable housing also requires solutions that facilitate comfort, affordability, a changing household structure, and lifestyle needs.

This paper outlines an initiative to provide building systems from novel materials that are designed specifically to facilitate the type of living that New Zealanders want and expect from their houses. In response to a growing global demand for materials that can be used as an alternative to synthetic products, Scion is now focused on creating plant-based biomaterials and new manufacturing processes as a basis for sustaining the consumer markets of the future.

Previous assessment of housing system needs in terms of householder behaviour (how do people use their homes, and how do some of these aspects affect the use (and needs) of the home) has allowed the main criteria for housing to be identified (Bayne et al., 2006, Bayne et al., 2002). A better understanding of the lifestyle requirements of NZ household provides more defined criteria for future materials, systems and supply chain infrastructure.

The development of a process to facilitate materials research, systems design, and building solutions that focus on and address sustainable housing criteria from a lifestyle needs perspective is the key outcome of this initiative. Four projects which address various aspects of lifestyle requirements have been identified and are outlined. The developed framework will be used to create novel systems that use bio-based materials, better facilitating transition to housing solutions that are not only environmentally sustainable, but socially sustainable also.

1. Background

1.1 Housing Sustainability

The links between a nation's housing and sustainability are numerous. Housing both impacts on the environment (in terms of e.g. materials and energy resourcing, waste and effluent, water supplies, land use) and is impacted in turn by the environment (through e.g. climate, neighbouring vegetation, dust and pollutants, human and animal populations, etc.). For most New Zealanders, housing will be the largest purchase ever made, and mortgage and rent payments impact significantly on a household budget. Keeping housing at affordable levels while maintaining a profitable construction sector is therefore an economic sustainability challenge. Housing also contributes much to a person's social wellbeing, and the building and expression of culture. Where we live, the design and character of the home environment, materials used, access to amenities and the community spirit that is present and support that is received impact greatly on ones' satisfaction from their personal housing locality and situation.

1.2 Current New Zealand situation

Housing in New Zealand has a number of sustainability challenges, including cost, performance and people's acceptance of, and adaptation to, changed urban living conditions. New Zealand housing is the least affordable in the world, with Tauranga the most expensive city to live in, and Auckland housing costs outstripping most of Australia's large centres (Gibson, 2008; Needham, 2008). Whereas the international standard for affordable housing has a ratio of median house prices to median income of 3.0 or below, New Zealand has a ratio of 6.3. A recent report by Demographia (2008) states Auckland, Wellington and Christchurch are 'severely unaffordable', with median Auckland house prices at seven times the median household income. Not only is our housing unaffordable, but our average housing debt is conservatively 129% of income (Needham, 2008).

Urban housing subdivision within individual housing lots, to provide a capital return or rental opportunity, has resulted in significant suburban infill. While intensification is welcomed by city councils and policies are in place to restrict further sprawl (such as the Auckland Regional Council policy to restrict the city expanding) subdividing puts added pressures on the existing infrastructure and surrounding house prices. It also impacts on residential lifestyle values, particularly in relation to reduced privacy and views, and increased noise. By restricting further urban expansion, housing affordability tightens also. As Property Council national director Connal Towsend states "if people can't afford to live in the city, what's the point of the [Auckland Regional Growth] policy?" (Gibson, 2008).

New Zealand indoor temperatures are also below World Health Organisation recommendations for a healthy indoor environment, with cold and damp living spaces (An estimated 30% are still not insulated in either the floors or ceiling, with many more having no wall insulation). This combined with overcrowding levels contributes markedly to respiratory and severe infectious disease (Baker et al., 2006). Recent studies by University of Otago's Wellington School of Medicine (Howden-Chapman et al., 2007) have shown a clear and demonstrable link between poor housing conditions (low indoor temperature and high relative humidity) and poor children's health. Their health and insulation studies (Howden-Chapman, 2007; Howden-Chapman et al., 2007) also show insulating the home can improve not only the health of the occupants, but also household finances due to reduced energy costs and less doctor visits. This allows lower-income families more disposable income with which to better prevent illness occurring

The New Zealand housing situation is therefore less than sustainable on a number of facets. Recent progress has begun to address the housing situation and bring it to a more sustainable level. The Leaky Homes scare during 2001 received much media attention resulting in a report ("The Hunn report") outlining a number of unsustainable building practices (BIA, 2002). This heightening of public awareness of building sustainability issues led to higher levels of building performance demand from consumers, and legislation to bring about higher building performance standards.

More environmentally sustainable technologies (e.g. heat pumps and double-glazing) are becoming increasingly standardized features in new (and some remodelled) residential dwellings. The revisions to the New Zealand Building Code (DBH, 2007) increasing thermal performance and energy efficiency (including a proposed new acceptable solution for solar water heaters) have been significant drivers for this uptake. Also contributing are the government endorsement and subsidies available to aid homeowners in installation of energy saving, clean heat and insulating technologies (including solar water-heating devices, insulation, hot water cylinder wraps and low-energy lightbulbs). The Energy Efficiency and Conservation Authority Energywise scheme (http://www.energywise.co.nz/) recently announced a government fund of $23 million for assisting residential energy efficiency and heating upgrades. The adoption of these technologies have been primarily promoted and installed to reduce household energy use, but insulation has also been promoted on health benefits due to recent studies conducted by the Wellington School of Medicine showing the links between uninsulated houses and childhood respiratory illnesses, particularly asthma (University of Otago, 2007). Similarly, reduced energy use at the sustainably designed NOW home (www.nowhome.co.nz) shows that building a well-designed home with commonly available green technologies such as passive vents, solar water heating, double glazing and thoughtful house layout can result not only in improved energy efficiency, but improved wellbeing for the occupants from reduced heating expenses, and more satisfaction with their living environment (Beacon Pathway Ltd, 2007). A biannual social research study "Quality of Life in Twelve of New Zealand's Cities" (www.bigcities.govt.nz) shows improvements across a range of indicators from previous studies (increased GDP, reduced crime, increasing access to kerbside recycling schemes).

1.3 Forward-thinking Housing Scenarios

Due to these recent initiatives, and growing concern of climate change impacts, greater awareness of the unsustainable issues surrounding housing supply in New Zealand, coupled with a growing adoption of sustainable products and government assistance is leading to strategies for homes that give positive lifestyle as well as environmental benefits. One recent initiative proposes a national regenerative built environment 'test-bed' be developed (Gomm et al., 2008), which takes into account the intricate links between human and ecological wellbeing, and the complex relationship that humans have with their buildings.

Regenerative architecture recognizes that the future of sustainable buildings will need to go beyond a 'less environmental impact' model, towards a model of both positive environmental benefit and promoting meaningful and enduring relationships between people and place (Reed, 2007). The emphasis of this regenerative model is on meeting the needs of the human populace from a lifestyle perspective – after all, buildings are primarily designed for people's use. Regenerative architecture is the participation of humans as part of the living system for the mutual benefit of both. It therefore recognizes that the most environmentally friendly and affordable 'box' of a house, while addressing certain key future sustainability needs is not very enjoyable to live in, and not mutually beneficial.

The following quote from the Joseph Rowntree Foundation (2005) sums up the present movement to reflect societal lifestyle requirements within sustainable community developments:

> *"A sustainable community is one where residents are satisfied and in which they are happy to continue living."*

Similar quotes can be found from the New Zealand Government which reflects this growing sentiment:

> *"Sustainability is sometimes defined as ensuring we can meet our needs now without compromising the needs of future generations. It is about more than protecting the environment and using resources efficiently. Sustainability also relates to ensuring continued social and economic wellbeing. It means that buildings in New Zealand must meet the needs of New Zealanders now and into the future."* Department of Building 2007, pg 13.

> *"Being sustainable involves improving the quality of life for current generations without compromising the wellbeing of future generations."* Nanaia Mahuta - speech at the launch of the Quality of Life report 2007.

Are we compromising the housing needs of future generations, what are their needs likely to be, and how can we prepare for these needs?

Scenarios can be useful indicators of how trends will impact on future society, to begin to look at future societal needs. In 2001, Scion created three scenarios of the Australasian built environment (Bates et. al, 2001) and used these scenarios to identify a number of building criteria for housing required by 2010 -2015. Future building needs were investigated by evaluating how each scenario in turn would impact upon a building's form and function, as well as the change in materials and building practices that might result due to these future trends. From this analysis, a set of future criteria for various buildings were derived (Bayne et. al, 2001). Those derived for residential buildings influenced the development of a housing design brief and sustainability footprint for affordable, environmentally friendly and desirable future housing (Bayne, 2003). Using a similar approach, Scion recently examined the Centre for Housing Research Aotearoa New Zealand's (CHRANZ) recent future housing scenarios for New Zealand in 2030 (Bates and Kane, 2005) , to investigate how these trends would change housing needs over time. Overlaying this analysis with known emerging consumer and building industry behaviour determined sixteen criteria for modern timber housing (Bayne et al., 2006; Bates et al., 2007).

These studies represent a forward-thinking approach to housing research and residential design, which aims to propel the sustainable housing research beyond environmentally friendly and 'green' design principles into housing that also improves residents' quality of living experience, and 'future proofs' housing supply.

2. The Life Home Initiative

2.1 Concept

International research on green building design recognises that sustainable buildings need to be designed for people (e.g. Storey and Pederson, 2007). There is significant thinking on how to integrate the design process such that buildings are designed to deliver healthy, desirable and productive living spaces. This indicates a movement away from focussing on technical (particularly environmental) issues alone, and towards thinking about increased social, functional and wellbeing outcomes for the building occupants through improving the design, and the technical elements that are used to create the building and its surrounds.

The concept of a 'Life Home' is one that allows future trends and consumer needs in the building sector to be applied to materials science (refer figure 1), delivering improved building systems. The 'Life Home' concept builds off two past initiatives undertaken by Scion:

A) The post-Kyoto house (Bayne, 2003) : During 2001, built environment researchers in New Zealand recognised that in order to meet Kyoto commitments, the Government's directions in terms of energy, transport, waste and urban design would require current building performance to be significantly enhanced. Scion established the 'post-Kyoto vision' that showed the residential building stock being brought up to this requirement, and 'future-proofed' to account for changing consumer needs. This vision was "the environmentally friendly home that people want to, and can afford to, live in" and consisted of :

Now homes – showing what could be done to meet future needs using currently available, advanced building systems and design thinking. This led to a collaborative design charette approach and ultimately the building of the Waitakere NOW Home® and forming of the Beacon Pathway Ltd. research consortia (www.beaconpathway.co.nz).

Then homes – a retrofitting programme for existing homes to meet future needs through using current technologies, in recognition that the vast majority of homes in New Zealand were already built.

Future homes – designing new homes using advanced (i.e. not even out of the lab yet) timber-based building systems, to reduce the carbon footprint of residential building materials.

B) Future Housing Criteria: 'The Future of Housing in NZ in 2030' (Bates and Kane, 2005) was a scenario planning report undertaken for CHRANZ in 2005. Using these scenarios, Scion extended the study to explore criteria that would be required to meet the future housing needs that were outlined in the scenarios (Bayne et al., 2006; Bates et al., 2007). These criteria were identified as:

- affordability;
- customised services;
- health and safety;
- comfort and energy efficiency;
- social responsibility;
- quality — fit for purpose and high performance;
- compatibility with denser living requirements;
- ease of maintenance;
- environmental performance;
- adaptability/flexibility of design;
- ease of (dis)assembly;
- desirability;
- self sufficiency in terms of water and energy;
- resilience to the impacts of climate change;
- smart technologies.

Life Homes continues research in this field, and by marrying past knowledge with our biomaterials research and life cycle capabilities, the project is very much in the 'future home' space. The Life Home programme complements investigation into physical elements of home, and is concerned with improving functionality and social wellbeing for the occupants through the design of the building system elements, and the materials these are built from.

2.2 Approach

The Life Home approach was established to enhance the ability of Scion (a leader of biomaterials research) to respond to the changing market needs of material users. The built environment is a large end user of timber and plant-based materials. To ensure science relevance to this end-market, especially given materials development lead times, the established future criteria for housing were used as a basis to explore technical implications for materials science.

One of the goals of the research programme is to create a Wellbeing Assessment Framework. While building assessment frameworks exist that account for environmental and economic aspects of a home environment, social elements are less easy to quantify. The assessment framework aims to establish a framework that can account for the social and cultural requirements of a home, thereby establishing a truly sustainable assessment framework.

Another of the main goals is to identify how the impacts of future housing criteria affect various areas of a home environment, and identify key indicators to achieve a more sociable and functional home environment. We are using a series of open discussion forums to aid us in this process.

The criteria were clustered into six key themes which were then explored using Strategic Conversations (refer Figure 1). Strategic Conversations involve a presentation by an expert in the field, followed by a facilitated discussion with the expert to further explore themes and questions arising out of the presentation material. These conversations were used as a basis of more in-depth idea generation, to interpret the criteria themes in terms of how the ideas and issues raised in the Strategic Conversation might impact on five key aspects of the home environment:

- *Shelter/Barrier* - The building envelope consisting of the structural walls, floor and roof, and the linings and detailing which make these elements internally weatherproof.
- *Functional elements* – Those systems which make a home workable (plumbing, lighting, telecommunications, ventilation etc)
- *Living space* – The interior areas of a home [building(s)]where home life occurs
- *The big outdoors* – The outside areas of a home environment, which includes a wider area than the housing lot. It is recognized that a person feels a sense of belonging (calls 'home') to more than the housing lot, but also the street and nearby amenities, and the community/ neighbourhood which they live with.
- *Soul* – the features and design elements which define the character of a home.

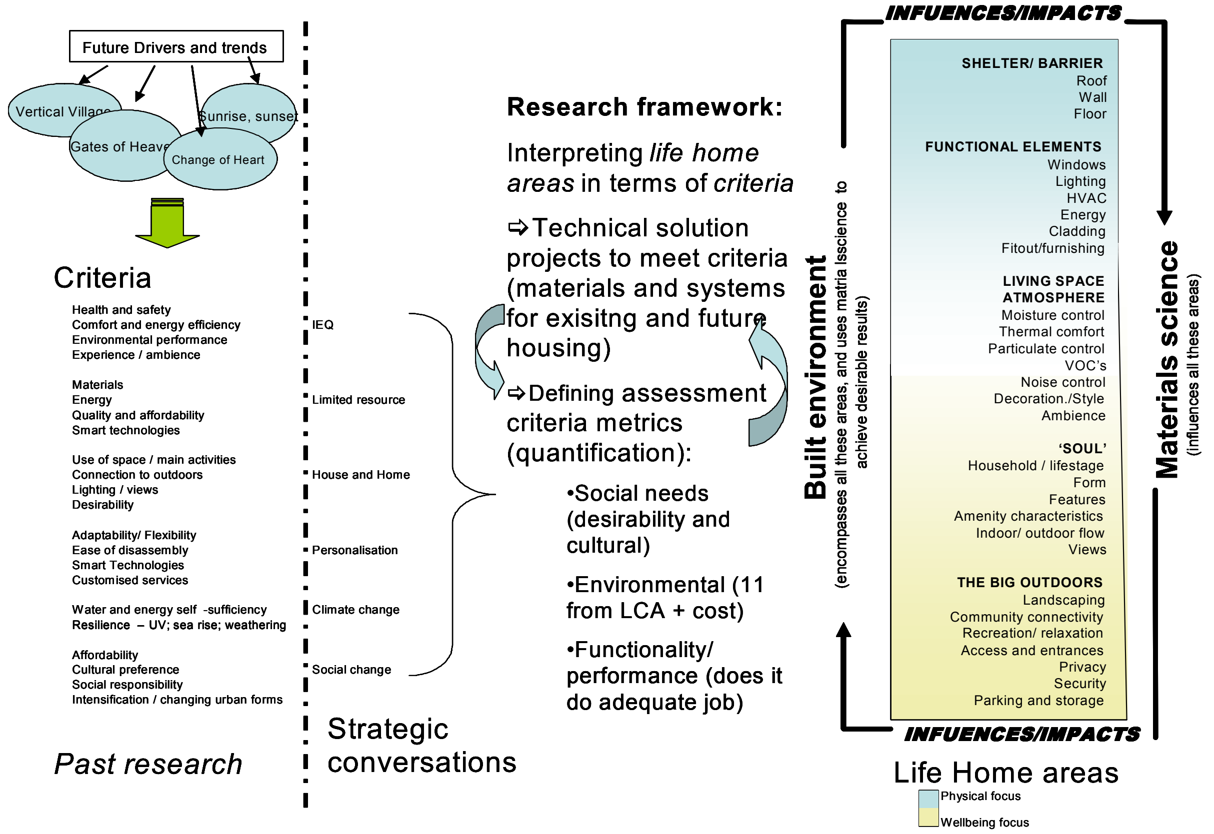

Fig 1: Life Home Conceptual Framework

These discussions also identified potential technical projects which could be undertaken as part of the technical research programme. The ability to enhance the delivery capacity of relevant science at Scion was the major driver in determining the structure of the technical programme. Additionally, the ability to enable cross-functional science thinking through a multi-disciplinary science Steering Committee allowed for the original technical projects which were put forward to be enhanced. Although creditable projects were proposed originally, merging and refining the project ideas that arose by this multi-disciplinary team resulted in a set of projects which were far more robust and encompassed a wider scope of research than had originally been envisaged. Using the criteria and Strategic Conversations as a basis for directing the technical programme, in contrast to brainstorming ideas from scratch or selecting 'plausible' proposed projects saw the establishment of some exciting programmes – none of which would have arrived without going through this process. This selection criteria was a strong one and impacted a lot on the shape of projects proposed. It was so strong that no proposal not addressing the criteria proceeded.

2.3 Outcomes

The initiative to date has identified through the process of Strategic Conversations, and multi-disciplinary refining of ideas, four main technical projects for the initial research programme:

2.3.1 Establishing a Wellbeing Assessment Framework

One of the main goals of the Life Home programme is to create an assessment criteria framework to help develop biobased materials, products or system solutions for the Built Environment, and can aid in project decision-making. This assessment framework needs to incorporate environmental, social and economic indicators. The indicators for environmental and economic aspects are well established through existing tools such as Life Cycle Assessment and Economic modelling. Social indicators, however, are usually subjective, and often due to the intangible nature, are left unquantified.

This project will use LCA methodologies, including the current research involving social components of LCA, to establish a set of criteria and metrics for social aspects of wellbeing in the home environment.
The outcomes will be a novel design framework to increase well being in the home, and at least one new material or build solution to validate the tool. Competency will be enhanced also through increased interaction and learning between the cross functional physical materials science capabilities in Scion, with social science and life cycle capability.

2.3.2 Eliminating mould from houses using natural biocides

Potential health risks caused by mould growth in residential houses is of major concern for home owners and insurance companies. Apart from physical health, significant mental health suffering is caused by mould growth in houses. Wilson et al. (2007) found the incremental health cost of leaky buildings, primarily affecting respiratory and mental health conditions through increased mould, are around $NZ474 million in present day terms.

Based on literature, moisture management remains the most critical factor for controlling mould growth in houses. However, it is unknown if other factors such as cleaning have an impact in inhibiting or promoting mould growth. Chemical fungicides commonly used to control the growth of mould are not often appropriate for indoor applications. Natural alternatives that are user friendly and have no toxicity to humans are therefore desirable for this application. Essential oils are known for their natural components, and are an ancient technology which have long been recognized for their antimicrobial activity. However, little work has been done on the use of essential oils as an anti-*mould* agent.

This project will evaluate the anti-mould activity of essential oil based products and the potential to develop anti-mould treatments for interior wall panel products, or interior surface sprays. The objective of this proposed study is to know the targeted critical measures for certain mould growth and then evaluate the ability of commercially available essential oil for mould inhibition. The project aims to exploit known natural products chemistry (essential oils) in a novel application - to control the incidence and extent of mould growth in housing in New Zealand - and includes testing on a new biomaterials panel to be developed by Scion.

2.3.3 Concepts of Modern Urban Pa

In contrast to the movement towards individual property ownership and separate housing spaces, some Western nations are experiencing a trend of increased communal living and shared use of recreational, food-growing and some living quarters. In many cases, persons of multiple generations, or multi-family groups are sharing the same housing unit or areas of a housing block. This is being driven by affordability; aging of elder generations; younger generations both working and requiring familial help in child raising; and a sense of wanting to belong to a community.

Similar to early settler communities and European villages, traditional Maori housing and village structures were communally based rather than nuclear-family modelled. Traditional Maori society was based on communal living in every respect with the wider iwi and hapu being the primary social reference point (as opposed to the nuclear family). Village location, outlay, functions, and buildings were designed to enhance this communal living pattern.

Maori papakainga developments aim to return the younger generations of mana whenua to reside back within their traditional home areas. However, many papakainga are rurally located, while 80% of Maori are urban-dwelling. It is reasonable to assume that many Maori may wish to remain in the city or urban area within or outside of their rohe, or traditional papakainga sites.

This project proposes to address issues of low Maori buy-in and meaningful ownership of housing, neighbourhood and community by creating a housing model for Maori-appropriate urban neighbourhoods. The model will draw strongly from traditional Maori communal life and marry this with the requirements of modern urban / suburban living including intensified living arrangements. Such a model offers significant potential to help address a raft of social and economic issues Maori face in urban areas, by creating a strengthened urban-Maori community soul based on desirable housing that builds esteem and personal mana, and enhancing the participation of Maori within the urban environment. The urban pa concept is likely to support improved social and economic wellbeing as it is not uncommon to visit Maori neighbourhoods and see poor nuclear family style housing right alongside a communal marae that is impeccably groomed. A similar occurrence is seen with Pacific Island neighbourhoods and their churches.

This project will establish the criteria and generic design brief for an ‘Urban Pa’ development, one that accounts for New Zealand cultural requirements as well as the growing demand for more intensified and multi-family housing design options. The outcomes of this project are expected to offer significant value to non-Maori urban communities, due to efficiencies now being demanded on all types of urban resource consumption, and the ability of more communal living to enhance individual safety.

2.3.4 Sustainable wooden furniture

Over the past 5 years or so, many countries (including NZ) have witnessed a major increase in furniture imports from China (and now Vietnam) with a corresponding downsizing of local furniture manufacturing. The economic sustainability of New Zealand’s furniture industry is threatened by the emergence of these Asian low-cost furniture factories. New Zealand’s balance of trade in furniture has deteriorated by $NZ 200m with steadily increasing imports and little or no growth in exports (Refer Figure 2).

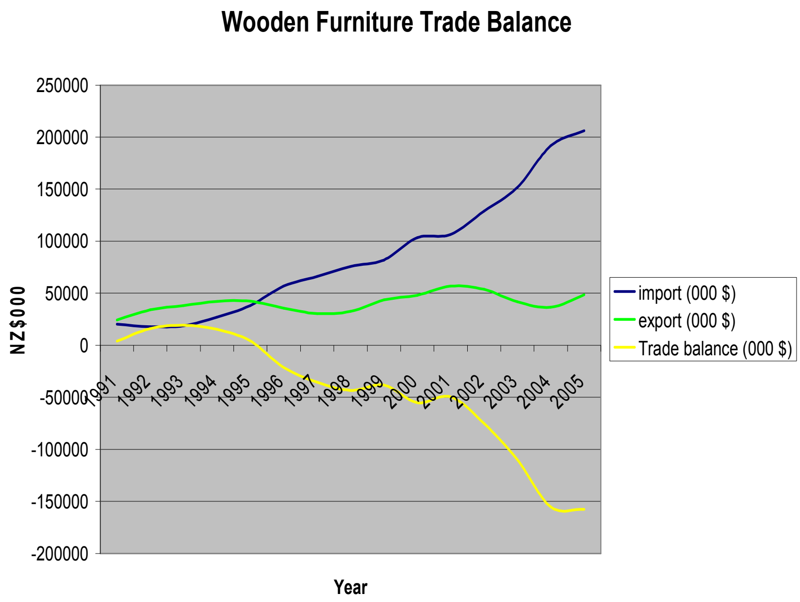

Figure 2: New Zealand Wooden Furniture Trade Balance

The huge environmental cost of furnishing (which may be replaced many times over during the life of a building) over and above the environmental cost of the building structure itself has been recognised by the Green Building Council and Green Star (in Australia) through office furniture rating systems. From an environmental perspective, furniture is coming to be viewed as a growing source of environmental impact. The reasons for this are several fold:

- There is a trend toward more frequent furniture replacement which leads to greater consumption of materials AND increasing levels of end-of-life waste.
- The growth in imports from developing countries is at the expense of use of cheap labour and production techniques which do not require the more rigorous environmental performance of New Zealand's counterpart manufacturing sector (i.e. in low formaldehyde emission control of panel products, and adherence to the Resource Management Act.)
- The use of low-cost materials which have high environmental costs of production (e.g. vinyl) and/or present hazards to the consumer (e.g. coating products).

At a time when "sustainable furniture design" is becoming a point of product/ market differentiation, how is the New Zealand furniture industry best placed to respond?

We aim to investigate the size and nature of the New Zealand furniture industry, drivers of New Zealand furniture ownership, and assess the sustainability impacts of current furniture ownership practices to identify areas that NZ furniture manufacturing industries could exploit to further the use of wood and other biomaterials as a "sustainable design" advantage. The research will provide the furniture industry the tools with which to allow the production of more sustainable (i.e. desirable to consumer lifestyle and environmentally advantageous) furniture products, and in doing so, a more sustainable home environment.

Conclusion

Sustainability is a strong part of New Zealand's current policy arena, which has an emphasis on ensuring sustainable community development occurs and quality of life is enhanced for all New Zealanders. In relation to housing, revisions to the Building Code to include wellbeing aspects, and a cross-governmental push towards social and economic wellbeing in urban developments (including regenerative architecture) supports a 'Life Homes' approach.

This initiative aims to explore in more depth the lifestyle needs of future generations, and to develop through a technical programme, a framework for building system solutions that incorporate bio-based materials to better provide for these requirements. The approach of holding Strategic Conversations around core topic areas, combined with a multidisciplinary steering committee has been central to the technical programme development, and the authors believe this process is responsible for the resultant technical programme being more rigorous and forward-thinking than a brainstorming or symposium approach would achieve alone.

An assessment framework for wellbeing will also allow the social and quality of life aspects of sustainability to be translated into the design of these systems. This will continue our ability to respond to the changing market needs of material users within the built environment.

Glossary of Maori terms

Pa – Maori village community; settlement
Papakainga - homeland, homestead
Marae – meeting grounds
Rohe – regional area
Mana – personal esteem, prestige, authority
Mana Whenua – people with authority over land, local tribal estate

A PATTERN LANGUAGE FOR A NATIVE INDIAN VILLAGE IN BRAZIL

Juliana CRUZ, architect[1]
Miguel SATTLER Ph.D[2]

Keywords: indigenous village; A Pattern Language; occupancy and building patterns.

Summary

Proposal: It is known that traditional communities strive for living in a land that fulfils the characteristics of their original territory. Such communities are considered very knowledgeable regarding sustainable strategies for the environment they inhabit as they are strongly connected with it. However, according to the literature, the areas usually allocated to indigenous settlements are far from having the carrying capacity required by their traditional way of living. The present work performs an analysis on the behavior of a Mbyá Guarani indigenous community, living in the municipality of Palmares do Sul, Brazil, more specifically on its construction and its space occupancy patterns. **Method of research:** The study was directed towards pragmatic questions and empirical studies in which observation, graphical expression and interviews were the main sources of evidence. The research strategy employed was an action research, aiming at identifying the community real needs and also tried to evaluate the community learning and behavioral changes resulting from the research process. **Results:** Part of the research problem included the approach adopted by the community in the development of projects and constructions for their village. Christopher Alexander´s Pattern Language (ALEXANDER *et. al,* 1977) instructed the construction of a specific pattern language for the community. **Contributions** / **Originality:** It is expected that this study enables a better understanding of the configuration of the Mbyá Guarani villages, built according to their own language.

1. Introduction

The struggle for social justice and cultural autonomy of traditional peoples has constituted one of the greatest research challenges, including practices aiming at the social welfare and the development of such communities. However, through this study, we want to show the existing interdependence conception between the Indians and nature, exploiting the cultural traces nowadays found within the villages. The studied literature indicates that for the Indians the space is based on their relationship with the different geographical and natural elements. The indigenous communities aim at living in lands contemplating all the requirements of their territory, but the inter-ethnic contact brought them to the re-elaboration of many aspects of their culture. The territory configuration of those communities was changed, as the areas where they were located became part of the settlers' demands.

Nowadays, the Indigenous lands are demarcated by the Government according to what is established in the Federal Laws dated of 1988. However, the choices that respond to their spatial preferences are exhausted, driving them to marginalized areas, far from having capacity of giving support to their cultural traits and their subsistence needs. However it is known that those communities have a deep knowledge of sustainability strategies and adaptation to the environment they are used to live, being strongly connected to the natural environment, and, consequently, to the resources found in such places. To characterize the fact, a reflection was made that specifically related to an Indigenous community, Mbyá Guarani, located in the southernmost Brazilian state and its construction and space occupation patterns. The community was chosen for being located in an area where many cultural activities are developed, being strongly influenced by the local ecological conditions.

Part of the survey problem considered the evaluation of the community participation in the plans and construction development in the village. Due to the survey approach, this study adopted Christopher Alexander´s A Pattern Language (ALEXANDER et. al, 1977), as a guide to establish an Indigenous Pattern Language. However, considering that this survey involves the analysis of only one village, it is believed that the patterns, which were found, enable just the definition of a preliminary language. It should be stressed that this article presents a speculative study, an attempt to formulate a list of ideas, and suggests how they could be developed and tested. We hope that other Indigenous ethnics could be analyzed , even with different characteristics from the one evaluated in this survey, making easier more creative plan solutions arise, adjusted to specific and different realities and taking into account their cultural needs.

1.1. Objective

The objective of this article is to define an Indigenous Patterns Language for the Mbyá Guarani community from the village *Yryapú*, aiming at identifying the elements characterizing the environment they live in.

Furthermore, this study is intended to supply elements to demarcate new Indigenous territories and enrich possible plans to be developed within those areas, contributing to the cultural sustainability of Indigenous peoples.

1.2. Building a Language

The idea of a "language" for planning and design is not a new concept. The studies developed by Christopher Alexander have been contributing to this concept along the years. According to Hanson (2005), in 1964 Alexander published "*Notes on the Synthesis of Form*" where he proposes a binary methodology, derived from fledgling computer science to develop a rational basis for the design process (HANSON, 2005). In the following years, he published the article "*A city is not a tree*", in which he considers the urban form mathematically, concluding that the structure of a healthy city is configured by a "semi-lattice" (containing multiple nodes and connections) (HANSON, 2005). In these works, Alexander continued to explore the nature of order, arguing that the majority of designers would equate order with elegance and simplicity, instead of trying to read and understand the more complex structures found in the world. In 1977, Alexander *et. al.* founded the "*Center for Environmental Structures*" and began the work that resulted in the book "*A Pattern Language*" and a series of interrelated volumes (HANSON, 2005).

"*A Pattern Language*" presents 253 patterns, extracted from different traditional cultures, which, combined, admit infinite language possibilities for the development of a plan. The elements of a language are called patterns. Each pattern describes a problem occurring repetitively within the environment, and, finally, it describes the kernel of the solution for the problem, so as to enable the utilization of this solution in different circumstances (ALEXANDER, 1977). Salingaros (2003) shows, in a simple way, that a "pattern" is a recurring solution, which can be a solution for an architectural or urbanistic problem, although also being able to solve other kinds of social or technical problems. The aim of developing a pattern language is to supply a vocabulary of design strategies which allow the efficient communication among architects, designers and customers.

The Alexandrine Patterns, as named by Salingaros (2003), begin with the language defining the city or the community. Those patterns cannot be quickly drawn or built, but they grow gradually, drawn in such a way that each individual action is always helping generate a global pattern and then build a community contemplating those patterns. After that, the part of the language giving form to groups of constructions or individual constructions and the spaces among them is described. Those patterns can be drawn or built. At this stage, the design of a construction is configured. Hence, the site plan is defined, marked on the soil with piles or drawn on the paper, as well as the heights of the rooms, with the exact size and place of windows and doors, the roof inclinations and the garden position. The last part of the language refers to the details, deciding how to make a building from a plan conceived for the site and how to construct it.

It is important to mention that the objective for the utilization of a pattern language consists on the idea that any individual can build, draw, and plan his/her own house, streets or community. However, this idea might be radical, implying in a change in architecture as seen by professionals (ALEXANDER, 1977). Alexander argues that the future depends on those who can learn to apply a pattern language within a holistic structure (HANSON, 2005). According to Capra (2006), the new understanding of life is considered as the scientific front line for the change in paradigm from a mechanicist view of the world to a holistic and ecological view. This change involves a "constellation of conceptions, values, perceptions and practices shared by a community, giving a particular view of the reality, constituting the basis of the way the community organizes itself." (CAPRA, 2006).

"Traditional cultures are far more attuned than ours to the larger wholes to which their buildings contribute. In recovering this sensibility architects must re-learn respect for the entirety of building culture (not just designers), and help those outside the building professions to participate too" (HANSON, 2005). According to Agenda 21 (PLESSIS, 2002), traditions offer examples of well-succeeded constructive patterns, besides the processes of social sustainability for the creation of the built environment based on principles of the proper utilization of materials, communitarian methods of construction and practices of environmental handling. The capacity of communicating patterns, inherent to human beings, enables the creation of an arsenal of knowledge reusable through the drawing. Then, a pattern language is connected to culture and tradition (SALINGAROS, 2003).

Novaes (1983) observes that evaluating the Indigenous house and the perception the members of a determined society have of the space they inhabit is extremely important. First of all, because it reveals the different possible ways of space conception, involving not only the ecological adaptation to the environment, but, especially, because it's possible to prove different ways of appropriation and hierarchization of the inhabited space. Latin America has a great diversity of flora and fauna as well as peoples inhabiting ancestral territories in equilibrium with their surroundings. Rescuing their constructive technologies, village and dwellings patterns may constitute a valuable support for their recognition.

2. Research Method

This article is part of a wider survey aiming at creating a tool to ease the understanding the importance of reconnecting the Indigenous communities with the land they previously inhabited. The present reflection is related with the Indigenous communities Mbyá Guarani under a current perspective. It aims at rescuing patterns of the Indians' interdependence with the environment in order to help in the discussion on the theme of sustainable development and contribute for its recognition. Nonetheless, the objective of this survey is neither to interfere on this people's culture, nor to alter the way they identify and design their territory and site. In this sense, the method was chosen because it is adequate when one intends to work with current subjects, collective and active in character.

Part of this survey is composed by the method of drawing in the practice as presented by Salingaros (2003). To give support to the survey, interviews were performed with anthropologists, EMATER[1] and FUNAI[2] technicians, and other agents working with indigenous communities, aiming at validating the collected data. Furthermore, the data collected empirically were analyzed with multiple evidence sources. However the dialogue constituted a great challenge, due to Guarani´s official language. Some of them, born in Argentina, speak Spanish and Portuguese, but without the same fluency in both languages. This difficulty resulted in strategies to make the communication easier. Interviews made with technicians from EMATER, revealed that the Indians express themselves very well through drawings. Thus, the graphical expression was the main tool of the study. Drawings, panels and texts were worked out in order to register visually what was being treated.

The work was developed in four steps. The **first one** involved activities proposed to the community in order to know more about the local characteristics and they were asked to: draw the VILLAGE TODAY and the DREAM VILLAGE. The **following step** consisted on examining in the literature twelve patterns found in the drawings developed by the Indians, besides other patterns that were verified empirically by the researcher and registered on a notebook. These patterns were shown and discussed with the community, containing adaptations to contemplate specifically the Mbyá Guarani cultural traces. The **third step** discussed new patterns not found within the existing pattern language. The **final step** proposed to put into practice a newly defined pattern language, not performed yet.

3. Analysis of the results

The survey presented in this article shows a network of patterns able to constitute a primary language for the Indigenous community Mbyá Guarani. Instead of describing in details all the patterns, the intention is to synthesize the various patterns found in *Tekoá* (village) *Yryapú*, through the description of the constructed environment observed and presented by the Indians along the drawing activities. Afterwards, the identified indigenous patterns will be described, presenting its name, the problem and the solution.

3.1. *Tekoá Yryapú*

TEKOÁ *Yryapú*, a Guarani name meaning Sound of the Sea, was homologated[3] as Indigenous Land by FUNAI in 2001. The allocated land makes border with private properties where rice is cultivated, pine tree reforested areas, and lagoons next to the coastal region of the State of Rio Grande do Sul. The village has a total 43 ha and is occupied by 26 Indians; eight of them are adults, eight adolescents and ten children. During the study, there were some visits from relatives coming from indigenous lands in the State; a whole family went to another *tekoá* and other family joined the "Cacique Duarte's" family nucleus always present in the *tekoá Yryapú*. The number of the members of an Indigenous Land varies according to its **SPATIAL MOBILITY.** The first Indians established in the region in 1993. In 2000, the first public policies were enforced in the village through the RS Rural Program[4]. In 2002, the Project called "the Indian House" (Figure 1), was put into practice, being developed by the Rio Grande do Sul State Planning Office together with Indians representatives.

Figure 1: Indian's house

Figure 2: Traditional House

Zanin (2006) presented a comparative analysis of the housing alternatives to the indigenous population made by the Brazilian government and their traditional construction. The author states that "the traditional HOUSE is symbolic, being a product of culture and social relations" (ZANIN 2006). According to Alexander *et. al.* (1977), in all cities, regions, neighborhoods or even communities, there are special places symbolizing those zones and the roots people have with such places. The indigenous community recognizes the importance of these SACRED SITES (24), and they valorize places and practices taking into account their cultural trace. Such fact can be observed through the construction of new dwellings and the ***OPỸ*** (praying house) in the *tekoá Yryapú*, made according to the traditional typology (figure 2), respecting the physical characteristics as **SHAPE AND DIMENSION, CONSTRUCTION TECHNIQUE** tuned to the **MATERIAL** available on site and **SOLAR ORIENTATION**. The location of the door is defined by the Indians in relation to the divinity. In general, they are used to making a LOW DOORWAY (224) representing a reverence act and permission request to enter the rooms (PRUDENTE, 2007). The houses built in the *tekoá Yryapú* fulfill the patterns considered traditional by the Mbyá Guarani, taking into account the **WOODEN STRUCTURE**; the roof made of witchgrass; **WALLS** made of hand-made mud, fastening made of vines, and the floor sitting on firm ground.

The constructions built through a **COLLECTIVE SYSTEM** (***potirõ***) reinforce the traditional collective dynamic, including the participation of the community in different construction steps. Looking at this dynamic, it was noticed the participation of children together with their parents, where the knowledge of traditional construction techniques is transmitted orally (**ORAL TRANSMISSION**). In their DREAM VILLAGE, the community members wish to build traditional houses for the elderly, while the youngsters keep on living in the Indian's House, already built in the *tekoá.* The present structure of the village includes ten dwellings, a communitarian center (Figure 3) and a Health Unit (Figure 4), built by the State Government, besides the two houses and *Opỹ* built according to traditional procedures.

According to Ladeira and Matta (2004) *Tekoá Yryapú* presents different elements representing the Mbyá Guarani culture. The authors identify the dwelling nucleus: *Monde* (Mundéo – hunting trap); *kokue* (field); fishing; hunting animals (armadillo); *Kurupika'y* (Bark); *Poã* (Medicinal Herbs); *Yvyra* (wood); *Takua* (bamboo); besides rivers and lakes. Furthermore, the community proposes to food growing large areas, as proposed by the government officials. The community grows witchgrass, abundant raw-material in the region, hence making the *tekoá Yryapú* an important source for many other Indian villages. There is also a support for growing fruits, mainly the native species. The tribal leader, Cacique Duarte observes the importance of orchards. The place near the *Opỹ* is indicated by the gods, according to his statement: "...the gods say this place is good for cultivating our orchards; here the plants will grow". On the same way the *pindó* (palm) is planted by the community along the lagoons. According to the tribal leader, the site that was chosen as determined by the gods and it is very adequate due to the proximity of the water.

The space distribution is made according to the **FAMILIAR NUCLEUS**, as shown in figure 5. In the path leading into the *tekoá* the prominent presence of eucalyptus and pine trees is noticeable. The access occurs through a small sandy path, without clearly defining a proper road. On the way one crosses a brook, where wooden boards, placed side by side, act as a bridge. Passing through two gates it will be possible to see some bee hives, indicating the involvement of the community in honey production.

The main access occurs from a **COURTYARD** that has many functions. It was observed that the spatial planning of the *tekoá* is characterized by the presence of this access courtyard (number 15), directly linked to the communitarian center and another courtyard next to the tribal leader house (number 14). This access courtyard is closely connected to constructions like the Indian's House and the Health Center, made of brick and fenced with metallic bars. Prudente (2007) points out this construction, made by FUNASA, as having a different style from those of Mbyá Guarani' constructions, including the space arrangement patterns, since it uses expensive materials and modifies the village image. Another element also built by FUNASA is the water tank, also fenced and looked after by the daughter of the tribal chief, who is responsible for the addition of chlorine to maintain the water potable and for distributing it to the community through a tap installed in front of the Indian's House. The ACCESS TO WATER (25) indicates that the water comes from the subsoil, from where the water is drawn by manual water pump located next to the lagoon. Alexander *et. al.* (1977) outstand the ocean beaches, lakes and the river margins as sacred places, as they are unchangeable and they advise that their proper use and conservation require a special pattern. Water has symbolic meanings which can be reduced to three main topics: source of life, means of purification, center of regeneration (CHAVALIE, 2007). For the Indians, water is linked to the sound *u*, to emotion (JECUPÉ, 1999). According to Jecupé (1999), the Guaranis say they have the *nhanderekó* (way of being) related to all the aspects of the being. The *nhanderekó* has tempers, linked to four elements, manifesting the humor and determining his personality: earth, water, fire and air. Then, the proximity to water is directly related to symbolic aspects of the indigenous culture which go beyond the water meaning, supplying the body needs.

The access courtyard is frequently used for activities as: visitors' reception; children playground; parking area for the visitors; ground fire; a place where they can after lunch continue the tradition of sitting on trunks, benches and chairs distributed in the area. On rainy days, the visitors are invited to enter into the Communitarian Center, where the fire is located with benches around it. The courtyard in front of the tribal leader house is used in different ways: MEN AND WOMEN (27) have distinct tasks. At home, there is always the presence of the woman, who moves between the house and the FIRE (181). The women stay there, preparing the food on a wooden table or sitting around the fire, while the men prefer to stay nearby, mainly in the courtyard, under the trees, where they receive their friends or brothers-in-law, sitting around the fire only at the sunset. Going to the forest for collection or hunting is a male task (LARRICQ, 1993 *apud* ZANIN, 2006).

Figure3: Communitarian Center

It is possible to verify, on the village site, the DEGREES OF PUBLICNESS (36), defined through a more protected area for the community – the courtyard of the tribal leader house, and another one that is less private – the access courtyard. However, Sylvia Novaes (1983) observes that the house is not the reference point to be taken for the construction of the indigenous identity. This is identified by a wider space, the village, or the traditional territorial space of the group occupation. Thus, the house can be considered part of this dominium, being it a more intimate, stricter and more reserved area" (RAPOPORT, 1972), although being place where it is very common for them to sleep together (COMUNAL SLEEPING, 186). Considering that the indigenous house is not limited to the building itself, it is observed that there is an INTIMACY GRADIENT (127), defined by the arrangement of public and private areas, starting from the main access.

Figure 4: Health Unit

There are three familiar nucleus defined in the *tekoá,* (see figure 5), each one with a HOUSE CLUSTER (37) interlinked by PATHS AND GOALS (120), being the PATHS SHAPE (121) marked on the ground according to the Mbyá "tread", crossing forests and corn fields, widened on the section with houses and yards (ZANIN, 2006). The main nucleus next to the access to the village is defined by the presence of the tribal leader and his family. The nucleus number 2, occupied by another family is configured by the presence of three Indian's house type. The nucleus 4 has an available building, built according to the Indian's house type. Each nucleus has its production area, but the food cultivation process is made collectively.

13 – Bridge
14 - *Opỹ* courtyard and tribal chief house
15 - Access courtyard

Figure 5: Sketch of Indian Village, Tekoá Yryapú

Planting is one of the most important activities for the Mbyá Guarani subsistence and they give priority to the traditional plants cultivation to maintain the species which have been cultivated for centuries, being called the "true" plants. Other important activities for the community *Yryapú* are hunting, fishing, harvesting and craftsmanship. These activities are conditioned to raw-material availability. In the *tekoá Yryapú,* craftsmanship is nowadays one of the main sources of income, being sold in the cities and coastal cities next to the village. However, according to tribal leader Augusto Duarte "... it is dangerous to go out of the village to sell craftsmanship due to assaults, the prejudice we suffer, waste of money for the bus and sometimes we sell not even a small animal craft". Besides selling craftsmanship, the community wishes to welcome tourists in the *tekoá* to share the Mbyá Guarani culture. There is a proposition for the definitions of tracks, crossing the forest, where they can show the traps and the existing vegetation. For the reception of tourists in the village and to make easy the selling of craftsmanship, they intend to build a big turtle-shaped house (*oga guassú karumbé*). At last, they dream of changing the village into a Mbyá Guarani model *Tekoá*,

3.2. An approach to an Indigenous Brazilian pattern language:

Tabela 1: A Mbyá Guarani Pattern Language

	**SPATIAL MOBILITY** It is common the number of individuals in the indigenous communities to vary, due to the cyclic displacements caused by religious, social and political reasons. **Ease the Mbyá mobility through policies favoring free circulation.**
	***TEKOÁ*** *Tekoá* is the place where the Guarani culture can be performed– *Teko*. **Configure villages in forested areas with a water spring, where the *Opỹ* becomes the main element, together with the jungle magnificence, surrounded by several dwellings, built according to traditional practices; verify the sun geometry and implement the *tekoá* according to the preference of the spiritual leader; occupy the woods clearings with the familiar nucleus, where the fire must be present; surround the constructions with squares and field areas; connect them through tracks or roads.**

FAMILIAR NUCLEUS

Besides defining the social and cultural characteristics, the familiar nucleus defines the layout of tekoá, according to its distribution on the local environment. Each familiar nucleus must contribute towards the Mbyá's daily social and cultural activities.

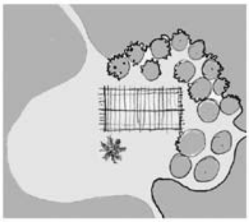
Define the *tekoá* access according to the location of the tribal chief's familiar nucleus which must provide a courtyard to receive the visitors; in the spiritual leader's familiar nucleus, establish the *Opỹ*, with the larger courtyard attached to it; each familiar nucleus shall have an area for houses, courtyard, field, vegetable garden, orchards and animals pits; all of them must be surrounded by woods and connected by paths. It is essential to the Indians' definition of orientation and location of the nucleus.

THE HOUSE

The traditional house is the place for the meals, rest, protection against heat, cold and storms. Most of the time, the house is used only as a bedroom, where all the family sleeps together.

Build houses to reflect the Mbyá Guarani cultural specificities; ease the presence of the fire through the use of natural materials, extracted from the forest surrounding the *tekoá*; supply an adequate thermal, light and ventilation comfort: it must have a rectangular shape with its dimensions varying according to the familiar nucleus that will live in the house; its use, preferably, must be during the night; respect the Mbyá definitions of priorities in the house, such as the solar orientation.

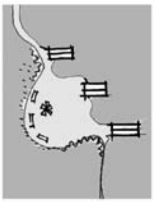
THE *OPỸ*



The existence of *Opỹ* - Praying House allows the practice of dancing and singing, elementary exercises devoted to obtaining the religious fervor and essential conditions to acquire spiritual fortitude and value.

Build the *Opỹ* being the center of *tekoá*, not geometric, next to a *pindó* (palm tree), in a place with privacy, surrounded by fruit trees; across from it, put a square; the solar orientation must be with the door to the setting (or according to the determination of the spiritual leader); protect the building with a rectangular traditional-wooden fence using the stud and mud technique for the joints and witchgrass or bamboo for the gabled roof.

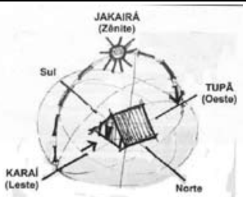
THE COURTYARD



The courtyard is a semipublic place of each family; it is the transition from the public communitarian space to the private space, inside the building.

Delimit the area of each familiar nucleus and, consequently, the space of the courtyard will be defined surrounding the houses. The courtyard must be defined to enable the contact among the householders. Define a courtyard around the *Opỹ*. Distribute benches and wooden trunks to receive the visitors.

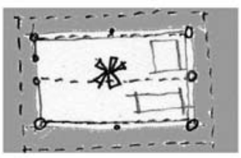
SOLAR ORIENTATION

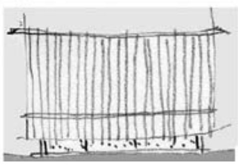


The sun is the cosmologic divinity, called *Nhamandú.* The house represents the *tekoá* life, fed and protected by the sun.

From the position of the door, orientate the house taking into account its relation with *Nhamandú*, varying between east and west. Let the decision of the adequate orientation to the *karaí* (spiritual leader).

DIMENSION AND SHAPE





Considering the climatic conditions, the availability of certain materials and appropriate technolgy, the factor contributing to the origin of a dwelling shape, that also models its spaces; its dimensions are a representation of the vision the people has of ideal life.

Build houses taking into account socio-cultural factors, climatic conditions, constructive methods, available materials and technologies. The traditional house has reduced dimensions and the shape is configured by walls covered by a gable roof, with the eaves almost touching the soil.

The dimensions of the house can vary:

- **3x4 m (12 sq.m.), lodging small nuclear families.**
- **4x5 m (20 sq. m) or 4x6 m (24 sq.m.), ideal to shelter bigger nuclear families.**

Build the *Opỹ* following the shape of the traditional house, but with larger dimensions sufficient to lodge all the community in its interior.

COLLECTIVE SYSTEM

The collective activities, known as *potirõ* – collective work dynamic – correspond to a celebration and collective event of mutual action.

Call a big group of relatives who will live in the house. Call an expert in construction to manage the construction process; the invitation can include the other dwellers of the tekoá, even dwellers from other indigenous communities; the dwellers of the house shall make food and lodging available to the participants. Stimulate the changes and knowledge transmission among the people involved.

ORAL TRANSMISSION

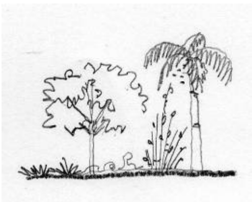
The knowledge of transmission is transmitted through practices and histories told by the elderly around the fire.

With the construction of dwellings, stimulate the transfer of traditional constructive knowledge to children and youngsters; enable the awakening of their aptitudes.

CONSTRUCTION TECHNIQUE

Technology is a resource to adjust to the environmental conditions, enabling the adaptive diversification.

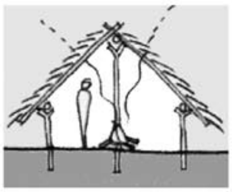
Make possible technologies demanding collective processes and consequently reinforcing the social rituals, make use of techniques adapted to the constructive materials available in the area.



MATERIAL

All the constructive materials are natural resources available in the Atlantic Forest's biome associated with symbolic and cultural values.

Use vegetal species and clay. In the *Opỹ,* choose sacred species preferably, such as: cedar (*yary*), the queenpalm (*pindó*) and the patagonula americana (*guajauyui*). Other materials which can be used are: the sweetwood (*ajuy*), mabola persimon , piptadenia (*kurupá pitá*), bamboo (*taquaraçú*), muskwood (*yywata'y*), cinnamon (*yvyra ovi*), vine (*yxypó eté*), witchgrass (*capi*), eugenia (*yva viju*), myrtaceous tree (*guavira*), philodendron - vine (*wembe'pi*), Brazil cherry (*anhangapiry*), stink insect (*takua ete i*) and dicksonia fern (*xaxim*).



WOODEN STRUCTURE

Wooden structure in Guarani is *oó ita*, *oó* meaning house and *ita,* base. *Itá* is the foundation stone sustaining the basis of the 'second earth' (*Avy Apy*) – the world they live today. *Itá* is related to solidity, stability and solid basis to the house (*oó*).

Pick arboreal species in the nearby forest, between 10 and 15cm in diameter, 2 and 3.5m in length, considering 1m more for the foundation. For the columns, choose trunks with one of the extremities in a fork shape to support the beams. Strip the bark from the trunks.

Build a rigid frame system with beams and columns, composed of three elements symmetrically arranged, using the bigger ones for the central portico and the smaller for the side porticos.

For the roofing, make available wooden rafters arranged perpendicular to the porticos. Tie the parts to the porticos with vine fastenings. When necessary, make grooves to fix the elements better and support the bamboo lathes longitudinally.

WALLS

The walls (*oó korá*) are very heavy, made of stud and mud, allowing the visual contact from the inside to the outside, hiding the dwelling interior spaces. The constant ventilation brings noise and smells with it.

Coat the building with round wooden trunks or bamboo. Dig a ditch 15cm deep and 10cm wide, approximately where the parts must be embedded and fixed vertically. Tie the parts with vine and apply a clay layer using the hand-made mud or coat with palm leaves.

4. Final considerations

The Mbyá Guarani indigenous community manifests the experience of its cultural trace through its interdependence relation with nature. It has the consciousness it is a part of the whole universe, fact mainly revealed by its spirituality. It values its symbolic and cultural elements using the oral tradition, aiming at transmitting to the future generations the elementary aspects of *nhanderekó* (way of being), thus, maintaining its culture alive. However, the non-indigenous society doesn't recognize this cultural trace. In this sense, this work tries to show in a summarized way some of their characteristics and their built environment, as a contribution on the discussion of sustainable development.

Some ideas of patterns of construction and space occupation are also presented, as dictated by the Mbyá Guarani's cultural trace. This work does not intend to clarify the deep and complex relation network existing between the Indians and the environment where they live, but it aims at trying to configure them as patterns. The experience is far from reaching the proposal presented by Alexander *et. al.* (1977), but, starting from this initial step, the work can develops, it is possible to consider and dream with more advanced results, reflecting the Mbyá Guarani's cultural sustainability and, hence, contribute to the re-evaluation of unsustainable patterns found in the current non-indigenous society.

ARCHITECTURE IN THE WILDERNESS: RECONCEPTUALISING PLACE THROUGH INTERPRETIVE ENVIRONMENTS

Ceridwen OWEN[1]

[1] School of Architecture and Design, University of Tasmania, Australia, ceridwen.owen@utas.edu.au

Keywords: regenerative design, ecotourism, Overland Track, wilderness, self-directed photography

Summary

Ecotourism is a burgeoning sector of the tourism industry and has been hailed as the fastest growing tourism sector at the end of the twentieth century and into the new millennium. One of the four criteria that differentiate ecotourism from the broader field of nature tourism is the objective of interpretation and education. Primarily this objective is concerned with the provision of information through a variety of textual, pictorial and verbal means. However, the opportunity also exists to consider a more active and reflexive form of interpretation through the design of the built infrastructure that supports and frames the tourist experience. The relationship between architecture and interpretation is implicitly recognised within ecotourism design guidelines but remains constrained by a dominant framework that views culture and nature as ontologically distinct realms. Nowhere is this relationship more pertinent or problematic than in the design of infrastructure within national park boundaries. This paper explores the complex question of the insertion of cultural artefacts within perceived 'wilderness' environments through a case study of the Overland Track located within the Tasmania World Heritage Area. Employing a visual-based methodology, the research shows how the built environment contributes to the interpretive experience of place and how this can result in a questioning of human/environment relations.

1. Introduction

Ecotourism is a burgeoning sector of the tourism industry and has been hailed as the fastest growing tourism sector at the end of the twentieth century and into the new millennium (Honey et al 2002). It is generally associated with pristine, remote places that exhibit cultural and, most particularly, ecological difference and it offers a relatively guilt-free environment in which to satisfy the desire for travel and adventure. The discourse is firmly entrenched within the dominant conception of sustainability, where nature is seen as a privileged 'other', untouched by humans, or at least by industrialised society (Hovardas et al 2006). Images of ecotourism destinations celebrate this ideology through the promotion of 'pristine' environments; however, a more complex question arises in relation to the facilities that support the tourist encounter with the natural environment.

Inevitably, the construction and operation of any facility results in impacts on the natural environment. Thus, the goal of the various ecolodge guidelines is to follow well-established sustainability principles that aim to minimise these impacts (Crabtree et al 2004, Mehta et al 2002, Hawkins et al 1995, Drumm 2004, Hyde et al 2005, Andersen 1993). This ideology of minimal impact and of nature and humans as ontologically distinct realms is also evident in the various references to the preferred aesthetic in the design of ecotourism facilities. For example, the International Ecotourism Standard states "Architectural and landscape plans shall ensure that ecotourism buildings and infrastructure are compatible with the physical and cultural landscape" (Crabtree et al 2004:9). Although there is a general lack of clarity on the intention behind such statements, there is an evident preference for a regional vernacular approach and a desire to 'blend-in' with the surroundings.

The lack of information on the issue of image and identity in the design of ecotourism facilities is not surprising since the primary focus of ecotourism is the external 'natural' environment and not the cultural artefacts of those who wish to visit. As Ceballos-Lascurain argues, "the most important thing about an ecolodge is that the ecolodge is not the most important thing" (quoted in Beyer 2003: 4). Thus, a common image within the niche ecotourism market is architecture that is minimal, temporary and insignificant. Nevertheless, the design of built infrastructure in ecotourism destinations still maintains a high degree of importance. For example, as Peace (2005: 321) argues:

> The promotion of ecotourism demands a higher degree of creativity than most other tourist sectors because the particularities of place have to be presumed to play a pronounced part in the choice of

destination. Ecotourists, it has to be assumed, are more concerned than most about the physical and aesthetic properties of locations in which they will spend their leisure time.

This low-impact approach to design is not problematic in itself, but it misses the opportunity to engage in a more 'regenerative' relationship with place. The term 'regenerative design' has emerged in recent years to challenge the perceived inadequacies and stasis inherent in the concept of sustainability (Lyle 1994, Moore 2001). Although sustainability is not tantamount to efficiency, the use, misuse and consequent renegotiation of this term has resulted in a reduction of its potency. Regenerative design diverges from this perception of sustainability in three key ways (Owen 2007). Firstly, it shifts the frame of reference from minimal to positive impact. Secondly, it questions human/environment relations based on the Cartesian separation of subject and object. Thirdly, it attempts to reconnect environmentalism with a socio-political dimension, which has been lacking in much sustainability discourse.

Thus, a regenerative approach to the design of ecotourism facilities should be focused on more that minimising impacts. Although these will inevitably form part of the pragmatic considerations such as siting, passive solar design and the use of renewable energy technologies, there are other opportunities for architecture to engage in a more productive engagement with place. One key opportunity is the relationship between architecture and the construction of meaning of place and identity (Owen 2007).

Interpretation and education is one of the core tenets of ecotourism that distinguishes it from the broader field of nature tourism. Primarily this is focused on a didactic form of interpretation based on brochures, signage, exhibitions and tour guides. However, the built environment offers other opportunities to engage in a more reflexive form of environmental awareness. The role of architecture in contributing to this imperative is implicit in the Design and Construct Standard within the premier global tourism benchmarking and certification program Green Globe, which promotes the goal of "Enhancement of the user's understanding and integration with the natural and social environments" before identifying the design of the 'architectural style' as a one of the key strategies to achieve this aim (Hyde et al 2005: 45).

There is a danger that such an agenda can be read as promoting a direct and universal experience of the world. Indeed Andersen (1993: 131) alludes to such grand aspirations by positing that "Properly designed, the ecotourism facility can become the window for human awakening to the world". I do not want to suggest that buildings can be 'read' like texts. As Leach (2006) argues, they are necessarily 'prelinguistic'. Nevertheless, architecture is inevitably part of any tourist experience and its role in the construction of meaning of place and identity cannot be dismissed (Lasansky et al 2004, Urry 1990). It does not simply address societal visions, but its very manifestation also serves to limit and structure the forms that these visions may take (Dutton 1996). This occurs not only through the visual realm, but also through other senses such as smell and sound, as well as the ritual activities and social relationships that the buildings support.

This dynamic and dialectical relationship between architecture and society is frequently debated within literature on place (for example Casey 1993, Malpas 1999). However, within sustainability discourse in general, and ecotourism discourse in particular, it is commonly ignored. Although certain theorists and designers have attempted to negotiate the culture-nature divide that is endemic within environmental and ecotourism discourse (for example Owen 2008), the uncritical ecological naturalism is a position that persists in the design of ecotourism facilities.

Nowhere is this culture-nature divide more strongly represented than in the design and construction of built infrastructure in wilderness environments. The term 'wilderness' is a highly contested term (Callicott 2003, Callicott et al 1998, Proctor 1998). It is generally conceived as a place that exists beyond the borders of civilisation and which remains free of human intervention. This notion is critiqued both from the practical perspective as to whether any such places actually exist, and from the theoretical perspective that challenges the ontological separation of humans and nature. A full review of these arguments is beyond the scope of this paper. Various definitions are possible to distinguish areas in which land, waters, flora and fauna remain relatively intact and 'untrammelled' by humans. Nevertheless, rather than the physical identification of wilderness zones, of greater significance for this paper is the emotional connection with the concept and experience of wilderness environments which can vary from person to person.

This paper explores these perceptions in relation to the design of built infrastructure in 'wilderness' environments through a case study of the Overland Track in Tasmania. The paper firstly addresses the background to the Overland Track and the visual-based methodological approach before discussing preliminary findings from the field research.

2. Overland Track

The Overland Track is Tasmania's most iconic and popular walking track with a significant profile both nationally and internationally (Whight et al 2006: 1). It is located within the Tasmanian Wilderness World Heritage Area, which comprises approximately 20 percent of the total land area in Tasmania and extends across a large area of the central-west and south-west of the State from Cradle Valley in the north to Cockle Creek in the south (Parks and Wildlife Services 1999).

The Overland Track itself connects the two ends of the Cradle Mountain-Lake St Clair National Park over 62.5 kilometres of walking trail. Although the area is now protected as a National Park, it was used extensively for trapping, logging and mining activities prior to its current use for recreational tourism. Tourism in the area first focused on Lake St Clair after it was 'discovered' by Frankland in 1835. Subsequently, in the early 1900s, tourism extended to Cradle Mountain with the establishment of the Waldheim Chalet by the pioneering tourist operators the Weindorfers (Byers 1996). Commercial interests in the region perpetuated well into the 1900s; however, increasing protection measures were enforced from the establishment of the area as a Scenic Reserve in 1922 and a wildlife sanctuary in 1927 (Byers 1996).

For some time, the two 'ends' of the park at Cradle Valley and Lake St Clair remained distinct and were administered separately. While several pioneers made crossings between the two ends, it was not until 1937 that the official linking of the two reserves via the newly named 'Overland Track' was completed via a marked walking trail. Administration for the park as a whole passed into the control of the Cradle Mountain-Lake St Clair National Park Board in the mid 1900s (Byers 1996). However, the division of the north and south zones perpetuated in the administration of the track itself by two separate field centres and it was not until 2003 that the Overland Track was managed as a single operation (Whight et al 2006).

The Overland Track is extremely popular, particularly during the summer months, attracting approximately 8,800 walkers annually (Whight et al 2006 based on 2004-05 data). Of these approximately 90 percent are independent walkers with the remaining 10 percent comprising guided walking groups. The popularity of the walk has led to the implementation of controls on the number of walkers from November to April. During these months, numbers are restricted to 60 people departing per day and all walkers must travel from north to south. The majority of the walkers are Australians from interstate (57 percent), followed by international visitors (35 percent) and Tasmanians (8 percent) (Whight et al 2006 based on 2004-05 data). The walk attracts visitors who have low levels of prior bushwalking experience, the majority of whom are aged in their 30s and come from professional backgrounds (*ibid*).

The length and popularity of the walk has seen the construction of a large quantity of infrastructure to support the tourist experience and to limit damage to the natural environment. In recognition of the intensity of occupation and consequent impact on the environment, the Overland Track is designated as a 'recreational zone' along a 1km wide corridor as distinct from the adjacent 'wilderness' and 'self-reliant recreation' zones. All Overland Track infrastructure is contained within this narrow corridor. Most significant built interventions are established at five key overnight nodes comprising Waterfall Valley, Windermere, Pelion, Kia Ora and Windy Ridge. An additional overnight node is available at Narcissus Hut for those who choose to walk the last section of the track rather than catch the boat across Lake St Clair to the Visitor Centre at Cynthia Bay.

At overnight nodes, huts, tent platforms and toilet facilities are provided for visitors. 'Free' camping is not permitted and in several cases raised boardwalks connect all key facilities at overnight nodes to minimise environmental impact. In addition, all waste, including toilet waste, is flown out by helicopter. Other forms of infrastructure along the Overland Track include various forms of track construction such as timber and stone steps, walkways in local and imported timber, treated pine boardwalks, hardened track junctions, raised earth causeways and a variety of bridges from simple bush timber logs to steel suspension bridges (Whight et al 2006). Limited signage and track markers are also located along the route including directional signage, locational signage and revegetation signs and snow markers. Where possible this signage is limited with further orientation and interpretive signage being restricted to overnight node locations.

Much of the track infrastructure has been implemented in a haphazard fashion and much of the current infrastructure is deemed 'unsympathetic' to the environmental context (Whight et al 2006). Major upgrades of huts and tracks were undertaken in 1986 and in 2005-6. However, the inconsistencies in approaches to infrastructure, particularly between the north and south ends of the track, are deemed to be problematic. As a response to this situation, the Tasmanian Parks and Wildlife Service produced a Draft Recreation Zone Plan in 2006 that outlines the strategic direction for planning and management of the Overland Track over the next ten years (Whight et al 2006: 2). One of the key aims of the vision for the track is that it will be a "distinct product that can be differentiated from other walking opportunities in Tasmania" (*ibid*: 6). To fulfil this aim, it is proposed that the track infrastructure, including huts, tent platforms, signage, and the track route, format and construction, be designed around consistent and recognisable themes based on the unique patterns of landscape, weather and historical occupation (*ibid*: 35).

The plan recognises the significance of the design of infrastructure on the quality of the aesthetic experience for the visitor. Although the report is replete with objectives of engaging with a 'sense of place' the specific guidelines for the design of the track infrastructure are more prosaic, promoting the popular minimal impact approach. This is emblematic of the limitations of design guidelines to describe such complex phenomena. Therefore, this research was undertaken with the support of the Tasmanian Parks and Wildlife Service to provide an alternative insight into the perceptions of place in relation to the design of built infrastructure in wilderness environments.

3. Methodology: Visual-based Research

The broad epistemological framework for this research is interpretivism, which is concerned with role of the agent in the construction of knowledge and meaning. This perspective acknowledges that there is no universal experience of an event or place and aims to give voice to different points of view that may otherwise not be heard (Bijoux et al 2006: 47). While this is a common position within the social sciences, there are numerous conceptual frameworks and research methods that are employed in order to interrogate the relationship between agent, experience and meaning.

This research employs a visual-based method as a means to extend interpretations commonly gleaned from language-based approaches such as interviews. While visual-based research has a relatively long history in anthropology, sociology, psychology and action research, it remains marginal to more conventional approaches (Bijoux et al 2006). It has also received very little attention within the field of tourism (Tussyadiah et al 2007, Balomenou et al 2007). Nevertheless, it is gaining in popularity in recognition of the benefits that it offers in a field that is dominated by the power of the visual image (Jenkins 2003).

Visual-based research comprises a series of methods including video and film, photography, drawing and mapping, and design as research. The majority of methods have focused on the researcher as the primary generator of the image (for example Prosser 1998). An alternative approach, in which the participant takes a more central role in the research, is self-directed photography, otherwise known as auto-photography, volunteer-employed photography, and reflexive photography.

This research method offers several advantages including the possibility of involving participants more closely in the research task, giving greater power and control to the participant, promoting participation through this empowerment, sharpening observation of the participant and overcoming the inadequacies of language (Bijoux et al 2006, Dodman 2003, Aitken et al 1993, Moore et al, Noland 2006, Balomenou et al 2007, Tussyadiah et al 2007). It is particularly appropriate for situations that involve the description of abstract concepts – such as the perception of place – since it provides an alternative to the verbal description of such complex phenomena.

There are also several potential disadvantages that must be considered. Since primary control is handed over to the research participant, results can be highly varied and not necessarily align with researcher expectations and interests (Bijoux et al 2006: 51). Thus the results can be highly subjective and differentiated, although this can also be an advantage when investigating people’s perceptions, particularly for initial exploratory studies (Balomenou et al 2007). The research method also involves a substantial amount of commitment of time and effort from research participants restricting sample group size (Bijoux et al 2006). Finally, although the use of cameras involves a minimum of training in most situations, the technology can be restricting and intimidating (Balomenou et al 2007).

The photographic images can be seen as a form of ‘text’ to be read and thus their meaning is constructed by both maker and viewer (Dodman 2003, Aitken et al 1993, Jenkins 2003). This can place increasing bias and power back in the hands of the researcher. To counter this tendency, self-directed photography is commonly combined with a verbal-based research method such as interviews and focus groups (Kerstetter et al 2007). However, in the tourism context such approaches are rarely feasible given the geographic diversity of the research participants. Nevertheless, further insight into the construction of meaning can be obtained by the use of solicited diaries in combination with self-directed photography (Bijoux et al 2006). In these diaries, participants are asked to provide further reflection on the content of the photograph and the reason for taking it.

For both content of photographs and diary reflections, directions are frequently open rather than prescriptive, but are directed along particular themes of interest (Bijoux et al 2006: 49). For the purposes of this research, participants were asked to document their perception of infrastructure on the Overland Track using a disposable camera by taking photographs of built interventions that provoked some kind of response. They were advised that built interventions could include examples of any type or scale that they liked or disliked or that they thought promoted either a connection or a disconnection with the environment. They were also asked to provide further reflective commentary in a booklet with approximately one A5 page per photograph.

Since this is a preliminary exploratory study, participant numbers were limited to ten visitors and four rangers. All tourists were selected from independent walkers over a period of two days in the peak summer season. This constitutes approximately 10 percent of all independent tourists departing over this period. Where possible, preference was given to the inclusion of a diverse mix of international, national and local tourists, of various ages and of both genders. Similarly, the rangers were selected as a representation of both genders from the north and the south ends of the Overland Track.

4. Perceptions of Place: Preliminary Findings

At the time of writing, data collection and analysis are still being undertaken. Thus far, 60 percent of tourists and 50 percent of rangers have returned the cameras and diaries. Of the tourists, three are male and three female, five are from overseas and undertaking their first walk on the Overland Track, with one being an inter-state regular bushwalker on the track. Most are professionals in the age range of 20 to 40 reflecting the general demographic of tourists on the track, with one participant over 60. The rangers are both male and are located at the north and south ends of the track.

A total of 130 photographs have been received with each participant taking between 6 and 24 pictures apiece. Of these, the majority explored a positive relationship with place (56 percent), with only 15 percent negative and the remainder representing mixed feelings. The main area of interest appears to be related to the track surfaces themselves (27 percent), closely followed by huts (23 percent) and signage (22 percent). The remainder are concerned primarily with tents and general infrastructure including toilets, waste and water collection.

The track represents perhaps the most direct relationship with built infrastructure on the walk, engaging the visual as well as acoustic and tactile senses. The varied and uneven surfaces draw the focus of attention from the ‘world out there’ to a more immediate and extremely localised frame of reference:

> *“It seems strange when there are so many stunning views that I need to look at my feet so much of the time. This scale of experience is often not thought about alongside wilderness.”* 9:3

This intimate 'scale' of experience provoked a range of comments from participants, from recognising the love, care and 'artistic' personality that has been put into the design and construction of the track, to an awareness of water flows, weather patterns, the impact of human occupation, the power and omnipotence of nature and the relationship between body and space (Fig. 1). Primarily these experiences were positive, promoting a stronger connection with the environment. However, there were also instances of disconnection, for example the connotation of highways through the use of bitumen-coated planks and the raised boardwalks that construct a direct physical separation from the landscape.

Figure 1 Intimate scale of experience on the track: body and space

Features such as boardwalks, bitumen planks and bridges prompted a mixed response from walkers, representing a conflict between a desire for safety and convenience versus a desire for adventure, as well as a desire for minimum intervention and a simultaneous recognition of the need for intervention to maintain the bushwalkers code of minimal impact.

A similar ambivalence featured in discussions surrounding the toilets, which are one of the more iconic and recognisable built features on the track (Fig. 2). The toilets are raised composting toilet structures, similar to those found in many National Parks in Australia. As a low-tech and familiar sustainable technology, these are seen as being appropriate in remote environments. However, the plastic 'sputnik' containers, which are used to remove the liquid waste by helicopter, present a more confronting image. For one participant, they provoked debate about social versus environmental priorities:

> *"Should we have to take ALL our waste with us??... How far do we take the pristine wilderness thing until we start excluding everyone?"* 9:9

Figure 2 Composting toilets and 'sputnik' waste containers, Pelion

Conversely, for this same participant, they also drew attention to the "*reality of the remoteness*." Thus, such 'alien structures', as another participant described them, also have the potential to reinforce the idea of a 'wilderness' experience. Discussing the ranger's quarters at Windy Ridge (Fig. 3), this participant stated:

"This pod is just cool…. I would say my sense of place at Windy Ridge hut has been increased because I will remember the "escape pod"…. Although it may not seem very rustic in terms of accommodation, it is still a unique aspect to the trail." 8:10

Figure 3 Rangers 'escape pod', Windy Ridge

The participant recognises that the accommodation departs from the accepted 'rustic' image of infrastructure in the wilderness. Nevertheless, it is still seen to reinforce the experience of place by providing a point of differentiation. The idea of the 'escape pod' also connects with other even more remote 'wilderness' worlds such as the deep ocean, polar regions or outer space.

Although the Overland Track is situated in a relatively remote region of Tasmania and surrounded by an expansive area classified as 'wilderness' the popularity of the walk led several participants to question the idea of a wilderness experience, with one participant arguing that it should instead be promoted as adventure tourism. While this participant was frustrated by the quantity of people on the track she also advocated improved facilities such as more huts, cooking shelters and even picnic tables at campsites.

Generally, overnight nodes prompted less criticism concerning the extent of human intervention. Aesthetic preferences remained framed in a desire for 'rustic simplicity', however this was contrasted with a desire for comfort and a tolerance or even welcoming of social interaction. Rather than the wilderness experience of the 'world out there', here photographs and comments focused on cultural metaphors of place. Participants appreciated the 'creature comforts' of the bench and the verandah as a point of mediation between 'home' and 'away'. For one international visitor, visually appealing huts reminded her of 'Swiss chalets' and 'neo-colonial African buildings' although her ultimate quest was to find 'Australian architecture'. For locals, huts and their associated infrastructure were more readily recognised as being grounded culturally in place. The 'Swiss chalet' is in fact Du Cane hut, an early example of pioneer building on the track and an icon of history for one of the rangers (Fig. 4).

Figure 4 Du Cane Hut

The meaning of the built environment is inevitably open to multiple interpretations in response to cultural norms and individual experience. Such ambiguity is not always desirable and more didactic forms of communication are also employed, particularly in the form of track markers, locational signage and environmental management information. The provision of such information is a balancing act between minimal intervention and effective communication. While the balance was generally seen as appropriate, in some instances communication was seen to be compromised. For example, a tin can on a stick provoked a positive response from one participant as 'rubbish' turned into 'wilderness way-finding infrastructure', while for another the same device was seen to provide insufficient security for a solo traveller.

5. Conclusion

The aim of this research was to explore how the built environment contributes to the interpretive experience of place. As these preliminary findings demonstrate, although more direct forms of communication are inevitably required, the built environment does provide an additional layer of interpretation that facilitates a more personal and reflexive engagement with place.

In particular, the experience of walking on the track itself prompted quite wide-ranging interpretations of place that extended far beyond the immediate frame of reference. The visual image remains the most powerful device drawing on both direct as well as symbolic connections (the tarmac road, 'artistic' personalities'). However, the interpretive experience is also enhanced by engaging the other senses, in particular the relationship between body and environment, which forces the more intimate and localised engagement with place while walking on the track.

At a more abstract level, the research demonstrates how the built environment can support the regenerative agenda of questioning human/environment relations. Rather than the 'low impact' approach to place, it was often the more confronting images, such as the scale of the toilets and the waste containers that prompted such consideration. These images do not necessarily provoke a negative response, but reveal complexities and ambiguities over the extent to which intervention is seen as necessary and desirable and the value of social versus environmental priorities. Furthermore, the insertion of 'alien technologies', such as the 'sputniks' and the ranger's 'escape pod', are not necessarily divorced from the experience of 'wilderness' but also reinforce images of isolation and unfamiliar worlds 'out there'.

These preliminary findings suggest that further investigation is required into the interpretive experience of place through the built environment. They also suggest that the dominant objective within ecotourism guidelines to produce a 'compatible architectural style' is limiting both for the interpretive potential of more confronting images as well as for the contribution of senses beyond the visual.

Summary

In order to intensify the use of industrial and mining wastes in the building sector as an environment friendly strategy, a research project was carried out to explore the possibilities of using different alternatives as raw materials to produce low impact construction components.

This paper refers to the segment of such research dedicated to development of pressed bricks containing different types of co-products and wastes from steel-making and marble and granite industries. The piloted mixes originated four experimental mixes that used wastes as binders, activators and different aggregates grading fractions.

Obtained physical, mechanical, durability and environmental characterization results for the bricks showed the potential for application as non-load bearing masonry components, with several possibilities for pigmentation and architectural composition. Simplified LCA analysis compared the environmental impacts associated to the production of the three types of bricks, making the superior performance of the proposed components evident. Industrial property protection applications were submitted concerning mixes, components and production processes.

1. Introduction

The awareness that the economic activities in the planet cause environmental problems deriving from waste generation, not always adequately disposed off, motivates the need of public policies so as to direct its use potential to decrease the consumption of non-renewable raw materials.

An adequate approach to the problem lies in the development of technologies and products aiming to reduce wastage generated in the whole productive chain, resulting in economically competitive solutions which also perform efficiently technical and environmental perspectives.

In this sense, the construction industry is an excellent ally, for being responsible for the production of assets and services with significant economic and social contributions, since it participates with 14.5% in the Brazilian GDP. At the same time, the huge housing deficit existing in the country, coupled to the high costs of basic inputs, incentive studies viewing new technologies, directing different researches in the quest for more economic products.

The establishment of new environmental paradigms propels the civil construction industry towards the integration of technology, economic and environmental performances, considering the whole life-cycle. Life-cycle analysis (LCA) is an internationally accepted methodology for environmental assessment, and aims to define an structured and holistic picture of production systems, allowing for a concrete and measurable visualization of potential impacts that each and every stage of a product's, process's or system's life-cycle may pose on human activities, the environment and natural resources.

In order to intensify the use of steel making co-products and marble and granite waste in the building sector as an environment friendly strategy, a research project was carried out to explore the possibilities of using such alternatives as raw materials to produce low impact construction components. This paper refers to the segment of such research dedicated to development of solid bricks.

The advantage of being able to incorporate steel-making co-products, such as blast furnace slag and different types of fines, positions the production of this brick as a potentially important contribution for reducing the consumption of non-renewable raw materials, while providing a more adequate destination for such wastes and allowing the implementation of public policies aiming at greater social inclusion.

For different reasons, both soil-cement bricks and solid ceramic bricks populate common sense imaginary as ecological products. Authors conducted simplified LCA analysis to compare the environmental impacts associated to the production of solid ceramic bricks, stabilized soil (soil-cement) pressed bricks and co-products pressed bricks.

2. Materials and methods

2.1. Materials

The materials used in this study are wastes originated at steel-making and marble and granite industries located in the metropolitan region of Vitória, ES, Brazil, as well as Portland cement blast furnace CP III-32-RS, gypsum, CH I lime, sodium silicate, and pigments. These materials were either applied as activators, fines to improve mix grading and compacity, or eliminated from the experimental mixes after pilot laboratorial testing.

2.2. Methods: physical and mechanical performance evaluation

As from an initial inventory, wastes with potential for use in the experimental mixes were preliminarily selected based on generation and storage data; on the chemical composition supplied by the company, with attention to the presence of harmful compounds and to the existence of potentially agglomerating compounds; on the information on environmental classification supplied by the company; on the visual analysis for the observation of qualitative requirements such as fineness, granulometry, color and humidity and on the company interest in recycling the wastes generated in function of the amount stored; monthly generation or of the environmental classification (Souza Filho, 2005).

Based on this assessment, seven types of co-products and wastes were selected and initially used in the study (Table 1).

Table 1 Source and average generation of the pre-selected wastes (NEXES, 2005).

Co-products and wastes	Source	Average generation (t/month)
Pre-calcitic lime stage	Calcination	1 700
Fine calcitic lime	Calcination	2 700
Blast furnace slag	Blast furnace	125 000
Dry-pit slag (gross)	Blast furnace	435
Sludge from the water treatment plant (WTP)	WTP	1 500
Marble and granite waste	Rock processing	10 000 (estimated)

Next, waste sampling was conducted, based on NBR 10007/1984. Waste characterization prioritized those with highest potential to succeed, such as ground granulated blast furnace slag (ggbfs) and dry-pit slag, which came from a known origin and showed promising results. Materials (Table 2) and wastes (Table 3) characterization encompassed physical and chemical tests, as well as micro structural analysis and environmental characterization (leaching and solubilization).

Table 2 List of materials studied and characterization tests conducted (Souza Filho, 2005).

Materials	Physical tests	Chemical tests
CH I lime Gypsum Portland cement CP III-32RS Sodium silicate Pigments	Fineness #200 (NBR 11579/1991) Fineness (NBR 9289/1986) Specific mass (NBR NM23/1998)	Chemical analysis

Table 3 List of wastes studied and characterization tests conducted (Souza Filho, 2005).

Wastes	Physical tests	Chemical tests	Microstructure
Dry-pit slag WTP sludge Ggbfs Ground marble and granite waste	Fineness #325(NBR 9202/1985) Fineness #200(NBR 11579/1991) Blaine surface area (NBR NM 76/1998) Humidity Bulk density (NBR NM 23/1998) Bulk density (NBR 9776/1987) Unit weight (NBR 7251/1982) Particle size distribution (NBR 7217/1987). Clay content (NBR 7218/1987) Clay and other fine material content (NBR 7219/1987)	Chemical analysis Qualitative chemical analysis by EDS	SEM Glass content Refraction index Particle size distribution (laser) X-ray diffraction

2.3. Methods: life-cycle analysis

LCA analysis was conducted using SimaPRO as a platform for data input and output interpretation aid. SimaPRO is a robust computer tool that includes a broad LCI database, which includes a diversity of raw-materials, energy scenarios, transport modes, production processes and waste management and treatment alternatives. This database was scrutinized for detection of commonalities with the Brazilian industry. All disparities were identified and local data was gathered and inserted in the platform. The boundaries set for the analysis encompassed, whenever possible, raw material extraction and semi-industrial transformation for manufacturing the bricks, excluding storage, distribution and post-manufacturing phases (use, reuse and maintenance, wastes recycling and destination) (SILVA, 2005).

Ecoindicator 99 is one of the possible environmental impacts evaluation methods to be used with SimaPRO. Such method considers in environmental impact valuation the influence of cultural values – and therefore personal preferences – on the results and the correspondent impact hierarchy. Based on distinct sociological, philosophical and psychological fundaments, criteria and weighting, individualist (I), equalitarian (E) and hierarchical (H) can be selected. In this work, the hierarchy perspective (H/A) was adopted, in accordance to GOEDKOOP; SPRIENSMA (2001) recommendations. Sensitivity analyses were carried out to investigate if and how the adoption of other cultural perspectives would interfere in the final results obtained. Scenarios with different types of cements available in the Brazilian market were also built, to allow for a more accurate evaluation of soil-cement bricks. For the complete analysis and discussion, see Silva (2005).

3. Production Process

Given current depletion levels of proper clay natural reserves, the search for alternative solutions for brick production has speculated on the suitability of different types of industrial and mining processes wastes (Malhotra and Theri, 1995; Ferreira et al., 2003).

For the production of the presented low environmental impact bricks, the same manufacturing technology used for soil-cement pressed bricks was used, according to NBR 8194/1984 specifications for the Type II brick class (23 x 11 x 5 cm). The co-products bricks however essentially incorporate wastes such as ggbfs (binder), sodium silicate (chemical activator) and dry-pit slag and different types of fines, such as rock cutting waste, WTP sludge (aggregates), contributing for reducing non-renewable raw material consumption, an efficient way of environmental preservation. Moreover, as burning is not necessary, there is an expressive reduction in energy consumption and, as a consequence, of environmental damages resulting from the manufacturing process (Silva, 2005).

Besides avoiding stockpiling or land filling of steel-making co-products, the proposed brick production dispenses both the soil and cement demanded for manufacturing soil-cement components, contributing for mitigation of environmental impacts inherent to excavation from natural deposits and reduction of energy consumption and CO_2 emission to the atmosphere. Furthermore, if damaged or broken, the bricks may be crushed and re-pressed, minimizing solid waste generation (Silva, 2005).

The bricks development and production phases encompassed waste sampling, reception control, identification and characterization of wastes and materials with potential for use, mixes piloting and selection of the experimental mixes, brick pressing and curing.

After the pilot mixes were tested, four experimental mixes were selected, using as components ggbfs, CH I lime, WTP sludge and a dry-pit slag and marble and granite waste. One of the mixes was formulated aiming at the use of as many types of waste as possible and, in this sense, CH I lime was replaced by rock cutting waste, without employing sodium silicate activator. The materials used in each mix are listed in Table 4.

Table 4 List of mixes tested.

Designed mixes	Materials
T-1	ggbfs, rock cutting waste and dry-pit slag
T-2	ggbfs, CH I lime, WTP sludge and dry-pit slag
T-3	ggbfs, sodium silicate and dry-pit slag
T-4	ggbfs, rock cutting waste, WTP sludge and dry-pit slag

According to Grande (2003), there is a relation between mechanical resistance and mix homogenization. A horizontal axis mixer was the most efficient alternative available and therefore chosen for this study (Figure 1) (Souza Filho, 2005).

Figure 1 Horizontal axis mixer (Souza Filho, 2005).

The bricks were pressed in a hydraulic press (Figure 2), resulting in excellent resistance and quality products. In real cases, such equipment would allow larger production scales, though presenting the inconvenient of being expensive and heavy (Grande, 2003; Souza Filho, 2005).

Figure 2 Hydraulic press (Souza Filho, 2005).

After being pressed, the bricks were stockpiled, respecting a maximum height of 10 bricks to guarantee the stability of the set. As a subsequent phase, the components were cured in wet chamber for 7 days (Figure 3).

Figure 3 Curing of the pressed bricks (Souza Filho, 2005).

The lab tests used for assessing components' properties were determination of compression resistance and water absorption (NBR 8492/1984), durability tests (dimensional variation and mass loss) adapted from NBR 13554/1996 and environmental characterization of the bricks (leaching, in accordance with NBR 10005/1987, and solubilization, in accordance with NBR 10006/1987).

4. Architectural possibilities

The pressed bricks, as a function of their production process, usually have the prismatic shape provided by NBR 8491/1984 of ABNT shown in Table 5.

Table 5 Types and nominal size of the soil-cement pressed bricks (ABNT, 1984).

Denomination	Dimensions (cm)		
	Length	Width	Height
Type I	20	9,5	5
Type II	23	11	5

The pressed bricks followed the specifications NBR 8194/1984 of the Brazilian Association of Technical Standards (ABNT) provides for the type II class of bricks, as can be observed in Figure 4a. The same standard requires that, when used, recesses on the brick's top and bottom surfaces must be 1.3 cm deep and placed at least 2.5 cm from the parallel edges.

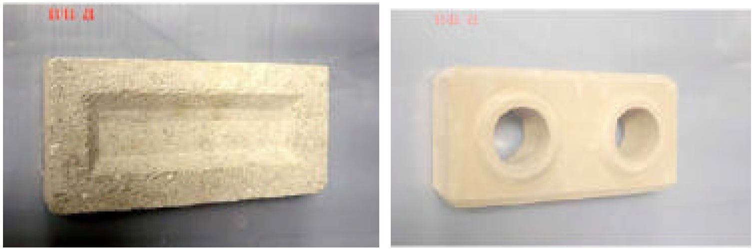

Figure 4(a) Prismatic brick with reentrance and (b) hollowed brick (Souza Filho, 2005).

Bricks with holes were also produced, with built-in fitting system (Figure 4b). Even though this system is not standardized, for the same mixes used for the solid components, the hollowed bricks reached good results concerning the production, handling and aesthetics. Satisfactory results were achieved for addition of 1% of pigment (dry materials weight). Brick configuration is variable to fit design needs and designer's creativity (Souza Filho, 2005).

Partitions and even facades walls using the co-products brick do not require plastering, as long as they are protected by the roof and waterproofed. Components' reduced weight, dovetails, and larger size further reinforce economic feasibility and execution easiness of the proposed masonry systems.

5. Presentation and discussion of obtained results

5.1. Physical and mechanical performance

Compression resistance and absorption results for the final mixes are shown in Table 6.

Table 6 Compression resistance and absorption results (Souza Filho, 2005).

Trace	Average compression resistance, at 7 days (MPa)	Average absorption, at 7 days (%)
T-1	11.25	17.58
T-2	15.38	15.90
T-3	12.34	16.43
T-4	14.50	15.63

When tested according to NBR 8492/1984, the bricks not only complied with the requirements, but attained compression resistance values at 7 days much superior than the 1.7 MPa, minimum individual value prescribed. Water absorption, an aspect that usually threatens most pressed bricks, was also analyzed and as well complied with the standardized limits.

Results measured according to a methodology adapted from NBR 13554/1996 Soil–cement: Durability test using wetting and drying cycles, when analyzed by descriptive statistics, showed no significant (lower than 1%) dimensional variation of the bricks.

Concerning weight loss, the results were again below 1%, by far complying with NBR 13553/1996 specification (Materials to be employed in monolitical non-load bearing soil-cement wall), which sets 10% as the maximum acceptable weight loss value for a granular soil.

Environmental characterization through analysis of the leached extracts showed that, for most parameters considered, concentrations were lower for bricks than for the original wastes, and that such results were extremely inferior to the maximum limits prescribed by NBR 10004:2004. As to the solubilization results, it was verified that the transformation process of co-products into pressed bricks was again beneficial, suggesting efficient encapsulation of most of the analyzed elements (Lorenzoni, 2005).

From the economic point of view, pressed bricks containing steel-making co-products and marble and granite waste would be economically viable and competitive (R$ 0.23, or USD 0.10, no subsidies included) for transportation radius of up to 20 km from the supplying industries. In same conditions, solid ceramic bricks would be priced around R$ 0.43 (or USD 0.20) (Souza Filho, 2005).

5.2. Life-cycle analysis

Ceramic solid bricks are perceived as ecologically-friendly in the south of Brazil, under the argument of using renewable fuel (firewood) for burning components. On their turn, soil-cement bricks are usually marketed in Brazil as ecological as well, under the argument of not needing to be burned at all.
When developing the Life-Cycle Analysis (LCA) of the production processes of solid ceramic bricks, soil-cement pressed bricks and steel-making co-products pressed bricks, Silva (2005) concluded that the latter masonry components presented the best environmental performance (Figure 5), independently of the cultural perspective adopted for environmental impacts inclusion, valuation and hierarchy, and of the type of Portland cement considered (either Portland Cement type CPI (95% of clinker) or type CP III (up to 70% of blast furnace slag as clinker replacement).
Aggregated impact for ceramic and soil-cement bricks showed to be similar, though the distribution among human health, and resource consumption impact clearly varied. The combustion of firewood constitutes the most significant impact flow of the ceramic brick production process. As well as other biomass elements, it is understood as "neutral" energy as the CO_2 emitted in the combustion is assumed as equivalent to the CO_2 absorbed during plant growth. It should not be forgotten, however, that the combustion of firewood generates other emissions that are not equally neutralized (methane, N_2O, NO_x and volatile mixtures except for methane, among other emissions).

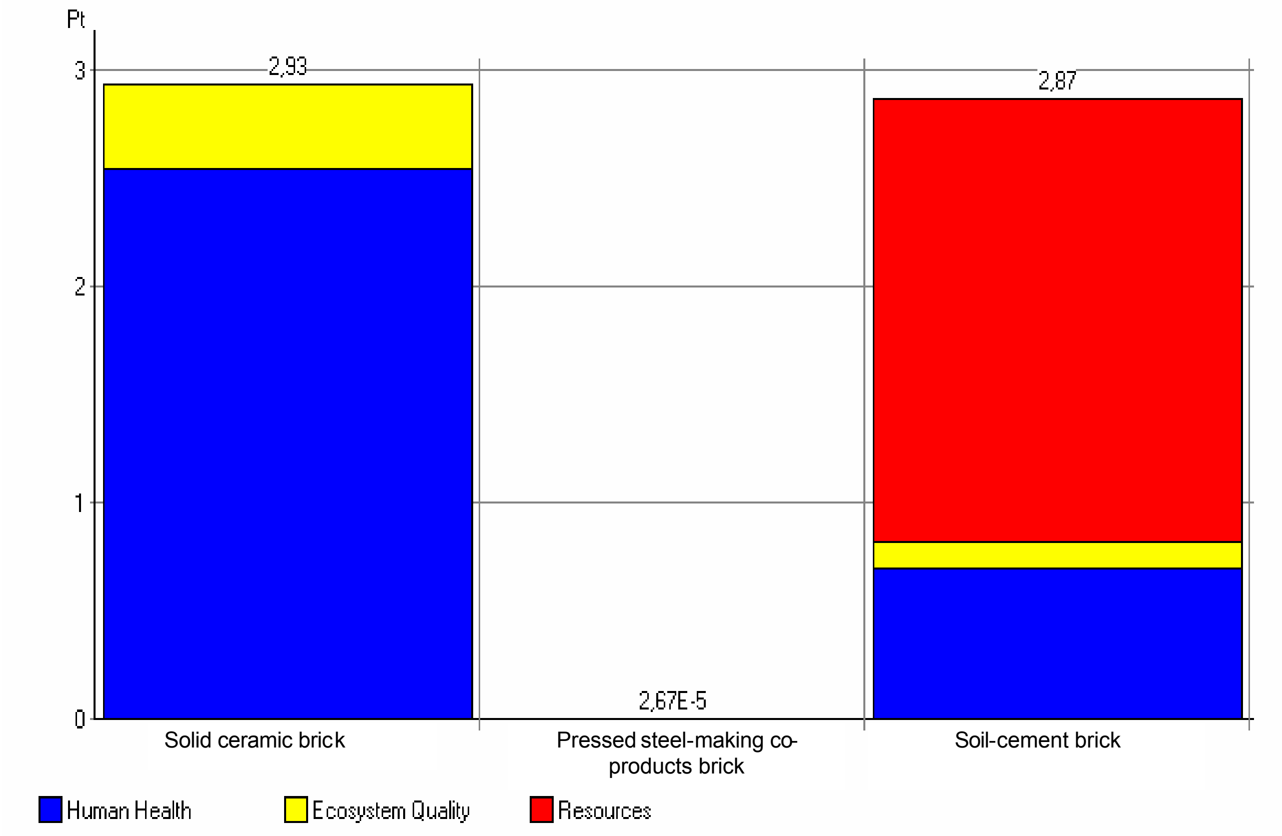

Figure 6 LCA results comparison for solid ceramic bricks, pressed steel-making co-products and soil-cement bricks (Silva, 2005).

6. Conclusions

The production of bricks containing steel-making and marble and granite waste showed to be viable under the economic, technical and environmental points of view, proving that finely crushed granulated blast furnace slag, dry-pit slag, rock cutting waste and WTP sludge are co-products with adequate characteristics for the production of pressed bricks.

The pressed bricks dispense burning, considerably reducing energy consumption for their production. Another advantage lies in the production process, which can be manual and easily assimilated, thus being suitable to several ongoing social housing programs. The components also offer costs benefits, excellent technical results for use as non-load bearing masonry components, and several aesthetic possibilities for pigmentation and differentiated architectural composition. The excellent physical and mechanical properties results obtained for the bricks suggest the viability of a large number of applications as other civil construction components, such as pre-cast flooring and paving blocks for bikeways and sidewalks.

As from the environmental characterization, it was observed that the transformation process of co-products into pressed bricks was beneficial, since most of the elements analyzed in the lixiviated and solubilized extracts were encapsulated and the pH of the samples analyzed.

Obtained LCA results objectively elucidated some interesting facts. First, because soil-cement bricks are frequently found in the literature as “ecological” bricks, as if having no environmental impact at all. However, the cement parcel in their composition should not fail to be considered, since it has important environmental consequences. Second, because ceramic bricks are equally advocated as environmentally more reasonable for using a renewable source of energy for baking the components. Nevertheless, they use non-renewable raw materials, are characterized by high energy consumption and/or high gaseous emission to the atmosphere (Silva, 2005).

This work, though not yet representative of the production practices co-existing within the Brazilian territory, contributes to overcome the initial inertia and trigger the construction of a national environmental database for building materials.

Keywords: aggregate, concrete, C&D waste, recycling

Summary

With the rapid economic development and urbanization, the demand for construction material is increasing vastly in China. Meanwhile，a large amount of construction and demolition waste (C&D waste) is produced in the process of construction and reconstruction. It is popularly recognized that it is a sustainable way to recycle C&D waste to meet the demand for construction material. Considering the present special phase of development in China, it is very important to develop a sustainable way to protect natural resources and reduce environmental pollution. Based on the statistic data on construction in China, the aggregate amount used in concrete will be demanded about 6400 million tons in 2010 and the amount of aggregate only used for hollow concrete block, concrete paving units, concrete porous bricks, solid concrete brick, concrete curbs is estimated about 74 million tons in 2005. And in same time, the amount of various wastes such as C&D waste, decorating waste is estimated about 812 million tons in 2005. So it has great opportunity to recycle the C&D waste in China. Considering the various recycling approaches it is possible method to used C&D waste to replace the aggregate in various concrete precast blocks.

1. Introduction

Nowadays resources, environment and development have become the subjects of sustainable development [1]. Facing the decrease of natural resources, environmental pollution and economic development，people hope to get to know the relationship between material consumption and social development especially population development and their mutual influencing factors from the past[2，3]，then obtain the approaches to sustainable development. We can't take it for granted that the environmental pollution will gradually decrease when the social economy has developed to some extent [1].The conflict between the decrease of natural material and the augmentation of environmental pollution is very conspicuous in the rapid development of social economy. Architecture has a great impact on resources and environment. It's effective to adopt the technology of reuse、recycling、and reduction which are named as "3Rs" to achieve sustainable development[4]. But the realization of technology sometimes depends on social economic condition. It needs social economic policies which can fit sustainable development [5]. Just like in China，a developing country which is developing very fast and whose industrialization, urbanization and modernization are still on the way, the resources can't satisfy the demand of development according to the present material-consumption model[6]. A quantitative calculation of resource consumption and the amount of reused resources is needed to make and carry out sustainable economic policies because it can provide foundation for the adjustive force of economic policies and choice of technology. From this point of view this, the demand of concrete and quantity of reused resource is estimated in this paper.

2. Analysis of the demand for construction material

2.1 Analysis of the demand for cement

The demand for construction material is increasing with the development of social economy and the enhancement of people's living standard. However, in different steps of social economic development, the demand for construction material is also in different levels. At the initial period of social economic development, we aim at meeting the basic demand of living, thus the demand for construction material is comparatively low; then at the middle period, we aim at meeting the demand of residence and activities, so the demand blooms; finally at the mature period, we aim at meeting the demand of mental life, so the demand scales down. The relationship between the construction material and social economic level can be demonstrated by the relationship between cement-consumption and Gross National Product (GDP) [7]. When the national income hasn't reached 10,000 dollars, the per capita cement-consumption is increasing. And when the national income is over 10,000 dollars, the per capita cement-consumption is decreasing. According to Chinese[8] and American[9，10] statistics, China's per capita cement yield and America's per capita cement-consumption since 1950 is figured out(Fig.1). From fig.1，we know that near China's per capita cement yield was less than 200kg in almost 30 years before 1990 and the demand for construction material developed slowly, for China was still in the initial period of development before 1990.Then after 1990,as the social economic development getting into metaphase, the demand increased quickly, by nearly three times in ten years. Looking at American per capita cement wastage, we can see that the per capita cement wastage didn't decrease but remain 300kg during its mature period. Furthermore, the consumption has increased continuously in the past ten years.

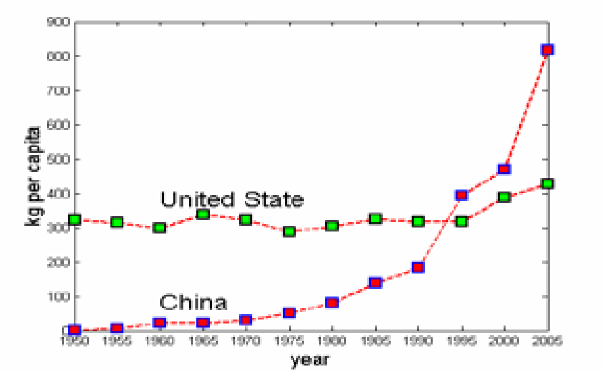

Figure 1 The Chinese and American per capita cement

If using the cement consumption of per 10,000 GDP (CCOPG) to estimate the demand for cement [12,13], we can figure out both China's and America's CCOPG, which is shown in fig.2. We can see that in America, CCOPG reduced gradually in the last 50 years, then it kept stable (about 895~810kg) since 1990.But in China CCOPG reached the maximum in 1980, then also kept stable as 4573~4418kg which was much higher than that of America since 2000.And this accords with the fact that China is a developing country while America is a developed country.

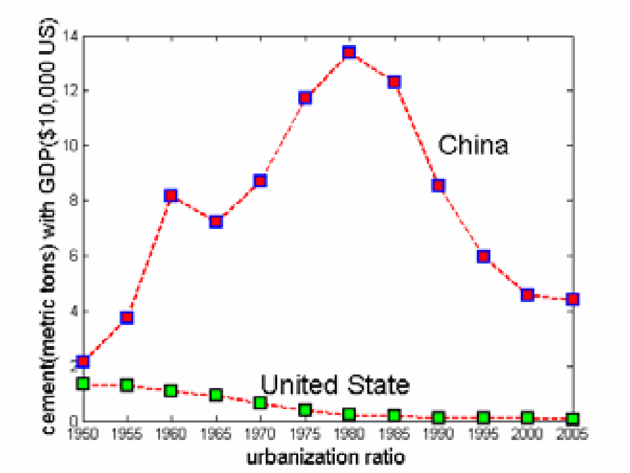

Figure 2　CCOPG in China and America

There is some kind of contact between the social economic development level or people's living standard and the degree of urbanization. Urbanization ratio reflects a country's economic development. So we could use urbanization ratio to reflect the demand for cement or its consumption [6]. As the Fig.3 showed, the connection between cement yield or wastage and urbanization rate is figured out in China and America from 1950 to 2005. We can see that it's difficult to establish a direct connection between cement yield or wastage and urbanization ratio. But it can also been seen that when the urbanization ratio is comparatively low (less than 50%), the cement consumption increases as urbanization ratio increases; while urbanization ratio is comparatively high (more than 50%),the cement increases slowly. But even if urbanization ratio reaches more than 80%, the cement wastage still increases.

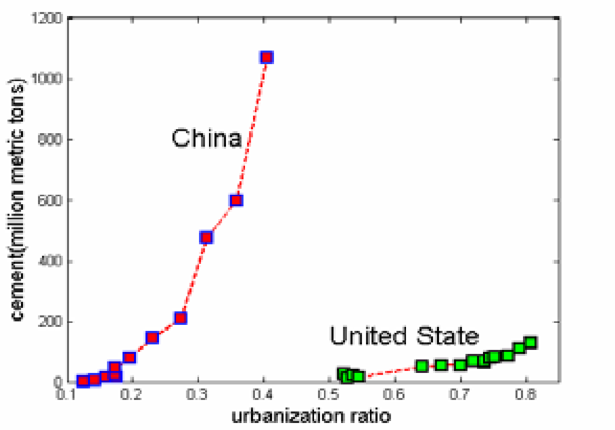

Figure 3　The cement yield or wastage and urbanization rate in China and America

As the law of the world urbanization proceeding step said: urbanization is in the elementary period when the ratio is under 30%, in the rapidly developing period when the ratio is between 30%-70% and in the mature period when the ratio is more than 70%. China and America are in different developing steps respectively. Urbanization ratio could reflect a country's economic development level, while CCOPG could also reflect it. The change of urbanization ratio and CCOPG both in China（1950~ 2005）and America（1930~ 2005）can be figured out ,as is shown in Fig.4, from which we could see a good continuous tendency. We proceed a polynomial fitting by the least square method with the data of China after 1980 and of America from 1930 to 2005.And a evaluator which reflects the connection between urbanization ratio and CCOPG is figured out, as is shown in Eqs(1). And urbanization ratio and CCOPG which are calculated with Eqs (1) are shown in Fig.5.

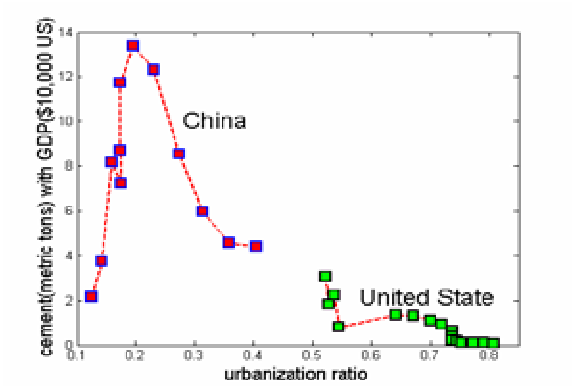

Figure 4 CCOPG and urbanization ratio in China and America

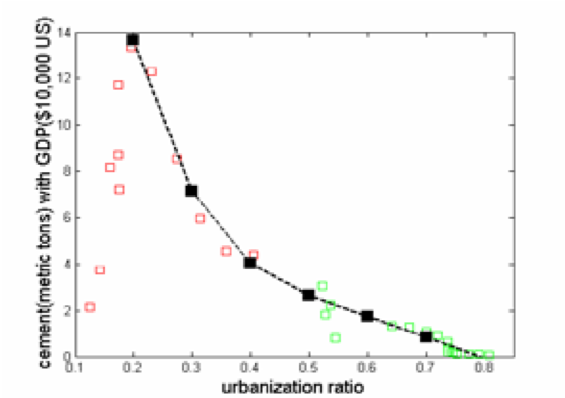

Figure 5 CCOPG and urbanization ratio

$$Y = 245.7X^4 - 633.3X^3 + 605.5X^2 - 263.4X + 46.8 \quad (1)$$

Where Y represents CCOPG（tons），X represents the urbanization ratio.

Substitute the predicted value of China's urbanization ratio [10] into Eqs(1) to calculate the future CCOPG. Based on the Chinese GDP of 2005, the Chinese GDP of 2010~2030 can be forecasted according to the economic growth rate, which is forecasted according to Chinese macroeconomic [15]. According to the CCOPG and GDP, China's demand for cement from 2010 to 2030 can be forecasted as Table (1) shows. In fact, China's cement yield of 2005 has already reached 1.069 billions tons. What are shown in Table (1) is comparatively conservative. But we can see that the demand for cement will increase continually in the recent 20 years.

Table 1 The Chinese demand of cement from 2010 to 2030

Year	urbanization ratio（%）	CCOPG（tonnes）	The rise ratio of GDP in5 years（%）	GDP (billion dollars）	The quantity of cement (billions tonnes）
2005	40.5	3.9475	8.1	2419.31	0.960
2010	45.1	3.2021	6.4	3571.25	1.211
2015	49.5	3.0167	6.4	4870.00	1.469
2020	53.6	2.7611	5.4	6641.05	1.833
2025	57.2	2.5064	5.4	8638.53	2.165

2030	60.5	1.4571	—	11236.80	1.636

Whether from national income or the period of urbanization point of view，China is still in the acceleratedly developing phase. Due to the large population，the demand for cement will increase quickly in the recent years [16] .

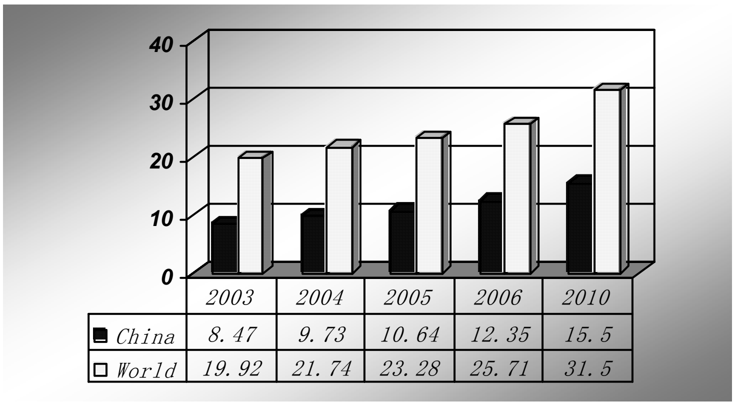

Figure 6　The cement yield in China and in the world(hundred million tons)

2.2　Analysis of the demand for the dinas

Dinas is the main body of the concrete, so the demand for it is increasing quickly as the cement-consumption increases. But owing to the decentralization and randomness of the dinas production, it's hard to make a precise calculation on true dinas production and dinas consumption. According to the assessment of dinas production from 2001 to 2003[17-19], the demand for dinas of each year and in the future could be estimated based on the ratio(1:4) of cement and dinas in concrete(Fig.7).The demand will reach 6.4 billion tons in 2010 in China.

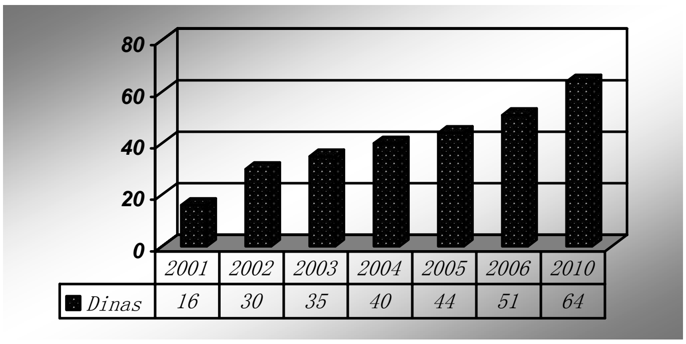

Figure 7　The dinas production statistics(2001~2006) and the forecasted quantity in 2010 (10 million tons) [17]

2.3　Analysis of the demand for the concrete products

The concrete products include concrete hollow block、concrete cork brick、concrete solid brick、concrete pavement brick and concrete curb stone, and so on. The demand for these products and their production are increasing quickly with the fast development of China's fundamental construction. From the yield from 2000 to 2006 shown in Fig.8, we can see that every kind of concrete products is on the rise. The consumption of concrete was about 74.41 million tons based on the yields of different kinds of concrete products in 2005.And the consumption of dinas was about 59.53 million tons based on the ratio 1:4 of cement and dinas.

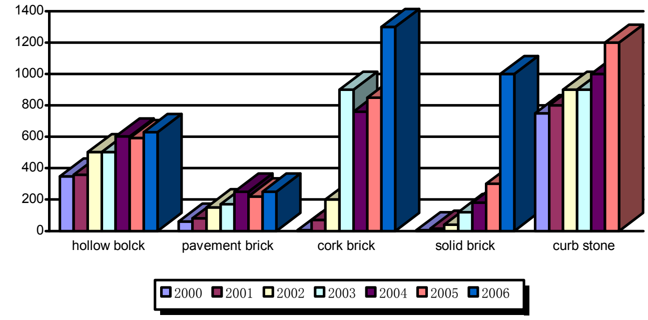

Figure 8 The yields of different kinds of concrete product (2000~2006) in China
concrete hollow block (hundred thousand m³) concrete pavement brick (million m²) concrete cork brick (ten thousand m³) concrete solid brick (ten thousand m³) concrete curb stone(ten thousand m)

3. Estimation and forecast of the quantity of C&D waste

It's inevitable to adopt reuse、recycle and reduction namely "3Rs" to meet the continuously increasing demand for construction material. The waste which is generated during the whole lifecycle of construction, decoration, maintenance and ultimate dismantlement is the best resources for reuse and recycle. There're different recycling technologies for different components in C&D[21].And using the C&D as main ingredient to produce concrete products is a way of recycling technology, based on the feasibility of economy and quality control.
The C&D includes constructing waste(CW)、construction decorating waste(CDW) and construction demolition waste(CDEW),which is generated during the period of building, using and demolishing. Because of the present mass construction and urban renewal in China, the quantity of C&D increases quickly. It provides a solving way for the large demand for construction material.

3.1 Analysis of the quantity of CW

The quantity of CW can be estimated via building area.30m^3 waste is produced in the process of constructing 1000m^2 building areas. The density of the CW is 1.5 metric tons/m^3, that is to say, 45 tons' waste is produced in building every 1000m^2 building areas. In China the total building area is 2275.88 million m^2 in 2005, so the quantity of CW is 102.41 million tons in 2005.

3.2 Analysis of the quantity of CDW

The construction waste of Shanghai in 1997 is calculated as 12.70 million tons. The residents in Shanghai have to pay 200~300 Yuan per family for the C&D in the decoration. Then we can estimate that about two cars of C&D are generated during decoration for every family. It means 4 tons of C&D are generated in each family, if a car of C&D is considered to weigh 2 tons [22].As is shown in the《Town building general statistics bulletin(2003)》promulgated by the construction ministry, per capita housing area of Shanghai has reached 29.4m^2, while the average number of family members of Shanghai in 2003 is 2.654 persons per family, namely, the average building area is 78m^2 per family. If we replace 78m^2 with 80m^2, we will get the result that the decoration of a 80 square meters' building will make 4 tons of waste. Meanwhile, referring to the data in Finland which are made by monitoring many construction scenes, they adopt 15~ 45 kg per m2 when estimating the CDW, which is similar to the estimation of Shanghai mentioned above. Considering the economic development degree of Finland and shanghai, the decoration of a 1000 square meters' building will make 35 tons of CDW.

In addition, data show that 10% of residents in shanghai decorate their houses, it means 10% of old buildings is decorated in Shanghai. Considering the economic development degree in Shanghai, I take 8% as the old building decorating ratio (OBDR) when estimating CDW all over the country in this paper.

The building area of countryside houses is neglected in the above estimation. On the one hand, the OBDR of countryside is much smaller than that of town, on the other hand, the quantity of CDW produced during decoration in countryside is also much smaller than that in town. So the town building area is taken as the radices of old building decorating area. The total building area in town is 16.451 billion m^2 till 2005, so old building area for decoration is 131.608 m^2 million. Thus the quantity of CDW is 4.606 million tons in 2005.

3.3 Analysis of the quantity of CDEW

The CDEW of every building relates closely to its structure. Generally 50~100m^3 or more CDEW is produced while demolishing 100m^2 building areas. As statistics show, a building with 7 layers and 49 households in Japan [22] makes 1.86 tons CDEW per m^3 .This paper takes 1.8 tons per m^3. RDC is defined as the ratio of demolition areas and building areas at the same time. According to the statistical data from 1996 to 2003 in China, the RDC was about 0.16[12]. The building area is 2275.88 million m^2 in 2005. The demolition area in 2005 can be estimated to be 368.69 million m^2. Thereby, the CDEW in 2005 is 663.64 million tons.

Add CW、CDW and CDEW to obtain the quantity of C&D. The C&D is 812.11 million tons in 2005 in China, and per capita C&D is 0.59 tons.

4. Analysis of recycle

The C&D is 812.11 million tons, while the consumption of dinas in concrete products is 59.53 million tons in 2005 in China. If the recycle utilization ratio of C&D can reach 8%, it could meet the demand for the dinas. Generally it costs 50 Yuan for a ton's dinas, so the output value of recycling dinas for producing concrete products could reach nearly 3 billion Yuan, while the value of the whole C&D could reach 40 billion Yuan.

Now 70% of Chinese building construction material is walling material, in which clay brick takes up predominance. We have to consume more than 1 billion m^3 of clay resources and 70 million tons of standard coals [23] to produce clay brick each year, which means to destroy field of 500 thousand mou. If the clays are substituted by C&D, we need a billion tons' C&D. At the same time we avoid destroying 500 thousand mou's field and save more than 70 million tons of standard coals.

Through the analysis, it is possible to realize material supply, production capacity and benefit when using C&D to produce concrete products. Meanwhile it has much developmental space and potential to recycle C&D for producing walling material, and has positive effect on saving resources, protecting land, reducing dissipation of energy, and so on.

5. Conclusion

Now China is on the way to industrialization, urbanization and modernization. In this special developmental period, a mass of different kinds of materials is demanded and simultaneously lots of waste and debris are generated because of China's large population. Carrying out the strategy of sustainable development and realizing the mode of recycling economy have become an urgent mission for China. The large demand for materials determines the importance of achieving recycle in construction field. According to the statistics both in China and America, the cement consumption of every 10,000 GDP has been related much to urbanization ratio. The analysis and estimation of the demand for construction material and the generation of C&D shows that it's possible to use C&D to produce concrete products whether from the point of material supply, production capacity or benefit. It has much developmental space and possibility to produce walling material with C&D, and it will bring positive effect to saving resources, protecting land and reducing dissipation of energy, and so on.

Keywords: waste management, on-site grinding, recycling, sustainable, residential

Summary

Residential construction sites present a number of opportunities for improvement in the management of waste.

This paper presents solutions for the management and minimisation of waste that were explored as a part of Australand's 'Best Practice in Waste Management' project. Australand, supported by the Victorian State Government Sustainability Fund, partnered with Sustainability Victoria to improve waste management practices on our residential construction sites around Australia.

Waste management practices are rapidly evolving in Australia. The management of construction and demolition waste is changing from the single activity of sending rubbish to landfill, to a more sustainable process involving reducing, reusing and recycling potentially valuable waste streams. This evolution is being driven by a number of business, social and environmental factors including: increasing cost of fuels; rapidly increasing landfill levies; legislative change; and increased community environmental awareness.

Australand adopted a comparative analysis of two development projects to trial a series of new initiatives and procedures to assess the effectiveness of current practices against the potential to be gained from improved waste management practices.

Sustainable waste management initiatives that were trialled and refined included:

Site waste management plans: As part of Australand's new Environmental Management Plan policy, construction sites are required to draft a waste management plan outlining recycling targets for the sites and methods for achieving these targets.

Waste separation: Many sites can now use a simple "one bin" solution where waste is sorted and recycled off site. Where regional recycling facilities are not available waste separation will still be required to achieve recycling targets

Waste Grinding: Australand has undertaken successful waste grinding trials in Victoria. Envirogrind Recycling was able to grind waste bricks, tiles, concrete and timber into valuable aggregate and wood chips which can then be reused on site.

These waste management practices have a number of environmental, social and financial benefits, which include:

- Preventing valuable resources from being disposed to landfill;
- The reuse of materials on site, which reduces the need to purchase virgin products where the reprocessed material is appropriate;
- Reducing the burning of fossil fuels and generation of greenhouse gases associated with decreased transportation of materials to and from the site

Australand is committed to demonstrating environmental leadership and continues to be proactively addressing sustainable waste management in all operations.

1. Project Introduction

Australand Residential recently conducted a waste management project, "Best Practice in Waste Management", which received funding support through the Victorian Government's Sustainability Fund. The aim of the project was to explore a number of options focussed on improving our performance in managing waste on site. Two similar medium density residential developments sites were selected as part of this project to provide a comparison. Each project had a similar number and nature of lots being developed and both were being developed on a similar construction timeframe.

Legend Hill is a medium density residential development on a green field site in Epping, on the northern fringe of metropolitan Melbourne. La Perouse is a medium density residential infill development on former golf course land at Bonbeach, in south east Melbourne.

Legend Hill provided the 'business as usual' site, while La Perouse was used to trial some waste minimisation initiatives. Both sites provided opportunity for innovation which could support improved waste minimisation performance for Australand Residential developments in the future.

Australand has previously trialled waste minimisation initiatives on residential development projects, including source separation, supplier take-back of packaging, pre-fabrication of components etc., and, where successful, has included some of these practices within day to day operations.

Figure 1 The two storey dwellings under construction at La Perouse, Stage 3, Bon Beach, Victoria.

2. Project Aims

With the support of the Sustainability Fund, Australand's "Best Practice in Waste Management" project, aimed to address objectives that included.

- Seeking a long term reduction in waste generation and in the volume of waste going to landfill;
- Gaining a better understanding of upstream drivers of waste generation and the most useful management levers to influence a reduction in waste to landfill;
- Trialling practical new concepts, technology and practices as appropriate;
- Promoting sustainability throughout operations through education and training of subcontractors and employees; and
- Developing a platform of understanding and experimentation for future work and improvement in Australand's waste management practices.

Australand acknowledged that this was an ambitious project, but sought to noticeably improve waste management performance through mechanisms such as its Sustainability Strategy and site specific Environmental Management Plans (EMPs),. The support of the Sustainability Fund provided a rare opportunity to review and evaluate some of the more challenging aspects of managing residential construction waste. The focus included data collection, performance monitoring, and capturing practical site based innovations, with the learning to be shared within Australand, and more broadly disseminated across the residential construction sector.

Australand's waste goal for the project was to reduce total waste generation and reduce volume of waste going to landfill by 50-80%. Australand has achieved this goal and exceeded it in some instances. The nominal recycling rate of material leaving the site was between 45% and 90%.

3. Site Waste Management Plans

It was determined that each site should have a site specific waste management plan that would be created as part of the site Environmental Management Plan (EMP). This has now been introduced as standard practice and has been included as a requirement of Australand's new site EMP policy.

This new requirement resulted in changes being introduced to our site establishment planning, daily site management practices and communications with site personnel. Both projects included in the trial were very busy and challenges included ensuring that sufficient area was set aside for collecting waste and managing the segregation of waste at the source where possible. The process also accounts for issues of site operations, signage, collection vehicle access etc.

Initially, our waste contractors did not process or recycle soil and many bins were being rejected for recycling and sent to landfill due to soil contamination. Australand was able to source a new waste contractor with soil screening facilities that enable soil to be recycled. This boosts our recycling rate by an additional 30%.

Australand had learned from previous waste management trials that the understanding and committment of all staff involved in the project would be required for any of the initiatives to be successful. To this end, a series of tools were developed to promote sustainability throughout our operations and to educate and train sub-contractors and employees including: subcontractor site inductions, regular discussions, posters, site signage and information handouts.

Ongoing reinforcement of the importance of waste management is critical and this involves promoting the value of recycling through site inductions and tool box sessions where on-site practices are discussed and personnel are kept abreast of changes occurring on the site.

A site induction handout 'Managing Waste at La Perouse, Your Responsibility as a Subcontractor' was developed for the site supervisor for issue during staff and subcontractor inductions. It outlines all the waste management systems and practices on the site, including requesting that subcontractors support the separation of discarded materials such as bricks, tiles and plasterboard, and that they place these materials in designated "drop zones" or on pallets for collection by the bobcat contractor for later recycling. The subcontractor information sheet was posted in the site office and staff lunch room together with the site's Environmental Management Plan.

An Australand Occupational Health, Safety and Environment (OHS&E) Induction DVD has been developed for use in the site induction process which involves all site staff and subcontractors. The 15 minute DVD addresses a range of site OHS+E issues including site cleanliness and waste management.

Australand also worked with waste management contractors to improve signage, data collection and provide regular performance reporting on waste management.

Australand Residential division conducts regular site audits to review OHS&E performance. The audit program has been modified to include the review of a range of waste management systems and supporting site based waste minimisation practices, ensuring compliance with resource efficiency initiatives.

4. Waste Separation and Supplier Take-back

Many sites in Melbourne can now adopt a simple "one bin" for waste recycling. This provides for waste to be collected in a mixed bin which is then sorted and recycled off-site, giving up to 95% recycling rates. These facilities were trialled for residual waste including concrete, plastic and metals, and are now being used as standard in Australand sites in Melbourne and Sydney. Reports for two Victorian sites that have had off-site recycling in place achieved 80% and 93% recycling rates in May 2008.

This system removes the very onerous requirement for ensuring that waste is separated into individual bins and is kept clean of contaminates. Previous trials undertaken by Australand Residential determined that the multiple bin solution was unsuitable for our sites due to space limitations, monitoring the content of bins and ensuring that all bins were close to the work area.

The recycling rates achieved were also enhanced by supplier take-back schemes for plasterboard, packaging, polystyrene from waffle pods as well as concrete recycling. Australand prefers to establish long term supply agreements with suppliers and these agreements include clauses pertaining to improved waste management practices including take-back, pre-fabrication etc.

Figure 2 *Plasterboard off-cut stockpiling awaiting collection.*

5. Waste Grinding

One of the key initiatives to be trialled in this project was the potential to adopt material recycling and re-use on site. Envirogrind Recycling Australia Pty Ltd was contracted by Australand to undertake waste material grinding during Stage 3 of construction.

The LaPerouse project offered opportunity for this trial as it was being developed in stages and areas of land in future stages was available for collecting and stockpiling waste materials for re-processing. This undeveloped area also had access to water for dust suppression during the grinding process.

Figure 3 *The Envirogrind Packer 750 mobile grinder & the 6m^3 tip truck.*

Initially bricks and tiles were stockpiled for reprocessing however, the Packer 750 mobile grinder used by Envirogrind can process timber as well as brick and tile materials. The grinder has the ability to capture and separate out gang nails and other miscellaneous metals from timber and on this basis, the range of materials for reprocessing was later extended to include discarded timber. The intention of the Envirogrind works was to reprocess this range of discarded materials into products that could be reused on site.

Envirogrind was also able to process plasterboard to produce a gypsum soil improver for clay soils, however Australands' take-back arrangement for the collection and processing of plasterboard was considered a better option resulting in a better use of the recycled material.

The bricks and tiles processed on site were reused in applications including the base aggregate for footpaths (prior to concreting) and also weather proofing surfaces for temporary paths and car parking areas. Any remaining crushed brick and tile material will was to be used as aggregate under driveways in Stage 4 of the development. The chipped timber material was used in broad area landscaping applications including mulch around large advanced trees planted in public areas throughout the site. The chipped timber was too coarse for mulching residential gardens however Envirogrind has indicated that processing the timber into finer grades will be possible in the future.

This was the first time that recycling and reprocessing of materials for reuse had been trialled on an Australand site in Victoria. Accurate data on the likely quantities of brick, tile and timber that may be generated during construction was not available from previous residential developments which complicated the programming of visits to the site by the Envirogrind equipment. As a result, the stockpiles of material were monitored by the site supervisor who contacted Envirogrind when it was considered there was enough material for reprocessing.

Three grinding sessions were conducted during Stage 3 of construction, which were over a two day periods due to the extensive stockpiles of material. Envirogrind has recommended that in future we should increase the frequency of grinding to regular intervals of every two to three weeks during the peak construction period.

5.1. First Grinding Session

The first grinding session was conducted about four months into the construction program. Only bricks and tiles were being stockpiled at this time. Envirogrind crushed the approximately $45m^3$ of material and deposited it directly into a $6m^3$ tip truck. This also enabled Envirogrind to transport the aggregate material to a preferred location on site for re-use and provide a measure the volume of material processed.

The final quantity of aggregate created for reuse was $39m^3$ which equates to the recovery of six and a half x $6m^3$ waste bin loads of brick and tile material for reuse and the saving of the purchase costs of new aggregate for use on the site.

5.2 Second Grinding Session

The second grind followed approximately five weeks after the first. Timber was introduced to the process this time, along with the bricks and tiles. The same process that was employed in the first session was followed. Bricks and tiles were ground and approximately $60m^3$ of crushed aggregate was produced. Approximately $30m^3$ of timber was chipped, producing approximately $18m^3$ of woodchips for reuse. In total this saved over fifteen x $6m^3$ waste bin loads of material leaving the site.

Figure 5 Wood and processed wood chips from grinding for landscaping use.

5.3 Third Grinding session

During this visit, Envirogrind Recycling processed 60 cubic metres of brick and soil resulting in 51 cubic metres of finished product of crushed rock supplied to Australand for re-use on site.

Australand contractors, in their enthusiasm to recycle all wood waste, inadvertently contributed treated wood to the pile. Envirogrind Recycling employees pulled this out and it was not recycled. The total wood ground on site resulted in roughly 25 cubic metres of wood chips being supplied to Australand.

5.4 Grinding Concrete Bricks

In the second grind there were a higher proportion of concrete bricks and pavers in the stockpile of materials.

The grinding had to be stopped part way through the process due to the teeth of the grinder being both worn and breaking off. It is believed that the concrete bricks, which are harder than clay bricks, may have contributed to the abnormal wear and tear on the teeth of the grinder.

Envirogrind is investigating a coating process which should help to reinforce the teeth of the grinder to improve the ability to grind these concrete bricks and pavers in the future. They are also looking at alternative crushers that are able to process harder materials, including basalt rocks commonly littering land in northern Melbourne.

As a result of all three grinding visits, a total waste diversion of 207 cubic metres, equivalent to 35 x 6 cubic metre bin loads, of waste was diverted from landfill. This waste was converted to a total of roughly 25 cubic metres of wood chips and 141 cubic metres of aggregate. This equates to approximately 30% of the waste stream being re-used on the site.

The on-site grinding initiative has a number of environmental, social and financial benefits, which include:

- Preventing valuable resources from being disposed to landfill;
- The reuse of materials on site, which reduces the need to purchase virgin products for the applications where the reprocessed material is appropriate;
- Reducing the burning of fossil fuels and generation of greenhouse gases associated with decreased transportation of materials to and from the site.
- Improved neighbourhood amenity and safety by reducing the amount of large truck traffic on local roads.

Figure 6 Left: Crushed tile and brick aggregate Right Concrete bricks which caused more wear and tear on the grinder.

6. Waste Collection

The site supervisors and bobcat contractors were observed to be key ‘enablers’ for improved waste management on site. It was evident that it was critical to involve them in the development, implementation, promotion and monitoring of waste management initiatives from the outset. It was important to ensure that this involvement did not add to their workload or distract from the core process of developing the project, and was able to be simply incorporated into the daily aspects of their roles.

At both the La Perouse and Legend Hill sites, the bobcat contractor was identified as a key person in supporting good site waste management practices. Consistently the bobcat contractor had a good working relationship with the Australand staff and other subcontractors on the site. One of the key roles of the bobcat driver is to maintain site cleanliness including keeping roads clean of mud, removing waste piles etc. The bobcat contractor is experienced with managing the materials discarded on site and, because of this, had a range of practical solutions to support better waste separation and collection. Methods of material separation and on-site collection practices are critical in improving the diversion of waste materials into recycling streams and these practices, if acknowledged and encouraged, will improve our waste management performance.

At Legend Hill, the bobcat contractor used a series of mini-skips, which could be carried by the bobcat, for the collection of materials. These mini-skips were placed in the front ‘drop zone’ of a house under construction enabling material to be placed directly into them. The mini-skips also helped by reducing the amount of soil contaminating the waste because discarded materials were not being scraped off the ground when collected and by frequently emptying and moving the bins as required. In addition, reducing the amount of soil that goes into the bins reduces the rate at which the bins fill, reducing the overall cost of collections and associated costs.

Figure7 Mini skip

The 1 m^3 mini-skips can contain about one tonne of material, which is the equivalent of four bobcat buckets, therefore the use of the skips reduces bobcat movements on the site.

At La Perouse the bobcat contractor sought to address similar issues of material placement and separation, which supported the recovery of bricks, tiles and timber for reprocessing on site and also plasterboard, which was collected by Clipstar Melbourne for recycling. Without the benefit of the mini-skip system, the bobcat driver sought to clearly designate ‘drop-zones’ for subcontractors. By using existing materials on site like old pallets, small areas were cordoned off on each house lot to define the “drop-zones” for the stockpiling of discarded materials. Waste materials were deposited directly onto the ground within the designated “drop zones”, so there was some soil loss associated with collection of this material. As with the use of the mini-skips, the practice of having designated “drop zones” helps to improve site cleanliness and reduce health and safety hazards.

The Legend Hill bobcat driver contracted the manufacturing of 12 mini-skips for use on construction sites. On the basis of the manufacturing costs of the skips, and the hire rate that Australand pay for their use, the period for cost recovery on the skips was 15 months each. Approximately six to eight skips are required for a 30 house development site.

Considering that the use of the mini-skips helps to improve site cleanliness, improve the quality of waste collected and also reduce bobcat movements on site, there are obvious environmental as well as occupational health and safety benefits associated with the use of the mini-skip system which must be considered for future projects.

7. Improving Recycling Rates

Australand staff and subcontractors worked well to divert a significant amount of brick, tile and timber material out of the waste stream and into the stockpiles for reprocessing. That said, over the course of the development these materials were still observed to be going into the general construction waste bins in small quantities. Ongoing reinforcement of the importance of separating out these valuable materials will be critical.

Promoting the value of recycling through site inductions and tool box sessions; reinforcing site practices such as placing these materials in designated 'drop zones' on each house lot for collection by the bobcat contractor; and staff seeing first hand the onsite reuse of these materials, will help to reinforce this waste minimisation initiative.

If Australand were to use soil screening products such as the innovative Australian product FlipScreen™ waste leaving the site would be further reduced by about 30%. Flipscreen is a soil screening attachment for a standard bobcat.

The collection of data relating to our volumes of waste has also highlighted the need to review our materials ordering processes, wastage allowances etc. This process will commence shortly.

8. Conclusion

Australand's "Best Practice in Waste Management" project has resulted in a number of changes to our waste management practices, especially in the areas of fomalising our approach to the issue though site specific EMPs, communication with site personnel and on-going collection of waste data. The project also resulted in us focussing on our waste management supplier agreement, seeking alternate waste management contractors who were more able to meet our needs and ultimately establishing an agreement with a new contractor. We have also paved the way for the introduction of new technologies including the mini-skip system, on-site waste grinding and a number of simple initiatives like the creation of "drop zones".

The grinding technology provides a sustainable approach to waste management, cutting waste to landfill by 30% or more and reducing resource depletion by using recycled materials on site. The technology also greatly reduces carbon emissions from transporting large amounts of waste off site. The trial diverted 130m^3 or almost twenty two 6m^3 bin loads of brick, tile and timber material into the on----site recycling and reuse program. There were issues with the amount of soil that was processed with the bricks and tiles and remained in the crushed rock aggregate. It is estimated that soil makes up to 30% of all construction waste as significant volumes topsoil are collected during site scraping and clean-up activities. On-site screening of wastes to remove and reuse soil could significantly increase recycling rates of the site.

The embedment of the lessons learned into our operational processes and the communication of the findings of this project in relation to the new technologies explored, will ensure that our waste management performance will continually improve into the future.

NATIONAL ACTION PLAN FOR CONSTRUCTION AND DEMOLITION WASTE AS FORMULATED BY THE INDUSTRY ITSELF

Rannveig Ravnanger LANDET Director /M.sc[1]

[1] The Federation of Norwegian Construction Industry, Oslo, Norway, firmapost@bnl.no, Rannveig.landet@bnl.no

Keywords: Construction and demolition waste, PCB, national action plan, cooperation, volunteer work, regulations, construction sector

Summary

In 2001 the Norwegian construction industry introduced its own National Action Plan for Construction and Demolition Waste in alliance with the waste and recovery industry. The plan was formulated and effectuated by people working in different parts of the industry: Producers of building materials, builders' merchants, property developers, contractors, architects, consulting engineers, demolition contractors, along with the waste and recovery industry. The work was coordinated by the Federation of the Norwegian Construction Industry.

Our main goals were:

- All hazardous waste shall be handled in a proper and safe manner
- No waste should be disposed in illegal ways
- 70 % recovery by the end of 2005

In 2004 recovery of construction and demolition waste had increased from under 20 % (1998) to over 60 %. By then collecting hazardous waste from demolition and refurbishment had become the object of much focus. PCB was regarded as one of the most important substances to keep out from landfills. The project introduced a new collection system for old windows containing PCBs. This system has been extremely effective.

The project had extensive contact with the national pollution control authorities. The main objective was to make the politicians agree that there was a need for national rules for handling construction and demolition waste. In particular there was need for a means of detecting hazardous substances in constructions that were going to be refurbished or demolished. 1. January 2008 we succeeded. New national rules on C&D-waste were introduced.

The National Action plan was evaluated in 2006 and a new plan for 2007-2012 was formulated. The cooperation between the actors in the construction and waste sector is continuing as is the cooperation with the authorities, but the construction sector is still in the driver’s seat when it comes to this Action Plan.

1. Introduction

In 1997 the major organisation for building material manufacturers, craftsman's enterprises and civil engineering enterprises in Norway decided to join forces. They established The Federation of Norwegian Construction Industries (BNL). The main issue was to provide services and deal with commercial policy, employer issues and internationalisation for member companies and associations. More focus on research and development was a part of this policy.

At the same time there was a new awakening due to environmental impacts from the building sector in Norway. More and more development projects were related to environmental issues. A group of persons from the construction industries established EcoBuild (ØkoBygg) in cooperation with the government authorities. EcoBuild carried out different reports which showed the environmental situation for the building sector. Amongst these there was a report that showed that probably 80 to 90 % of the construction and demolition waste (C&D-waste) in Norway were sent to landfills. Only about 10 to 15 % were reused or recovered. The data were in fact very insecure. Nobody had exact figures for the quantities.

It was also said in the EcoBuild report that about 40 % of the waste in the world was generated in the building sector. These facts were quite new to many of us in 1998. People who had worked in the construction industry all their life were not aware of the situation. In fact, the most frightening information in the report was that the construction waste contained a lot of dangerous substances, and that these substances obviously were spread all over due to lack of control with the general waste stream from the sector.

These facts, combined with an offer of help from the Green Warriors of Norway, made us decide to try to do something serious about the waste situation. In cooperation with the most important organisations in the building sector and the recovering industry, BNL carried out a status report on C&D-waste in Norway in detail (as far as it was possible at that time). The project was financed by EcoBuild and the participants themselves.

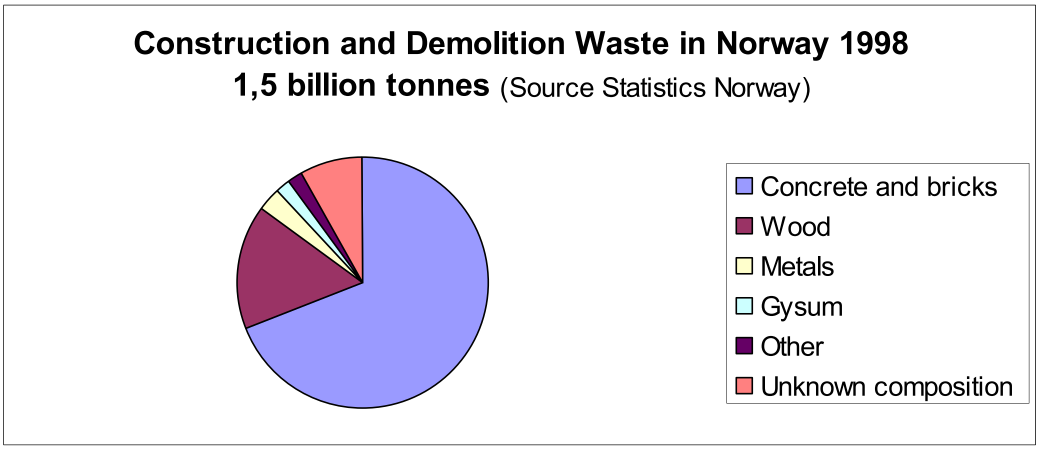
2. Results from the first Status Report

Our initiative was welcomed also by Statistics Norway. A reference group from the construction and the recovering industries was established to help the institution make better statistics for C&D-waste. Our status report contained the first generation statistics for this kind of waste in Norway, carried out by Statistics Norway in cooperation with us for the year 1998. Generated amounts were estimated on the basis of waste factors because no measurements were to be found. The figures are therefore uncertain.

The results showed that about 1.5 billion tonnes C&D-waste were generated in Norway in 1998 (the population of Norway was 4.4 million people). This does not include refurbishment waste from private households and excavations (clean soil and stone). The amount of C&D-waste was at that time about the same level as household waste in Norway.

The major part of the waste was generated from demolition (62 % of total weight), refurbishment generated 24 % and waste from new building projects 14 %.

About 70 % of the C&D-waste were concrete, bricks and other heavy materials. Then came (in decreasing order) wood, metals, gypsum, paper and cardboards, plastics, hazardous waste, insulations and glass. Unknown waste accounted for about 8 %.



Disposal (treatment) of the waste was not a part of the statistics due to lack of information, but it was believed that probably a minimum of 80 % of the C&D-waste was sent to landfills. There was more or less no control with the C&D-waste at the landfills, and it was assumed that quite a lot of it went to illegal landfills. This was known both by the state and local authorities, but, except for the capital of Norway (Oslo) and a few neighbouring municipalities –hardly anybody did anything to avoid the illegal filling.

Serious contractors that had an environmental policy and wanted to do a good job by sorting materials for recovery, had problems by getting contracts for demolition and refurbishment. They could not compete with companies that had “no costs” for sorting hazardous waste and “getting rid of it”. The customers, both from the private sector and public authorities, were not conscious of the environmental impact of C&D-waste (at least they did not want to acknowledge it). This lead to that the serious part of the construction sector was not able to demonstrate their environmental ambitions and take responsibility for the environment in building projects.

3. Working out a National Action Plan for C&D-waste

The first status report made it clear to BNL and our cooperating organisations from our own sector and the recovering industry that we had to act and take responsibility for what was going on. We had to stop further pollution from C&D-waste and recover more of the clean waste.

We gathered people from all parts of the sector for a work shop. This included producers of building materials, builders' merchants, property developers, contractors, architects, consulting engineers, demolition contractors, along with the waste and recovery industry.
A project manager was engaged. She reported to a core group which was lead by BNL.

More than 70 people from different companies took part in this effort. They were divided into 11 groups that worked with different fractions of C&D-waste, laws and regulations and others. After a period when the groups were working on their own with some help from our project leader, we had a last, joint work shop. The core group collected the information and developed it into a National Action Plan for C&D-Waste.

The whole effort lasted for about six months. The project manager was the only one who was paid. All other participants attended on a voluntary basis on behalf of their employees.

The National Action Plan for C&D-Waste was presented on the 15 February in 2001 and handed over to the Minister of the Environment. It had then already been approved by BNL's Executive Committee.

4. The main Topics of the Action Plan for C&D-Waste

Our vision: The building industry should have a reputation as responsible and offensive both as regards managing waste and environmental issues in general.

Our main goals:
1. All hazardous waste should be collected and disposed in a proper manner
2. Prevent illegal landfills
3. Maximum 30 % landfill within the end of 2005 (or: 70 % recovery)
4. Within the end of 2005 all new projects should be planned for generating less waste (minimizing) and more source segregation

To reach the main goals 27 action points were implemented. The most central point was to get new national regulations for C&D-waste and mapping before refurbishing. This was considered most urgent and would impact almost all other actions in the action plan, especially in relation to controlling the hazardous waste from demolition and refurbishment.

The construction industry had no instrument to force customers to take environmental issues into consideration before selecting a contractor. Of course they could do their best if they won the bid, but then there is the risk of loosing money on their projects. As everybody knows; only the winner gets the job. The serious tenders are therefore likely not to demonstrate their skills for handling C&D-waste. Unfair competition could only be avoided through legislation.

5. Implementing the Action Plan

5.1 Organisation of our Efforts

As for the implementation phase, this was based on volunteer work from the firms and people in the whole value chain of the construction industry and the waste and recovery industry. A networking group containing the 13 most important federations, organisations and government agency (Public Roads) was established to coordinate projects and take joint initiatives. This group was lead by a networking leader from BNL. A written collaboration proclamation of was signed by all parties. However, all participants were free to do as they wanted. There were also a lot of initiatives from different parts of the sector that worked separately to fulfil our common action plan.

To BNL it became most important to show that the serious part of the construction sector take responsibility for the environment, and the more we worked and showed results, the more positive attention we received.

5.2 Hazardous waste

The attention was however not always positive. After just at short time it became clear to us that our central goal had to be goal no 1: All hazardous waste should be collected and disposed in a proper manner. This included mapping dangerous substances in existing constructions, conditions that were not known to neither the construction industry, nor to the public at that time. This lead to one of our most important endeavours: to get control of PCBs in buildings.

We found that that the dangerous environmental pollutant PCB had been used in Norwegian constructions in sealants, floorings, paints, mortars, double-glazed windows, capacitors in light fittings, other capacitors and cable outlets in power supply units. Because the property owners and people in the construction sector had no ideas of this, most of the PCBs from refurbishment and demolition went to landfills (and maybe also as unknown pollution in recovered materials). This information (brought into light by us) was put on the front pages of the newspapers: “Glaziers are dumping poisonous windows at landfills” and related articles. This negative public focus is perhaps the price that you have to pay for bringing to light facts about dangerous substances in buildings.

In fact we did a lot to get control over PCB in buildings. In 1980 PCB was forbidden to use in Norway, but we still had a lot in existing constructions. At the time we started our work most of the remaining PCB in Norway was supposed to be in buildings. The Norwegian Pollution Control Authority assumed that there were about 450 pure tonnes. About 44 % of this, 200 tonnes came from double-glazed windows and 100 tonnes from capacitors in light fittings.

In the project period the authorities forbid PCB-capacitors in light fittings to be used in buildings, and existing capacitors had to be substituted by January 2008.

This is in short what we did regarding PCB:

- Mapping of PCB in buildings in Norway
- Developed and distributed the folder “Identifying of PCB in Norwegian Buildings”
- Established a return company for PCB polluted double-glazed windows. The return company, Ruteretur, should ensure that it would be no more expensive for the property owner to deliver their polluted windows to a recovery plant than to deliver a clean window
- In cooperation with the environmental authorities, made new regulations that forces property owners to participate in a return scheme for polluted windows.
- Campaign (including information brochure) to eliminate capacitors in light fittings from buildings in cooperation with the Norwegian Pollution Control Authority (who was responsible for inspections)
- Arranged a Nordic seminar on Demolition and PCB in buildings
- Developing courses in PCB refurbishing
- Speaking about PCB in different seminars and work shops for the construction sector

For people who do not know about PCB in windows we have to add that the PCB is found in the sealant behind the metal spacer between the two glasses, and not in the glass itself. These kinds of windows were much used in Norway during the period from 1965 to 1979 because they were insulating much better than the windows used earlier.

The action plan also dealt with other hazardous waste as e.g. CCA-polluted wood, asbestos, mercury, lead and others, but our main focus were on PCB because of the risks and the large quantities that were present in existing buildings.

5.2 Regulations of Construction and Demolition Waste (C&D-Waste)

As mentioned before, the construction industry had no instrument to force customers to take environmental issues into consideration before choosing a contractor. The lowest tender gets the contract. The price charged for mapping hazardous waste, refurbishment of this, source segregation and safe waste handling were not part of the most common contracts, including public sector contracts. Only through legislation could unfair competition be avoided.

This statement became vital trough our work with the National Acton Plan for C&D-waste. To implement a new practice concerning the handling of C&D-waste we had to argue with the environmental authorities and the politicians and request new regulations.

The Municipality of Oslo already had such a regulation which had been adopted the late 90s, and they were very satisfied with their results, but almost none of other of the 433 municipalities in Norway had any focus on this. They were not aware of the hazards in the C&D-waste either.

In 2002 the authorities introduced guidelines for handling C&D-waste, but they made it voluntary for the municipalities to implement the rules. This had almost no effect. Only some 30 municipalities adopted the regulations, and only a few maintained them. Our network had a hopeless job of encouraging all 433 municipalities to adopt the regulations.

5.3 Recycling

Recycling of different materials was a part of our action plan. The materials we gave priority were concrete and bricks, gypsum, plastics and cardboard, wood, glass, insulation materials, roof coverings, metals and electronics in buildings in addition to hazardous waste. For the two last ones there are regulations that state that you have to deliver these kinds of waste to certain plants, but as long as you don't know what materials are hazardous, they are not handled correctly. Skills for the right persons are key here.

With regard to concrete and bricks there were some ongoing projects where especially the Public Roads Administration, some major contractors (mainly Veidekke) and the recovery industry were participants. A lot of very important know how and reports have come out of these projects. These actors joined forces with our project.

The asphalt industry also had an ongoing project which was coordinated into our action plan. Because of a voluntary agreement within the sector they soon gained impressing recycling results. The agreement included a fee on bitumen.

5.4 Competence

The competence about C&D-waste was rather low in the construction sector when we started our effort. It was therefore of the utmost importance to increase the skills. In short this was done by:

- Developing guidelines for handling C&D-waste and spreading these
- Developing guidelines for handling of hazardous waste
- Developing a new Norwegian standard for removal of hazardous substances, disassembly and demolition
- Developing and holding pilot courses
- Giving lectures in different settings and sectors (many!)

All material developed in the project is free of charge. Our main goal in this respect has been to get as many as possible to make use of our guidelines and material.

6. Results: Did we reach our Goals?

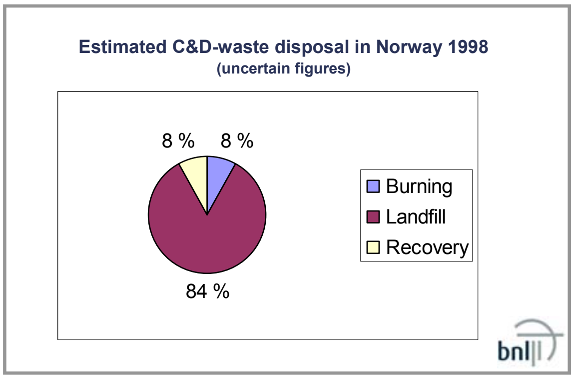
6.1 In general

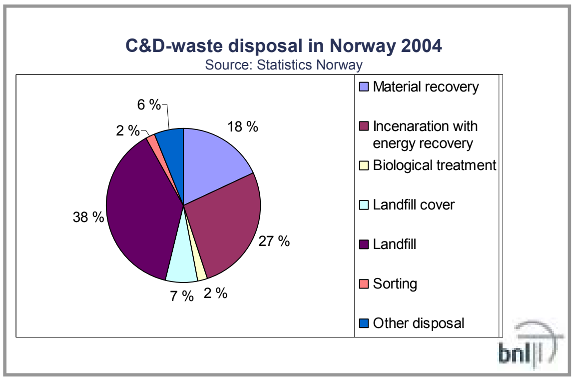
Only the most important results are reported in this paper. The full report is found on our common web site for environmental issues in the construction sector: www.byggemiljo.no (for the time being only in

Norwegian).

6.2 Recovery

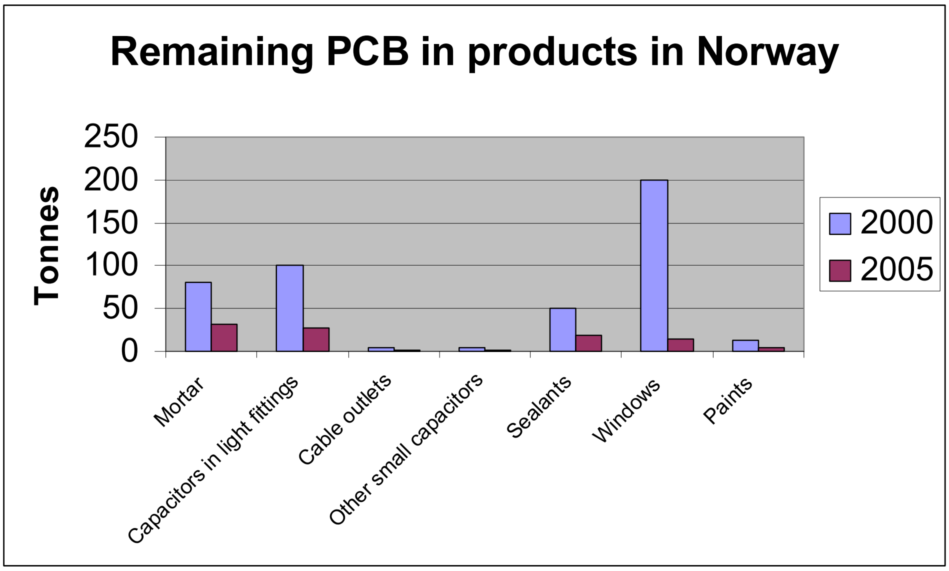
Our action plan was very ambitious at the time of implementation, 70 % recovery at the end of 2005 seemed unattainable when we started. Unfortunately Statistics Norway does not have statistics for the year 2005. Figures are shown below for the situation in 1998 and in 2004, one year before our first plan came to an end. (The situation in 2001, when our work started, is likely to be about the same as in 1998, but the data are very uncertain). It shows that in 2004 38 % went to landfills. It is therefore impossible to say whether or not we reached our goal; maximum 30 % landfill at the end of 2005. The fact is nevertheless that the recovery percentage has more than tripled in the period.





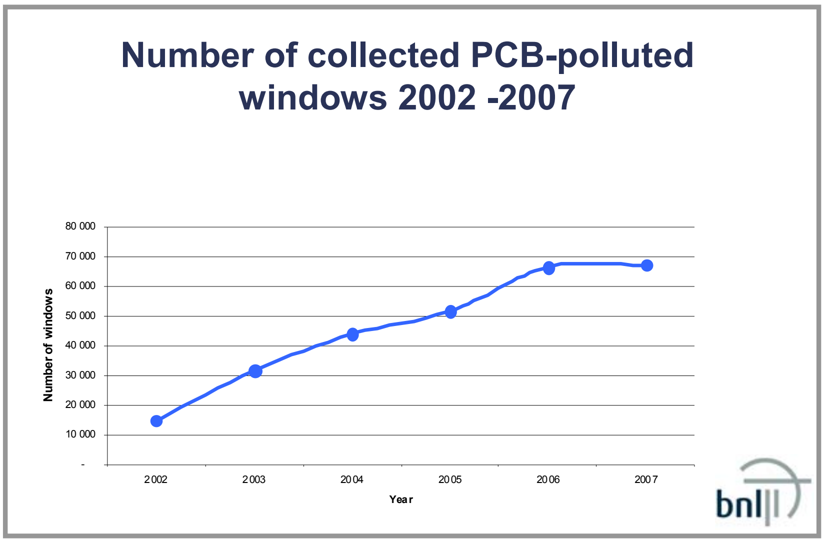
6.3 Hazardous Waste

In respect to hazardous waste we have statistics for collection of PCB from the Norwegian Pollution Control Authority. Remaining PCB in products has decreased from 453 tonnes in 2000 to 155 tonnes in 2005. The largest reduction in PCB was in windows and capacitors.



Source: Norwegian Pollution Control Authority

From 2002 to 2007 the collection of windows have increased from 15 000 to 70 000 pr year. This is approximately 100 % of what was expected to be the rate of yearly generated quantity of windows for condemnation. The effect of establishing of the return company Ruteretur has been remarkable, so has the effect of the campaign (and regulations) to end the use of capacitors in light fittings



Source: Ruteretur AS (www.ruteretur.no)

6.4 Breakthrough for National Regulations on C&D-Waste

At last, 1 January 2008, we could reap the results of our lobbying with regard to the political system. New regulations for mapping hazardous waste, refurbishment of this, source segregation and safe waste handling were introduced for the entire country. Our network in the construction industry is of course very satisfied, but if these national regulations had come in 2002, we could have been 6 years ahead with regard to practicing safe waste handling in the construction sector.

The new regulations give us great opportunities to get hold of all hazardous waste in refurbishment and demolition projects. The property owner has to carry out and show the local authority a list of all hazardous waste in the construction that is going to be refurbished or demolished. He also has to report how he is going to handle/deliver the waste. This means that the development firm will have to get the job priced, and the contractors will have information of what kind of waste he is going to handle. It is unnecessary to say that this is of the highest interest for the workers and their safety.

7. Further Efforts

In 2006 our network evaluated The National Action Plan for C&D-Waste of 2001. A new plan was implemented for 2007 to 2012[1]. This time as well all the work was done for free, on voluntary basis, except for the manager. You can find the report on www.byggemiljo.no (in Norwegian).

The cooperation between the actors in the construction and waste sector is continuing as is the cooperation with the authorities, but the construction sector is still in the driver's seat when it comes to this Action Plan.

Keywords: Green Building Material, Sustainable Building, Life Cycle Assessment

Summary

The Green Building Material (GBM) Labeling System of Taiwan proposed by the Architecture and Building Research Institute was officially launched in 2004 to systematically and effectively evaluate the performance of green building materials (Chiang 2004). The connotation of the GBM Label is mainly to enhance the built environment and to provide the actual benefit toward the concept of human health and earth sustainability. The system carries out quantitative assessments and laboratory tests based on a variety of measures in different stages of the life cycle of a building. Its criteria and standards are established accommodating with the subtropical climatic condition. In addition, the regulation of at least 5% mandatory green building material utilization has also been involved into Taiwan's Building Code and become effective since 2006.

The GBM system covers four major aspects, including Health, Ecology, Recycling, and High-performance (ABRI, 2007a). The Healthy GBM for improving the indoor environmental quality requires low emission, odor free, and no asbestos. The Ecological GBM typically includes low toxicity processing and natural materials without shortage crisis. The Recycling GBM aims to reduce wastes and to reuse abandoned materials and recycling aggregates. As for High-performance, it basically refers to the materials with high permeability and high noise insulation. By the end of June 2008, 131 Labels have been conferred covering 1,032 green products. Among these products, the healthy material occupies 74%, and followed by the high-performance category 16%, recycling 9.2%, and ecological 0.8%. The percentage distribution indicates the health issue has been highly emphasized and points out the development trend of the building material market in Taiwan. The latest statistics and relevant studies also show that the GBM Labeling System is well coordinated with the current local sustainable building evaluation practices and can be further applied to the development of the eco-community and eco-city in subtropical zone.

1. Introduction

Green building material is one of the basic elements of a sustainable building. The serious energy and natural resources shortage that our living environment is currently facing shows an imperious demand on developing a better building material certification and management mechanism. Followed by the promotion of green building evaluation and labeling more than a decade, the Architecture and Building Research Institute (ABRI) of Taiwan proposed the Green Building Material (GBM) Labeling system in 2003 and officially launched in 2004, shown in figure 1. The system aimed to promote a sustainable built environment for the earth and a healthier living quality for human beings. It was established based on ISO15686 series, ISO21930 series, ISO14040 series, as well as the Integrated Building Performance (IBP) system proposed by the EU, to ensure the evaluation criteria and standards meeting the current development trend of the world. Both of the global and local environmental issues, such as anticipated exhaustion of fossil fuels, increasing and fluctuated energy prices (Meadows et al., 2006), environmental pollution problems, high dependency on imported resources, high temperature and high humidity, a large amount of CO_2 emission from the building industry, as well as over 10 million-ton construction wastes generated annually, must also be taken into consideration to develop a comprehensive assessment tool for green building materials. In general, the assessment of green building materials begins with establishing criteria for evaluating the environmental performance of building materials. The criteria may incorporate low toxicity, minimal emissions, low-VOC assembly, recycled content, resource efficiency, recyclable and reusable materials, energy efficiency, water conservation, IAQ improvement, locally products, etc (Froeschle, 1999). The GBM evaluation system of Taiwan systematically comprises of four categories, including health, ecology, recycling, and high-performance. Its assessment mainly adopts the life cycle assessment approach, covering four stages of the life cycle of a building: resource exploitation, production, usage, and disposal and recycling.

Figure 1 Taiwan green building material label

Among the above categories, healthy green building material is the major promotional emphasis in the system. With extensive material usage of indoor decoration and remodeling for housing, the formaldehyde (HCHO) in building materials and volatile organic compounds(VOCs) emitted in a warm environment can result in fairly high risk to be harmful to health (Shao et al,2003). According to relevant research results (Wu et al., 2003), the risk values of carcinogens such as the formaldehyde in building materials and VOCs in office spaces in Taiwan are 100 to 1,000 folds over the WHO standard, causing people to suffer from respiratory and skin diseases. With respect to the relationship between the GBM labeling system and the current EEWH green building evaluation system in Taiwan, analyzed as table 1, the GBM system can typically contribute to a healthier indoor environmental quality. The issues of indoor air quality (IAQ) (Wolkoff••1998), indoor environmental quality (IEQ), and indoor environmental health (IEH) have been addressed and being further studied. From the perspective of the “Architecture Doctor (AD)” concept, now researchers and experts would diagnose causes of IEQ problems and prescribe recipes, for instance, strategies of green building and green building material application. The GBM labeling system can thus provide for architects or designers with proper measures that are capable of accommodating local climatic conditions and meeting people’s health needs. For ecology, recycling, and high-performance, the GBM evaluation items can also effectively correspond to green building evaluation indicators and feed back to green building design.

Table 1 Relationship between Taiwan’s Green Building Evaluation and Green Building Material Application

Green Building Rating System EEWH		Green Building Material
Category	Evaluation Indicators	Applications
Ecology	Bio-diversity	--
	Greenery	--
	Water Soil Content (Water infiltration and retention)	High-performance GBM (permeability), Ecological GBM, Recycled GBM
Energy Saving	Energy conservation	High-performance GBM (energy saving)
Waste Reduction	CO_2 emission reduction	Ecological GBM, Recycled GBM
	Construction waste reduction	Ecological GBM, Recycled GBM
Health	Indoor environment	Healthy GBM, Ecological GBM, Recycled GBM, High-performance GBM (sound insulation)
	Water conservation	High-performance GBM
	Sewage and garbage improvement	--

Since July 2006, the mandatory green building material utilization has been involved into Taiwan’s building code. For indoor decoration and floor materials in buildings, green building materials shall cover at least 5% of the total indoor decoration and floor material uses. Fulfilling the requirements of ecological, recycling, healthy, and high-performance attributes, the green building material regulation may effectively reduce environmental impacts and improve the IEQ, so as to gradually achieve “human health and global sustainability.”

2. Evaluation system, implementation and management

The major purposes of the GBM labeling system can be described in three aspects: 1) promotion of high-quality and healthy life; 2) protection of ecological environment; and 3) enhancement of industry competition ability. The system focuses on the entire building quality and effective management and control of human health risk factors. Its general requirement includes basic environmental protection aspects, such as no asbestos, no heavy metal, no radioactivity, etc. The evaluation system consisting of four categories is illustrated as figure 2 and described as follows:

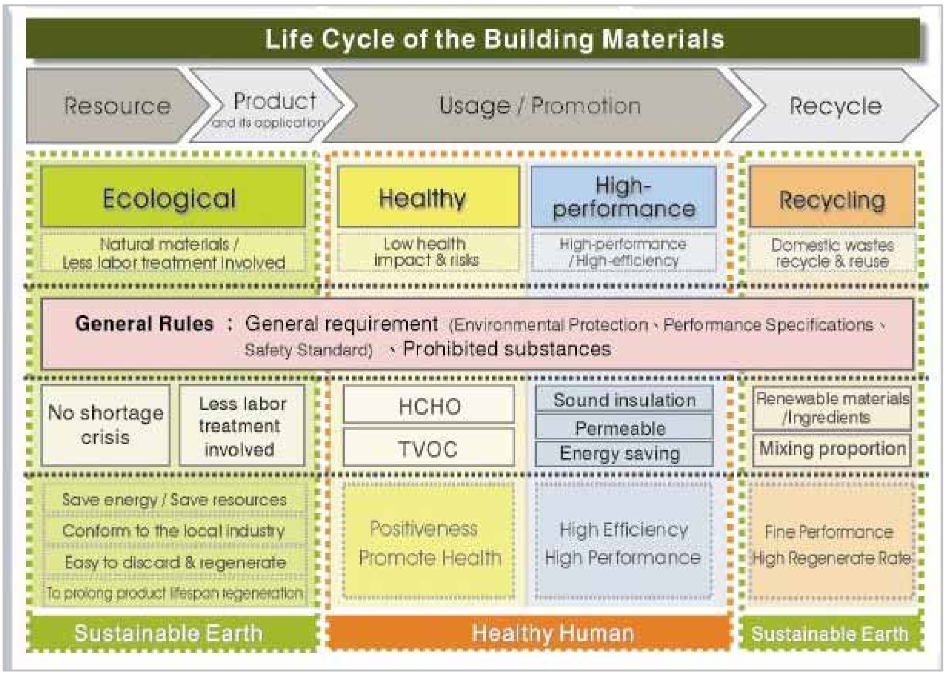

Figure 2 Framework of Taiwan green building material evaluation system

Ecological GBM:

What is taken from nature shall be used in nature. The Ecological GBM is that, during its life cycle, the building material fulfills general requirements, uses natural materials (Berge 2001) without shortage crisis, consumes minimal resources and energy, requires less labor treatment, or possesses recycled characteristics after disposal. The goal is to promote the natural building material that is good for both the environment and human health. For example, ecological wooden structure materials shall come from the forest with sustainable management. The assessment includes the certificate of FSC (Forest Stewardship Council), PEFC (Programme for the Endorsement of Forest Certification schemes), or other certificates of origin, shown as figure 3.

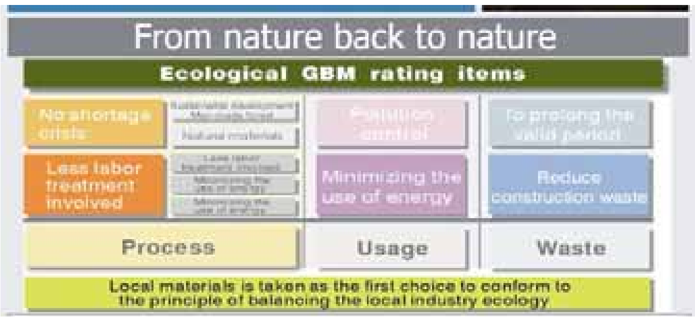

Figure 3 Evaluation of ecological green building material

Healthy GBM:

Since formaldehyde contained in building materials, and VOC_S added during the production of indoor construction materials, application and glue preparation, under the climate condition of high temperature and humidity, harmful chemical substances may be emitted in the air and directly affect human health and indoor environmental quality (Chen et al. 2006). Thus, the system focuses on the management and control of the relevant hazards. The test is based on ISO16000, and the standard is HCHO is less than 0.08 mg / $m^2 \cdot$hr and TVOC less than 0.19 mg / $m^2 \cdot$hr, shown as figure 4.

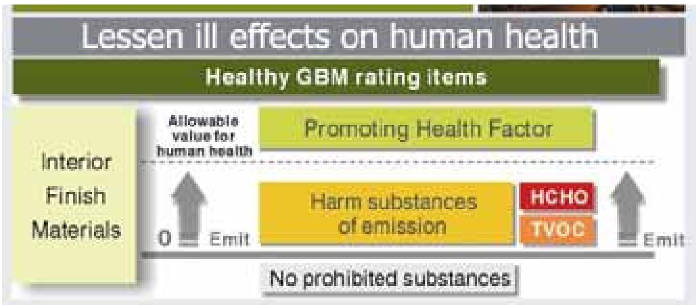

Figure 4 Evaluation of healthy green building material

High-performance GBM:

In response to the green building design issues, such as building environment noise, poor ground water retention, glazed curtain wall causing energy consumption, and the problem of dazzling sunlight, the environmental performance of a building material should be concerned and involved. By improving building materials to resolve the problems and increase efficiency, the system intends to promote building quality and standard of the living environment (noise insulation, permeability, etc), and also reduce entire energy consumption, which is in the scope of high performance green building material. The assessment includes ISO717-1, ISO717-2, ISO11654, and the test follows ISO140-3, ISO140-8, ISO354, and ISO9050, shown as figure 5. The approach also presents the harmonization with the ISO standards in Taiwan's GBM system.

Figure 5 Evaluation of high-performance green building material

Recycled GBM:

In order to reduce construction waste, and to reuse and recycle the materials, the system focuses on the regeneration of green building materials, in order to ensure basic functional demand, and improve reuse rate of waste materials, in order to achieve a sustainable society, which is in the scope of recycled green building materials. The assessment includes the types of recycled materials, their sources, and recycled content percentage, and its test is based on the ISO and Taiwan's CNS standards, shown as figure 6.

Figure 6 Evaluation of recycling green building material

For the practical operation of the GBM labeling system, the testing departments are national grade laboratories passing TAF accreditation. The factory owners of building materials can file the application and supply test data with TAF certification, proofs of production, ingredient and quality control, and registration document of its legality. Through the review by the Green Building Material Labeling Review Committee, suggestions of approval or rejection are given. For those who pass and obtain the green building material label conferred by the Architecture and Building Research Institute, the label is valid for 2 years and renewable. In terms of post-market management mechanism of green building material labeling, non-scheduled spot checks are implemented to ensure the use of the GBM label and the quality of green building materials.

3. Evaluation results and market trend analysis

By the end of June, 2008, 131 Labels have been conferred covering 1,032 green products. Among these products, the healthy material occupies 74%, and followed by the high-performance category16%, recycling 9.2%, and ecological 0.8%, shown in figure 7. The percentage distribution indicates the health issue has been highly emphasized and points out the development trend of the building material market in Taiwan. For a non-toxic and healthy architectural environment, as well as sound-proof and permeable function of building materials, there are 1,032 green building material products, including 379 building decoration paints, 56 wooden floors, 63 wooden boards, 92 gypsum wallboards, 71 inorganic boards, 2 organic boards, 1 rug, 3 glue preparations, 2 crack fillings, 11 soundproof door, window and wall systems, 3 floor coverings, 28 high pressure concrete ground bricks, 2 absorbent material systems, 194 permeable bricks, 73 ceramic face bricks, and 52 healthy PVC products. Mostly, paints ranked the highest, followed by permeable bricks, as well as wooden boards and gypsum wallboards.

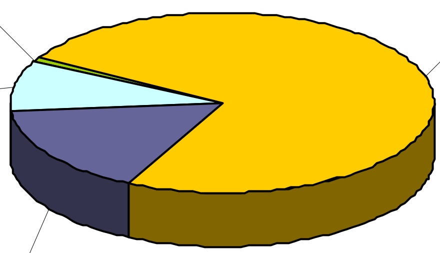

Figure 7 Percentage of four categories of GBM labeling promotion

Currently, the ratio of new and existing buildings is 3% to 97% in Taiwan. Using green building materials and green technology to improve indoor environmental quality and architectural environment, people can renew, reuse and prolong the life cycle and value of old buildings. Meanwhile, interdisciplinary integration of architecture, medicine, ecology, interior design and material technology transform traditional construction into a sustainable and circulating industry. Starting from energy saving and resource efficiency by combining an ecological circulatory system, corresponding local environment, community civilization, as well as historic and regional features, the GBM system creates a core concept of sustainable built environment in Taiwan.

4. Applications on sustainable building in the subtropical zone

Long-term research results indicated that the green building material evaluation standard should be based on its local environmental condition in the subtropical and tropical zone, which is applicable to the climate of high temperature and humidity. The GBM system also should be able to be applied to green building design and IEQ improvement. Building materials that meet the standards of the GBM labeling system may be used in various green building evaluation indicators. For example, indoor building material construction evaluation and sound environment evaluation among indoor environment indicators encourage the use of all of healthy green building material, ecological green building material, recycled green building material, and high performance soundproof green building materials. Specifically, preferential credits are adopted in the green building rating system to reward ecological green building material uses. In addition, soil water content indicators may choose high performance permeable green building pavement materials to increase water retention and storage. It is to alleviate the effect of urban heat island effect and reduce the capacity of a public drainage facility, as well as the occurrence of city flooding. The recycled green building materials meet the demand of CO_2 and waste reduction indicators. It can reduce the environmental burden caused by waste accumulation and the expenditure resulting from new resource development. High performance energy-saving glasses may respond to the daily energy-saving indicator for reducing energy consumption.

The application of Taiwan's GBM Labeling System on sustainable buildings in the subtropical zone focuses on the evaluation of chemical and physical building material evaluation. In response to the climate of high temperature and humidity, biological factors are added into items of evaluation (Wu et al, 2005). In a continuing effort of research and national policy, emphasis is on the ecological city in tropical zone. From green building materials, green construction, eco-community, and, furthermore, eco-city, a complete circle has been constructed to build a healthy and efficient sustainable homeland. The promotion experiences of green building materials and green building technology can be expanded to the living environment of countries in the subtropical/tropical zone and responded to the theme of SB08: "Connected, Viable, and Liveable."

EFFECTS OF ENERGY SAVING MEASURES AT RENOVATION

Margaretha BORGSTRÖM Ph.D[1]

[1] School of Business and Engineering, Halmstad University P O Box 823, 301 18 Halmstad Sweden, Margaretha.Borgstrom@hh.se

Keywords: energy saving measures, dwellings, multi-dwellings buildings, renovation

Summary

This study focuses on the necessity of having knowledge about different energy saving measures when renovations and reconstructions are planned and designed. It is also of great importance to have routines to follow up what effects the actions taken have had on the energy consumption as well as on the indoor climate when the renovation is completed. A big part of the existing buildings in Sweden are built during a ten-year period between 1965 and 1974. When these buildings are to be renovated there is a great potential for energy saving.

1. Introduction

The Swedish government attaches great importance on energy saving. The goal for the government is to reduce the total energy consumption per sq. meter heated floor space in dwellings and non-residential premises with 20% until 2020 and with 50% until 2050, compared with the energy consumption 1995. The use of energy for heating and ventilation can be minimized if the houses are well-insulated and have a controlled air-exchange.

Many dwellings in Sweden were built during a ten-year period between 1965 and 1974. During this period, there were no requirements on low energy consumption in buildings, so there when these buildings are to be renovated there is a great potential for energy saving. Common energy saving actions are:

- replacing the windows with windows having a low U-value or adding one more pane of glass
- supplementary insulation in the attic
- supplementary insulation of the outer walls
- sealing of windows and doors
- adjusting the heating- and ventilation system
- use of heat recovery system

According to SABO (The Swedish association of municipal housing companies) the interval between façade renovations, change of roof-material or change of windows is 30-40 year. For adjusting heating system the interval is 10 year. Energy saving measures in connection with renovation of facades and roofs are supplementary insulation and changes to more energy efficient windows. Buildings that will be affected by such measures are built from about 1961 to 1980. During this period a large number of dwellings were built in Sweden, about 996 000, which corresponds to about 41% of all dwellings in multi-dwelling buildings in Sweden 2006.

About 30% of all dwellings in multi-dwelling buildings existing the year 2006 have been reconstructed between 1976 and 2006 SCB (2006). Of the dwellings built 1961-80 about 15% have been reconstructed between 1990 and 2006. According to Boverekt (2003), about 50% of the dwellings renovated between 1975 and 2002 have been subject to façade renovations, and on about 56% of the dwellings actions have been taken on the roofs. These measures can be change or repair of the facing, possibly combined with supplementary insulation.

Energy saving measures on the ventilation system consist of adjustments of the existing system and installation of heat recovery system. About 60% of all multi-dwelling buildings in Sweden built before 1975 had natural ventilation in the year 1980, which corresponds to more than 1 million apartments. About 700 000 apartments built before 1975 had in 1980 original mechanical exhaust ventilation. During the 1950´s balanced ventilation was introduced and at 1980 this kind system was used in about 100 000 apartments. When the buildings were modernized in the period 1975 to 2002 about 400 000 apartments have changed ventilation system, totally or partly. 54% of the renovated apartments in multi-dwelling buildings have a changed ventilation system in 2006 Boverket (2003).

When reconstruction/renovating buildings it is important that the actions taken result in buildings with both low energy consumption and a good indoor climate. To obtain knowledge about the effects it is necessary to follow up the energy consumption and to evaluate the indoor climate. Experiences in form of successful solutions and how to avoid bad solutions must be transferred to future building projects. It is necessary that the developer demands low energy consumption and a good indoor climate early in the planning and design phase both when houses are constructed and renovated.

The selection of methods used in renovations are in many cases based on recommendations obtained from computer programs. After renovation very little feedback is received on how effective the energy measures were, whether the energy goal has been reached or if the computer program has given reliable results.

2. Energy efficiency buildings with a good indoor climate

2.1 Energy efficiency in planning and design phase

One example of means for assistance in the planning and design phase for energy efficiency buildings is the so callad “Energilotsen” produced by the companies Skanska Teknik, Cementa, Strusoft and Lunds institute of technology, www.energilotsen.nu. The city of Stockholm have produced a written report called “A program for environmentally adapted construction (miljöanpassat byggande vid nybyggnad)” to help the client to specify his demands in order to obtain energy efficient and sound buildings when constructing multi-dwelling buildings Stockholm Stad (2006).

The project “Teknik för hållbarhet I 50-60-70 talens bostadsområden” has compiled good experiences and facts about measures that enhances the environmental aspects at renovation. The research group has not evaluated the measures Vidén (2004-).

2.2 Evaluation of indoor environment

Today there are many different methods for evaluating the indoor environment. One example of a method to estimate both the indoor and outdoor environment for buildings is the so called “Ecoeffectmetoden”. This method shows the effects concerning energy consumption, use of material, indoor environment, outdoor environment and lifecycle costs. The indoor environment is evaluated by questionnaires, technical measurements and by looking at critical details. Glaumann (1999). One other method is the so called “P-märkning” where the indoor environment is evaluated by inspection and measurements. Defects are measured SP (1995). Evaluating the buildings environmental status and assessing the environment of the building are other methods to study the indoor environment. MIBB (2001). Investigation of indoor environment problems can be carried out by using check-lists Swesiaq (2006) or by using questionnaires Andersson et al.(1990) and Stockholm Stad (1990). Requirements and specifications for the indoor environment are presented in different reports Boverket (1998) and VVS-tekniska föreningen (2006). There is also a method for planning for a good indoor environment Hult (2002).

3 Evaluation of energy saving measures in reconstructed buildings

Two examples on studies involving evaluations of energy saving measures at reconstruction of multi-dwellings buildings in Sweden are the so called “Energisparkvarteren” Anderlind et.al.(1986) and the so called “Högskoleprojektet Elmroth et al. (1989). By realizing energy saving measures in existing buildings all around Sweden and then evaluating them carefully, owner of buildings may be convinced that the energy saving actions are profitable. At the project “Energisparkvarteren” about 1800 apartments built during the 1950´s were evaluated. The measures taken were:

- replacing the windows with windows having low U-value or adding one more pane of glass
- supplementary insulation in the attic
- supplementary insulation of the outer walls
- sealing of windows and doors
- adjusting the heating- and ventilation system
- use of heat recovery system

In these projects no evaluations of the indoor climate have been carried out. The table 1 below shows some examples on the energy savings from different energy saving actions

Table 1 Energy savings from different energy saving actions

Measure	Number of buildings	Energy saving
Adjusting the heating- and ventilation system	5	8%
Adjusting the heating- and ventilation system+ supplementary insulation in the attic (120 mm)+replacing the windows	5	15%
Adjusting the heating- and ventilation system+ supplementary insulation in the attic (120mm)+ supplementary insulation of the outer walls (120mm)	5	18%
Adjusting the heating- and ventilation system+ supplementary insulation in the attic (200mm)+ sealing of windows	9	18%

In the other project "Högskoleprojektet" a number of multi-dwelling buildings been have investigated in order to show the results of different energy saving measures. 36% of the buildings were built before 1940, 37% were built between 1941 and 1969 and 27% were built between 1961 and 1975. Results from the actions taken are shown in table 2.

Table 2 Energy savings from different energy saving actions

Measure	Number of buildings	Energy saving
Replacing the windows	27	9%
Supplementary insulation in the attic	29	5%
Adjusting the heating- and ventilation system+ replacing the windows	6	11%
Adjusting the heating- and ventilation system+ supplementary insulation in the attic or façade	16	11%
Adjusting the heating- and ventilation system+ sealing of windows	10	8%

An important result from the investigation was the knowledge about how different energy saving measures co-operate and how they have influence of each other. The conclusion from "Energisparkvarteren" was that every building must be treated individually when selecting energy saving measures. Measures that give god results in one building can give bad results in another building. Combination of different energy saving measures showed the best results when the combination was made especially for the building in question.

4. Energy saving measures at reconstruction and evaluation after reconstruction

A research project at the University of Halmstad describes the actions taken when renovating buildings constructed between 1966 and 1970 in Halmstad Sweden, Borgström (2006). The purpose of the renovation was to lower the energy consumption and to renew the exterior of the buildings. The actions taken have been evaluated both before and after the reconstruction in order to find out if the right actions have been taken with regard to the energy consumption and the indoor climate. This was done by comparing the measured energy consumption before and after the reconstruction, by measuring the indoor temperature before and after reconstruction and by analyzing some parts of the building where no actions were taken.

Students from Halmstad University have in their degree project compared different actions taken to decrease energy consumption in some of these buildings, Jörgensen, Olsson (2002). This study was made before the renovation. The computer software, Enorm 1000, has been used for the calculations. Calculated measures are replacement of existing windows with triple-glazed windows, supplementary insulation in the attic, supplementary insulation on the facades and all measures used together. Results from the calculation are shown in table 3.

Table 3 Calculated energy savings

Measure	Energy saving
Replacing the windows	8%
Supplementary insulation in the attic (500mm)	2%
Supplementary insulation of the façade (50mm)	28%
All measurements	38%

When the buildings were renovated the actions taken were:

- 100mm supplementary insulation on the attic
- 50mm supplementary insulation of the facades
- The windows in the facades have been replaced by triple-glazed windows
- Adjusting the heating system

- Sealing of balcony door
- New inlet terminal

No actions were taken to neither the external wall nor the windows at the insert balcony. When analyzing the indoor climate it is of interest to look at both those parts where actions have been taken and those parts where nothing was changed. The part of the building that is of special interest is the section composed of the walls and windows at the inset balcony. Measurements have been made of the indoor temperature close this part of the building.

Through this renovation the use of energy have decreased with 19% which is lower than the estimated value. This is due to that the thickness of the insulation used in the attic was 100mm compared to the estimated 500mm. In addition, not all windows were replaced with triple-glazed windows.

The indoor temperature does not exceed the limits for temperatures indoor set by the National Swedish Board of Health and Welfare (2005). When the outdoor temperature is below zero, the surface temperature on the windows at the inset balcony is low. This can result in cold downdraughts and cold radiation and an uncomfortable indoor climate.

5 Conclusions

Following conclusions can be drawn:

- Many dwellings in Sweden were built during a ten-year period between 1965 and 1974. When these buildings are to be renovated there is a great potential for energy saving.
- It is important that all parties in the construction process are joined in aim for low energy consumption and a comfortable indoor climate. It is also important that they are all aware of the close relationship between the use of energy in buildings and the indoor climate.
- It is also important to evaluate the outcome of actions taken at renovation. A good indoor climate should be an important target in the planning and design phase even at renovation.
- It is necessary to increase the knowledge about different energy saving measures that can be used at renovation/reconstruction, and also to establish routines to follow up both the effects on energy consumption and to evaluate the indoor climate after renovation/reconstruction.

6 Further research

Give an overview of the methods some real estate company's uses and describe disadvantages and advantages of the methods.

THE BIG INDOOR AIR EMISSIONS THREAT – SECONDARY EMISSIONS

Hal Levin

Building Ecology Research Group, Santa Cruz, California 95060 USA hal.levin@buildingecology.com

Summary

Substantial progress has been made understanding volatile organic chemical (VOC) emissions from indoor sources including building materials, furnishing, and some cleaning and maintenance products. During the past two decades, emissions from building materials and other sources have declined significantly in many developed countries. Researchers have begun to understand the potentially larger health threat posed by secondary emission, the chemicals formed by the interactions between oxidants in indoor air and chemicals on surfaces, and by hydrolysis. Many of the by-products of these interactions are more irritating, odorous, or toxic and may pose a far greater health hazard than the chemicals from which they are formed. Building materials, cleaning products, and many consumer products contain chemicals that react with oxidants to form formaldehyde and other, higher molecular weight aldehydes, acidic aerosols, and fine or ultrafine particles. Researchers have identified some of the most important indoor sources that combine with ozone (O_3) at common indoor concentrations to form these secondary products. The fundamental processes and critical building material and cleaning products have been identified along with recommendations for minimizing occupant exposure to hazardous chemicals resulting from indoor air chemistry and secondary emissions. Exposure to harmful secondary emissions can be reduced to improve indoor air quality

Key words: Indoor air quality, secondary emissions, volatile organic chemicals, ozone.

Background

Contaminants found in indoor air come from either indoor or outdoor sources. Among the most important of the indoor sources are building materials and furnishings, especially when they are new. Surfaces exposed to the interior are important, especially if they are periodically cleaned, re-finished, or renewed with wet-applied products that emit many of their constituents while drying or curing. The quantity of such materials can be very large over the lifetime of a building, and for some regularly-applied cleaning and maintenance products, large over even short periods of time. For example, the total mass of floor wax applied to a resilient floor product following manufacturer's instructions for regularly renewal can equal the mass of the flooring itself in a period of one or two years (Levin, 1999). Other indoor air pollutants enter a building from the outdoors and are carried in by ventilation air from mechanical or natural ventilation or through infiltration. Finally, occupant activities such as food preparation, cleaning, and personal hygiene, or from equipment and appliances can be sources of indoor air pollutants. Among the most well-known and important of these pollutants are volatile organic chemicals ((VOCs), chemicals that are found in air at normal indoor conditions of temperature and pressure.

Volatile organic chemicals in indoor air

Substantial progress has been made understanding VOC emissions from primary sources indoors including building materials, furnishing, and even some cleaning and maintenance products. As early as the late 1970s, researchers in Denmark were measuring emissions of formaldehyde from building materials and furnishings (Mølhave, 1981). By the mid-1980s, emissions testing of formaldehyde from composite wood products (particle board, plywood, fiberboard) used in federally-subsidized or insured housing and mobile homes in the U.S. was required. Apart from the formaldehyde emissions, early reports of emissions testing from building materials were primarily from research projects and were not generally reflected in guidelines and standards for building materials and finishes. In the mid-80s and onward, emissions testing began being applied to buildings in design (Levin, 1985; 1986; 1989; Tucker, 1990; Levin and Hodgson, 1996). And in the 1990s, emissions testing of many building products began to become increasingly common, at least in "green" building design processes (Tichenor, 1996; 2007). A comprehensive review of emissions testing became available in 2007 (Tichenor).

During the past two decades, concentrations of VOCs emitted from building materials and other sources have declined significantly in many developed countries. The decline is partly attributable to emissions testing and increased awareness of the importance of emission in determining indoor air quality. According to one review, a large fraction may also be attributable to regulation of emissions into ambient air where many VOCs are precursors of photochemical smog (Hodgson and Levin, 2003a; Levin and Hodgson, 2006).

Figures 1 and 2 (from Hodgson and Levin, 2003a) present results of VOC measurements from several studies. Figure 1 compares survey results from offices and residences reported between 1990 and 2001. Figure 2 compares Figure 1 residential results to surveys done prior to 1990. From the results it is clear that with several exceptions, the concentrations of most of these VOCs generally found indoors had decreased significantly from the levels found prior to 1990.

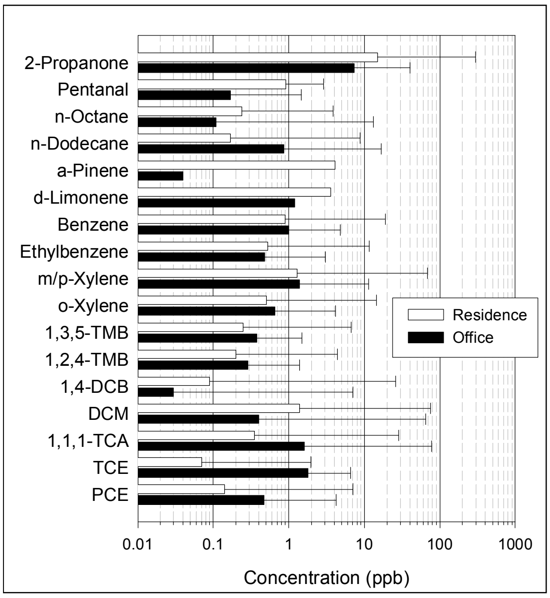

Figure1: Residential vs Office buildings: Comparison of central tendency and maximum concentrations (whiskers) of selected VOCs (1990-2001 studies). TMB = trimethylbenzene, DCB = dichlorobenzene, DCM = dichloromethane, TCA = trichloroethane, TCE = trichloroethene, PCE = tetrachloroethene.

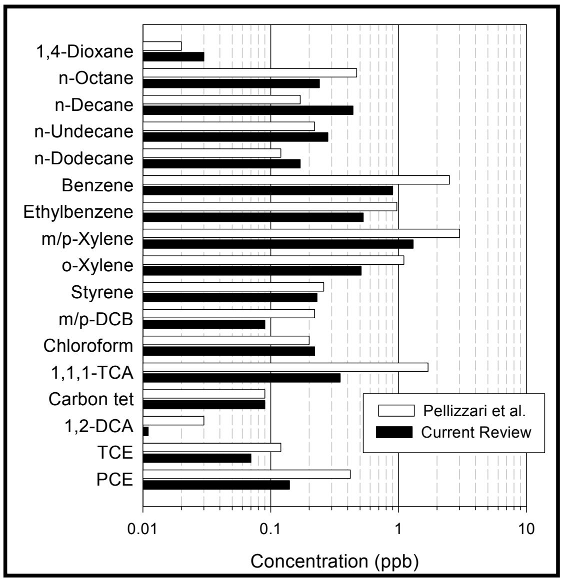

Figure 2: Residential buildings: Comparison of geometric mean (GM) concentrations of 17 VOCs (U.S. EPA TEAM studies prior to 1990 as reported by Pellizzari et al.1986 vs 1990-2001 studies). DCA = dichloroethane.

Formaldehyde

Not shown in these two figures is formaldehyde, probably the most well-characterized of indoor air pollutants in terms of health effects which include nose, eye, and skin irritation, upper respiratory tract irritation, and cancer. In the late 1970s and into the 1980s in the United States (U.S.), formaldehyde concentrations in indoor air often were found exceeding one part per million (ppm). The U.S. Occupational Safety and Health Administration's guideline value for protection of workers exposed to formaldehyde was 3 ppm, and this concentration was occasionally approached in indoor air where large quantities of plywood, particleboard, and hardwood veneer plywood were used, especially in mobile homes and manufactured housing where these materials dominated interiors. More commonly, in new homes and offices, concentrations often reach several hundred parts per billion (ppb).

Today, the OSHA regulations require that employers whose workers are exposed to more than 300 ppb inform the workers of their exposures, and formaldehyde measurements in new buildings in the U.S. are more commonly in the 10 to 30 ppb range, a decrease of roughly a factor of 10 generally and as much as a factor of 100 in extreme cases. It was not unusual to find concentrations exceeding 100 ppb throughout the 1980s and even into the 1990s. Formaldehyde has once again become a pollutant of major concern indoors because a lot of composite wood products entering the U.S. and Europe from Asia have very high formaldehyde emissions. So designers and builders need to continue verifying that the products they are specifying and using are low emitting products. The State of California has recently passed regulations that would limit the emissions of composite wood products to the 100 ppb range.

Emissions testing and product labeling

Other volatile organic chemicals also continue to be a concern, and emissions testing and certification programs are becoming common means of screening products for green or sustainable buildings. However, these screening programs are often driven by the product manufacturers rather than public health agencies or population concerns, so there continues to be much to do to limit occupant exposure to emissions from building materials and furnishings (Tichenor, 2007).

Early concern about secondary emissions

While there is still substantial and appropriate concern regarding VOC emissions from new building materials as well as from cleaning and maintenance products and occupant activities, recent interest among many of the pioneers of emissions testing and indoor air research has shifted to "secondary emissions." In the last 15 years researchers have begun to recognize the potential importance including the large health threat posed by secondary emissions, the chemicals formed by the interactions between oxidants in indoor air and chemicals on surfaces. Many of the by-products of these interactions are more irritating, odorous, or toxic than the chemicals from which they are formed.

Nazaroff, Cass, and other early indoor air chemistry researchers

One of the earliest to document the importance of these chemical reactions in indoor air reactions was William W Nazaroff of UC Berkeley. Nazaroff studied chemical reactions indoors both in air and on surfaces in southern California museums. His 1986 paper written together with Glen Cass of Cal Tech, "Mathematical Modeling of Chemically Reactive Pollutants in Indoor Air," described some of the basic processes that form the background of indoor air chemistry research since that time. Their work was funded to investigate the impact of polluted air on art works, and what better place to study this than in Los Angeles of the early 1980s? Their article's abstract reads, in part: "A general mathematical model is presented for predicting the concentrations of chemically reactive compounds in indoor air. The model accounts for the effects of ventilation, filtration, heterogeneous removal, direct emission, and photolytic and thermal chemical reactions." Near the end of the paper, it states: "The model is formulated to be a general tool for studying chemically reactive air pollution systems." In other words, their work could be used to estimate the effects of increasing or decreasing outdoor air ventilation rates as well as the use of filtration but also to predict the impact of airborne chemical reactions on building and other indoor material surfaces and on airborne concentrations of various pollutants.

Several researchers prior to Nazaroff and Cass had looked at indoor air chemistry; a very early publication was by MG Wilson in 1968 (Wilson, 1968).) An early paper on by-product formation from surface reactions was by James Pitts (1985). But nobody really pursued the topic of secondary emissions vigorously, and it did not gain much attention from the indoor air research community until the early 1990s.

Charles J. Weschler, Ozone, and Indoor Air Chemistry

Among the most important of those who took up the challenge and opportunity highlighted by the Nazaroff and Cass paper and the earlier work by Wilson, Pitt, and others is Charles J. Weschler. Much of the present awareness of indoor air chemistry is due to Weschler's work. First he called attention to the significant ozone concentrations indoors at a time when it was widely believed that concentrations indoors were inconsequential due to ozone's reactivity (Weschler et al, 1989). He reported that indoor concentrations of ozone were inversely related to the outdoor air ventilation rate and directly related to the outdoor ozone concentration. A typical office ventilation rate of just under 1 air change per hour (h^{-1}) results in an indoor-outdoor (I-O) ozone ratio of approximately 0.2. A school or assembly space with an air change rate of ~3 h^{-1} will have an I-O O_3 ratio of ~0.5. and a laboratory or other space with approximately 6 air changes per hour has an I-O O_3 ratio of about 0.7. To this day there are still many building, health, and chemical scientists who hold to the myth that ozone is not present in significant concentrations or important in indoor air.

Weschler raised awareness of ozone reactions indoors and the resulting secondary emissions in his 1992 paper reporting experiments with ozone and carpets (Weschler et al, 1992). He showed that the emissions from carpet of styrene and of 4-phenylcyclohexene (4-PCH), a by-product of the styrene butadiene rubber (SBR) latex manufacturing process, would rapidly react with ozone indoors to form formaldehyde, acetaldehyde, and other, higher molecular weight aldehydes. SBR latex backings were the most common on commercial carpet in that era and represented about 85% of the commercial carpet market. Weschler reported that the concentrations of VOCs that were markedly reduced "…in the presence of O_3 are those that contain unsaturated carbon-carbon bonds (4-phenylcyclohexene, styrene, and 4-ethenylcyclohexene)."

Not long after Weschler presented his findings described in the 1992 *Environmental Science and Technology* article, the present author received a call from an architect whose client, a law firm, had just moved into a newly renovated office space. All the secretaries were complaining of eye and skin irritation among other symptoms by the end of the first week in the office. Each secretary had their own laser printer at their work station, and laser printers emit ozone. The firm had called an industrial hygienist to measure the 4-PCH in the air, but the hygienist found very low concentrations. The apparent reason was that the ozone from the printers was reacting with the 4-PCH so that there was no 4-PCH left in the air to measure. As a result of the reaction, formaldehyde and other aldehydes were formed, and these are known irritants. Thus, the lessons of the researchers began to inform the design of buildings, and laser printers were recommended to be isolated in rooms equipped with exhaust directly to the outdoors. This kind of finding led Weschler to the title of a talk on his ozone and carpet research titled "Indoor VOCs: Is What You Measure on

Tuesday Night the Same as What You Measure on Wednesday Afternoon?" The title conveyed dramatically the problems indoor air chemistry causes for investigators of indoor air complaints and illustrates the importance of understanding indoor air chemistry processes.

Weschler has since published many papers on the subject of indoor air chemistry and especially reactions of materials commonly found indoors with ozone, and he has collaborated with others in experiments in Europe and America, in the lab, in buildings, and in simulated aircraft cabins. These experiments have shown that the ozone concentrations are lower indoors than outdoors because the ozone was reacting with indoor surfaces. He (and many others as well) reported that the products of these reactions included formaldehyde, higher molecular weight aldehydes, acidic aerosols, and ultrafine particles. The outcome, as Weschler has often said, is that the ozone is removed but the reaction products are more hazardous than the chemicals from which they are formed. Two of his most important and useful overview papers are "Ozone in Indoor Environments: Concentration and Chemistry" (Weschler, 2000) and "Ozone's Impact on Public Health: Contributions from Indoor Exposures to Ozone and Products of Ozone-Initiated Chemistry" (Weschler, 2006).

Fundamentals of ozone chemistry in air and on surfaces

Ozone is very reactive and easily reacts with unsaturated compounds that are commonly found in typical buildings. These compounds include citrus based solvents, the so-called "green" solvents (containing d-Limonene and other citrus oils) that have gained popularity as replacements for the toxic traditional solvents formerly found in many products. They also include chemicals found in many softwoods, the terpenes like alpha-pinene. Pine oil cleaner is an example of such products. Ozone also reacts with the oils found in linseed oil resulting in the very strong and persistent odor of linoleum floor covering. These oils, composed primarily of esters of linolenic, linoleic, and oleic acids, have also been found by other researchers to form the aldehydes and odorous compounds emitted from linoleum and other products using linseed oil in their formulation (Morrison and Nazaroff, 2002). What these chemicals have in common is unsaturated double carbon bonds that react very quickly with ozone.

Researchers have begun to understand the processes involved in the generation of secondary emissions and have identified some of the most important indoor sources that combine with ozone at common indoor concentrations to form these secondary products. In 2007 at UC Berkeley, some of the leading researchers gathered to discuss "interfacial chemistry in indoor environments" at a workshop sponsored by the National Science Foundation and the California Air Resources Board and organized by Glenn Morrison of the University of Missouri, Rolla. The following section summarizes some of the presentations and discussions at that workshop based largely on Morrison's report of the workshop to the sponsoring agencies (Morrison, 2007) and his article in the journal *Environmental Science and Technology* (Morrison, 2008).

The fundamentals of indoor air chemistry are illustrated in Figure 3 provided by Glenn Morrison from his presentation at Healthy Buildings 2006 in Lisbon, Portugal.

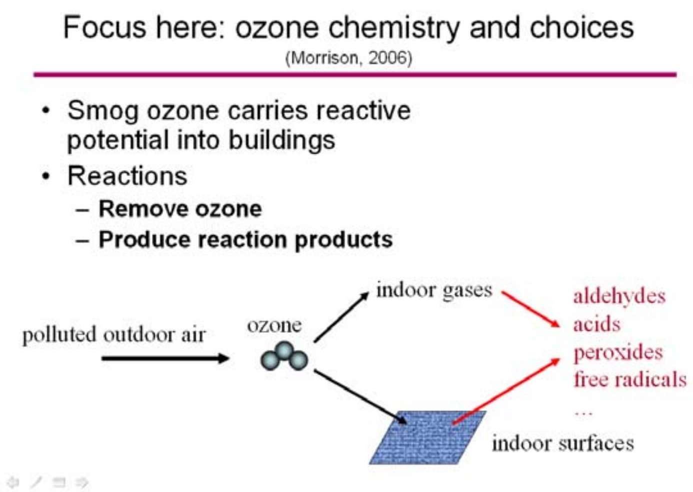

Figure 3. Fundamentals of Indoor Air Ozone Chemistry (source: Morrison, 2006)

Ozone Reactions with Surfaces

Many of the most widely-used building materials, cleaning products, and consumer products are made from chemicals that react with ozone and other oxidants to form formaldehyde and other, higher molecular weight aldehydes, acidic aerosols, and fine or ultrafine particles (Weschler 2000; Nazaroff and Weschler, 2004;

Nazaroff et al, 2006). Thus, as indoor air researchers probed deeper into the sources of the chemicals found in indoor air as well as the disappearance of some that enter the air but are not found in the expected concentrations, they discovered the importance of chemical reactions for explaining the presence of (and determining the fate of) some of the more important chemicals.

One of the active and most productive research areas has been the study of ozone reactions with various indoor surfaces and compounds found on these surfaces. The basic schematic relationships are shown in Figure 3 below from a 2006 presentation by Glenn Morrison. Ozone readily reacts with an ample supply of unsaturated compounds that generally exist in typical buildings at concentrations many times greater than observed outdoors. Products of this chemistry include carcinogens (formaldehyde, acrolein), irritants (carbonyls, dicarbonyls, acids), free radicals, and other oxidation products of concern (e.g. pesticide oxidation products). The volatile products have been coined “secondary emissions”, and the resulting concentrations of chemical reaction products are large enough to have health and comfort consequences at typical indoor ozone levels.

Perhaps the most important overall finding is that reactions between ozone and indoor surfaces strongly influence human exposure to ozone, the chemicals and surfaces with which ozone reacts, and to the chemical by-products. As illustrated by Weschler and Shields (1989) and later by Lee et al (1999), the reactions of O_3 on indoor surfaces reduce occupant exposure by factors ranging from 2 to 10. The surface area available for such reactions is extremely large, far larger than the planar surface area because the reactions take place at the molecular level and the surface area available is large compared to the building volume. The reaction products can be attached to surfaces by sorption thus extending the average length of time the products are indoors and increases the probability that conversions will occur, and unique compositions and morphologies at indoor surfaces can promote some reactions or promote selectivity in reaction pathways.

Chemicals in Products Applied to Surfaces

One of the major concerns emerging from the interfacial chemistry research is that many of the O_3 reactions occur with chemicals commonly found and unintentionally applied to indoor surfaces. Ozone reacts with the common pesticide cypermethrin (Segal-Rosenheimer and Dubowski, 2007). It also reacts with the terpenes used as the active ingredient in cleaning or other scented products (Singer et al, 2007). Researchers have now found that cleaning products and air fresheners increase the ozone deposition on surfaces (Singer et al, 2007). Compounds that had sorbed to the surfaces made up as much as half of the ozone reactions.

Two examples, orange oil cleaner and pine oil cleaner, are presented in Figure 4. The concentration of ozone introduced in these experiments, 40 ppb, is not uncommon in indoor environments. In residences without air conditioning or mechanical ventilation, open windows can easily result in such concentrations on a summer day in most cities in North America. What is most impressive here is how long the concentration of formaldehyde formed by the reaction lingers in the air after application on an apparently “dry” cleaned surface.

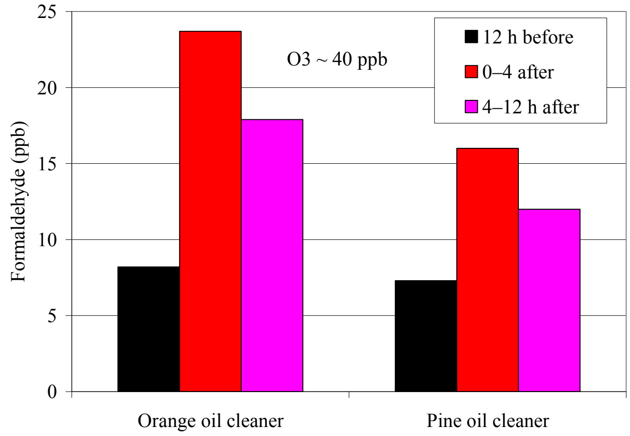

Figure 4. Cleaning products exposed to O_3 and formaldehyde formation (Singer et al, 2007)

Reactions of ozone with people

An extremely interesting and potentially very important finding is that the interfacial chemistry is taking place at the “human surface”. This became apparent in simulated aircraft cabin experiments, densely occupied with human subjects (Weschler et al, 2007; Wisthaler et al, 2006) and in studies of the “personal cloud,” (Corsi et al, 2008). Ozone delivered by the fresh air system in aircraft cabins forms compounds somewhat unique to its reaction with human skin oils or sebum. The researchers also concluded that in aircraft cabins, people are major O_3 sinks – larger than carpet, seats and dirty HEPA filters combined, and that O_3 and its oxidation products adversely affected 12 of 29 self-reported symptoms based on questionnaires from occupants. Evaluation of individual aircraft surfaces, in small-chamber experiments, confirmed these findings (Coleman et al, 2007). Coleman also found ozone chemistry formation far higher with soiled human clothing than with laundered clothing, suggesting that the skin oils, perhaps among other accumulated chemicals on soiled clothing, were reacting with the ozone to form formaldehyde, acetaldehydes, and other typical ozone reaction products (see Figure 5).

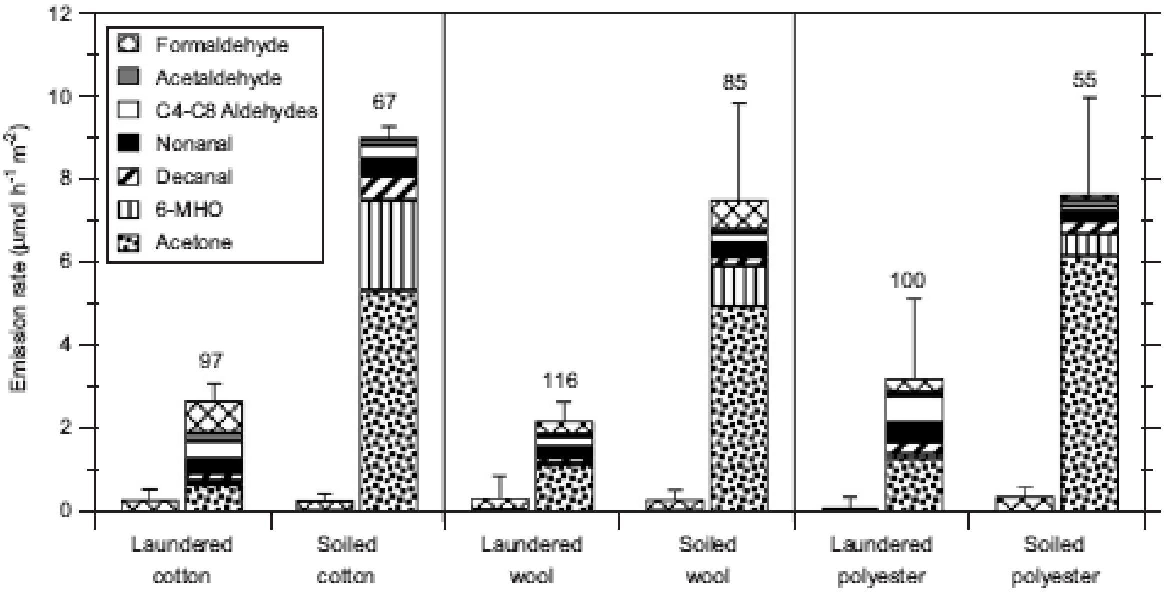

Figure 5. Clean and soiled clothing exposed to O_3 and chemical by-product formation (Coleman et al, 2008). For each material presented, the left bar represents the average emissions without ozone during a 180-min conditioning period (no ozone), and the right bar represents the average emissions during the initial 90-min ozone exposure period. The number above the right bar is the 90-min average residual ozone concentration in ppb; the supply air concentration was always 160 ppb. Error bar indicates plus one standard deviation from analysis of replicate integrated samples

Corsi et al (2008) investigated the presence of personal reactive clouds that result from ozone reactions with terpenes and terpenoids emitted from personal care products. “Screening experiments were performed with three perfumes and two hairsprays to determine the extent of secondary organic aerosol formation in the breathing zone of a subject who had applied these products. The results of screening calculations and preliminary experiments confirm that chemistry occurs in the “near-head region” of individuals who apply scented personal care products to their hair or facial skin.”

Even human hair reacts with ozone. Studies showed a very high probability of ozone reacting with hair follicles (Pandrangi and Morrison, 2007). When humans are in densely occupied environments such as classrooms, theatres, or airplanes, their aggregated reactivity will reduce their exposure to ozone but increase their exposure to the products of ozone-sebum reactions.

Reactions of other outdoor air pollutants with indoor surfaces

Reactions of other components of smog such as nitrous oxides (NOx) (Sakamaki et al, 1983) have also been studied on indoor surface; Pitts et al. (1989) showed that this chemistry also occurs on indoor surfaces and can generate nitrous acid (HONO) levels that exceed outdoor levels when NOx is released from indoor sources such as improperly vented gas burners.

Hydrolysis

Some important chemical reactions and physical processes indoors do not involve pollutants that are part of photochemical smog. The importance of hydrolysis (the decomposition of a chemical compound by reaction with water, such as the dissociation of a dissolved salt or the catalytic conversion of starch to glucose) is now recognized as an important source of indoor air pollutants as well as the potential deterioration of building materials. These processes in indoor environments are known to cause toxic and odorous chemical emissions.

One of the more important of these breakdown processes is the hydrolysis of plasticizer (e.g., di-ethylhexylphthalate -DEHP) generates mono-ethylhexylphthalate (EHP) (Lundgren et al, 1999) which may be associated with asthma (Norback et al, 2000). Plasticizers are often used in vinyl flooring and in adhesives to improve their functional properties. When vinyl flooring is applied to insufficiently cured concrete (high moisture content), hydrolysis will occur. Concrete flooring and gypsum board which are both highly basic can help catalyze this hydrolysis. (Corsi et al, 2007). Hydrolysis reactions depend on local pH and moisture conditions, but these parameters are rarely quantified accurately or sufficiently, and their influence on hydrolysis is poorly understood.

Indoor Chemistry and Occupant Health

“Secondary emissions”, the reaction products of ozone chemistry, include carcinogens (formaldehyde and acrolein), many irritants (including carbonyls, dicarbonyls, and acidic aerosols), free radicals, as well as other products of the oxidation process (e.g. pesticide oxidation products). It is apparent that the concentrations of these chemicals produced by such reactions have potentially important occupant health and comfort implications at ozone concentrations typically found indoors (Weschler, 2004).

Exposure to these secondary emissions may pose a far greater health hazard than the chemicals from which they are formed (Weschler, 2004; 2006). Weschler has also suggested that since a significant fraction of people’s exposure to ozone does occur indoors due to the far larger fraction of a typical person’s day spent indoors and since when ozone is removed from indoor air through indoor air chemistry, many of the reaction products are toxic, that some significant fraction of the morbidity and mortality reported by epidemiologists during periods of high outdoor ozone may be attributed at least in part to pollutant exposures that occur indoors (Weschler, 2006).

Some provocative recent findings

Ozone is nearly always present in sufficient concentrations in outdoor air to present concern for the health of building occupants. A recent analysis of the U.S. EPA’s BASE study data showed that outdoor ozone concentrations were associated with increased SBS symptoms (Apte et al, 2008). Additional analysis of the same data showed that a combination of higher outdoor ozone and synthetic fiber filters resulted in very large increases in the risk of SBS symptoms (Buchanan et al, 2008).

Summary of health implications

As is the case for most indoor pollutants, little is known about the health outcomes of exposure to most of the reaction products of indoor chemistry. Weschler’s analysis (2006) suggests that the reported epidemiological correlations between outdoor levels of ozone and morbidity or mortality are due, in large part, to indoor exposures to ozone and the byproducts of its reaction with other species indoors. His estimate is that indoor exposure to ozone transported indoors from outdoors is conservatively 2/3 to 3 times that of outdoor exposure to ozone. Meanwhile, indoor exposure to ozone oxidation products is often many times greater than outdoor ozone exposure. It can be anticipated that indoor levels of reaction products may correlate with outdoor levels of ozone, but this hypothesis still needs to be fully evaluated in field settings. Many human and animal experiments have shown adverse reactions to homogeneous ozone chemistry (see references in Tamás, G. et al, 2006). It appears, therefore, that real toxins, irritants, sensitizers and so forth are generated, and seemingly generated at levels of concern.

Controlling Indoor Chemistry

“Controlling indoor chemistry means controlling sources, reactants and conditions that promote that chemistry…. Indoor air and outdoor air are part of the same continuum. Yet scientific, legislative, and philosophical separation of these domains has adversely affected our ability to target efficient solutions for reducing exposure to smog and its consequences. We now see that smog chemistry does not stop at the door, but churns away in the indoor spaces where we spend most of our time. Thus indoor air and its chemistry need the same attention given to ambient air for the past 50 years” (Morrison, 2008).

What can be done?

There is a general agreement in the indoor air research and professional communities that source control is the alternative of choice. Then, after eliminating indoor pollution sources, authorities recommend dilution and removal by ventilation for indoor source pollutants. But ozone and its reaction products indoors present a dilemma in terms of the ventilation strategy. Where outdoor air contains any significant quantity of ozone, it may be important to limit the amount of outdoor air intentionally introduced into a building.

One of the ways to address the problems presented by indoor ozone reactions is to select materials that are less likely to react with ozone or to form harmful reaction products. It would clearly be wise to avoid introducing products that contain many of the chemicals that are especially reactive such as citrus-based solvents and cleaning products and terpenes (e.g., pine oil cleaners) that have been shown to react strongly with ozone to form undesirable products. Glenn Morrison has illustrated the processes and provided some preliminary data on ozone and formaldehyde formation with common indoor materials as shown in Figures 6. Extension of his work with more materials and application of the results can reduce occupant exposure to formaldehyde and other important indoor air pollutants from the ozone that is almost always present in sufficient concentrations to cause the reactions.

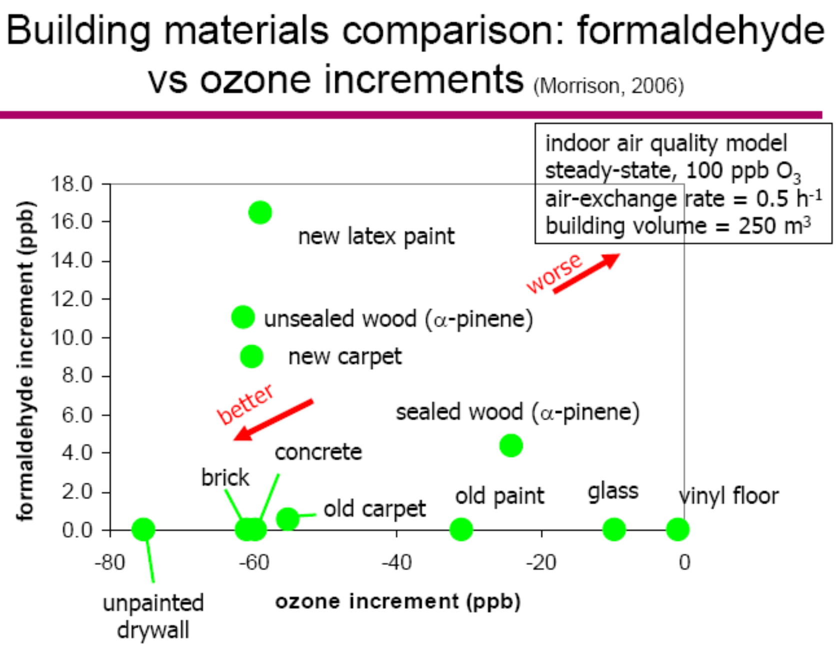

Figure 6. Building materials comparison: Formaldehyde vs Ozone increments (source: Morrison, 2006)

An alternative to attempting to address the ozone indoors by careful selection of materials is to remove the ozone by air cleaning when mechanical ventilation systems are used. Controlling indoor chemistry means controlling sources, reactants and conditions that promote that chemistry. Ozone is a clear target and its removal from buildings is anticipated to lower indoor concentrations of aldehydes, ketones, organic acids, free radicals and secondary organic aerosols. Activated carbon (AC) filtration is available for commercial buildings and is effective at removing ozone, and some VOCs, from supply air. Standard 62.1 from the American Society of Heating Refrigeration and Air Conditioning Engineers (ASHRAE) requires AC filtration for high ozone areas, but the standard is rarely implemented and is not enforceable unless adopted or incorporated by reference by the jurisdiction having code authority. ASHRAE is currently revising Standard 62.1 to make intentional ozone removal (e.g., activated carbon filters) more widespread in commercial buildings. No standards exist for AC filtration in residential buildings and its use is negligible (Siegel, 2007). A proprietary catalytic agent available from BASF is used in aircraft cabin air systems to remove ozone when aircraft fly at high altitudes or latitudes where stratospheric ozone concentrations can result in ozone entry into aircraft cabins. Without removal, ozone concentrations can reach 200 ppb in aircraft cabins, and that is after the removal that occurs by interfacial chemistry.

Charles Weschler has written: “Reducing ozone levels in urban areas has proven to be a difficult and costly problem. It is easier to remove ozone from indoor air than from outdoor air. Filters are available to accomplish this with only small energy penalties. At present, the health consequences of exposure to the products of ozone initiated indoor chemistry are poorly characterized; adverse effects are inferred from several loosely connected studies. However, further examination of the hypothesis expressed in this article [The associations between ozone concentrations measured outdoors and both morbidity and mortality may be partially due to indoor exposures to ozone and ozone-initiated oxidation products].is warranted since it affects overall mitigation strategies. For example, if even partially true, it would be beneficial to remove ozone from the supply air of mechanically ventilated buildings, especially schools, hospitals and daycare centers located in regions that continue to experience elevated outdoor ozone concentrations.” (Weschler, 2006).

Acknowledgments

Preparation of this paper would not have been possible without the work of all the authors cited in the text and many others not mentioned here, and especially Charles J. Weschler, William W Nazaroff, and Glenn C. Morrison who have taken the time over many years to try to help me understand. What is correct in this paper is in large part due to their help, and any errors here are strictly the author’s.

Keywords: Large enclosures, Thermal stratification, Vertical temperature distribution, Thermal comfort

Summary

The purpose of this study is to analyse the characteristic of an indoor thermal environment in large enclosures under heating and cooling conditions. This study measured the indoor thermal environment in winter and summer seasons. We examined the indoor thermal environment of large enclosures, namely, the vertical, horizontal temperature distribution and the thermal comfort environment.

1. Preface

1.1 Background and Purpose

Recently, the construction of large enclosure buildings such as an international airport, sport facility, atrium, convention center have been increasing. And the discussion on attracting of dome stadium and large enclosure, which meet the purpose to use, such as popular sports, events and meeting spreading the interests of representative landmark and lucrative business at the competitiveness securing level in each country.

But a large enclosure building has a general characteristic of frequent thermal movement toward to indoor/outdoor due to its great height, large volume, small residential area for total volume, and lightweight outer shell of the building directly exposed to open air. In addition to the normal residential and office buildings, large enclosure buildings can to customized to meet various requirements, such as the indoor environment, the number of persons, purpose of use, and residential area. Because of such requirements, a large enclosure building has difficulty in securing thermal comfort in the indoor area, an issue that needs to be solved for proper control of the indoor environment.

This study I analyzes the characteristics of the indoor thermal environment by actual measurements of the indoor thermal environment of a large enclosure building and provides basic data for planning a reasonable cooling & heating and air conditioning system of a large enclosure building in the future.

1.2 Scope and Method

The indoor stadium located in the Seoul Olympic Athletic Park of Seoul, Korea was chosen as the representative large enclosure building for this study. The analysis method uses 1/2 of the total area as the measurement area because of the symmetry of the total area for analysis of the summer and winter characteristics of the building. The outdoor weather conditions were measured(:) thermal environment index(MRT, PMV), wind velocity, and ventilation quantity.

The outdoor weather data were measured and stored in the installed, real time weather instrumentation, such as the Anemometer, Pyranometer and Relative humidity transmitter and Weather Station of DAVIS Co.Ltd. Many Thermistor sensors were installed to measure the temperature in the stadium, and the data provided by these sensors were stored automatically by the Data logger. The relative humidity of the supply & exhaust port was measured by a potable digital temperature-humidity meter(SK-L200Ⅱａ).

2. Measurement Method

2.1 Summary of the building to measure

The indoor stadium, which is located in the Seoul Olympic Athletic Park of Seoul, Korea, was selected as the test building, whose specification is summarized in Table 1. This building has capacity to hold 6 858 persons with changeable guest seats (1 635 seats) and fixed guest seats (5 223 seats) on the 1st and the 2nd level, and offices are posted by the corridor of the building. The heating system is divided into the stadium zone where central supply in the park supplies the steam and the office zone where Korea District Heating Corporation supplies medium temperature hot water. The heat source from each zone will be supplied to air conditioning system of the building through the basement common duct. The air conditioning system has 1 unit for cooling/heating and 1 unit for ventilation of each zone and supplies cooling & heating to the blow down system of wall sides and the 2nd floor guest floor.

Figure 1 Exterior view of the measured building

Table 1 Summary of measuring building

Completion	April.1986
Scale	B1F, 3F (diameter : 97 m, height : 22.35 m)
Structure	Reinforced concrete
Roof structure	Cable
Building area	8 658 ㎡
Floor area	16 358 ㎡

2.2 Measuring condition and Method

The measurement was executed for non-air conditioning, intermittent air conditioning and air conditioning (considering the body load) in the summer/winter season for 3 days on Feb 7 ~ 8 and Feb 24, 2007 in the winter season and 3 days on Aug 22 and Aug 24 ~ 25, 2007 in the summer season for the indoor gymnasium to evaluate the thermal environment of large enclosures.

The measurements for the non-air conditioning condition are shown in Table 2 and those for intermittent air conditioning were measured by 1st, 2nd and 3rd in real time. The measurements for the air conditioning condition were conducted during a match or an event. The indoor thermal environment was measured at selected points located at regular intervals, with the starting point being the center of the indoor gymnasium. The circular indoor total area was divided in half as shown in Fig. 2 and all of opening & shutting parts in the building were closed because they were expected to influence the temperature distribution.

The weather station of DAVIS Co., Ltd was installed adjacent to the building to measure the outdoor weather and to store the temperature, humidity and solar light quantity data. The temperature and humidity of the supply/exhaust port were measured at 10 second intervals by a potable digital temperature-humidity meter(SK-L200Ⅱａ), and the velocity of air at the supply/exhaust port by Hot-wire wind velocity meter. Vertical temperature was measured at V2 ~ V5 points at 0.5m interval up to 3m high and 1.5m interval over 3m high with the installed Thermistor sensor, and horizontal temperature was measured at A1 ~ A7, B1 ~ B7 and C1 ~ C7 points with the starting point being the guest seat floor with the installed temperature sensor at 1.0m and 1.1m high and stored at 10 second intervals by Monitoring Device.

The air stream velocity for guest seat was the average value of velocities measured 12 times at 5 second intervals measured by a Hot-wire wind velocity meter, and the globe temperature was stored at 10 second intervals by the installed temperature sensor in the globe. PMV was measured by a thermal comfort meter at 20 minute intervals according to the ISO 7730 setting of 1.2clo of wear test and 1 met of activity test in the winter season, and 0.5clo of wear test and 1 met of activity test in the summer season. The equipment and measurements are listed in Table 3.

Table 2 Measurement schedule and condition

Division	Measuring schedule		Measuring condition		
Winter season	Non heating condition	Feb 7. 2007	Heating off		
	Intermittent heating condition	Feb 8. 2007	1th	09:00 ~ 11:00	Heating on (293K)
				11:00 ~ 11:50	Heating off (294K)
			2th	11:50 ~ 13:30	Heating on (294K)
				13:30 ~ 14:00	Heating off (297K)
			3th	14:00 ~ 15:30	Heating on (294K)
				15:30 ~	Heating off (297K)
	Heating condition (With heat loads from occupant)	Feb 24. 2007	08:00 ~ 12:00		Heating on
			14:00 ~ 18:00		Volleyball game
Summer season	Non cooling condition	Agu 24. 2007	cooling off

3. Result and Analysis

3.1 Analysis of vertical temperature distribution

3.1.1 Vertical temperature distribution and changes in the winter season

As shown in Fig. 3(a), the indoor temperature under the non- air conditioning condition was the lowest temperature of the day, indicating an even temperature distribution just after sunrise, regardless of the location and height, and the highest indoor temperature of the day with the outdoor temperature before & after 16:00 pm. It is concluded that the greater vertical temperature rise in the upper area than in the lower area is due to the difference of the lighting load and sunlight quantity with time at 9m above the upper floor part of the arena under the non-air conditioning condition.

The difference of temperature stratification and build up occurred for the heating condition set by time under the intermittent air conditioning condition. The vertical temperature by height was uniform before the operation of the heating system, was 279K of the high/low temperature difference in the arena 2 hours after operation of the heating system as Fig. 3 (b) and was 276K high/low temperature difference at the guest seat on the 1st and 2nd level due to the relative low height of the building.

It is estimated that there would be air space by moving low temperature air to the lower space as blow down air stream with high temperature risen by buoyancy positioning to the upper space. High/low temperature difference was generally reduced 11 hours after heating, showing 276.5K high/low temperature difference 50 minutes after the end of the heating supply, as shown in Fig. 3 (c). In the case of heating condition (considering the body load), the temperature rose rapidly and air space occurred by the 279 ~ 280.5K vertical temperature differences by location, as shown in Fig. 3 (d) after heating, and the temperature stratification formed during heating was slowly relieved, showing 274.5K ~ 275.5K vertical temperature differences 2 hours after the end of the heating supply, as shown in Fig. 3 (e), when the volleyball game started.

Relieved air space has been maintained until the end of the game at 293 ~ 295.5K indoor temperature in the residential area. However, the actual temperature decreased rapidly after the game. The body heat of the guests of the volleyball game acted to maintain the actual temperature to 293 ~ 294K, the 1st heating setting temperature of the intermittent air conditioning condition. This resulted in the exchange of indoor thermal energy with low temperature air removing body heat by opening/closing the exits after the game.

The indoor vertical temperature for heating and non-heating times is compared in Fig. 3 (f). The high/low temperature difference upon heating was 279.7K, and that upon non-heating was 274.2K. The temperature at 3m height increased rapidly upon heating. This is the reason why the blow down air upon heating to a high temperature moves toward the upper space by buoyancy to form temperature stratification.

3.1.2 Vertical temperature distribution and changes in the summer season

Due to data error and loss of non-cooling and cooling (considering the body load) condition in the summer season, the vertical temperature distribution was analyzed only for the intermittent cooling condition. Air space with high temperature on the upper space was formed at 9 ~ 11 am upon the 1st heating, unlike what was done for the intermittent cooling of Fig. 4 (b). It is considered that low temperature blow-down stream with big density moves to the residential area to keep the indoor temperature 297.5K, but temperature stratification was formed by the buildup of high temperature air that rose from the upper space of the roof. In the case of Fig. 4 (b) in which the cooling supply was ceased, the temperature in the lower space by location influences the residential area by continuous heat transfer between the high temperature formed from in the upper space of the indoor area to show higher temperature distribution than 299K cooling setting temperature by higher 275K than that of Fig. 4 (a).

3.2 Analysis of horizontal temperature distribution

3.2.1 Horizontal temperature distribution and changes in the winter season

Horizontal temperature at 1.1m high on the guest seat at the 1st level in the winter season is shown in Fig. 5. The maximum horizontal temperature difference was 273.8K at each measurement location because the outdoor air from the exits at the guest seat of 1st level on non-heating condition, and the horizontal temperature changed slightly until 9 ~ 15pm during intermittent heating in the intermittent heating condition. During the volleyball game in the heating condition (considering the body load) from 13:30 ~ 18:00, the horizontal temperature distribution by measurement location was 294 ~ 294.5K, which was maintained until the end of the game; this temperature range was higher than 293 ~ 294K range of the1st heating temperature condition of intermittent air conditioning condition.

3.2.2 Horizontal temperature distribution and changes in the summer season

The horizontal temperature at 1.1m height on the guest seat at the 1st level in the summer season is shown in the Fig. 6. The horizontal temperature is similar to that of the non-cooling condition and is slightly different from that of the intermittent cooling condition, except in the B1 area , but is greatly different from that of the cooling condition (considering the body load).In spite of continuous cooling during

(b) Intermittent cooling condition – 12:00 (cooling off)

Figure 4 Vertical temperature in summer season.

10:00~17:00, the horizontal temperature rose slowly by the body heat of students and their parents during the 12:00~18:00.

3.3 Indoor Thermal Comfortableness

3.3.1 Indoor thermal comfortableness in winter season

The result from PMV with the measurements of the indoor thermal environment in the winter season is shown in Fig. 7. PMV in the non-heating condition is -1.89 ~ -2.99, which indicates discomfort due to low temperature, as shown in Fig. 7 (a), but the PMV value decreased rapidly after heating and there was a small change of the PMV value due to the movement of the guests during thestart and end of the 2nd volleyball game, but indoor thermal environment satisfied the comfort standard of ISO-7730, showing -0.46 ~ -0.12 PMV value during the game for 15:00~17:00.

In the heating condition (considering the body load) of Fig. 7 (b), the PMV value at all of 6 measuring area was -0.12 ~ +0.15, 2 hours after the start of heating at 10:00, representing the improved indoor thermal environment according to the ISO-7730 comfort standard. PMV values from 5 measurement locations, except 1 PMV - 0.5 value, satisfied the ISO-7730 comfort standard -0.5 ~ +0.5 at 14:00, 2 hours after 12:00, the duration of 4 hours of continuous heating.

Figure 6 Horizontal temperature in summer season

3.3.2 Indoor thermal comfortableness in the summer season

PMV result with the measurements of the indoor thermal environment in the summer season is shown in Fig. 8. As the non-cooling condition of Fig. 8 (a) shows, the PMV value is 0.52 ~ 1.16 , which indicates discomfort due to high temperature after 11:00am, resulting from the rise in the indoor temperature due to the influence from the outdoor temperature. In the intermittent cooling condition, the PMV value varied according to the cooling condition set with time and satisfies the ISO-7730 comfort standard, except during the period of dawn. PMV values measured from 6 areas at 10:00am, the starting time of cooling in the cooling condition (considering the body load), are +0.58 ~ +0.81, exceeding the ISO-7730 comfort standard and PMV values at the time of 4 hours passed from the cooling start are +0.12 ~ +0.39 to maintain the indoor thermal environment satisfying the improvement of PMV value and ISO-7730 comfortableness standard on starting cooling.

4. Conclusion

The indoor thermal environment of a large enclosure during the summer and winter seasons was investigated. An indoor stadium was selected to obtain indoor vertical & horizontal temperature distributions and evaluate indoor thermal comfort. The results of this study are summarized as follows.

(1) The vertical temperature distribution showed a large high/low temperature difference of the arena by about 279K. The vertical temperature difference in the guest seat at 1st and 2nd levels was reduced greatly by the influence of the relatively low height of the building in the intermittent heating and heating conditions in the winter season. The temperature stratification, which reduced after stopping the heating in the heating condition (considering the body load) until the end of the game, was believed to have been maintained by the body heat from the guests at the volleyball game. In the summer season, the low blowdown stream with big density moved to the lower space and 297.5K indoor temperature was maintained in the lower space by location but the temperature stratification was formed by the buildup of high temperature air that rose in the upper space of the roof. The high temperature stratification formed in the upper space did not influence the residential area upon operation of the exhaust fan, which was installed in the upper space.

(2) The horizontal temperature distribution by location during the volleyball game for 13:30~18:00 in the winter season was 294 ~ 294.5K , which was until the end of the volleyball game by the influence of the body heat from the guests at the volleyball game. This temperature distribution was higher than 293 ~ 294K of the 1st heating temperature condition, by 273.5 ~ 274K. In the cooling condition (considering the body load) in the summer season, in spite of continuous cooling for 10:00~17:00, the horizontal temperature rose during the school festival for 12:00~18:00 by the body heat from students at the event and from the guests.

(3) With respect to the indoor thermal comfortableness, the ISO-7730 comfort standard was satisfied by the -0.46 ~ -0.12 PMV value for 15:00~17:00pm after the heating was stopped in the winter heating condition (considering the body load) because of the body heat from the guests at the game. In the summer cooling

condition (considering the body load), -0.35 ~ -0.49 PMV value with 53.1~59.2% humidity and 0.43 ~ 0.86 ㎧ air stream from 12:40 ~ 16:20 during the event maintained the indoor thermal environment that satisfied the ISO-7730 comfortableness standard.

Before planning a reasonable cooling and heating air conditioning system of a large enclosure building, several items must be considered such as large enclosure problems and indoor thermal characteristics.

First of all, an air-conditioning system supplying jets flow velocity from seats at air current rate of within 0.5m/s must be adopted no produce cold draft heating load in residential area. Secondly, an air current induction fan assuring swirl in the residential area must be adopted to achieve thermal comfort although set up higher the temperature of a room.

It is decided that the result of this study could be used as basic data to plan a reasonable cooling/heating air conditioning system of a large enclosure building and in the future, studies of various outdoor environment conditions of middle and rainy periods are needed.

Summary

The introduction of compulsory energy certificates for existing and future buildings as well as the development, testing and implementation of schemes for the description, assessment and certification of the sustainability of buildings are linked to a number of prerequisites. Drawing on examples from German experience, this contribution aims to demonstrate how a broad-based social consensus can be reached by making use of the “Round Table” instrument - a consensus which at the same time is based on the current state of research and standardisation and is integrated into the strategies of the European Union. In particular the transition to an assessment and certification scheme which is mainly based on quantitative assessments represents a major challenge. A substantial effort will have to be made to develop methodologies, to make data available for the environmental and economic assessment and to establish assessment criteria. At the same time, investors and planners must be provided with suitable tools to formulate objectives, to examine different options and to exchange information. This paper will demonstrate how a certification scheme can be integrated into a package of complementary and supporting planning and assessment tools. Finally, the development of a manageable solution for investors acting at international level to assess the sustainability performance of buildings at very different locations is suggested.

1 Framework and trends in Europe

1.1 Selected directives and research projects of the EU

The Federal Republic of Germany as a member of the European Union is an active player in shaping the process of a stronger orientation of the European building, housing and real estate industries towards the principles of sustainable development. Germany transposes regulations of the European Union and the European Commission into national legislation and supplements these provisions by national initiatives and programmes.
The role and responsibility of the building sector in shaping the built environment to be socially equitable and environment-friendly, in maintaining and creating employment and conserving resources, on one hand, as well as the importance of modernising the existing building stock to save energy, conserve resources and protect the environment, on the other hand, has been recognised in Europe. Concerning the update of the European Construction Products Directive [EU 1989] for example, which already contains requirements on hygiene, health and environmental protection in the production and use of construction products, there is currently a debate on if and what kind of supplementary requirements to combat climate change and achieve sustainability (in this field particularly the sustainable use of resources) should be included in the directive.
The EU’s Energy Performance of Buildings Directive [EU 2002] which entered into force in 2002 sets out requirements for the evolution of the description and assessment of the energy efficiency of buildings, the large-scale introduction of energy certificates for existing and future building as well as for the systematic maintenance and repair of the heating, ventilation and air conditioning systems of buildings.
Existing methods and instruments to evaluate the environmental compatibility and sustainability of buildings – cf. information available on PRESCO at http://www.etn-presco.net - are analysed and compared in concluded and current EU funded research programmes under German participation, and elaborated by means of the LEnSE principles for the development of a uniform European label for sustainable residential buildings (cf. information available at http://www.lensebuildings.com) and put up for discussion.

1.2 Selected strategies and standardisation projects

In view of the importance of the building, housing and real estate industry, the EU aims to develop "sustainable construction" into a lead market [EU 2007] over the course of the next years. In this endeavour, the EU is pursuing the Thematic Strategy on the Urban Environment [EU 2004] which was established as early as in 2004. The strategy includes a stronger emphasis on sustainable settlement development and sustainable construction as well as the further development of the energy certificate into a document which describes and assesses the sustainability of buildings. This involves integrating additional aspects such as indoor air quality, accessibility, noise levels, comfort, environmental quality of the materials, the life-cycle cost of the building and the ability of the building to resist environmental risks, such as flooding, storms or earthquakes into the methods to assess the sustainability of buildings.

The development of harmonised methodologies for sustainability assessment in Europe takes place within the framework of the standardising activities of CEN TC 350 taking into account the results of international standardisation according to ISO TC 59 SC17. The state of discussion reached within CEN TC 350 in early 2008 can be described as follows:

- The assessment of the sustainability of buildings is to be carried out on the basis of the description and assessment of economic, ecological and social aspects while at the same time taking account of the technical and functional quality of the building.
- The object of assessment is the building including the land on which it is build. It shall be assumed that a prior decision-making and assessment process regarding the building's location has taken place.
- The assessment is to be based mainly on quantitative methods, which means that the assessment of the environmental impact of the building should be based, amongst others, on the results of the life-cycle assessment and the assessment of the economic aspects mainly on the results of a life-cycle cost calculation.
- The issue of the health, comfort and safety of the users, visitors and neighbours should be taken into consideration when assessing the social quality of a building.
- Issues of defining assessment criteria (reference, limit and target values) and assessment processes should be settled at national level.

Germany is actively participating in the international and European standardisation process and makes use of the achieved results as a basis for developments at national level.

2 Starting positions and first experiences made in Germany

2.1 Actors and activities

For more than a decade, Germany has been working towards implementing sustainability principles in all spheres of daily life and economy. In this effort, the building, housing and real estate sector or rather the need area of "building and housing" in connection with sustainable settlement development have been identified as key action areas. Considerable efforts have since then been undertaken by the construction materials industry, the building, housing and real estate sector, the scientific community, the financial and insurance sector, policymakers and public administration as well as by associations and representatives of all stakeholders. These efforts aim at developing and implementing strategies to save energy, conserve resources, consider environmental and health aspects as well as to achieve cost efficiency and profitability when planning, building and operating buildings while at the same time taking account of quality aspects in terms of functionality, technology, design and urban planning. Activities focus on the development, testing and implementation of new products, technologies and construction methods, refined design and planning principles as well as of planning, assessment and optimisation tools and methodologies for the assessment of economic, environmental and social adequacy of buildings as well as of further education and training schemes for professionals in this field.

The explanations in subsequent Section 2.2 are mainly based on the perspective of the public sector in its different roles of legislator, client and owner, funding body and coordinator and elaborated by means of examples of activities of the Federal Ministry of Transport, Building and Urban Affairs.

2.2 National legislation on energy efficiency in the building sector

The transposition of the EC Directive 2002/91/EC on the Energy Performance of Buildings into national law brought about comprehensive amendments to the German legislation on energy conservation (Energy Conservation Act, Energy Conservation Regulations). On this basis, the Federal Government adopted the Energy Conservation Regulations in 2007 which entered into force on 1 October 2007. They provide, amongst others, for a phased introduction of energy certificates for the entire building stock. In the future, an energy certificate must be presented for any transaction (in this case: sale or letting) in connection with buildings or apartments. This certificate will contain an assessment of the energy performance of the building as well as voluntary information on its CO_2 emissions.
Experiences made in Germany have shown that any reservations that may exist concerning the introduction of energy certificates can be overcome by a preceding trial period, the involvement of all stakeholders in a dialogue as well as by making necessary data and calculation tools available. While for example energy billing services, craftsmen and chimney sweeper focus on issuing relatively inexpensive energy certificates which are based on the assessment of energy consumption, architects, engineers and energy consultants offer energy certificates which require a calculation of the energy demand and can easily be expanded to represent an entire energy concept. In Germany, both types of energy certificates are considered acceptable (more information at www.dena.de/en/). The certificates are meant to provide information on the energy efficiency of buildings, on one hand, and suggestions for upgrading the building shell and the heating, ventilation and air conditioning systems, on the other hand. In doing so, they can serve as an instrument for increasing transparency in the real estate market.

The EU council adopted comprehensive strategic objectives in the field of combating climate change and conserving resources. Key issues are
- reducing CO_2 emissions in relation to the initial basis of 1990 by at least 20 % by 2020.
- increasing the share of renewables in the total energy mix to 20 % by 2020.
- reducing end-use energy consumption by 20 % compared with the forecasts for 2020.

Against this background, Germany intends to tighten the legal requirements regarding the energy efficiency of buildings by around 30 % and to adopt additional provisions – the Renewable Energy Heating Act – which specify mandatory quota for the use of renewables to heat buildings and hot water in new buildings. The Renewable Energy Heating Act and the amended Energy Conservation Regulations will both enter into force on 1 January 2009. In the medium term, Germany is aiming to achieve a passive house level for new buildings.

2.3 Round table and Sustainable Construction Guide

In 2001, the Round Table on Sustainable Building at the Federal Ministry of Building, Transport and Urban Affairs was established as a result of a joint initiative by the building industry and the Federal Ministry of Building. The tasks of this Round Table are, amongst others, counselling the Federal Government and the Federal Ministry of Building, Transport and Urban Affairs in all matters of sustainable building, establishing a platform for discussion for all relevant stakeholder groups, preparing statements on international and European legislation and standards, developing bases for a national certification scheme as well as presenting and debating the latest research findings. Information on these issues can be found at www.nachhaltigesbauen.de. At present, the work of the Round Table is focused on establishing concrete criteria and requirements for the assessment of the sustainability of buildings. These topics were incorporated into the initial version of the Sustainable Construction Guide of 2001 [BMVBS 2001] which has been revised and expanded to cover the topics of planning and construction in the existing building stock.
Germany has made positive experiences concerning the work of the Round Table. It became clear that an instrument serving to form and exchange opinions has been and still is urgently needed in order to find out more about the different motives and interests of the stakeholder groups and to take them into account. In the meantime, a considerable development has taken place. Originally, mainly the construction materials industry and the building industry were actively involved. It was in the construction materials industry's interests, to identify the impacts of sustainable construction for the production and distribution of construction products and to participate in this process at an early stage. The building industry, supported by the Federal Ministry for Building, pursued a strategy of integrating the sustainability issue into a general debate and campaign to improve building quality. For about one year now, funders, insurers, rating agencies and renowned companies from the consulting sector have also been putting forward their viewpoints and interests. These interests are mainly orientated towards developing and shaping a uniform scheme to describe, assess and certify the sustainability of buildings – see section 4.

3 System of complementary planning and assessment tools

In addition to the development, testing and implementation of a certification scheme on building sustainability, further measures will be required. It is true that a credible label will contribute to marketing and market penetration as well as to the establishment of compact requirements on the part of the public sector and investors to be met by sustainable buildings. Planners and building companies, however, further need bases and tools to achieve the objectives required by the certificate, by means of planning and structural measures. In addition a quantitative approach for the assessment and certification of buildings will require data for establishing life cycle assessments of construction products, construction processes and buildings, for the life-cycle cost determination as well as for the estimation of the useful life of building components and the time period they remain part of the building.

Therefore, the scheme of complementary planning and assessment tools explained in **Figure 1** and **Table 1** was developed and realised. Different tools for optimising building parts and buildings as well as for certification are drawing on an identical basis of data (qualitative information - such as health risks in the handling and use of material- on construction products, life cycle assessment data, service lives, cost characteristics) and can exchange data via defined interfaces. In the course of the design development, it is thus possible to replace product and vendor neutral data from the planning phase gradually by product-specific information from the bidding phase.

The integration of key certification requirements into the planning process shall ensure that essential information is already produced in the planning phase instead of having to be collected within the context of the actual certification process – which would, in general, involve additional costs. The building passport will be an important basis for information in the certification of existing buildings.

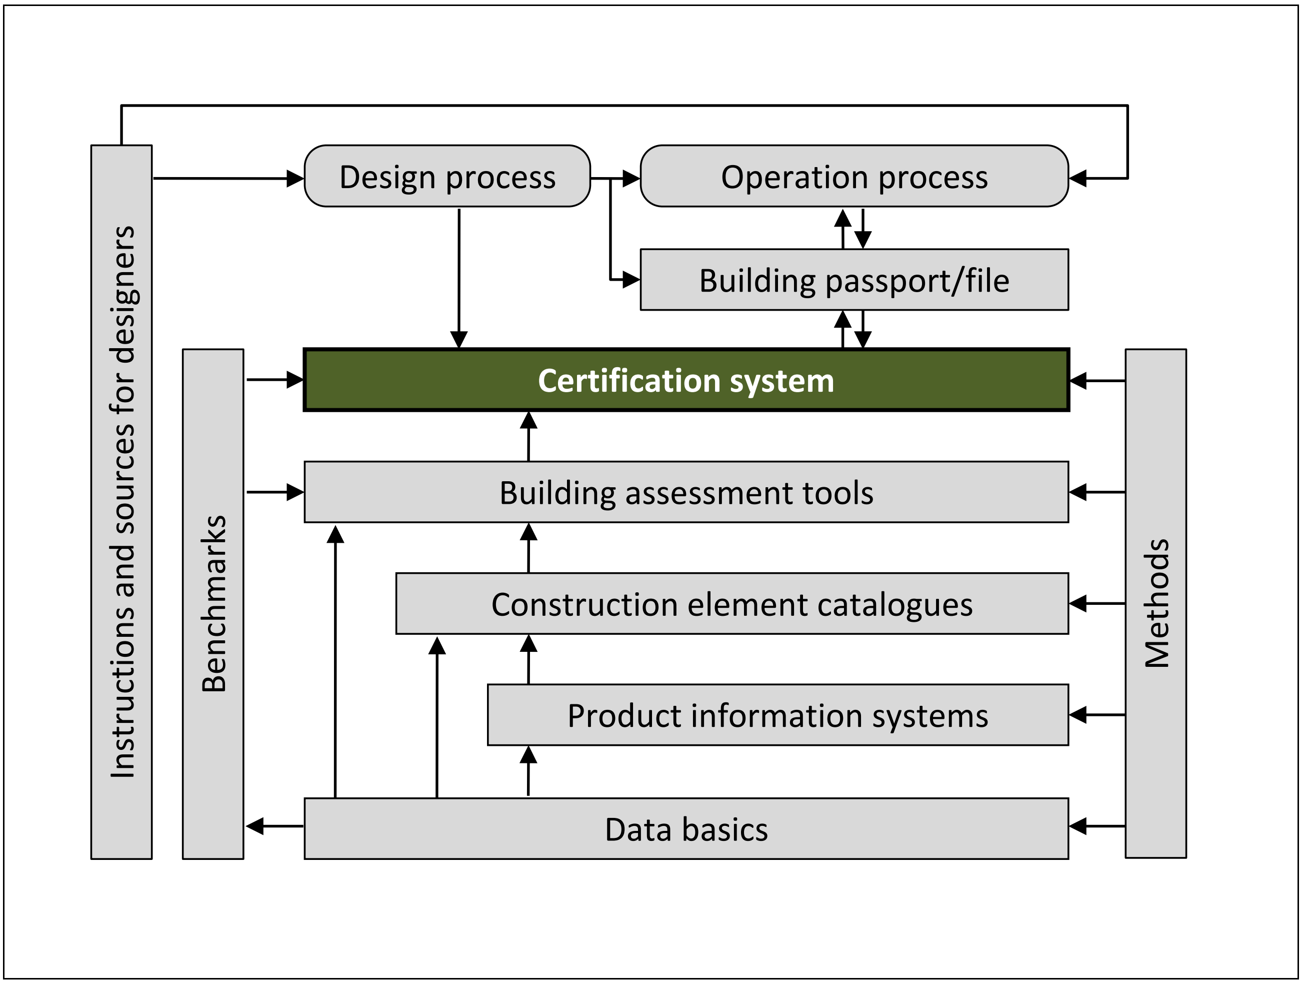

Figure 1 The place of certification in the system as a whole

Table 1 – overall system - overview

Basic data	**Data for the life-cycle assessment of construction products and processes** A national database with data regarding the life-cycle assessment of relevant construction products is established, continuously updated and enlarged, serving as a basis for life-cycle assessment of buildings and structural works. Current efforts focus on the life-cycle assessment of the heating, ventilation and air conditioning systems of buildings.
	Data regarding the useful life of construction parts Data regarding the useful life of construction parts are a prerequisite for life-cycle assessment and life-cycle costing. A database is established on the basis of research findings.
Methodologies	**Method development** Methodical bases for the following aspects, amongst others, were developed as a basis for the assessment of the overall performance of buildings. - an assessment of the resource and land use - the assessment of the quality of planning, construction and management - assessment of the stability of the building's value - inclusion of external costs in profitability assessments
Benchmarks	**Establishment of reference, limit and target values** Benchmarks are established and applied, amongst others, for the development of assessment criteria for the following areas: - data on the life cycle assessment of (reference) buildings - operating costs / life-cycle costs - data for the assessment of efficient land use - data for the assessment of the overall energy consumption in operation
Planning and evaluation tools	**Building products and hazardous materials information systems** Building product systems make environment and health relevant information on building product categories available on the network and thus contribute to decision making in planning processes. Hazardous materials information systems draw attention to environmental and health risks in connection with the handling and use of construction products (German examples of such systems: WECOBIS, WINGIS)
	Element catalogues and design optimisation tools For building components (such as walls with their complete layer structure), the findings of life-cycle assessments and costing are made available, applying the element method which is commonly used for cost calculation in Germany. The tools which are used for drawing up element catalogues can also be used for design optimization under economic and ecological aspects (German examples: SIRADOS; bauloop)
	Complex planning and assessment tools & construction optimisation As a means to support planning and at the same time as a basis for certification, complex tools are used which, based upon a one-time description of the building structure, establish construction costs, operating costs, energy consumption in the operation phase as well as the life-cycle assessment for the entire life-cycle and serve as a basis for building optimisation (German example: LEGEP).
	National scheme for the assessment and certification of sustainable buildings The scheme describes and assesses the sustainability of buildings, including the results obtained by means of other tools – see section 4.
Tools for the tendering process	**Supplementary environmental requirements for calls for tender** Supplementary environmental requirements to be integrated into the specifications are prepared and made available in the form of text modules.
Tools for planners	**Guidance and recommendations for action** In a network-based guide, planners are made aware of sub-steps in the planning process which are of enormous importance for sustainability aspects. They are then provided with target oriented and problem specific information by means of references to standards, guidelines, literature and case studies.
Documents	**Building passport / building dossier** Throughout the building's life cycle, relevant information on the building is described, managed and updated in the building passport or building dossier.

4 National scheme for the assessment and certification of sustainable buildings

The multitude of methods and tools which are already available for the assessment and certification of the environmental and health compatibility and the sustainability of buildings has been described and analysed repeatedly. Looking at them more closely, it becomes clear that so far the larger part of them have focused on applying criteria from the fields of locational quality, energy efficiency, climate change prevention, conservation of resources and health and thus contribute to describe the environmental and health compatibility of green buildings. Mainly qualitative assessments which are expressed in point systems, but which are also frequently based on the results of the preceding calculations of the energy efficiency of the object are widespread. Schemes which additionally take economic aspects into account and which also consider the results of life cycle assessment and life-cycle costing, however, are not very common yet.

In its current work on the development, testing and implementation of a national system to describe, evaluate and certify sustainable buildings (German Sustainability Assessment Method – GeSAM), Germany is focussed on the current state of international and European standardisation in ISO TC 59 SC 14, ISO SC TC 59 SC 17 as well as CEN TC 350. The aim is to assess the sustainability of buildings by including ecological, economic and social aspects in all their dimensions. This assessment should be based on quantitative methods of life cycle assessment and life-cycle costing and thus on scientifically recognized methods. The actual draft national certification scheme is based on a concept [Graubner 2007] developed by the Technical University of Darmstadt and the University of Karlsruhe which was commissioned by the Federal Ministry of Transport, Building and Urban Affairs. The scheme was the object of intensive discussions with all interested stakeholders and the German Sustainable Building Council which took place amongst others at the Round Table on Sustainable Building and at the Congress on “Sustainable Planning, Construction and Operation of Buildings” in December 2007.

The “GeSAM - German Sustainability Assessment Method“ envisages including economic aspects in addition to the environmental und social performance of the building and thus expands the “green building approach” towards a “sustainable building approach”. The method gives equal importance to ecological, economic and social aspects and takes account of this fact in the weighting of the three dimensions of sustainability assessment. In addition to the evaluation of the building’s sustainability, the quality of the building’s location and the quality of the planning, construction and management is described. **Table 2** provides an overview of the criteria applied by the scheme. Only selected examples are given for the criteria. The entire list of criteria currently contains around 70 criteria.

Table 2 German Assessment and Certification System – overview and examples (as at 03/2008)

Criteria category	*Partial aspects*	*Examples*
Ecological Quality	Global environmental impacts	Global warming potential
	Local environmental impacts	Particulate emissions from heating systems
	Use of resource	Use of primary energy
Economic Quality	Life cycle costs	Operating costs
	Value stability	Forecast development of the building’s value
Social and functional quality	Health and comfort	Indoor air quality
	Functionality	Barrier-free access
	Design and urban quality	Art in architecture
Technical Quality	Compliance with technical standards	Compliance with thermal insulation standard
	Quality of building facilities	Quality of heating system
	Durability, resistance	Hail resistance
	Aspects of conversion and demolition	Recycling potential
Process Quality	Planning quality	Stakeholder involvement
	Quality of construction activities	Low-noise construction site
	Management quality during operation	Operative cost controlling
Quality of Location	Conditions and risks of the microlocation	Risk of flooding
	Access to transport links and media	Public transport links
	Possibilities of expansion	Reserved space

In establishing criteria and developing measuring procedures and assessment standards, Germany is oriented towards its national objectives which however at the same time based on the commitments made at European and international level. These are, inter alia:

- limiting the land take per day for traffic and settlement areas to 30 hectares per day in Germany, for example by giving priority to the inner development of settlements rather than to their expansion – to be taken into account in the evaluation of land use due to the type and size of the land plot.
- improving energy efficiency by tightening the requirements on the permissible primary energy consumption of new buildings of 30 per cent from 2007 to 2009 and additional 30 % by 2012 – to be taken into account in the evaluation of non-renewable resources consumption.
- increasing the share of renewable energy for heating in buildings from around 6 % in 2006 to 14 % in 2020 - to be taken into account in the evaluation of renewable resources use.
- giving more weight to life cycle costs when making investment and procurement decisions with the objective of reducing these costs – to be taken into account in the evaluation of economic performance.
- improving indoor air quality - to be taken into account in the evaluation of the environmental compatibility in terms of social performance.

The Sustainable Construction Guide of the Federal Ministry of Transport, Building and Urban Affairs contains a comprehensive presentation of objectives and possible approaches in connection with the planning, construction and management of sustainable buildings. An updated version which includes additional provisions for the existing building stock will be published in the course of 2008.

The following preparatory measures for the introduction of the certification scheme are currently undertaken in Germany:

- Development of training and examination programmes for certifiers
- Completion of the basic data for the life-cycle assessment of buildings
- Revision of the basic principles for estimating the actual time during which a component will remain part of a building (estimated service life period)
- Further development of methodologies for the calculation of external costs
- Trial of the certification approach by applying it to selected objects

First results of the trial of the certification approach will be included in the presentation of national example objects at the SB Challenge 2008.

5 Summary and perspective

Against the background of the experiences made in Germany, it can be said that the establishment of a Round Table on Sustainable Building involving all relevant stakeholder groups is a key prerequisite for developing a national consensus on issues concerning the integration of sustainability aspects into the building, housing and real estate industry. Hereby it is possible to initiate and coordinate preparatory work in the form of research projects, on one hand, and to formulate joint positions on the development of a national assessment and certification scheme, on the other hand This scheme, however, is embedded in a package of complementary information, planning and assessment tools which is based on a uniform basis of data and oriented towards the current state of international and European standardisation.

For the investors acting at European or international level, however, the problem of having to deal with a multitude of different national assessment and certification schemes persists. For this reason, Germany will take part in initiatives which aim towards a mutual recognition of certificates or a joint assessment approach while applying the individual national target values and weighting factors. Intensive discussions with neighbouring states on this issue are planned to take place in late 2008.

SPACE FRAME WALLS: FACILITATING POSITIVE DEVELOPMENT

Janis BIRKELAND Prof Architecture[1]

[1] Faculty of Engineering and Built Environment Design, Queensland Institute of Technology, Brisbane, Australia, janis.birkeland@qut.edu.au

Keywords: Positive Development, sustainable development, Green Scaffolding, Green Space Wall, living walls, ecological design, virtual modelling, building information modelling, ecosystem goods and services

Summary

This paper reports on progress in developing new design and measurement concepts, and translating these concepts into practical applications. This research addresses gaps in 'best practice' green building, and is aimed ultimately at replacing green buildings with *sustainable* urban environments. Building on the author's previously articulated concepts of Design for Eco-services and Positive Development, this research will demonstrate how to eco-retrofit cities so that they reverse the negative impacts of past design and generate net positive ecological impacts, at no extra cost. In contrast to 'restorative' design, this means increasing ecological carrying capacity and natural and social capital through built environment design. Some exemplars for facilitating Positive Development will be presented in this talk, such as Green Scaffolding for retrofits, and Green Space Walls for new construction. These structures have been designed to grow and change over time, be easily deconstructed, and entail little waste. The frames support mini-ecospheres that provide a wide range of ecosystem services and biodiversity habitats, as well as heating, cooling and ventilating. In combination, the modules serve to improve human and environmental health. Current work is focused on developing a range of such space frame walls, optimised through an innovative marriage of eco-logical design and virtual modelling.

1. Innovations in Design and Measurement

1.1 New Design Concepts

The talk will present a range of eco-logical design concepts that are currently being developed and digitally modelled. These new design modules can create urban 'eco-services', mitigate climate change and address other sustainability issues on virtually any site, at a net resource savings. The term 'eco-services' is used here to encompass ecological health and resilience for its own sake, as well as the essential functions provided by the natural environment. With Professors Robin Drogemuller and John Frazer, and students from the Queensland University of Technology, the prototypes are being 'virtually' modelled in 3D CAD systems to optimise the modules for different applications, sites and contexts through generative feedback loops. The research will show that simple software tools can support the uptake of sustainable design within professional decision making and design processes. This digitally-supported Design for Eco-services process will facilitate further in-depth peer review and collaboration with 'green' building firms and organisations.

1.2 New Measurement Methods

New kinds of benchmarking and measurement concepts are being developed to facilitate Positive Development. These are necessary for assessing urban eco-services, and the 'positive' ecological impacts generated by the new design concept. This research aims to correct biases against sustainability that are now embedded in existing assessment tools (below). The project applies a new 'sustainability standard', where the building leaves the ecology healthier after construction than before (Birkeland 2003). With PhD students, a prototype computer-aided tool is being created to aid both the design and assessment of Positive Development projects in different urban contexts and micro-climates. User-friendly, illustrated guidelines will explain the logic underlying the new form of assessment.

2. Beyond best practice

'Best practice' green buildings are not sustainable. There are, however, already many isolated examples of technologies that reduce the *rate* of future resource consumption, compared to standard buildings - at a good return on investment (Katz 2003, Lucuik 2005, RICS 2005, GBCA 2006). There are, for example:

- Resource autonomous developments that generate their own energy and treat their own waste (Vale 2000 and 2002, Mobbs 1989)
- Building retrofits that increase worker health and productivity while saving resources (Romm 1998)
- Appliances that operate on direct solar energy, and so on (Poole 2006)

Green approaches reduce impacts, but still increase total resource flows and externalize impacts. For example, most green buildings increase the 'urban heat island' effect, where cities are much hotter than their regions. The 2003 European heat waves resulted in up to 35,000 deaths (IFRC 2004). To be sustainable, then, buildings must ultimately generate net positive impacts and create surplus eco-services. The foundation of the proposed research is the author's 'Positive Development', whereby new construction would have net positive impacts, and compensate for embodied energy and waste. A 'Positive Development' is defined as that which *adds* social and ecological (as well as environmental) value to the urban environment by expanding both the:

- 'Ecological base', which encompasses natural capital, biodiversity and habitats, ecological health, and bio-security (ie the life support system)
- 'Public estate', as substantive democracy ultimately depends on equitable access to the means of survival

3. A pre-requisite to sustainability

As we have already exceeded the Earth's carrying capacity, urban development that supports the ecology, as well as improving the human environment, is essential to sustainability. Ecological restoration is not enough. Sustainability cannot occur without a new kind of built environment design that generates surplus eco-services, habitats and ecosystems. Currently, built environment design drives excessive demand for materials and energy in other industries, shapes resource consumption into the future, and closes off future development options and social choices. While the built environment is central to social and ecological problems, this research will show how development can be converted into a sustainability solution (Birkeland 2002). Therefore. this research addresses the essential pre-requisites of a sustainable built environment, as follows.

3.1 A fundamental paradigm shift in green building theory and practice.

A fundamental paradigm shift in green building theory and practice is required. The concept of re-designing development to reverse prior impacts and generate net positive gains represents the next stage in the evolution of environmental management paradigms (Birkeland 2003). The theoretical stages have thus far progressed from: (a) 'compliance' or end-of-pipe design, through (b) 'eco-efficiency' or front-of-pipe design (Weizsacker, Lovins and Lovins 1997), to (c) 'zero-waste' or closed loop design, where waste is designed completely out of production and consumption systems (McDonough and Braungart 2002). Natural systems can replace or reduce most capital and energy intensive mechanical systems (see Beattie and Ehrlich 2004, Benyus 1997). However, the proposed paradigm will enable us to aim beyond zero waste and/or carbon neutrality to net Positive Development through (d) Design *for* Eco-services.

3.2 An approach that can address the scale of the problem.

Any solution must contemplate the scale of the problem. Current management approaches (eg incentives and trading) cannot address the sustainability imperative in time. Several international bodies, such as the OECD, have warned that material and energy flows need to be reduced by 90 percent within a few decades (Hasegawa 2002). Overall, the built environment generates about half of those resource flows (Roodman and Lenssen 1995). 'Green' buildings increase total material and energy flows. Also, only 2-4 per cent of the building stock is new each year, and half of building energy is embodied in construction itself. So even if *all* new buildings were 'green', they would only address 2 percent of 20 percent energy flows (ie .04), and would still have other negative impacts. Due to the material and energy flows in existing buildings then, 'eco-retrofitting' of cities is a pre-requisite to sustainability. The proposed retrofitting concepts support this imperative, as they can be adopted and replicated virtually anywhere on a large scale. They can also be applied in new buildings.

3.3 A practical strategy for implementing eco-retrofitting.

The research offers a practical strategy for implementing eco-retrofitting as well. Eco-retrofitting has already proven to pay for itself in human and natural resource savings, while generating employment and low-risk investments (Romm 1998). Any extra R&D and construction costs can be recovered from the net resources savings and capital gains in a short period of time (Edwards 1998, Katz 2003). Retrofits of commercial buildings bring substantial savings and increased worker health and productivity, while reducing externality costs as a whole (Hargroves and Smith 2005, Esty and Wilston 2006). For example, the market value of a retrofitted home, on average, instantly increases more than the cost of the retrofit (US EPA 1998). Indeed, investments in greening buildings compare favourably with investments in stock and bonds (Romm 1998). The savings from water, energy and material efficiencies will increase as their true costs are eventually reflected in their price (see Meyers and Kent 2001). While the contemporary approach is to rely on indirect and hence unpredictable incentives, this project will harness market forces towards 'direct action'.

3.4 New design and measurement concepts for the conversion to Positive Development.

New design and measurement concepts are required to support the shift to Positive Development. Although eco-retrofitting would cost society less than doing nothing, 'best practice' exemplars and tools will *not* drive the fundamental systems change in the construction industry that is needed. Current environmental management and assessment tools are biased against eco-retrofitting (Drogemuller 1999), as well as ecological sustainability (Birkeland 1993). In fact, sustainability is deemed to be 'addressed' by tools that simply predict, measure and trade off negative economic, social and environmental impacts to reduce relative future harm. Because our computational tools focus on negative inputs and outputs, they encourage change at the margins. Further, they do not take into account the unique nature and intrinsic value of living things. They reduce complex, location-dependent, living ecosystems to generalized resources and impacts. The focus has been on impacts (ie measuring symptoms) rather than design (ie identifying causes and solutions). The proposed approach would address significant systemic biases in building design and assessment tools (below).

3.5 New methods for increasing positive impacts at the building and urban scale.

This research aims to develop new methods for increasing net positive impacts at the building and urban scale. There are myriad measurement methods for buildings, but they largely ignore eco-services and ecosystems. Ecosystem goods and services refer to natural systems that, for example: support biodiversity and productive ecosystems; treat organic wastes; sequester carbon; control pests; produce food, fibers, and pharmaceuticals; help regulate the local (and global) climate; develop fertile soils and prevent erosion; purify air; store and recycle water; and alleviate floods, drought and storm water runoff (Daily and Ellison 2002). The term has been used to refer to human benefit only. Thus we need a term that includes ecosystem health, resilience and integrity, or 'eco-services' (ie not just 'good and services'). Existing methods indirectly encourage the substitution of ecosystems by built and manufactured capital. The proposed approach would replace fossil fuel driven machines with natural systems.

3.6 Contribution to building information modeling ('BIM').

Finally, this research will contribute to building information modeling ('BIM'). The construction industry is rapidly moving towards BIM. It provides a single information model for 'real time' information exchange between participants in the building design and construction process. At present, however, BIM cannot deal with crucial sustainability issues like embodied energy, greenhouse gas emissions, biodiversity and health. The project is contributing to, and benefiting from, current work at QUT, led by Professors Robin Drogemuller and John Frazer, toward better integration of BIM and virtual modelling to support more sustainable design and construction. This research project is essential to ensuring that such technical advances in the building industry integrate deep sustainability principles and criteria.

4. Sample space frame modules

The primary advances provided by this project are: a) design for eco-service concepts and prototypes and b) eco-service measurement concepts and tools. This project will show that net contributions to the ecology, as well as society, are possible through development itself, despite unavoidable 'ecological waste' (Birkeland 2007b). Two generic prototypes are illustrated here: a) Green Scaffolding for eco-retrofitting, and b) Green Space Wall for new buildings. These generic types are briefly presented before the discussion about how they address sustainability issues and represent an advance over what is now called 'green building' design.

4.1 Green Space Wall

The Green Space Wall is an ecosphere that doubles as an exterior wall or mixed interior/exterior spaces in new development. Despite the unavoidable resource flows embodied in new construction, there will always need to be new buildings, which currently have significant embodied waste. New building can, however, reduce the impacts of the urban areas by *substantial* positive on-site and off-site ecological gains. These walls can create multiple, synergistic uses of space. For example, they can generate clean energy, air, water, food and soil - while providing social space. This approach contrasts with many 'green buildings' which minimize space to reduce the *additional* resource flows and negative impacts created by conventional materials and forms.

This Green Space Wall may be applied in a national sustainability (education, exhibition and collaboration centre. The proponents are a coalition of NGOs known as the ANSI that has garnered significant national community, public sector and professional involvement and support for the proposal.

A range of functions are included within an expanded double-skin building that redefines the human-nature barrier. Some modules support ecospheres for biodiversity protection or food production. The building acts like an integrated space frame sitting above a flood plane (with footings that do not require concrete). The solar stacks and light weight mini-wind generators are fully integrated with the vertical triangular structural trusses.

Figure 1 Example of new building using a Green Space Wall

4.2 Green Scaffolding

Green Scaffolding applies mainly to eco-retrofitting. It essentially wraps a light weight structure around the exterior of *existing* buildings to provide the full range of climatic and ecosystem functions. Such ecospheres are low in embodied energy and waste, adaptable, demountable and portable. Similar modules can also be installed in public spaces, or over some streets and parking structures, to contribute aesthetic and social values while increasing urban eco-productivity.

Virtually any building can be retrofitted to reduce its heating, cooling, lighting and ventilating bill, while cleaning air and water, reducing the urban heat island effect, producing soil and food, and adding environmental and social amenity. Such modules can be supported by horizontal or vertical triangular trusses that also support environmental controls like air ducts, solar stacks or shading devices.

Figure 2 Example of eco-retrofit using Green Scaffolding

5. Advances in design

These design innovations address basic omissions in 'best practice' green building design, by providing for the expansion of: (a) natural functions in urban systems to improve the ecology and eco-productivity of cities, (b) the integration of infrastructure and 'ecological space' for ecosystem re-generation with less net land cover, (c) the provision of eco-services to reduce mechanical equipment, fossil fuels, the urban heat island effect, etc, described below.

5.1 Improving eco-productivity and urban ecology

Green Space Wall and Green Scaffolding can increase the eco-productivity and ecology of cities. Design has largely ignored the need to design *for* nature, in addition to design for people. At best, green design aims to design *with* nature or *like* nature, and generally adds passive or active environmental controls onto a non-sustainable building archetype. This is partly because, in the name of 'efficiency', architectural spaces have sometimes been segregated and minimized. For example, contemporary best practice, 'double-skin' buildings reduce energy consumption, but create 'dead' spaces, adds costs, and increase the urban heat island effect. Design for Eco-services, in contrast, increases and optimises space for *both* social and natural functions.

5.2 Integration of infrastructure and ecological space

Green Space Wall and Green Scaffolding integrate infrastructure with ecological space to support ecosystem regeneration and productivity. Integrated 'whole systems' design approaches are understood to provide more efficiency gains per dollar because they create positive synergies, rather than trade-offs (Hawken, Lovins and Lovins 1999). However, conventional eco-retrofitting concepts have not been fully integrated with the structure, so they can add to construction costs even though saving resources. In the proposed prototypes for retrofitted and new buildings, the structure and eco-services themselves replace many high maintenance and fossil-fuelled mechanical systems. Being integral with the structure, they can prolong the functional and structural life of buildings. More importantly, this approach can improve ecosystem and human health, and universal access to the means of survival (eg food, heat and water).

5.3 Provision of multiple eco-services

Green Space Wall and Green Scaffolding aim to *demonstrate* means to overcome certain common deficiencies in green building. These are reflected in the proposed design of the Australian National Sustainability Initiative (Figure 1). The proposed sustainability learning centre will demonstrate a whole new typology of architecture that creates net positive ecological and social impacts. A lightweight, demountable space frame structure supports a Green Space Wall, composed of double-skin ecospheres. These modules create a variety of ecosystem goods and services ('eco-services') as well as providing environmental control functions. The modules not only heat, cool and ventilate the building, but produce clean energy, air, water and soil. Depending on the orientation and other functions, the exterior Green Space Wall would contain, for example:

- Vertical landscapes for water and air purification
- Habitats for small animals (eg frogs, beetles, lizards) that can be viewed from inside
- Sail and shade cloths designed for circulating cool air as well as providing shade
- Solar stacks and shower towers integrated into the vertical truss structure
- Bird and possum nests, fish ponds and butterfly breeding areas
- Pipes for exterior mists (cooling and fire prevention) integrated in the vertical truss
- Internal Trombe walls (from local construction rubble) for thermal rock storage
- Vertical composters and worm farms that are visible to building users
- Living machines to treat grey water and even sewage (in sealed modules)
- Light weight vertical wind turbines integrated with vertical structural truss
- Corridors, external walkways and/or decks that move through some modules

The next stage is to quantify and test the positive contributions to social and ecological sustainability made possible through this new design approach.

6. Biases in measurement

The project will apply new measurement concepts, to the design of a new computer-aided tool to quantify and assess Design for Eco-services. Just some of the problems with existing methods that the tool will address are listed below (Birkeland 2008):

- Traditionally, environmental planning and management has only tried to measure negative impacts, even though this is - by definition - impossible in a 'complex system' (Birkeland 1993). Predicting negative impacts requires an understanding of bioaccumulation and the interactions of toxins with immune systems. In contrast, development that did no harm would only need to be a good investment. Yet most assessment tools do not even count positive ecological impacts. The new tool will put net positive ecological and social gains on an equal footing with the relative reduction of future negative impacts and risks.

- The economic costs of environmental damage that conventional development will have in the future are downplayed in assessments, due to the inherent difficulties of predicting and measuring open systems. Yet many assessment methods do not even count the economic benefits of an *undisturbed* natural environment. They apply a meaningless relative standard, comparing green building to 'typical' buildings of the same kind, rather than to ecological conditions existing prior to any development (the author's 'sustainability standard'). The new tool will put the economic benefits of a healthy environment on an equal footing with the economic costs of green development.
- Most assessment methods favour existing, fossil-fuel driven, industrial processes and non-sustainable building types, in that their impacts are treated as 'normal'. An eco-retrofit or innovation is expected to pay back its costs (and sometimes even its embodied energy) whereas standard building equipment usually does not. That is, mechanical equipment is *not* seen as costing 'extra', even though they require regular maintenance, repair, spare parts and specialist mechanics. The new tool will put passive systems on an equal footing with fossil fuel equipment.
- Because our measurement methods treat current urban conditions as a neutral baseline, rather than negative, we usually only count the costs that will be incurred from this point on. Thus, our tools not only count the 'sunk cost' in existing systems, they exclude the 'opportunity cost' of poor design. To overcome this bias against eco-retrofitting, the benchmark should be the pre-development ecological conditions on the site. Thus we would compare *both* the original building - and the proposed retrofit - to pre-development conditions (ie sustainability standard). The new tool will put eco-retrofitting on an equal footing with new construction.
- As ecosystem services cannot be directly measured, 'surrogates' have always been used to enable quantification, such as the area of wetlands or volume of biomass (Heal 2000). However, such surrogates usually only look at one or two values of natural systems, such as carbon sequestration or water purification. Even holistic concepts like 'ecological footprints' can really only measure a reduction in relative negative impacts. Therefore designers do not try for multiple and surplus eco-services (Birkeland 2007a). The new tool will put the expansion of ecosystems on an equal footing with resource conservation and efficiency measures.
- Our conventional building assessment and rating tools do not assist in design as a creative process. Most, if not all, so-called 'design tools' only measure pre-conceived designs. Further, their measurement concepts are based on, and thus perpetuate, conventional building typologies. This project will provide means to help designers to create something that does not yet exist. That is, to 'design'. The new tool will put creative design processes on an equal footing with reductionist analyses.
- Because assessment methods treat complex living ecosystems as mere resources, this 'legitimizes' the substitution of natural for built and manufactured capital. Reducing the ecology to mere inputs and outputs conceals the need to increase ecosystem integrity and environmental flows - not just reduce consumption. Our current tools also discount the future by, among other things, not counting the time and cost of replacing living ecosystems or 'ecological waste' (Birkeland 2007b). The new tool will put ecological time on an equal footing with financial time.
- Our assessment methods do not consider how conventional development can transfer resources and increase disparities of wealth over time. Equitable concepts like 'environmental space' (ie the available renewable resources divided by the relevant population) are not yet applied to built environments. New concepts are also needed like 'negative space' to reflect the distributional impacts resulting from the conversion of (public) land and natural capital to private development. The new tool will put the distribution of resources, including space and access to the means of survival, on an equal footing with the distribution of negative impacts.

7. Biases in assessment

The 'DNA' of current assessment and rating tools - based on input-output accounting rather than design - encourage marginal improvements to an unsustainable archetype. They act as a barrier to Positive Development. Design tools needs to be very different than current approaches. The design concepts and measurement tools will help us move beyond green buildings to sustainable ones. Some biases to be overcome include (Birkeland 2008):

- From retrospective analysis to future-oriented design. The analysis of the predicted impacts of a proposed design can reinforce old forms and patterns of development at the expense of forward-looking processes that seek to value add and create new synergies.
- From impact reduction to impact reversal. The emphasis on mitigating negative impacts can be at the expense of eco-innovations that seek to improve social and ecological conditions through positive off-site and on-site impacts and health improvement.
- From building on templates to changing underlying concepts. Tools that encourage incremental modifications to conventional building templates can delay or prevent the re-design of basic infrastructure, spaces and forms that would increase the ecological base.
- From universal engineering to natural systems solutions. The perceived need to reduce everything to numbers can lead to mechanistic approaches that exclude the ecology, because natural systems defy simplistic measures (being complex systems).
- From aggregating impacts to mapping flows. Analyses that aggregate measurements to get a point value can obscure the potential for whole systems efficiencies to positively affect total resource flows by creating synergies among systems on different scales or levels.
- From sequential and segmented processes to integrated ones. The focus of LCA-based analyses on inputs and outputs of processes at separate stages during the construction process can encourage sub-optimal changes at the expense of rationalizing the whole supply chain.
- From data-driven indicators to implementing change. Overvaluing factors that we have data for can come at the expense of mapping systems dynamics to find better means of meeting needs or better 'leverage points' for generating positive ripple effects throughout the system.
- From an individual project to a contextual perspective. The focus on the efficiency of individual buildings and their components can be at the expense of rethinking buildings in relation to their context to improve social, structural and ecological deficiencies of the urban area.
- From fossil fuel reduction to a shift to solar resources. The emphasis on energy reduction through efficient use of fossil fuels distracts attention from means to convert to healthier *sources* of energy, and tends to lead to 'under-design' of passive solar systems.
- From reducing space to value adding space. Pseudo-efficiency and cost reduction through zoning and minimizing spaces in buildings can come at the expense of optimizing spatial resources by simultaneously accommodating human activity in viable ecosystems.
- From reductionist accounting to design reporting. Reductionist analyses can lead to tradeoffs between positive and negative factors at the expense of holistic design processes that explore wider options with the aim of increasing social, natural and economic capital.

Processes which frontload ecological design can help to overcome the inherent biases in our current assessment and measurement tools.

Conclusion

The transition to development that increases sustainability (rather than reducing negative future impacts relative to standard buildings) will require radically different design and assessment concepts and tools. The paper has provided a brief overview of progress toward new design and measurement processes presaged in *Positive Development* (Birkeland 2008). The talk focuses on *design* concepts and eco-technologies that can facilitate Design for Eco-services.

Summary

A major barrier to realising dramatic improvements in the environmental performance of buildings' structures is the inability to accurately quantify the environmental impacts of design alternatives. This paper presents a framework for determining the environmental performance of building materials and assemblies in Australia.

Presently being developed under the working title of "Building Assemblies and Materials Scorecard (BAMS)", this project aims to establish a method and reporting format to assess the environmental performance of building materials and assemblies. Learning from international initiatives, BAMS uses life cycle assessment (LCA) to ensure consistent and science-based evaluation of construction options. The underlying LCA framework of BAMS is unique in that it combines a number of essential LCA ideas in one scheme. It is intended that in the short term BAMS will provide a common basis for materials assessment in a number of existing environmental building rating tools in Australia such as Green Star. The potential applications as a long term goal however, may be far more extensive.

1. Introduction

The relationship between global climate change and energy use is well documented (Garnaut 2008, IPCC 2007, OECD, 2002, 2003). Building construction, maintenance and operation is responsible for the bulk of energy consumption in the developed world, and increasingly so for the developing world (Bressand et al, 2007, Farrell et al 2008). In keeping with worldwide trends (World energy demand is expected to jump by 71% by 2030 (Huberman et al 2008), total energy consumed by Australian buildings is expected to grow, further contributing to greenhouse gas emissions and other environmental impacts (CSIRO 2008).

The environmental impacts of buildings can be divided into three life cycle stages: i) 'construction'; ii) 'operation'; and iii) 'deconstruction'. Construction being those impacts associated with producing the materials, transporting them to the site and the assembly of the building; operation being those impacts associated with energy use, water use and other activities such as maintenance over the building's life; and deconstruction being those impacts associated with disposal of the building at the end of its life, which may include some recycling. Traditionally, the operational impacts have tended to dominate the total environmental impact of a building over its life cycle.

This paper centres on the Building Assemblies and Materials Scorecard (BAMS) Project. Drawing from international experiences, this project aims to understand the environmental impacts of building assemblies and materials. The project received funding from the Victorian Sustainability Fund. The deliverable at the end of the first phase was to develop a proof of concept for the BAMS project. The founding partners included Victorian local and state government organisations and a national peak industry organisation. As the founding partners are many, the project brings together key tool-developing organisations and potential users to jointly develop and implement a common methodology.

This paper presents the development to date for the first stage of the BAMS project, addressing base building materials for residential and commercial applications. The focus is on the broader concept and the approach, rather than the technical detail in the development of the scorecards. The long term future includes setting up an operational BAMS governance and accreditation system, refinement of LCA data, increasing the number of assemblies, including branded products and integration with other developments as appropriate.

2. Aim of Building Assemblies and Materials Scorecard

The Building Assemblies and Materials Scorecard project was initiated and developed to:

- Provide a common basis for assessment and comparison of building materials environmental performance across a growing range of tools and approvals processes;
- Provide a basis for minimising the impacts and optimising the environmental performance of building products and materials over their life cycles through incorporation of an agreed method in a range of relevant tools and systems; and
- Generate increased awareness about the potential for the appropriate use of building materials to reduce the total environmental impact of the construction sector.

Specific deliverables were to:

- Prepare a State of Knowledge report outlining key issues and opportunities;
- Undertake stakeholder workshops as part of a needs analysis and stakeholder consultation process;
- Develop an LCA-based scoring methodology for a range of common building assemblies incorporating generic building products;
- Use the developed methodology to score a number of generic building assemblies; and
- Assist partners in implementing the scorecard in their respective contexts through training and workshops outlining the scorecard's approach.

Strengths of the BAMS approach include:

- It is based on scientific life cycle data rather than qualitative estimates and is designed to support the National Life Cycle Inventory Initiative (auslci);
- It considers the whole of life performance, including construction, operation and deconstruction;
- It looks at environmental performance based on the application - where and how building products are used such as in a wall, or floor, or roof;
- It brings together key tool-developing organisations to jointly develop and implement a common methodology, offering for the first time a single reporting format for materials performance assessment;
- It helps manufacturers, suppliers and design teams respond proactively to growing interest in the environmental performance of building products and materials.

The stakeholders directly benefiting from BAMS include:

- Building rating tool users and industry professionals;
- Building rating tool owners and developers;
- Building materials and product manufacturers and representative organisations;
- LCA practitioners;
- Building and materials policy development professionals.

3. Research Design

A literature review provided an understanding of the state or play with regards to sustainable building material use in Australia and internationally. The literature review identified the following:

- Data on environmental impacts is currently generally insufficiently available or accessible.
- There is insufficient interoperability between existing tools and systems.

- Capabilities such as the Australian Life Cycle Inventory are still in development while others do not exist, such as an Australian damage indicator including effective biodiversity metrics.
- The high level of tool development (particularly at a local government level) has led to the multiplicity of overlapping approaches that are generating confusion and 'measurement fatigue'.
- International developments, in particular the development of ISO 21930 for Type III standards, have the potential to streamline the standardisation of environmental considerations into the Australian context and into Australian Standards.
- While Type III labelling provides a basis for reporting of environmental information, the standard was established on the basis that comparisons would not be made between products except on the basis of whole-of-life considerations. An additional step will be required to operationalise Type III results for decision-makers including specifiers, through an approach that takes an assemblage life cycle perspective.

To provide the capacity to address these issues, the BAMS project framework needed to enable a life cycle and assembly (rather than individual materials) approach to be taken, and create an effective platform for standardisation of approaches and growing interoperability in the Australian context. The framework also needed to allow for investigation of the possibilities and limitations of single-score weighting. Accordingly, Figure 1 illustrates the framework for activities and staging of the BAMS project.

The BAMS project considers the inputs into building construction, as well as operation and deconstruction scenarios. Building operational energy requirements (major drivers of operational environmental impacts) are addressed through a set of performance levels for energy efficiency as appropriate for the assemblage. For example, operational performance is critical for assessing the life cycle performance of cladding systems, however it is a less important consideration in cladding systems currently.

A range of environmental impact indicators were used, determined by the project partners. Generic building assemblies have been designed to be benchmarked on the basis of their life cycle performance, so that assessments can be made of relative performance against generic measures, such as standard performance and leading performance. Following the benchmarking exercise, a method of rating performance was devised, using a range of factors such as uptake, performance range and potential for future market transformation.

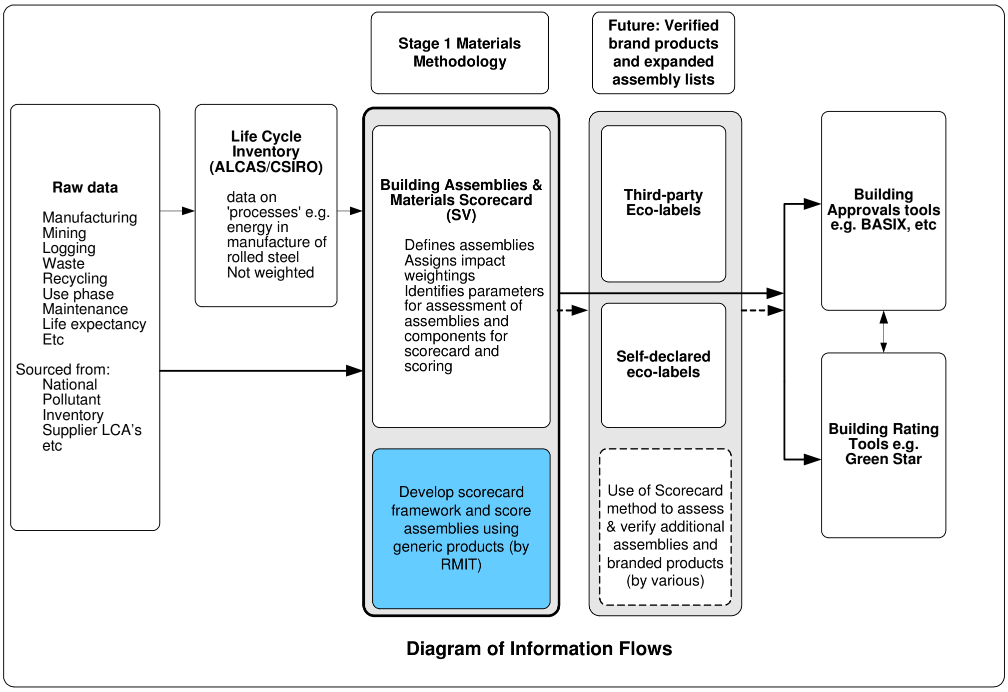
Consultation with stakeholders and the building industry as a whole indicated a strong preference for a single score output for BAMS. To achieve this single score, environmental impact indicators needed to be weighted. The project partners worked with the research team to build a shared understanding of opportunities and effective approach for weightings.

4. Development of the scorecards

The main phases that comprised the development of the scorecards were:

- data collection;
- method development;
- weighting process;
- life cycle impact assessment (LCIA);
- scoring process (develop scoring methodology, producing scorecards);
- peer review and stakeholder review.

The stipulations set out in ISO 14040:2006 were followed for data collection. The data categories used in the various life cycle stages included resource use, energy use, water use, land use, emissions to air, water and soil, and final waste. The quality of data complied with the data quality assessment method currently under development in the AusLCI project.



Formatted: Top: 3.17 cm

Figure 1 BAMS Framework: Activities and information flows for the Building Assemblies and Materials Scorecard

Deleted: ¶
¶

The methodology followed close parallels with the AusLCI project. However, since the method for BAMS was developed prior to the AusLCI project, it was agreed that the allocation rules follow the Dutch NEN 8006:2004 standards. Figure 2 shows the initial drafts of these scorecards.

The life cycle stages included in the BAMS project were:

1. Construction: extraction of raw materials; production of intermediate products; manufacture of assemblies; transport to the building site; building assembly on site .
2. Operation: energy consumption; maintenance and replacements.
3. Deconstruction: disassembly and waste treatment at the end of life cycle.

Transport between each of the stages is included in the LCA.

The five main indicators used for the BAMS project were:

- Resource use – measured as the additional energy required to extract future resources including fossil fuels and mineral resources.
- Water use – direct water extraction from the environment noting the water supply stresses in the location of the water extraction.
- Climate change – greenhouse effect based on fossil carbon dioxide equivalent emissions.
- Human health damage from pollution (excluding human health damage from climate change) – measure in WHO measure of death and morbidity (Disability Adjusted Life Years – DALYS).
- Land Use – measure of land occupation measured in area and time.

The environmental profile was calculated for each of the impact categories. Environmental impacts were checked to see if they were characterised. Normalisation and weighting followed next, leading to the scoring.

When the LCA of an assembly is completed, the result is expressed as a single indicator. It was anticipated that the user of the BAMS scorecard would like to make informed decisions regarding the sustainability of an assembly, when compared to its direct alternatives. The “BAMS score”, has been created to facilitate this decision by providing a relative environmental performance score of an assembly that is the result of directly comparing the performance of products providing similar functionality.

The scoring system was based on the BREEAM’s A-B-C system, where “A” represents best practice and “C” represents the worst. Therefore, “A” represents the most sustainable assemblies and “C” the least sustainable assemblies in their functional group. A separate set of BAMS-scores is determined for each group of assemblies. It is envisaged that for the Australian system, as “A” represents industry best practice, it may be incorporated into the leading best practice sustainability rating tool: the Green Star suite of tools, developed by the Green Building Council of Australia (GBCA). It is also envisaged that as “C” types of assemblies would represent minimum requirements, they would be equivalent to minimum standards set up by the Building Code of Australia (BCA).

It is important to note that the BAMS scores need to change over time. As new products are added to the group of assemblies and/or the environmental performance of existing products (assemblies) changes, the benchmark will change accordingly.

At every stage of the process, the project partners had opportunities to provide feedback. A peer review of the methodology was undertaken to ensure that the approach used for the BAMS project was robust and credible.

5. Conclusions

There is a rapidly expanding range of evidence demonstrating that environmental impacts are real and that significant steps are required to address them. The significant contribution of buildings to global environmental impacts, makes them an appropriate area for focus. Across the building life cycle, materials and assemblies can be significant contributors to total building performance, hence there is a need to optimise the selection of materials and assemblies in new designs to minimise environmental impact.

Furthermore, provided accurate and reliable information is available to decision makers regarding the environmental implications of different assemblages, and there is appropriate motivation to drive optimal environmental choices, significant reductions in the environmental impacts of buildings can be expected through the optimal use of materials and assemblies.

Figure 2 Draft concept of the presentation of the BAMS scorecards

Currently, the operational impacts of buildings are expected to dominate total environmental impacts over the building life cycle. However, as regulations dealing with energy efficiency, technical advancement in this area, rating tools and policies are developed to reduce energy consumption, the balance between operational and embodied (construction and deconstruction related) impacts is expected to shift. This shift in emphasis toward the embodied impacts of buildings will be expected to make projects like BAMS, which focus on materials and assemblies, even more important.

An initial analysis of barriers and opportunities showed that a broad range of stakeholders will benefit from the BAMS project, through provision of a valid, tested, publicly available method and protocol for building materials assessment. Stakeholder engagement is essential in ownership of the project and its process. Moreover, adoption and use, in concert with policy and market drivers, will lead to the significant environmental outcomes required as outlined above. The role of stakeholders in the project and in this endeavour is critical. It will ultimately assist in the uptake of BAMS and its sustainability outcomes.

6. Future Developments

The first phase of the BAMS project that has been described in this paper has concentrated on developing a proof of concept for Australia. Obviously, further work needs to be undertaken to move from the generic scorecards, to that of specific assemblies and materials from information provided by manufacturers.

Beyond this, however, there are a range of future developments that could flow from the development of the scorecard and methodology. These include:

- Development of a procedural manual for the method to allow certification of assessments to it by third parties (e.g. by Good Environmental Choice Australia (GECA) or others) or producing companies;
- Development of a procedural manual to allow peer-reviewing of scored assemblies and potentially products; and/or
- Lists of assemblages incorporating brand-specific products assessed either by third-party certifiers (e.g. GECA or other) or by supplying companies. Such lists could be used and facilitated by interested parties e.g. local governments and/or responsible authorities.

Keywords: wooden building, bioclimatic design, smart house, energy zero, renewable energy

Summary

The Gruppo Polo – Le Ville Plus building firm from Cassacco (Udine-Italy) and the University of Trento (Italy) are developing a prototype of a smart green building where a family of four people will live and that will be monitored for one year to check the correspondence to the project purposes.

The total cost of the research project, included the construction, has been financed by the Friuli Venezia Giulia Region and by the Gruppo Polo – Le Ville Plus.

The building is called "casa energy zero" referring to the fact that it does not use energy coming from conventional nets or from nonrenewable sources mainly of fossil origin. In addition the building is classifiable as autonomus house because the consumed energy is produced in situ by alternative and clean sources.

The main features of this smart green building are:

- carbon neutral;

- built with renewable materials and innovative building elements producing clean energy (sunspace, LVP intelligent window® , etc.);

- low energy consumption and with bioclimatic characteristic;

- integration between energy systems using alternative and clean sources;

- use of intelligent systems to manage clean energy sources in order to guarantee both inner environmental comfort and energy saving.

In order to test and validate the research expected results, the theoretic behavior of the prototype hypothesized during the design phase will be compared with the continuous on site monitoring of the functioning and performance of the active and passive systems, paying attention to the energy saving and the users' comfort conditions.

The building is now under construction. It will be completed in Autumn 2008 when the monitoring and evaluation phase will start.

1. Introduction

This paper deals with a research activity carried out at the Laboratory of Building Design of the University of Trento (Italy) aimed at the development of an integrated design process of a prototype building, whose performance will be monitored and evaluated on a real scale model. The main features of the design process are:

a. use of natural materials both for the bearing elements, made of wood, and for the finishing realized with dry systems;

b. attention to the energy performance of the envelope both in winter and in summer period, working especially on their structure and composition as well as on the inner joints (between the base-elements) and the outer ones (between the sub-elements);

c. integration with energy systems using alternative and clean sources: passive solar systems (sun space, Trombe wall, natural ventilation), thermal and photovoltaic solar systems, biomass and geothermal systems;

d. installation of an intelligent system for the managing of both the active and passive solar devices in order to minimize the total energy consumption but assuring in the meantime the best inner users' comfort conditions, even through self learning procedures;

e. development of innovative building elements as the so called "LVP intelligent window®" that will generate low speed air draught in order to contribute to the cooling and warning of the rooms together with an intelligent system for the draught modulation and optimization.

The prototype will be monitored to check the correspondence to the project purposes. Comparative analysis with simulation model will be performed.

In the following chapters, the most relevant aspects of the project mentioned above will be deeply analyzed and explained.

2. The Bioclimatic Concept

For what concerns the bioclimatic strategies, the building (design by arch. Arnaldo Savorelli – Solarch Studio in Bussolengo – Italy) presents both passive elements for winter heating and for summer ventilation and cooling (Figure 1 and 2).

First of all, it must be noticed the particular position of the construction inside the building site, situated at the northern side in order to let the widest part of the garden and the livable spaces directed to the South. The whole shape is interesting and studied in accordance with the local climate. The main body of the house, in fact, has a compact rectangular plant with an unique roof pitch facing the North with a double result: to protect the house from the northern cold winter winds and, in the meantime, to expose the widest part of the southern façade to the warm sun radiation during the cold season. Moreover, there is a little difference in altitude from the main roof and the secondary one on a lower level: it allows the presence of several little windows at the top of the building that, being inaccessible from the outside, can be left completely opened even during the night in order to guarantee a proper ventilation of the inner spaces during the warm season.

The southern façade, facing the garden and the pool, is a wide glass surface that takes advantage of the sun irradiation and let it enter the house till the back of the space during winter, while in summertime it is shaded by overhangs and provided with brise-soleil in order to avoid over irradiation and glare phenomena. In addition, a sun space and a Trombe wall are present. The northern façade, on the contrary, has little windows most of which are used just for summer night ventilation and to allow a proper views to the north side of the landscape.

Figure 1 Rendering of Casa Zero Energy – South-East view

Figure 2 The building under construction – North-West view

The façades facing East and West have themselves bioclimatic features, presenting low windows but large enough to let the user be delighted of the outer space without causing discomfort coming from the apparent daily sun path. Moreover, adequate shadows are provided.

3. The Building Technique

The prototype is a timber framed building with external and internal timber walls.

The building is built with natural and renewable materials excepted the hardware of the carpentry that is in steel. For this reason the building is classifiable also as natural building.

Actually in Italy there are few timber buildings, but their construction is increasing for the raising consciousness of users in relation with environmental issues and green buildings. In Italy, the majority of timber buildings are built with panel systems borrowed from the close Austria. Only few systems are planed and made in Italy, most of all with handmade systems.

For this research we chose to experiment a framed system that could be produced with industrialized techniques and that is completely designed in Italy by the Gruppo Polo – Le Ville Plus with the support of the University of Trento. The choice of this building system instead of a panel one is due to the greater building tradition in framed construction, also if limited to the Italian Alpine Region. In addition, it allows an higher constructive flexibility and it is easier to adapt to different configurations, even if the various building components are made with industrialized processes. The expected time for the construction of the prototype was 10 months, but the real time for the end of the works will be presumably 14 months. The delay is due to the experimental feature of the building site and to the necessity to modify some building details during the construction phases in order to improve their performance.

The pillars have a square cross-section 16x16 cm, they are connected to the basement by steel structure and steel plug. A knee wall connects together all the posts and it closes the frame. The main beams and the secondary beams (used sometimes as wall plates) are in glue-lam with a square cross-section 16x16/24 cm. The intermediate floor and the roof are built with glue-lam beams with a square cross-section 8x24 cm and a step of 50-80 cm. In both cases, the floor is built with board and insulation materials. In particular, the roof floor has a U value (thermal transmittance) of 0,197 W/m^2K. The external walls are made up by thermally insulated elements and by timber panels. With this kind of wall it is possible to reach a value of thermal transmittance of U=0,192 W/m^2K (Figure 3 and 4). The basement is a crawl space finished on the extrados by a reinforced-concrete slab. In this way concrete volume, which has a great heat capacity, can accumulate energy to help the heating system in the winter season.

The inner walls have a timber framework and plasterboard cladding. Wood fiber, a natural insulation material, is positioned in the free space between the frame grid. Nowadays, in Italy the most diffused type of inner wall is built by steel section and plasterboard cladding. This solution is in contrast with the natural house concept because the steel section set can determinate a Faraday cage that can reduce the inner environmental quality for the presence of electric charges that can not be disperse. In the prototype, a new type of inner wall will be tested that has not this problem because the frame is in timber and the elements are made by industrialized processes. The horizontal elements are lists 40x60 mm, the posts are two coupled lists 30x 50 mm. The system planned in this research is patented by the Gruppo Polo – Le Ville Plus and the University of Trento .

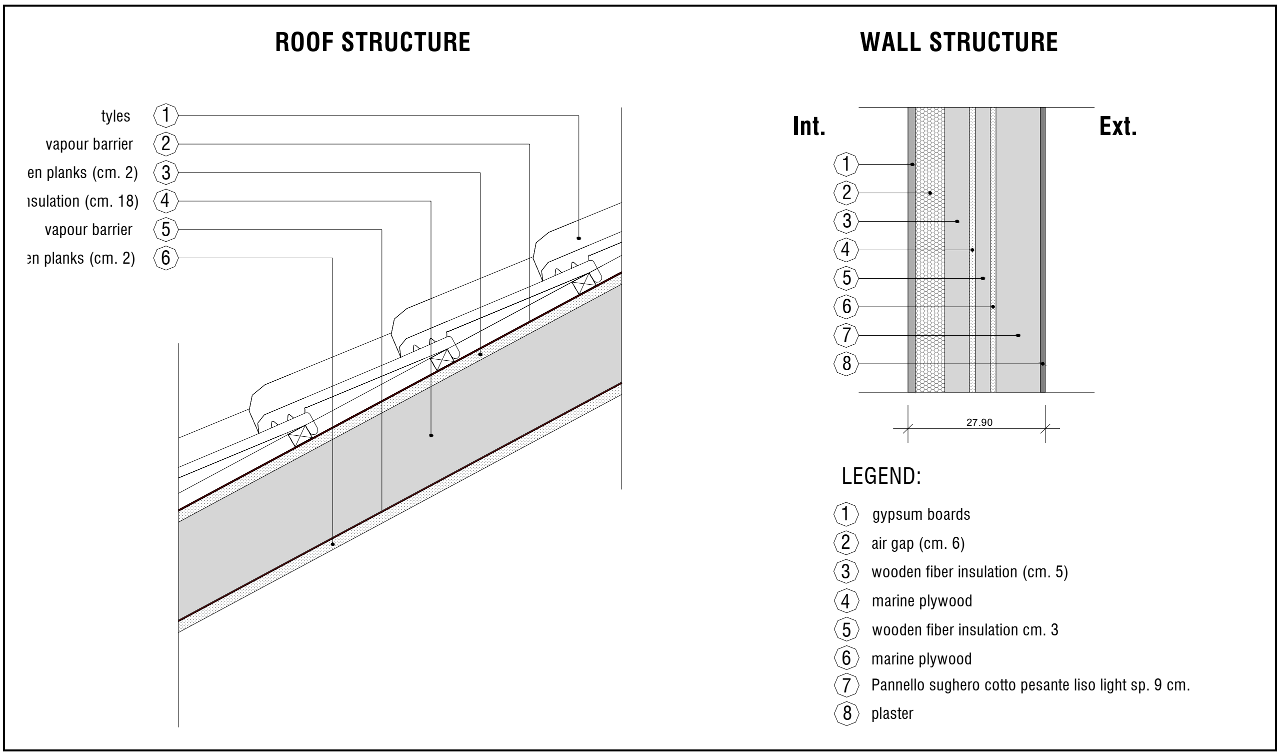

Figure 3 Detail of the roof and external wall structure

Figure 4 Picture of the inner part (main wooden frame) of the external wall under construction

Another innovative element planned in this research, is the LVP intelligent window®. It is built by two glazed panels with an interspace of 30-45 cm (depending on different solutions). Each panel has two openings with a flap putted on the top and on the bottom. In order to improve the air circulation in the interspace, a small fan is positioned in the lower part. The fan is operated by a small electric motor powered by a small photovoltaic system. The opening and the closing of the flaps manages the circulation of the air inside the interspace. In this way it is possible to run warm air into the house during winter, taking advantage of the greenhouse effect. In the same way, opening the opposite flaps it is possible to extract warm air from the inner space incrementing natural ventilation. The flaps are managed by the intelligent supervision system of the house and the opening/ closing is totally automatic depending on inner and outer environmental conditions (especially temperature values).

The building is now under construction. It will be completed in Autumn 2008 when the monitoring and evaluation phase will start.

4. The Intelligent System

The smart solutions implemented in the prototype building focus on the followings main goals:

- to test and verify the utility and the effective use of scenarios for the flexible utilization of automated passive solar systems;

- to quantify the contribution of automated control for the lighting, shading and conditioning systems;

- to experiment the possibility to guarantee both safety and security to the house users.

The devices and the correspondent functionalities of the smart system have been specifically established, in order to manage the interactions of all the technological system components in compliance with the peculiar issues of the prototype. In particular the following input devices have been included in the smart system design: temperature and humidity sensors, magnetic contacts to check the opening or closing state of the windows, occupancy and movement detectors, illuminance sensors (IEA, 2000).

Each device will be connected with a weather station in order to monitor the outside climate conditions (temperature, illuminance level, wind speed, rain) and with supervision touch screens in order to visualized and control the parameters available on the bus.

The design of the automation system has been developed in collaboration with the *bpt group*, in order to define both technical characteristics and programming possibilities of each device. Moreover in this phase the wiring structure, the topology of the bus system and the position of the smart elements have been identified.

The sunspace of the building is completely automated. It is a passive solar system, used mainly to heat the indoor spaces in the winter season. The automation system gives a specific signal about the proper functionality mode based on the outside weather conditions specifically connected with the proper use of the sunspace in winter season and with its complete opening in summer time.

The implementation of its functionality program has been previewed in two specific temporal modalities: seasonally and daily running function.

The functionalities of the smart system for the sunspace are:

- automated control of the opening/closing system of the windows, in order to optimize the convective fluxes of the air and the temperature level not only inside the sunspace but also in the adjacent rooms (automated control and priority of the manual operation);

- local and remote visualization of the windows opening/closing state and of the sunspace shading system according with the best position dynamically calculated;

- detection of the temperature values in the sun space.

The cooling system of the building is based on natural ventilation strategies. The functionality of the automation system for the natural ventilation improvement in the inner space is focused on the activation and the trigger action of the windows automated opening system. The main input parameter of this regulation function is the local detection of the inside temperature in order to support the air fluxes. The opening modalities of the opening systems are the same described above for the sunspace.

The building is equipped with shading systems. Their automated control is applied in different complexity levels: from the simple motorized action of the shading system to the complex control of smart shading systems, able to change properly the brise-soleil position according to indoor and outdoor environmental conditions (temperature and illuminance level). In this way, by means of the automation control system, it is possible to adjust both the slope level (angle of descent) of the brise-soleil elements and their movement speed (step by step or up and down).

The heating system of the building is controlled by the automation system. It is previewed, indeed, the integrated control of the heating system by means of the simultaneous use of radiant heating, solar panels and pellets boiler with height efficiency (the so called “integrated fireplace”). The whole system is regulated using a supervision system with seasonal mode. It is based on the subdivision in thermal zones of the radiant heating system.

The smart functionalities of the control system for this specific application involves the integration of the radiant heating with the solar panel, the proportional opening in continuous of the thermal valves of each single zone, the separate and differentiated activation of each defined thermal zone and, at least, in addition, the possibility to get, a remote control of the whole heating system.

The photovoltaic panels are connected to the automation system only for what concerns the data related to the hourly production of photovoltaic energy. It is indeed useful a comparison of these data in relation with the weather parameters values recorded by the outdoor weather station, correlated with the sun position and the sky conditions.

The smart system has been included as tool to guarantee the users’ safety in the experimental house, because it is able to monitor the domestic environment for what concerns faults and malfunctions of the systems or fire dangers. Moreover the automation system could help the normal manage of the domestic environment, for example by the automated opening of heavy shading systems.

With smart systems it is possible to have, as well by remote position, a constant security control of the building, through outside and boundary alarm and detection systems. At the same time it is possible to visualize the visitors’ identity using the connection with video-phone or mobile-phone. For this issue, the same magnetic contacts on the windows and occupancy detectors installed for the energy saving management could be used.

Significant data about the daily use of the building elements are controlled and monitored by the bus net of the devices installed. The supervision system allows indeed not only the recording of environments parameters but also the users’ behavior analysis. With these data it will be possible to improve the theoretic model of the building analyzed in relation with both weather conditions/building constructions characteristics and the user’ action in real use situation (Reinhart, 2004).

5. The on Site Monitoring

Even in Italy, summer average temperature are slowly increasing causing brief but very intensive muggy periods. The design and the construction of a light envelope building in a temperate Mediterranean climate is therefore a challenge directed towards the investigation of two main aspects: the possibility to guarantee adequate summer comfort conditions in bioclimatic free-running buildings, that is design with great attention to the local climate (most of all with reference to the sun position and prevailing winds direction); the necessity to provide building elements with an high thermal capacity in order to diminish temperature rises. This second aspect has been recently faced by the Italian regulation (Legislative Decree 311/06) providing a minimum mass value of the elements of the envelope of 230 kg/m^2 if the average daily solar global irradiation of the site in July is over 290 W/m^2. The mass, however, is not the only parameter to be taken into consideration speaking of thermal inertia and, most of all, it is also important *where* massive elements are positioned, even considering the building inner spaces.

In order to prove and to verify that this approach guarantees an high quality result, better users comfort conditions (following the recent adaptive comfort theory - Nicol and Humphrey 2002), an higher energy saving and the possibility to built using wood even in temperate climates, the research approach is based on to main activities:

1. the continuous thermal survey of the building;
2. an energy simulation in dynamic state conditions.

5.1 Continuous Thermal Survey

It will be carried on by recording data of the temporal courses of some specific environmental parameters (air temperature, relative humidity, air velocity, globe temperature, walls surface temperature) related to the most used thermal comfort indices (PMV and PPD – Fanger 1970) and to the adaptive comfort theory (Figure 5). Probes will be positioned in a certain number of rooms chosen for their exposure, their level and their different use. In addition surface temperature probes will be position both inside and outside the outer wall of the building together with fluxmeters, in order to reconstruct, during real life conditions, the thermal profile of the walls and their thermal behaviour in terms of thermal inertia (phase shift and temperature decrease).

In a second time, a new approach (already experimented by the authors) concerning the measurement on site of the thermal transmittance of the opaque elements of the envelope will be deepened by means of

Figure 5 The probes used for the assessment of the inner thermal comfort conditions

thermal fluxmeters and thermovision technique, both in a quasi steady state condition (winner period) and in thermal transitory one (spring and autumn).

The results of the research will increase a data bank concerning several thermal survey campaigns of real buildings that have been carried on by the Building Design Laboratory since 2002. In this particular experience, the surplus value (besides the possibility to monitor a building with mixed-mode systems, both passive and active, put all together one near the other in the same climatic context, with the same boundary conditions and so contemporarily assessable) is that, as far as the research goes on, some parts of the building can be modified in order to improve the thermal performance and the comfort conditions according to the output of the research itself.

5.2 Energy Simulation in Dynamic State Conditions

Once the building has been monitored, a virtual model of will be realized using specific software (EnergyPlus and its pre-processor DesignBuilder for the thermal simulation, Flovent for the fluid dynamic one) in order to determine the virtual temporal courses of indoor temperature and of the heat transfer through the building envelope as well as the circulation of the air flow in the indoor spaces and its capability to cool down the space and the structure. In a second time, a critical calibration of the model will be made in order to take into account the real behaviour of the inhabitants and their use of the building components (by means of specific questionnaires as well as a careful analysis of the recorded data), with particular reference to the bioclimatic strategies (shading elements, natural ventilation, sunspace, Trombe wall). When the annual recorded temperature trend is comparable to the virtual one (concerning both the temporal courses and the absolute values), the model can be assumed to be the “perfect virtual copy” of the building during the real life conditions for the duration of the study. Finally, it is possible to modify some building elements characteristics on the virtual model, in particular the mass value of the structure materials (but being careful to leave unchanged their thermal transmittance in order to verify only the influence of one parameter -in this case mass- on the building thermal performance), the shape and positions of the windows used for the ventilation, the disposition of the inner spaces and so on.

Following this methodology, it is possible:

- to compare the inner temperature trend in the base situation, that is the real one, and in the different versions analysed in order to evaluate the maximum, minimum and mean differences during the day when the mass of the building envelope is changed;

- to analyse the influence of an heavy envelope on indoor comfort conditions;
- to evaluate the influence of the building shape on a proper passive ventilation and cooling strategy.

The final goal is to propose guidelines useful in order to design proper bioclimatic and light weight buildings even in a Mediterranean temperate climate.

Acknowledgments

The research project has been possible due to the incessant activity of Loris Clocchiatti, president of Gruppo Polo – Le Ville Plus, that has hardly longed for the experimentation briefly described in this paper in order to improve the quality of the final product of his firm towards a better and new way of living. The on site construction of the buildings has been followed by arch. Carlo Rugo and geom. Denis Giammarini. The design of the electric and heating systems has been made by p.ind. Luigi Battista.

TITLE: ENVIRONMENTAL ASSESSMENT OF RESIDENTIAL BUILDINGS IN CHINA

Grace K C Ding

School of the Built Environment, University of Technology Sydney, Australia, grace.ding@uts.edu.au

Keywords: residential development, green buildings, sustainability, environmental assessment methods

Summary

China is the fourth largest country and has the largest population in the world. With its economic growth since the economic reforms starting from 1978 the government has struggled to contain environmental damage and social strife related to the economy's rapid transformation. The environmental degradation in China has been accelerated with the rapid growth in population and urbanization and the foremost problem that has challenged the government is the insufficient supply of housings. The growth in residential development has increased the demand for energy and natural resources for the manufacturing of building materials. Any improvement in the sustainable performance of residential developments in China will have significant impacts on environmental deterioration on a global scale. The concept of sustainable residential development is adopted in many countries and rating tools have been developed to guide and assess environmental performance of buildings. The purpose of the paper is to analyze the tools that are available in China to assess the environmental performance of sustainable housings and to present the results of an on-line survey and interviews in Beijing.

1. Introduction

According to the Department of Communities and Local Government (CLG) in the UK in 2004, approximately a quarter of the CO^2 emissions came from the energy consumption of homes (CLG, 2006). Sustainable residential development is about considering possible design options and to evaluate their life cycle impact. The information available during the design stage is limited and requires tools that can guide designers with default data and intelligence. Environmental building performance assessment tools for residential developments are designed to improve the overall building performance, minimize environmental impacts and costs. Most of these tools have been developed to transform the design goal into specific performance objectives and to provide a framework to assess the overall design. However most of the tools are voluntary only and are undertaken at the discretion of developers.

The purposes of this paper are (1) to examine the main issues and problems in relation to sustainable residential development; (2) to analyze the methods/tools that are available in China in assessing environmental performance of residential developments; (3) to present results of an on-line survey and semi-structured interviews in Beijing to explore the impact of environmental performance assessment tools for residential development in China.

2. An overview of sustainability assessment of residential developments

In recent years, a growing number of sustainable housing projects have been completed and sustainable housing is increasingly becoming part of common building practice. Sustainable residential development was one of the issues addressed in the United Nations Conference on Environment and Development at the Earth Summit in Rio de Janeiro in 1992 (Bhatti, 2001; Li & Shen, 2002). Bhatti (2001) states that sustainable residential development can make major contribution towards an environmental future. The method by which residential development is produced, consumed and managed, and the way it contributes to social and cultural life has major impacts on the environment.

IEA (2006) suggests that sustainable residential development can be achieved through preservation of the global environment, harmony between house and environment, and promoting health and pleasant living. From this viewpoint, a sustainable residential development is characterized by futurity and equity issues which aim to ensure that everyone today and the generations to come have a decent place to live which uses less resources to run than most existing homes. In addition to considering land use, orientation, shadow and light, concerns need to focus on the long-term costs - social, environmental and economic. Sustainable housing will be a growing part of the housing industry, making it a business opportunity waiting to be explored.

The purpose of sustainable housing is to raise the standard of living and to offer an opportunity for people to have a decent house to enhance social unity, well-being, economic growth and social improvement. Sustainable housing concerns not only the fabric of buildings but also the social and environmental context of construction practices. In sustainable housing construction, the concept of eco-efficiency is important and implies that a reduction in the environmental impact of housing construction can be undone by trends such as an increase in the average size of houses, and a decrease in the average number of persons per house (Klunder 2004). Sustainability is not just about low energy; it also means that people are happy to live where they live and that they live in a healthy environment.

Conventional residential developments are designed and constructed in accordance with the building codes, whereas green residential developments are designed, constructed and operated to consider environmental performance and minimize environmental impact. Most of the assessment tools have been used for planning and design development with specific performance objectives and provide a framework to assess the overall design using either rating system or assessment criteria.

3. The green challenge of sustainable housing in China

China is the fourth largest country in the world and accommodates more than 20% of the world's population (CIA, 2006). With its economic growth since the economic reform in 1978 China's GDP has increased more than tenfold while the environment has been deteriorating at an alarming rate (Cai, 2004; Ho, 2006). In 2005 China stood as the second largest economy in the world after the United States (CIA, 2006) and the second largest greenhouse gas emitter in the world and will be the leading emitter within the next couple of decades (Rousseau & Chen, 2001; Cai, 2004, Ho, 2006).

With economic development the government has struggled to contain environmental damage and social strife related to the economy's rapid transformation. According to the United Nations seven of the ten most polluted cities in the world are in China (EIA, 2005, Glicksman & Lin, 2006). The ongoing environmental deterioration such as air pollution, soil erosion and loss of arable land poses serious threats to economic growth in the long term if the Chinese government fails to control the environmental problems as a matter of urgency.

The environmental degradation in China has been accelerated with the rapid growth in population and urbanization and the foremost problem that has challenged the government is the insufficient supply of housing. According to the United Nations (2004) China has 1.56 million households still in need of housing and 350,000 households are still living in situation where they have less than $8m^2$ of gross floor area per capita and there is an increasing demand for residential housing needed to house the ever increasing population. As such any improvement in the design, construction and operation of residential housings will have significant impact on the rest of the world. The residential sector has already developed rapidly since the economic reform and is also the fastest growing sector in terms of energy and materials demands. Environmental pollution and insufficient housing are the two obstacles for achieving the goal of sustainable development in China (Ho, 2006).

Housing development in China is detrimental to the environment in many ways. Housing development is the main cause of loss of arable land for agriculture. The rapid growth in residential development has increased the demand for energy and natural resources for the manufacturing of building materials. In 2000 the total energy consumption in China had already exceeded total energy production by 17% of the same year (Ho, 2006).

In 1996 the Chinese government adopted housing reform to advance quality design standards and high quality construction methods and materials. However sustainability was not addressed to include energy conservation standards, healthy building features, durability and low maintenance features, water conservation standards, or recycling building materials (Rousseau & Chen, 2001). In 2006 the Central Committee of the Chinese Communist Party approved the 11th Five-Year Plan with the aim of reducing energy consumption by 20% per unit of GDP by 2010. The plan states that conserving resources and protecting the environment are basic goals, but it lacks details on the policies and reforms necessary to achieve these goals (CIA, 2006).

4. Toward sustainable housing

4.1 Laws and regulations

According to Rousseau and Chen (2001) China's rapid housing development was partly caused by the changes in the economic structure from a planned economy to market-driven economy which has led to the rapid expansion of the property market. The changes have led to the conversion of home ownership from government assigned to private ownership and the introduction of mortgage banking. The rapid economic development has stimulated serious migration of people from the rural areas to seek work and better living environment in the cities. The rapid modernization and industrialization in urban areas have escalated the demand for residential spaces.

Faced with the problems of insufficient housing especially for the low income people, affordable and appropriate housing has become a main focus of the Chinese government. In the series of Five-Year Plans for National Economic and Social Development, the government set goals to satisfy four key principles of housing development, namely affordability, livability, sustainability and adaptability. In recent years the government has established codes and standards to guide sustainable residential development. As Zhu and Lin (2004) state environmental building assessment systems developed by others will not be useful in China due to cultural and regional differences.

The Technical Assessment Handbook for Ecological Residence was introduced in 2001. This was the first rating assessment system for assessing sustainable housing which aims at improving environmental quality of residential buildings (Zhu and Lin, 2004). The handbook clarifies the concept of ecologically sustainable development as well as provides guidance in the planning, design, construction and management of residential buildings. It is constantly updated and the latest edition was published in 2006. The handbook is developed based on a list of performance standards and a set of design guidelines which are stringent requirements for pre-requisites. The handbook is only a simple rating system without explicit weighting. The usefulness of the handbook may be restricted as it only relates to residential projects and is voluntary only without clear consequences for non-compliance. The Technical Essential for Construction of Healthy Housing was introduced by the China National Engineering Research Centre for Human Settlement in 2004. It is very similar to the Technical Assessment Handbook for Ecological Residence. It also provides a standard for the design and construction of sustainable housing and emphases that green housing will need to concern environmental health as well as community welfare.

The development of the Green Olympic Building Assessment System (GOBAS) has impact on the development of environmental assessment tools in China. In order to integrate the goal of ESD into the development of Beijing Olympic 2008, the GOBAS was developed in 2002 and launched in 2003 supported by the Ministry of Science and Technology. The GOBAS gives a clear introduction on the design, assessment criteria and methodology of green building for the Olympic buildings. It lays down guidelines and principles for improving quality of buildings as well as reducing resource consumption and impact on the environment. It is Olympic buildings only. The assessment system was developed based on the concept of building environmental efficiency as in the CASBEE and LEED on a whole of life approach (Lin et al., 2005). Beijing Municipal Construction Committee has issued official document to adopt GOBAS as the Beijing local green building standard.

Following the launch of GOBAS, the Evaluation System for Green Buildings in China was developed as one of the 10th five-year national research plan. This system is an extension of GOBAS to be more regional specific and overcome the weakness of GOBAS to be a national standard for the evaluation of green buildings. It can be used to assess different types of construction in different climate zones (Qin & Lin, 2005).

In addition to sustainable housing assessment tools there are codes and standards issued by the government as a mean to improve building performance and to promote green buildings construction. The Outlines and Technical Principles for Green Ecological Residential Quarter Construction was introduced in May 2001 and it outlines the principles and targets on saving water and energy, ecological land use and pollution abatement. The Assessment Criteria for Green Building was issued in June of 2006 and it was the first nation-wide criteria on project construction in China to assess the green building from multiple objectives and criteria based on the whole of life approach for residential buildings. The assessment criteria clarifies the concept of green building and set up a legitimate assessment approach to assess housing performance. According to the assessment criteria, a green building should save resources (energy, land, water and materials), protect the environment and reduce pollution maximally, provide healthy, applicable and high-efficient space, and harmonize with nature during its life cycle.

Laws and regulations on energy conservation in China can be dated back as early as 1998 and the Design Standard for Energy Efficiency Building was issued in July 2005 as the first national wide criteria in China for energy saving design of public buildings. It is applicable to the design for energy efficiency of new and existing buildings. With improvement to the building structure and insulation, the standard aims at reducing the total energy consumption to 50% of that in 1980s. In 2006 the Regulations for the Administration of Energy Conservation in Civil Buildings came into force with the aim to develop household-based heat metering technique and equipments. It aims at enforcing the administration of energy conservation to improve the efficiency of energy use, and promote indoor environmental quality. It was applicable to residential but not applicable to low-rise residences built by peasants.

4.2 Research method

The introduction of the Technical Assessment Handbook for Ecological Residence in 2001 has marked an important era of sustainable housing in China. The Handbook has no doubt raised environmental awareness among construction professionals and guidelines that they can follow in the design and construction of sustainable housing. In order to examine the extent of impact an on-line survey was designed and conducted among construction professional in Beijing in December/January 2008. The questionnaire survey was designed and distributed online for a wider coverage and provided a quick and easy platform to return the completed survey. The purposes of the survey were to examine construction professional perception on green buildings and to explore the role of these assessment systems in the construction industry in enhancing sustainability in residential developments. Following the survey two semi-structured interviews were undertaken with representatives from the Beijing Institute of Architectural Design and Beijing Urban Engineering Design & Research Institute Co. Ltd. in January 2008.

The questionnaire was divided into three parts. The first part was intended to obtain general details of the respondents. Part two was intended to obtain the views of respondents in respect to their understanding and acceptance of green buildings in construction. It contains twelve questions. Part three was designed to identify the level of expertise the respondents have on the criteria for assessing sustainable housing and how familiar were they in using the Assessment Handbook for Ecological Residence for sustainable housing in China. This part contains eight questions. In addition to choice-based questions the questionnaire also contained several open ended questions whereby the respondents were asked to provide written opinions and have received tremendous replies.

The survey was undertaken in conjunction with Tianjin University of Technology (TJUT) and assisted by the China Engineering Cost Association (CECA) in distributing the online survey as well as organizing personal interviews for the research. The anonymous questionnaire was sent to practitioners in the construction industry in Beijing via email with a URL containing the online survey in December/January 2008. Many of the participants also forwarded the URL to other practitioners in the industry. Therefore it was difficult to determine the exact response rate. At mid February, 59 completed questionnaires had been received via online.

4.3 General information

Of the 59 returned survey 66% were from male respondents whilst 34% were from female respondents. Respondents came from a variety of background. The cost engineers and engineers have contributed the majority of the returned survey of 39% and 34% respectively. Architects and contractors have only contributed 10% and 9% respectively whilst the remaining 8% of the respondents were developers, project managers and academics.

Approximately 91% of the participants have less than 16 years of work experience and 65% were 26 to 35 years of age. The survey result reflects the keenness of younger professionals to take part in the survey and to provide personal opinions. Of the 59 returned survey 78% have provided written responses on the government regulations on environmental issues and their opinions on what the government could do to protect the environment. The responses will be summarized and reported later.

The respondents were asked to express their concern about the environment, 32% claimed that they were concerned about the environment a great deal, 59% were only concern a fair amount whereas 9% responded only little concern. The feedback indicated that they are quite skeptical about environmental protection and this may reflect the level of environmental awareness among the professionals. It is further reflected through their experience in working with environmentally related projects. About 23%% have less than 1 year work experience on environmentally related project whilst 69% have between 1 to 5 years and 8% have between 16 to 20 years working experience with environmental design, construction, maintenance and assessment. However with the respondents having work experience in environmental projects about 78% have done less than 5 projects whilst only 22% have done from 5 and up to 16 projects so far. The outcomes indicate that the respondents have insufficient exposure for dealing with environmental issues in construction and experience in relation to environmental projects. However considering that the first environmental assessment handbook was published in 2001 the result is quite encouraging.

In addition to the limited years of work experience in environmentally related project, based on the survey returns work experience of practitioners in construction industry in environmental project had been immature and at an early stage. Overall the respondents were rather young and inexperience. The outcome may be due to the majority of respondents (approximately 91%) having less than 15 years of work experience. It demonstrated that practitioners in the construction industry have very limited experience in environmentally related construction projects.

The survey also discovered that only 10% of the respondents with work experience in environmentally related project have received training in order to perform the work such as post-graduate studies, energy saving courses, clean technology courses or attended environmental CPD seminaries. Environmental training should be an area that the construction industry supports in order to equip professionals to improve their competence in environmental projects.

4.4 Observations and discussions

Part II was designed to obtain opinions and feedback on greening the construction industry. The questions were designed as a standard Likert scale where respondents were asked to rate each question from strongly disagree to strongly agree. The results are summarized in Table 1. Based on the returned survey the majority of the professionals agree that environmental issues are important for the construction industry and should be incorporated in construction projects. Approximately 95% agree that the demand for green buildings will increase and 90% believe that green buildings will increase in importance and increase in workload in the next few years.

About 84% believe that adherence to environmental practices can help the industry to grow further. This indicates that people are gradually realizing the benefits of green buildings to the well-being of humankind. This result was in line with the opinions from the two semi-structured interviews as they experience an increase in demand for sustainable housing in Beijing and people tend to prefer staying in green buildings as opposed to conventional buildings. The table also indicates the opinion from the survey respondents that laws and regulations will become more demanding and it was also confirmed in the semi-structured interviews. This is particularly serious for the energy conservation laws passed in October 2007 and in place in April 2008. In addition in December 2007 the government issued the Government Procurement List of Energy Saving Products which was the first mandatory energy law to enforce the use of energy saving products to reduce impact on the environment.

With regards to whether the construction industry has done enough to protect the environment the respondents had diverse opinions and only 28% agree, 34% disagree and 38% are not sure. About 70% disagree that research and development of green building is sufficient and further development is crucial in this area. However about 55% believe that the construction professionals are well aware of the importance of green buildings to the environment as opposed to the 21% that disagree. In relation to the level of expertise of construction professional in the design and construction of green buildings only 47% agree but 36% disagree that professionals have the expertise in the design and construction of green buildings.

Table 1 - Summary of opinions on greening the construction industry in China

Proposition	Responses (%)				
	Strongly Disagree	Disagree	No Opinion	Agree	Strongly Agree
Environmental issues are important for the construction industry	2	0	5	55	38
Environmental issues should be incorporated in construction projects	2	2	3	59	34
The demand for green buildings will increase	2	0	3	54	41
Green buildings will increase in importance in the construction industry	2	0	8	53	37
The workload in the design and construction of green buildings will increase in the next few years	2	0	8	63	27
Adherence to environmental practices helps the industry to grow	2	2	12	71	13
The law and regulations on green buildings will become tougher	2	0	25	49	24
The construction industry has done enough to protect the environment	5	29	38	23	5
Research and development of green buildings is sufficient	24	46	12	13	5
Construction professional are well aware of the importance of green buildings to the environment	2	19	24	50	5
Construction professionals have the expertise in the design and construction of green building	2	34	17	30	17

The survey results only provide a rough indication of the current situation of environmental awareness among construction professionals. However the survey results provide insight into the areas that may require attention. The overall result indicates that the construction professional's environmental commitment in Beijing is immature and lacks exposure. The situation will change dramatically when government environmental protection rules and regulations will be more and tougher.

Table 2 - Impact of Technical Assessment Handbook for Ecological Residence in the construction industry

Proposition	Responses (%)				
	Strongly Disagree	Disagree	No Opinion	Agree	Strongly Agree
The handbook is user friendly	6	6	35	53	0
The handbook is useful in assessing environmental performance of residential developments	0	6	35	59	0
The handbook is a useful guide in the design of green residential developments	0	6	53	41	0
The criteria set in the handbook are achievable	6	6	59	29	0
The handbook will help to provide better sustainability outcomes in residential developments	0	12	35	53	0
The assessment criteria are sufficient to cover the environmental aspects of promoting green residential developments	6	18	29	47	0
The cost of building green residential developments will be more expensive than traditional developments	6	6	35	47	6
Green residential building will take longer to complete	6	12	23	47	12
The handbook should be improved and applied to other types of construction	0	6	23	65	6

Part III of the survey was designed to examine the impact of the environmental assessment tools for residential building performance. The survey chose particularly the Technical Assessment Handbook for Ecological Residence as an example as this was the first assessment tool introduced in China. These questions were also designed as a standard Likert scale and questions were rated from strongly disagree through to strongly agree. Based on the returned surveys about 8% have used the assessment handbook before whilst about 20% only knew about it but had not actually uses it. This indicates that environmental assessment tools for sustainable housing in China were not very well accepted as compared with other countries. The use of the Handbook is voluntary and it is up to the developers to decide whether to adopt the guidelines set in the Handbook or not. For the performance tools to be more effective in enhancing housing sustainability they may need to be mandatory such as BASIX in Australia. Summary of survey results are included in Table 2 above.

As summarized in Table 2 about 53% agreed that the Handbook is user friendly. About 59% agree that the handbook is useful in assessing sustainable housing performance and 53% believe that the use of the handbook will help to enhance housing sustainability. However only 41% believe that the handbook is useful in guiding design and construction for residential projects. With regards to the assessment criteria set in the Handbook only 29% agree that the criteria set in the handbook are achievable whilst a majority (59%) is not sure. This indicates insufficient exposure to the Handbook and lack of environmentally related work experience of respondents. There are also not enough details about the area that they believe to be unachievable.

In general the respondents agree green buildings will cost more and will take longer to complete as compare to the traditional approach. Finally about 71% agree that the Handbook should be applied to other types of construction. However some respondents believe that the handbook is only a concept and lacks practical structure for implementation. With regards to improvement that can be made to the handbook, some respondents suggest to comprise statistical data to exhibit the usefulness and potential of the tool in promoting housing sustainability in addition to use case studies for demonstration. Some recommend a more detailed investigation to ascertain the usage and impact of the tool. Others suggest that an environmental assessment tool cannot be single dimensional and environmental aspects should be taken into account at the same time with economic considerations. On the other hand both environmental and economic appraisals need to be considered in the assessment framework on a whole-of-life approach. Due to lack of experience from the respondents in the tool the survey can only provide a superficial reflection on the impact of the tool and further research will be required.

Two semi-structured interviews were undertaken in January in Beijing. Representatives from Beijing Institute of Architectural Design and the Beijing Urban Engineering Design & Research Institute have experiences in both design and construction of green buildings in Beijing. At the interview they stated that green residential development is still at an early stage in China. Firstly, most developers still place financial return at high priority because green designs generally cost more. They prefer the traditional construction in the design and construction of residential buildings. They believe sustainability can only be put into practice if it becomes mandatory. Secondly, the existing sustainability assessment systems need further development. The existing system is either insufficient or incomplete in guiding design and construction. In addition the system is not appropriately known or understood by most professional in the construction industry. Thirdly, there is a lack of financial incentives by the government to encourage green development. This is particularly important as green construction is generally costly. Unless green construction cost is reduced, developers will not have the motivation to build green. Fourthly, the general public is commonly fond of living in green residential buildings as they all accept that these buildings can provide with healthier and better living environment. However since the supply of these building is generally insufficient and expensive they are inclined to stick to traditional residential buildings.

5. Conclusion

Sustainable housing has profound effects on human beings' daily lives and well-being. In China with a huge population and rapid urbanization, housing shortages has become an important task confronting the government. More effort needs to be made to provide sufficient accommodations to the people as well as minimizing load to the environment. The task needs a more systematic and holistic approach to assess and promote housing sustainability. There is no doubt that environmental assessment tools contribute significantly to achieve the goal of sustainable development within construction. On one hand, it provides a methodological framework to measure and monitor environmental performance of residential development, whilst on the other it alerts the building profession to the importance of sustainable development.

Sustainable housing is multidimensional and the evaluation of sustainable housing cannot be achieved using a single criterion and single objective function. The decision-making process for sustainable housing uses multiple criteria and objectives and needs to be considered on a whole-of-life approach as it is not just considering economic and environmental problems. It also needs to include social and economic evaluations during the service life of the building. Therefore a set of multiple goals and criteria needs to be considered simultaneously. The sustainable housing industry needs to appreciate the affordability for home buyers especially those issues relating to design and cost. The reality is that home buyers will respond to environmental issues providing it is affordable and does not come at a cost penalty. Professional designers should maximize the environmental performance and concentrate more on achieving lower costs. If additional cost items are to be included, developers, builders and governments will need to consider introducing innovative financial incentives.

The questionnaire survey and interviews have provided a preliminary insight into the current situation of sustainable assessment of housing development in Beijing. Beijing is the capital of the country and any conclusions drawn will provide an indication of the condition of environmental awareness among construction professionals in the country. However China is a huge country with regional variations, therefore further research may be required in other regions of China in order to obtain a better understanding of the situation. In order for housing sustainability to be made more important, environmental awareness should be made in a more radical way to promote sustainable housing for the sake of creating market demand and stimulating business interest in developing sustainable housing. The government by developing and coordinating sustainable housing polices in a more systematic way as well as providing financial incentives to encourage more sustainable housing. On the other hand supporting and providing further education and training to construction professionals, researchers and academia will contribute to the design and technology advancement of sustainable housing.

QUANTIFICATION OF BUILDING/ENVIRONMENT SYSTEM PERFORMANCE

Krystyna PIETRZYK Ph.D.

Built Environment and Sustainable Development, School of Architecture, Chalmers University of Technology, Gothenburg, Sweden, krystyna.pietrzyk@chalmers.se

Keywords: building performance, risk, reliability, probability, environment, climate

Summary

The paper points out the role of risk analysis methods in applications for sustainable development. The method for quantification of system performance in terms of probability of failure and reliability, referring to this kind of methods is presented. It is proposed to support urban, architectural and structural design of buildings in the context of comfort, healthy living conditions, and sustainability. The results of applications of the proposed methodology to evaluate the probability of excessive heat loss through the two types of building envelope are presented.

1. Introduction

Building design has to ensure structural stability and well-being of people both indoors and outdoors under limited negative impact on environment for example in the form of excessive energy use. It includes urban, building (form, façade and material) and installations design in relation to the environmental and climatic conditions of the place where the building is constructed. Climatic conditions, human activities inside a building and criteria for human comfort are random in nature. Even the properties of structures are comparatively uncertain. Probabilistic analysis appears as the appropriate approach to account for those uncertainties when evaluating building performance. Eventually, probability of poor-performance (failure) or reliability, which is a complement to the probability of failure, can be calculated.

The application of probabilistic methods of analysis in building design reaches back to the sixties and mostly concerns safety of structures (Ditlevsen 1996). In the fields of building design including human health, comfort and well being, some attempts to adopt probabilistic methods to support design have been introduced. The concept of evaluating the hazard of improper moisture conditions was introduced by (Nielsen A. 1987, Nevander et al 1991). This work has been continued by (Harderup 2000) (Monte Carlo Simulations), and (Pietrzyk et al 2004, Kurkinen et al 2004) (FORM, First Order Reliability Method). The risk of radon concentration in a building enclosure was analysed by (Ljungquist & Lagerqvist 2005). The probabilistic model PROMO has been developed and validated by (Pietrzyk 2000) to estimate the probability of insufficient air exchange or excessive heat loss. The limit state approach based on a random variable model and FORM techniques for applications in building physics is presented in (Pietrzyk & Hagentoft 2008). This enables quantitative comparisons of different design options, and hence the reliability-oriented (probability-based) analysis (Pietrzyk 2005).

Probabilistic model for evaluation (quantification) of building/environment system performance based on load-resistance (demand-capacity) random variable model (Kottegoda 1997) is referred to in this paper. It gives opportunity to take into account a random character of system load and also random character of system capacity expressed in the form of performance criteria stated for human health, human comfort, to meet economic standards or in order to prioritise the sustainable solutions. It offers estimation of the probability of performance failure using mathematical relationship between probability density functions (pdf) of the load parameters.

2. Risk analysis for sustainable development

2.1 General

Risk analysis has become a very important tool in assessment and governance of environmental and societal risks to sustainability. Figure 1 illustrates designing for sustainable urban development. The goal is stated to ensure well being for individuals (space of acceptable solutions is represented by the shaded area) under limitations introduced to prevent or mitigate the high risks (see bounds drawn with dashed lines – models 2). The bounds cut off and diminish the space of the satisfying solutions. The high risks (of great importance to mankind, societies or human beings, usually with catastrophic consequences) are identified by risk analysis methods and if not ignored, result in various decisions towards sustainability. Risk analysis methods are also used in order to ensure people well being (see models 1) for example in built environment or inside the buildings. In this case the appropriate design can be perceived in terms of reliability as the focus is put more on ensuring acceptable performance of the building rather than on defeating high risks.

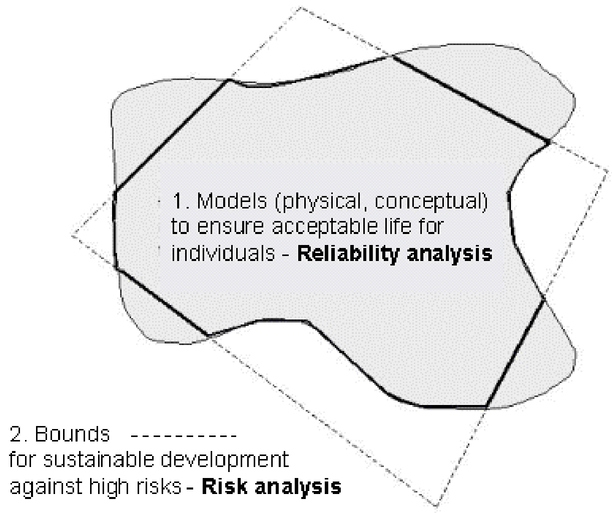

Figure 1 Designing for sustainable development

2.2 Towards quantitative risk assessment

Qualitative risk assessment describes a nature and source of the hazard, identifies alternative scenarios for the risk outcome and the severity of the consequences (McDaniels & Small M.J., 2003). There is a trend for completing the qualitative risk assessment with quantitative evaluation of probability of failure. Likelihood of occurrence of failure events multiplied by their consequences results in quantitative risk assessment. This allows more rigorous comparisons of alternatives. Probabilistic risk assessment offers estimation of the probabilities assigned to the outcome of the model representing variability and/or uncertainty in the model and its inputs.

3. Reliability of building/environment system performance

3.1 Definition of (considerations about) building/environment system

Building performance depends on the structure and the way that it is used, but also on the environmental conditions of the site and the microclimate in a vicinity of structure, which is influenced by the building itself. It supports the idea of using the concept of building/environment system performance. Generally microclimatic conditions outside the structure act as a boundary layer for processes inside the structure and in the building enclosure. But, there is also a reverse influence of the structure on the nearest environment, for example on the wind field in its neighborhood. It can encompass pedestrian discomfort or excessive heat loss through a building envelope, followed by consequences against sustainability in the form of increased energy consumption to warm up buildings or excessive use of motorized transport.

Figure 2 shows interdependence of the processes inside a building enclosure, in a building structure, and outside of a building. Focus is put on the measures important for humans' health, comfort, and energy performance of a building. Quantitative analysis may be used to examine such factors like ventilation, heat loss, moisture performance of building components etc. Many of them are listed within the gray boxes.

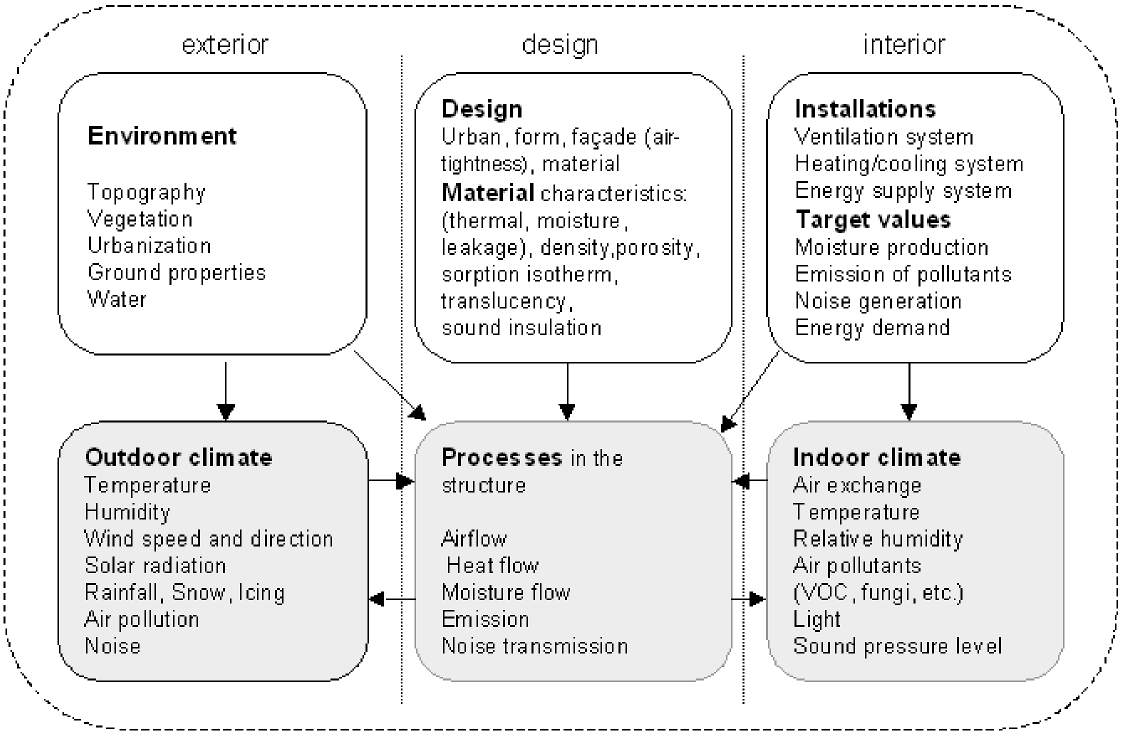

Figure 2 Interdependence of the processes inside a building enclosure, in a building structure, and outside of a building.

3.2 Evaluation of building/environment system performance – methodology

In carrying out a reliability analysis of building/environment system performance, a list of all hazards should be compiled. Those hazards are associated to failure events characterized by some sort of unacceptable serviceability (for example: insufficient air exchange, excessive energy loss, too high sound pressure level). Failure events are usually the consequences of the physical state of the building characterised by the parameters (performance aspects) S not meeting prescribed limits (performance criteria) R as presented in Figure 3. Unacceptable performance caused by air-, heat- and moisture flow through a structure, the illumination conditions, noise transmission, wind/structure interaction etc, can appear in the form of unhealthy conditions (mould growth, emission of irritating compounds from the material), discomfort (insufficient air exchange, esthetical changes of the surfaces, odour, draught, mites propagation, high level sound propagation, insufficient illumination, pedestrian discomfort), damage of the material (changes of physical or chemical properties of the material), and excessive energy loss (for example caused by high wind speed and turbulence around buildings).

In the probabilistic modelling the design variables and parameters are explicitly identified, as well as, load (demand) S and resistance (capacity) R probability distributions are determined (see Figure 3). Probability density function of load S is approximated, taking into account uncertainties of input parameters describing external and internal load and the structure (see fields within dashed rings in Figures: 2 and 3). Fundamentally, two common types of uncertainties may be present in any calculation: uncertainty resulting from the lack of information or uncertainty caused by the natural variability in a parameter. Uncertainties that arise from the lack of knowledge about parameters can be modelled with the help of expert judgement that can lead to assignment of probability distribution. Uncertainties that arise from variability can be modelled with the help of statistical approach if enough data is available (experiments, simulations).

Requirements for the system are specified in the form of performance criteria. The performance criterion R indicating the conditions favourable for a performance failure can be treated as a random variable with the probability distribution function evaluated from the probabilistic approximations based on deterministic function of input random variables, from experiment or by expert judgment. Generally, performance criteria result from the analysis of economic and social costs and benefits. Some of them are defined in the Code of Practice or in the international standards elaborated by International Organization for Standardization (ISO) or European Committee for Standardization (CEN). Minimum air exchange rate, minimum or maximum internal temperature, maximum speed of airflow inside the building, maximum relative humidity, the maximum overall average U-value of a building envelope or the minimum air tightness are examples of type minimum and type maximum limits for building performance parameters.

Reliability of the design is estimated by comparing if the system can carry effect of applied loads without jeopardizing well-being of people. It can be carried out with the help of performance function $Z = R - S$. The state $Z = R_2 - S = 0$ (for maximum type with threshold R_2) or $Z = S - R_1 = 0$ (for minimum type with threshold R_1) divides the response space into safe (positive Z) and unsafe (failure) (negative Z) regions characterized by reliability or probability of failure P_f.

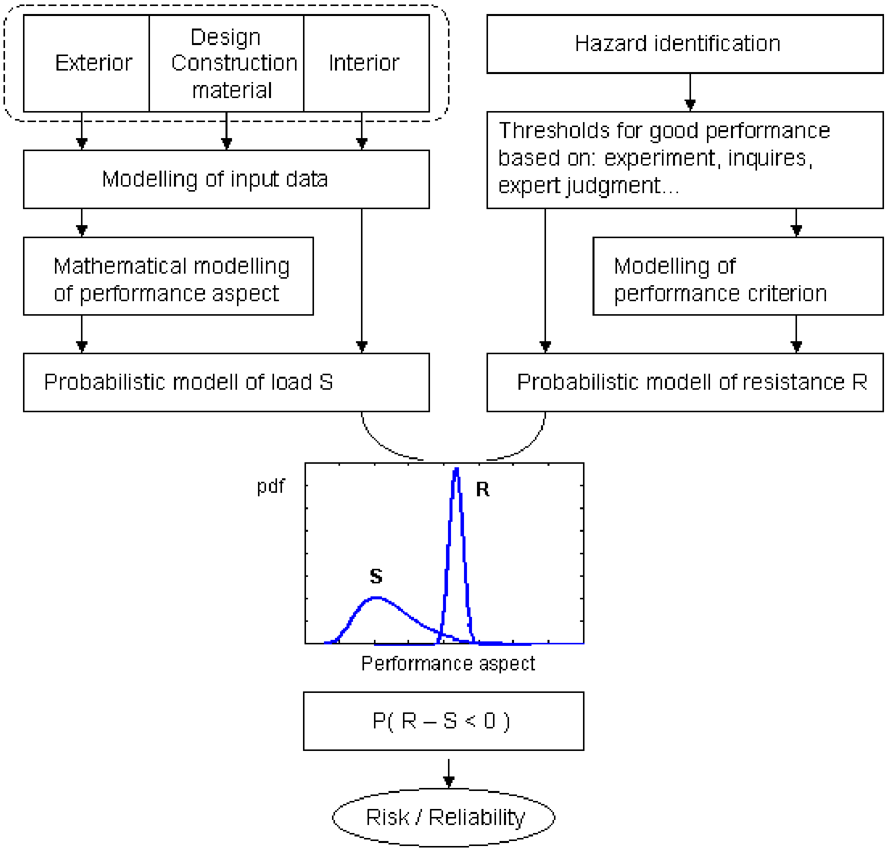

Figure 3 Methodology of quantification of building/environment system performance. Concept of load-resistance model applied (extended) to the problems of unhealthy conditions, discomfort, and excessive energy use

The process of reliability analysis does start with the hazard identification and description of the physical relationships between all influencing parameters. Analysis of the parameters leads to the conclusions about the importance of their variability or/and uncertainty to the investigated response of the system and the decision if they should be treated as deterministic parameters or random variables in the model. The time dependence of the random variables should be examined to choose an appropriate model for the system. The following steps should be performed:

- Description of the hazard of building/environment system performance
- Choice of the performance aspect
- Statement of the performance criterion ensuring that the system meets performance requirement R
- Specification of the mathematical models describing the performance
- Identification of the parameters important in the modelling of the performance
- Description of the uncertainties associated to the parameters
- Sensitivity analysis of the influence of the parameters on the model response
- Specification of the character of the time dependence
- Model formulation (performance functions) on the basis of the physical relationships, input data and time dependence analysis
- Decision on the reliability measures to be used
- Application of the reliability method in order to estimate the reliability measure for the stated hazard

4. Examples

Two examples of estimation of probability density functions (pdf) of heat loss (performance aspect S is presented by power loss (kW)) for two buildings of the same size with different properties of the envelopes and different ventilation strategies are presented. Performance requirement in the form of threshold power loss for heating can be introduced at the deterministic level of R (kW) (see Figure 6). The input parameters, which should be treated as random variables, are selected. They include temperature difference across the building envelope ΔT, thermal transmittance U and air change rate ACH. Probability density function of ACH is estimated in air infiltration model with wind and temperature input variables (Pietrzyk 2005). The modelling flow is shown in Figure 4. Performance function for heat loss Φ is proposed. Final results for the chosen examples are presented in terms of probability density function of power loss. It depends upon the interaction among the envelope construction, the local climate at the site and the chosen ventilation system.

The modelling details can be found in (Pietrzyk 2000). Two cases are considered (see Table 1). The first one for the building envelope working according to the dynamic wall principle with the thermal properties depending on the air infiltration rate when natural ventilation is assumed. The second case includes a tight envelope and balanced ventilation causing the constant (deterministic) air change rate equal to the mean value of the air change rate noted for the case 1: ACH = 0.7. For this case thermal transmittance depends only on the temperature of the material, hence indirectly on ΔT. The examples are calculated for the period when $T_{int}>T_{ext}$ (T_{int}=const) for the house situated in northern Sweden.

Table 1 Description of the calculated examples

Case	Envelope	Ventilation	Air exchange		$\Delta T = T_{int} - T_{ext}$	
			Mean / St.dev.	distribution	Mean / St.dev.	distribution
1	dynamic wall	natural	0.7 / 0.3	lognormal	15.3 / 9.5	truncated
2	tight	balanced	0.7 / 0.0	(deterministic)		normal

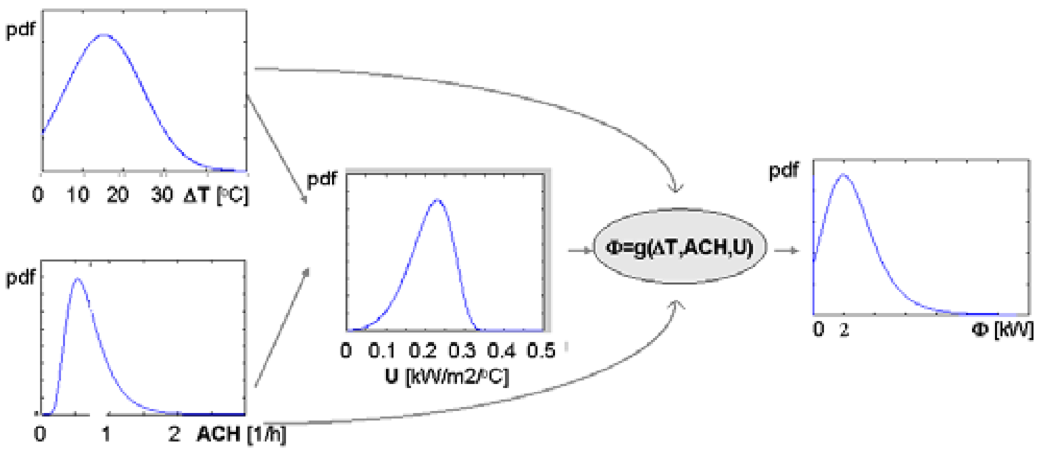

Figure 4 Modelling flow of random variables for estimation of probability distribution function of heat loss (case 1).

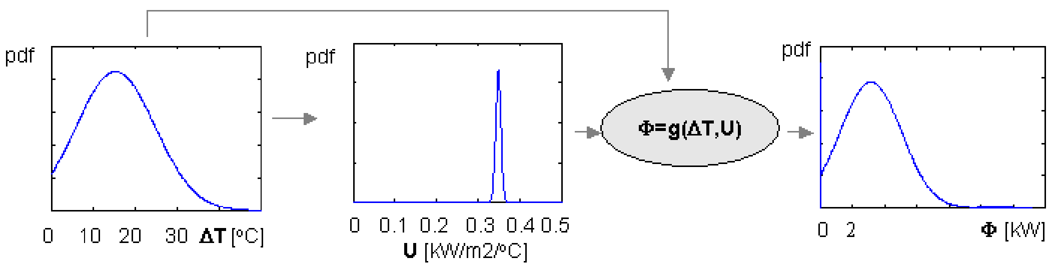

Figure 5 Modelling flow of random variables for estimation of probability distribution function of heat loss (case 2).

The power needed to compensate for heat and ventilation losses is presented in Figure 6 in the form of probability density functions for both cases. Threshold R can refer to the assumed maximum effective power of heating device. If other heating sources are absent, the probability of failure P_f defined as T_{int} decreasing below assumed constant value is equal to the area below the pdf to the right from the threshold. Probability of failure can be translated into the total time during which the prescribed performance criteria are not met.

Case	Reliability	P_f
1	0.91	0.09
2	0.86	0.14

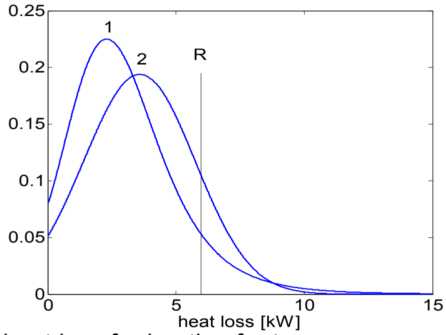

Figure 6 Results of probabilistic approximations of heat loss for heating for two cases: case 1 – naturally ventilated building with dynamic wall, case 2 – mechanically ventilated building (balanced ventilation) with tight envelope.

Comparison of these two options can be carried out in terms of probability of failure or in terms of reliability = 1- P_f. For R = 6.0 kW the results are given in Figure 6. For the assumed sufficient power of heating system, the conclusions about the uncertainty of the energy consumption for heating can be drawn.

5. Conclusions

Risk analysis methods can be used in order to ensure people well being in built environment or inside the buildings. In this context the appropriateness of a design can be better expressed in terms of reliability as the focus is put more on ensuring acceptable performance of the building rather than on defeating high risks.

Quantification of building/environment system performance in the form of probability of satisfying performance is proposed. It gives opportunity to probability-based approach in the design process relying on estimation of the reliability of a building performance for the alternative designs. It also allows obtaining the reliability-based assessment of existing buildings exposed to the changed conditions (climate change, local climate change due to urbanisation etc.) in order to promote the sustainable solutions.

A probability-based evaluation of building/environment system performance delivers an input to the risk-management models. The risk-management models prioritising different requirements should be developed.

Keywords: sustainable design, building materials, building envelopes, energy savings, semi-scale testing, interior thermal insulation system

Summary

Advanced semi-scale device is introduced as an effective tool for the sustainable design of new building materials and structures in the paper. At first, the requirements of building designers on the development and production of new materials with reference to the sustainable development principles are formulated. The main attention is paid especially to the savings of energy for heating and air conditioning of buildings. Then, the procedure of semi-scale testing is described which is aimed at the assessment of hygrothermal performance of building structures and materials. Since the energy expenses of buildings are mostly consumed by heating systems, in the final part of the paper an application of semi-scale device for the analysis of hygrothermal function of newly designed interior thermal insulation system on hydrophilic mineral wool basis is presented. Within the experiment, the insulation system is exposed to the difference climate conditions corresponding to the typical winter period which is the most critical part of year for buildings and their energy consumption. On the basis of the experiment it can be concluded that the analyzed system performs in satisfactory way from both thermal and hygric points of view.

1. Introduction

Continuous decrease of fossil fuels supplies, an increase in their prices and last but not least impact of their consumption on the living environment is reflected in the operating expenses of buildings. Another serious problem represents an increase in building materials production. The building materials are manufactured mainly on natural basis, what has harmful effect on the living environment quality. For example among all construction materials, around 65% is concrete, produced in the world at an approximate rate of 4600 millions of m^3 per year. In concrete production, around 90% of all energy consumed is used to obtain cement, which is also a major source of CO_2 emissions. Within the production of 1 t of Portland cement, 1 t of CO_2 is evolved in the atmosphere.

Therefore, development of new, advanced building materials having higher utility quality is necessary in the sense of the sustainable progress of building industry. However, not only the final advanced properties of materials should be considered. Also the energy and natural materials consumption should be taken into account. Hence, the secondary raw materials (i.e. waste materials) find widespread use in building materials production.

In this work, we have focused on the reduction of operating expanses of older buildings, where the heating costs represent almost 80% of the total energy costs. With reference to the sustainable development principles, especially the passive and low energy buildings should be constructed. In Table 1, there are given specific energy consumptions dividing buildings into several categories according to the European technical standard CSN EN 730540-2:2007 – Thermal Protection of Buildings. Since the most of existing buildings do not meet the requirements of the current strict thermal technical standards, there is need to improve the existing structures in order to eliminate thermal bridges and decrease the heat losses.

The improvement of thermal performance of existing buildings can be simply done by additional thermal insulation systems that can be applied on exterior or interior surface of the building envelopes. Exterior thermal insulation systems are quite simple and popular solution. In this manner, the thermal bridges are fully eliminated and standard thermal insulation materials can be applied. There were developed many thermal insulation systems taking advantages of assorted types of thermal insulation materials as on organic basis (expanded plastics, wood wool, cork, straw, technical hemp) as well as on inorganic basis (foamed glass, glass and mineral fibers). Particular products differ in thermal resistance, heat capacity, shape, flammability, specific composition of their structure, etc., what in the relation to the designers' requirements assigns the possibilities of their application in building practice. For example, application of 10 cm of mineral wool on exterior surface of residential house having floor space 120 m^2 leads to the 60% decrease of natural gas consumption for heating systems. However, the exterior insulation systems can not be applied universally. The typical example represent historical buildings, where the preservation of original architectonical view of facades is one of the top interests of conservationists. Also in case of too complex facade surfaces, the exterior systems fail. In these cases, the interior thermal insulation systems find use.

Table 1 Specific Energy Consumptions of Residential Houses

Energetic type of building	Unit	Energy consumption of residential houses	
		Heating systems	Total
Passive house	[$kWh.m^{-2}.h^{-1}$]	15	42
Low energy house	[$kWh.m^{-2}.h^{-1}$]	50	130
Standard new building	[$kWh.m^{-2}.h^{-1}$]	115	170
Old building	[$kWh.m^{-2}.h^{-1}$]	220	280

Since the interior thermal insulation systems are not natural solution, they represent particular problems for proper hygrothermal performance of improved buildings. The main problem is risk of water vapor condensation in thermal insulation layer transported from the interior air. A common solution to this problem consists in placing a vapor barrier just under the internal plaster on the surface of the insulation layer, so that both the insulation layer and the load bearing structure are protected against water vapor. This solution assumes that no mechanical damage of water vapor barrier will appear during the service life of building. However, this assumption can perform on the theoretical level only. In the practice, it is very difficult to avoid mechanical damage of the water vapor barrier placed in such an inappropriate way.

In the insulation system, which functionality is verified in this paper, a water vapor retarder is used instead of the water vapor barrier and placed between the wall and the thermal insulation layer. Since this solution is quite new and innovative, new types of materials for water vapor retarder as well as for thermal insulation layer were designed and manufactured.

The materials were designed and manufactured according to the directed design principles. We will not go into the details but a short description of the directed design methods is necessary. At first, there is essential to perform computational analysis of the studied problem with the special attention to the optimization of material properties. Especially the thermal and hygric material properties should be closely investigated. Within the computational design of material properties, the requirements of thermal technical standards have to be taken into account. Using the computational simulations, the information for design and production of required materials is obtained. The second step of the directed design represents materials' manufacturing. In our case, the thermal insulation material was produced by Rockwool, Inc., the water vapor retarder was developed in a cooperation with Mamut-Therm, Ltd..

After that, the developed materials have to be tested in laboratory in order to check whether the requirements on materials properties were met or not.

The last step in the development of new materials involves the verification of their functionality in the real conditions of buildings. This can be done basically in two ways. The first possibility is to build special test house were the developed materials will be applied in the insulation system layers and exposed to the real climatic and service conditions of structure. The performance of inbuilt materials is then continuously monitored. This procedure is very popular and gives probably the most predicative information on materials' performance. On the other hand, it is highly time consuming and rather expensive.

In this paper we present relatively new approach to the evaluation of the functionality of newly designed building materials and structures which is markedly cheaper and less time consuming. Hence, it could find widespread use in the sustainable planning and design of effective and environment friendly buildings. Laboratory character of the proposed method allows also testing of smaller building components as window frames, transitional details of roofs, insulation materials, plasters etc..

2. Semi-scale experiment

The effective design of new materials according to the exact requirements of building designers requires development of sophisticated and precise enough method for the verification of the materials performance during their climatic loading. On this account we have focused on the design and development of new testing method that will allow predicting of hygrothermal behavior of building structures and components in the conditions very close to reality. Design of such testing method represents certain substitution of full-scale test house measurement of field variables of heat and moisture transport and requires development of new testing device.

The presented experiment uses the sophisticated testing device that enables simulation of climatic conditions that are as close as possible to the real climatic conditions on building site. Nevertheless, it still maintains laboratory character, so that the expenses can be kept considerably lower compared to the test house testing. That is why we denote it semi-scale experiment.

For the realization of semi-scale experiment, climatic chamber system that enables simulation of difference climate conditions of a building envelope samples with the real thickness of all its components was developed. The climatic chamber system consists of two climatic chambers, connected by a specially developed tunnel for placing the studied specimens. The test space is water and vapor proof and thermally insulated. The climatic conditions in the system are controlled by programmable microprocessor that makes possible to simulate relative humidity and temperature corresponding to the real climatic data of the test reference year. To the climatic chamber system, there is possible to connect accessory water drench system for rain simulation. The scheme of the climatic chamber system is shown in Figure 1.

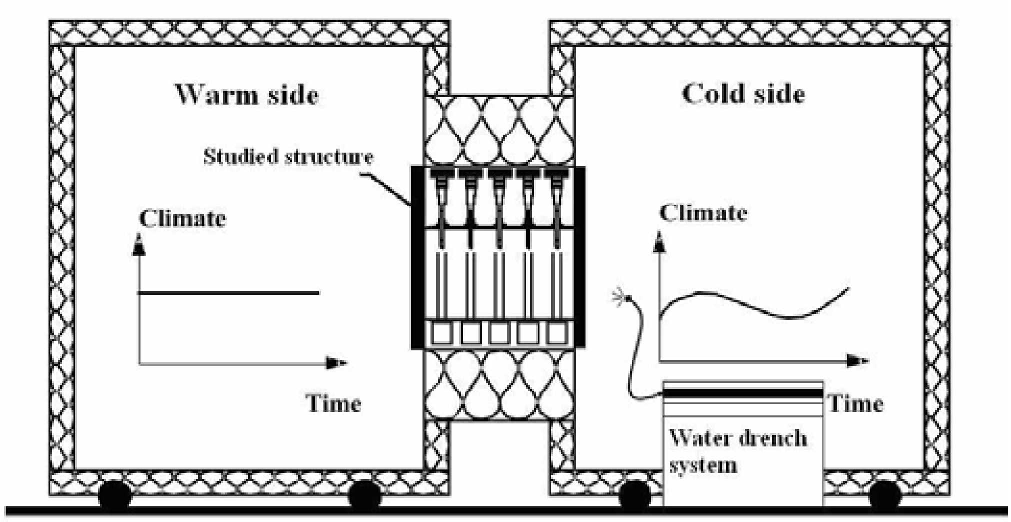

Figure 1 Scheme of the climatic chamber system.

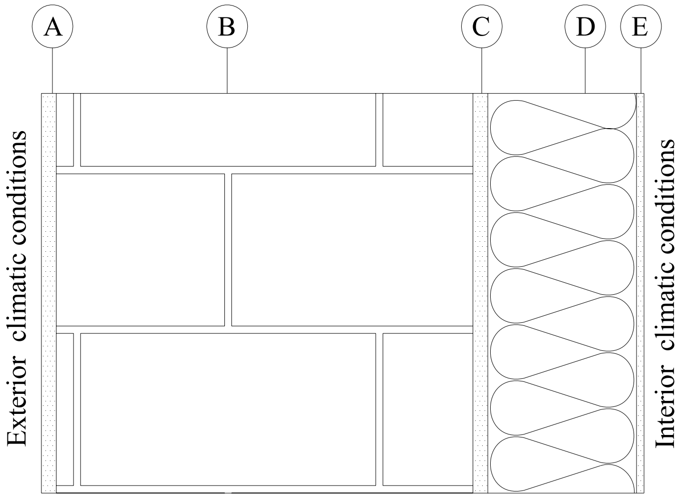
In the tested structure, monitoring of moisture content, relative humidity, salinity, capillary pressure, temperature, air velocity and heat flux, is possible. Since the system has laboratory character, modified advanced laboratory meters are used. The details on the particular sensors and meters can be found in (Pavlík and Černý, 2002, Pavlík et. al, 2002). The sensors that were used within the experiment presented in this paper will be described in the following section.

The sensors are installed in the structure into prepared bore holes and the upper part of the bore opening is water and vapor proof insulated by silicon sealing. Only the thermal flux sensors having plate shape are spot glued on the front sides of the investigated structure. In the installation of the specimen into the connecting tunnel, its thermal and hygric insulation from the tunnel walls performed for the sake of simulation of one-dimensional heat and moisture transport in the envelope belongs to the main tasks. We employ extruded polystyrene boards in a combination with mineral wool, the front sides of insulation materials are covered by polyurethane foam.

After installation of all sensors and insulation of the investigated structure in the tunnel, the tunnel is connected with the climatic chambers and the experiment can be started. The measuring system should simulate the hygrothermal processes in building envelopes in the conditions close to the reality. Therefore, the external and internal conditions simulated in the particular climatic chambers have to be realistic. We employ hourly reference-year based data for temperatures and relative humidities in the chamber simulating external climate and proper constant temperature and relative humidity data in the chamber simulating the internal conditions. Because our water drench system does not allow simulation of controlled water drops, only total amount of rain water for every day is simulated. The rainfall data are also taken from the test reference year. The measured data of field variables are processed and evaluated by measuring control units that are continuously controlled by external computer.

3. Experimental

In the experimental part of the paper we present the application of semi-scale testing approach for the verification of functionality of newly designed interior thermal insulation system which basic principles were given above. On the basis of laboratory tests of material properties, following new materials were chosen as an optimum solution for interior thermal insulation system: hydrophilic mineral wool Dachrock (Rockwool, Inc.), water vapor retarder SM-T FLT – a material on flexible cement glue basis (Mamut-Therm, Ltd.), and interior plaster SM-TJ VJ (Mamut-Therm, Ltd.) on lime basis. The insulation system was applied on fragment of brick wall 300 mm thick. The arrangement of the studied structure is given in Figure 2.



A lime plaster SM - T VJ, Mamutherm, 10 mm
B brick wall 300 mm
C retarder - cement glue SM - T FLT, Mamutherm, 3 - 10 mm
D mineral wool Dachrock, Rockwool, 100 mm
E lime plaster SM - T VJ, Mamutherm, 5 mm reinforcing plastic net

Figure 2 Arrangement of the studied structure.

Since we did not apply the rain simulation within the experiment, the brick wall was before beginning of the climatic loading partially wetted by water. In this way, the building-site conditions of real brick wall were roughly simulated.

The tested structure was exposed to the difference climatic conditions corresponding to the typical winter period, which is the most critical part of the year from the point of view of water condensation in building structures and their hygrothermal performance. On the exterior side, climatic data corresponding to the time interval of November 1 to March 27 were simulated. As climatic data, the test reference year (TRY) for Prague was used. On the interior side, constant climatic conditions were applied which were chosen according to the standard computational values for residential houses (relative humidity 50%, temperature 21°C).

In the tested structure, continuous monitoring of liquid moisture content, relative humidity and temperature was performed. For monitoring moisture content special device from Polish company Easy Test working on TDR (Time Domain Reflectometry) principle was used. The accuracy of moisture content measurement given by producer is ± 2% in volumetric moisture range 0-100%. Details on the TDR method, measuring technology, calibration and applied two rod sensors are given e.g. in Pavlík and Černý (2006), Jiřičková (2004). For monitoring relative humidity and temperature, commercially produced combined sensors by Ahlborn were employed. The accuracy is as follows: capacity humidity sensors are applicable in the humidity range 5-98% with accuracy ± 2%, resistance thermometers have accuracy ± 0.4°C in the temperature range from -20°C to 0°C, and in the temperature range from 0°C to 70°C is the accuracy in temperature measurement ± 0,1°C.

4. Results and discussion

The measured experimental results are presented in Figs. 3-5. Figure 3 presents the temperature profiles in the investigated brick wall provided by the interior thermal insulation system. We can see that the interior surface temperatures are typically higher than 20°C. This finding clearly demonstrates the proper thermal function of the designed interior system. Since the interior surface temperature is high enough, the quality of indoor climate from the point of view of well-being of building occupants is achieved. This temperature also reduces the risk of biological pollution of indoor climate as well as of the interior surface.

Regarding the thermal loading of the brick wall, the temperatures only rarely decreased deeper under the water freezing point. This finding which reflects the relatively mild weather conditions in Middle Europe is very positive, particularly regarding the durability of exterior surface layers.

The relative humidity profiles are given in Figure 4. We can observe increased relative humidity values in the brick masonry what corresponds with the measured liquid moisture profiles. The measured content of liquid moisture was typically between 3 and 5% (see Figure 5). Since the accuracy of TDR moisture sensors is ±

2%, we can conclude that the liquid moisture was evenly distributed. This moisture is a result of partial wetting of the studied structure within the specimen preparation which within the experiment was not evaporated because of applied winter climatic conditions. Nevertheless we can estimate, the liquid water will be within the summer period evaporated what was proved by the results of computational simulations.

In the whole thickness of thermal insulation board Dachrock, the relative humidity values were lower than maximal hygroscopic moisture content. It has proved that the application of designed insulation system does not cause water vapor condensation in insulation layer or on its surface. Hence, the thermal insulation properties are preserved and the harmful effect of mould growing is eliminated.

5. Conclusions

The experiment presented in this paper has proved the usability of semi-scale experiments in the process of sustainable design of building structures and components. It can be used not only for design of new materials and structures but it can find application also in verification of their functionality and behavior under almost real climatic conditions. The main benefits of the developed testing methods are as follows: lower expenses of experiments in comparison with full-scale test house testing, use of advanced laboratory meters for monitoring of field variables, possibility of controlled climatic loading.

Concerning the verification of newly developed interior thermal insulation system, the obtained results represent the valuable information that will help to the application of designed insulation system in building practice. Very positive finding is also fact that the measured relative humidity, liquid moisture and temperature fields are in a good agreement with the computational simulation of the studied problem. Hence, the semi-scale experiments can be also applied for calibration and validation tests of computer codes solving the problem of coupled moisture and heat transport in porous materials.

Summary

In the present day context energy play an important role in every pursuit of life. In a country like India, where economy is rising at a rate of more than 8 percent per annum, the need of energy is also increasing manifold, particularly with the coming up of MNCs & Real Estate developments. Design & planning of buildings and settlements can play a major role to curtail the energy demand and thus can help in achieving the global objective of sustainable development.

In India the majority of the areas come under composite climate and our buildings are often designed without taking enough consideration of climate. If we can place our built areas under shade for majority of times by virtue of design & planning, we can save lot on energy bills. From the studies, it is shown that 40% of energy needs can be reduced by only designing the buildings with proper specifications & placing them in a best orientation. In a study for Delhi region, the orientation of buildings if kept with longer axis as East –West i.e. major façade facing North & South and shorter facades on East & West, the building performs best for thermal comport. If it is tilted 15 to 20 degree north then it also gets the advantage of air movements. Further having higher building blocks on south side rows, we get the advantage of the shadow on north side blocks by the movement of sun from east to west. This pattern of planning give the maximum advantage of energy saving. In the paper, the design & planning approach to save energy for a small settlement for a 5000 population has been discussed as a strategy for sustainable building development.

1. Introduction

Energy in all forms is vital to sustain life. In housing it is used for cooking, heating, cooling, illumination and to run various gadgets. In the light of large demand of energy over the last 10-15 years and its short supply,, building industry in India has become quite energy conscious. Further the program on Global security and sustainability has given priority to the areas like conservation and sustainable development. Here we are more concern with conservation of energy in built environments. It is also necessary for sustainable development as the sources of non-renewable energy are limited and getting depleted day by day. The alternative sources of energy could be biogas, biomass, solar energy, wind energy, hydropower etc. For sustainability we have to depend on renewable sources of energy which are available in abundance and non-depletable in nature.

Now a days every country is very much conscious about the use of energy. As per a study in USA the energy consumption in buildings accounts for 36% of country's energy supply and energy use is growing at a rate of 3.3% a year. Heating and cooling equipment consumes 42% of all building energy use at a cost of $ 81 billion. A passive solar design can save as much as 50% on heating bills for only 1% more construction cost. These facts illustrate the capability and importance of passive solar building design with respect to conservation of both energy and money. Apart from general lack of norms and regulations, one reason that buildings are poorly adapted to the climate is lack of knowledge among building designers, whether an architect or engineer or town planner.

In the field of passive solar architecture related to individual buildings many research works have been done. Some studies have been carried out on tree shade effects on residential energy use at California using different type of trees (e.g. shape, size) and location around buildings. Tree shade reduces summer air conditioning demand and increases winter heating load by intercepting solar energy that would otherwise heat the shade area. Similarly studies are available on shading of windows, their designs etc. In all studies the effects have been limited to single building only. In this paper the impact of energy conservation has been studied at a settlement level with different planning patterns through design of buildings, their orientation and distances among the buildings of different heights for shading effect.

In India two solar houses have been constructed in Ladakh. A NGO, Ladakh Environment and Health Organization (LEHO) has taken the first step at 3500 m above sea level for designing a building using passive system of heating. They introduced solar buildings in Ladakh with the help of a France based NGO, Geres. Similarly few buildings with passive features have been constructed in the plains of North India at Delhi & Gurgaon etc. to save the energy loads. The seminars / conferences are being held by various concerned departments to reduce the transmission / distribution losses and to use low energy saving devices & equipments like fuse less systems etc. In this background a project was under taken to achieve energy conservation through design and planning of small settlement.

2. Methodology

The methodology adopted involves to finding out the physical requirements for a settlement of 5000 population for which energy requirements are to be analyzed. This includes the various types of residences, education facilities, recreation facilities and shopping facilities. Then area of the site is to be find out considering an assumed density of population.

To calculate the energy requirements of a settlement the number of residences, their design, specifications, orientation and design of other buildings like shopping, schools etc. are all important. The requirements of different buildings adopted in the study for a population of 5000 persons are :

2.1 Requirements

1. No of houses	-	1000 @ 5 persons / family
2. EWS[i]/LIG[ii] houses	-	600
3. MIG[iii] houses	-	230
4. HIG[iv] houses	-	170
5. Primary school	-	1
6. Nursery school	-	2
7. Convenient shops	-	2

i EWS Economically weaker sections
ii LIG Low income group
iii MIG Middle income group
iv HIG Higher income group

The number of low category houses has been taken as 60 per cent of the total houses as majority of the population in India belongs to this section of population and as a policy government also want that in any urban housing scheme major share of houses should be assigned to low income group people. The other building requirements are also kept as per prevailing planning norms in India. The density of population has been assumed as about 125 persons / acre or 315 persons /hectare. This comes out to about 50 houses per acre assuming 5 person per family and total requirement of land comes about 40 acres or 16 hectares approximately. Accordingly a plot of 400m x 400m has been theoretically selected for the study point of view.

2.2 Architectural Design

To calculate the energy load of a building their architectural design and specifications are important consideration so the designs for various categories of houses, a primary school, a nursery school and a shopping center have been developed. The areas for LIG, MIG and HIG houses have been taken as 36.00 sq.m., 72.0 sq.m. and 108.0 sq.m. respectively. The areas for primary and nursery schools are 421.65 sq.m. and 90.74 sq.m. respectively. Shopping complex with 20 Nos. of shops has been designed with area of one shop as 12.00 sq.m.

2.3 General Specifications

1. Brick work in cement mortar for 9” (23cm) thick brick walls and 4½ “(11.5cm) thick brick with ½ inch (10mm) thick cement plaster on both sides.
2. 4” (10 cm) RCC roof with 10cm thick mud fuska including insulating layer of tar felt, & 2” brick tiling.
3. 4 cm thick cement concrete flooring on 7.5 cm lean concrete in two room set.
4. 5 cm thick cement concrete flooring including 1.5 cm thick moisac finish and 7.5 cm thick lean concrete.
5. Windows with plane glass of 3 mm thickness with wooden frame.

2.4 Energy Considerations

For the above designed buildings energy flow have been calculated for 22nd June temperatures putting these buildings in eight cardinal directions and having 2 and 4 Storey developments by using TRNSYS software. The energy simulation curves have been prepared for Delhi Region. Annual simulation curve and simulation curves for 22nd June for LIG two storey house buildings have been shown for four cardinal directions i.e south facing, south west facing, west facing and north west facing in graphs 1 and 2. During temperature simulation process shading factor on the building surface is also required. For this purpose, software/program has been developed using FORTRAN programming language to calculate the shadows. It calculates the height of shadows on the opposite buildings placed at a given distance at different orientations of the building for different altitudes and azimuth of the sun at different hours of the day.

North - West Facing

Graph 2 Simulation curve for LIG 2 storey building for 22nd June.

3. Layout Planning

Three layouts have been developed, two with normal / traditional type of clusters & road patterns having 4 storeyed walkup apartments for LIG group and 2-4 storey apartments for MIG & HIG group. Here the buildings have been placed in all the directions as depicted in FIG. 1 & 2.

The other layout has been developed considering orientation of all the buildings in E-W direction as longer side (facing north & south) because it consumes minimum energy. It is also depicted from the cooling load tables 1, 2 & 3 and corresponding histograms fig. 3, 4, 5 for LIG, MIG & HIG houses.

Further, while placing the blocks of buildings the height of blocks on the northern side rows have been reduced while of the blocks on the southern side has been increased to get the maximum advantage of the sun movement. It is reflected in the different design of residential clusters. Then these clusters have been grouped in a plot area of 400 m x 400m i.e. 16.00 hectare plot giving a density of 315 person / hectare or 126 persons / acre approximately. The development has been envisaged from 2 to 12 storeyed. The plantation of trees has been proposed on western side of clusters with a continuous belt of trees all round the boundary line of the site. The layout has been enclosed as Fig. 6.

Figure 1 Settlement layout plan for a neighborhood of 5,000 population, Alternative – I

The energy conservation in a settlement is a function of so many things because a settlement comprises of houses, community buildings and services. As the study was specifically to conserve energy through planning patterns and land uses, it is important to understand the concept of planning pattern and land uses taken in the study.

4. Planning Patterns & Land Uses

Planning pattern at city level may be taken as an out come of major road patterns i.e. linear, grid, radial or a combination of these. At a small settlement level-planning pattern in general is the disposition of various buildings, in a locality in different fashion. This is the type of development in terms of height, number of storeyes and orientation of building blocks. The height or number of storeyes play an important role in conserving energy because in a multi-storeyed building more number of floors are in shade. The top floor can be provided with proper insulation. Placing the buildings with respect to each other in a space in terms of distances and directions is also very important because of various patterns of shadows displayed on the opposite or side buildings. Orientation also plays a role as north & south surfaces get negligible quantity of sunrays.

The land use is a direct result of type of development or planning pattern. As we go higher we consume less space on ground and we reduces the land area for a particular land use like residential and get more open area as a more green/open land use for recreational activities i.e. parks, playgrounds, landscaping etc. for a better environment.

The distances and direction becomes significance because in a particular direction the building consumes less energy as compared to other direction. Further the distance & direction changes the shadow pattern of the blocks and the advantage of the shadows of higher buildings can be taken on the other buildings if higher blocks are placed in a fashion giving maximum shadow on the other blocks.

Figure 6 Layout plan.

5. Discussions and Findings

The results of the studies through temperature simulation curves drawn using TRNSYS for 22nd June indicates that orientation having longer sides on E-W direction is the best for energy considerations. So the orientation of the blocks of a building should be with E-W as longer side and facing north or south. The results for cooling load calculations for a LIG cluster planned in a traditional fashion of four storeyed development having 64 houses required a load of 40.78 KW while a cluster of similar houses planned in the proposed fashion requires a cooling load of 30.05 KW only i.e. a saving of 25% of cooling load. In these calculations the impact of shading has not been considered, if it is also taken in to account a saving of 35-40% of cooling load can be achieved easily. Shadow pattern studies show that maximum shadow on the buildings can be obtained on east & west surfaces placed against each other. This indicates that the surfaces of the building facing east and west should be put closer to each other to get the maximum advantage of the shadow. On north and south faces of the buildings there is hardly any shadow of opposite buildings. The shadows on south east & south west direction of blocks are generally thrown from the side blocks placed at an angular position on south side.

Further the higher blocks of buildings / residences can be put on southern side of the other buildings so that advantage of the shadow of these blocks from movement of sun from east to west can be taken on the southern side by the blocks situated at angular position i.e. blocks which are on the E / W sides of the immediate north side blocks. For example, if we take a cluster of houses (figure.7) as described above having six blocks in two rows A & B. Blocks of row B on south side are higher then blocks of row A on north.

The block No.5 is situated on southern side of blocks No. 1&3 of row A at angular position and both the blocks will get the advantage of shadow of block No. 5 on south. Similarly, the blocks No. 2&4 on north side would get the advantage of the shadow of south side block No. 6 which is higher and placed at an angular position. Now in this cluster of 6 blocks practically every critical side having undesirable heat gains is protected except the west and south-west sides of blocks No. 1&5 which can be taken care of by providing suitable landscaping / planting of trees.

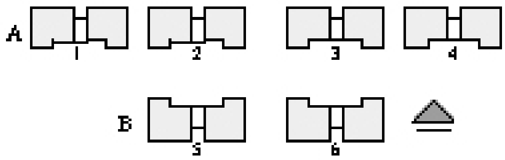

Figure 7 Block layout.

6. Conclusions

India is at a threshold of overall development including its economic and physical development. Physical developments include the design and planning of buildings and settlements where lot of energy is required as maintenance and in the process of material development. By proper planning and design energy of the order of 40 percent or more can be saved easily using proper specifications and orienting the building blocks in suitable direction. Study for Delhi region shows that if residential blocks are placed in east –west direction with 15 to 20 degree tilt on north side, the advantage of sun and air movement taken together and providing some insulation in roof finish can save the energy bill upto 35- 40 percent. This saving can further be increased if southern side blocks in the layout are taken of more height than northern side blocks which may provide shadow on northern side low height blocks with movement of sun from east to west. Thus we can contribute in achieving the broad objective of global sustainability by way of planning and design of buildings.

Keywords: high performance concrete, fly ash, metakaolin, ground granulated blast furnace slag

Summary

Complete sets of mechanical and durability properties of high-performance materials containing alternative silicate binders are not available even for very common types of these materials, at least not in the form that they could be directly used as input parameters of computer codes for durability analysis. As without a good knowledge of these properties it is impossible to perform any serious durability analysis of particular elements of building structures based on these materials, the determination of mechanical and durability properties of high-performance materials based on alternative silicate binders is a very actual problem. In this paper, compressive and bending strengths and moisture and heat transport and storage parameters of high performance concrete containing alternative silicate binders, namely metakaolin, fly ash and ground granulated blast furnace slag are measured.

1. Introduction

During production of Portland cement carbon dioxide which is one of the greenhouse gases is emitted to the atmosphere. Approximately 1 tone of CO_2 arises during the production process of 1 tone of Portland cement, about one-half of it originating from decomposition of limestone, which is the main raw material for Portland clinker, and the second half from fuel combustion necessary for cement production. Globally, in 1995 the amount of production of cement was about 1.4 billion tones. This means that the manufacture of Portland cement contributed about 1.4 billion tones of CO_2 to atmosphere (Malhotra, 1999). Therefore, with respect to a necessity to decrease the amount of carbon dioxide in atmosphere, alternative materials such as fly ash, ground granulated blast furnace slag, silica fume and metakaolin/calcined clay have a high potential to replace a part of Portland cement in concrete. Fly ash, ground granulated blast furnace slag and silica fume are waste materials. Metakaolin is produced by thermal decomposition of kaolin without production of CO_2. This supports the application of these materials or their combinations as environmental friendly cement substitutes.

High-performance materials based on silicate binders are characterized essentially by their compressive strength. Therefore, when the first high-performance materials (HPM) appeared, they were merely considered as high-strength materials. However, within the last several decades, this basic view has changed substantially. In the new HPM, some other properties such as water, heat and salt transport and storage parameters, freeze-thaw resistance or abrasion resistance began to gain higher importance and in some cases they even became decisive for the solutions made in the design process.

Despite the gradual shift of using alternative silicate binders in the HPM design and application philosophy towards a generally recognized necessity to measure a wider scale of HPM parameters, mechanical properties still remain the far most frequent parameters investigated. We will give only a few examples of the investigations done during the last couple of years on various types of HPM containing alternative silicate binders. An extensive review on the effect of silica fume on the mechanical properties of concrete was published by Chung (2002). Qian and Li (2001) studied the relationship between stress and strain of high-performance concrete with metakaolin. Li and Ding (2003), Khatib and Hibbert (2005) analyzed the effect of metakaolin and slag on compressive strength of concrete. Badogiannis et al. (2004) studied the strength development of metakaolin concrete. Wong and Razak (2005) compared the efficiency of calcined kaolin and silica fume for strength performance of concrete.

For water and water vapor transport and storage properties of HPM containing alternative silicate binders only very few references were found in common sources within the last years. For instance, Khan (2003) determined the sorptivity of several high-performance concretes incorporating fly ash and microsilica prepared with different water/binder ratios. Khatib and Clay (2004) studied water absorption characteristics of metakaolin concrete. Razak et al. (2004) compared water sorptivity of concrete with metakaolin and silica fume. Bai et al. (2002) measured sorptivity of concretes with pulverized fuel ash and metakaolin.

In this paper, measurements of mechanical and moisture and heat transport and storage parameters of three different HPMs containing alternative silicate binders as partial replacement of Portland cement, the first with ground granulated blast furnace slag, the second with metakaolin, and the third with fly ash are presented and compared with the results obtained for reference material containing only Portland cement as binder.

2. Materials

Four different types of high performance concrete were studied. Three of them contained alternative silicate binders, namely metakaolin (BM), ground granulated blast furnace slag (BS), and fly ash (BP). The fourth was reference HPC mixture with only Portland cement as binder (BR). Table 1 presents the composition of the studied concrete mixtures.

Table 1. The composition of concrete mixtures [kgm^{-3}]

Component	BR	BM	BS	BP
CEM I 42.5 Mokrá	484	440	440	440

3. Experimental methods

3.1 Basic properties

Among the basic properties, the bulk density, matrix density and open porosity were measured. Each sample was dried in a drier to remove majority of the physically bound water. After that the samples were placed into the desiccator with deaired water. During three hours air was evacuated with vacuum pump from the desiccator. The specimen was then kept under water not less than 24 hours.

From the mass of the dry sample m_d, the mass of water saturated sample m_w, and the mass of the immersed water saturated sample m_a (the so called Archimedes weight), the volume V of the sample was determined from the equation

$$V = \frac{m_w - m_a}{\rho_l}, \qquad (1)$$

where ρ_l is the density of water.

The open porosity ψ_0, the bulk density ρ and the matrix density ρ_{mat} were then calculated according to the equations

$$\psi_0 = \frac{m_w - m_d}{V\rho_l} \qquad (2)$$

$$\rho = \frac{m_d}{V} \qquad (3)$$

$$\rho_{mat} = \frac{m_s}{V(1-\Psi_0)} \qquad (4)$$

The samples for determination of basic properties were cut from the standard prisms; their sizes were 40 x 40 x 20 mm in the case of open porosity and matrix density, and 40 x 40 x 80 mm in the case of bulk density determination.

3.2 Mechanical properties

The measurement of compressive strength and bending strength was done using the hydraulic testing device VEB WPM Leipzig 3000 kN. The apparatus consists of a stiff loading frame having the capacity of 3000 kN. The 100 x 100 x 400 mm samples were used in the experiments. A constant strain rate of 0.1 – 0.2 MPa/s was imposed on the specimens.

3.3 Water and water vapor transport properties

Two versions of the common cup method were employed in the measurements of the water vapor diffusion coefficient (Roels et al. 2004). In the first one the sealed cup containing silica gel (5 % relative humidity) was placed in a controlled climatic chamber with 97 % relative humidity and weighed periodically. In the second one the cup containing the saturated solution of K_2SO_4 (97 % relative humidity) was placed in the 25 % relative humidity environment. The measurements were done at 20°C in a period of two weeks. The steady state values of mass gain or loss were determined by linear regression for the last five readings.

The water vapor diffusion coefficient D [m^2s^{-1}] defined as

$$j = -D \; grad\rho_m , \tag{5}$$

where j is the water vapor flux [$kgm^{-2}s^{-1}$] and ρ_m the partial density of water vapor in the porous body [kgm^{-3}], was calculated from the measured data using the equation of state of an ideal gas according to the equation

$$D = \frac{\Delta m \cdot d \cdot R \cdot T}{S \cdot \tau \cdot M \cdot \Delta p_p} , \tag{6}$$

where Δm the amount of water vapor diffused through the sample [kg], d the sample thickness [m], S the specimen surface [m^2], τ the period of time corresponding to the transport of mass of water vapor Δm [s], Δp_p the difference between partial water vapor pressure in the air under and above specific specimen surface [Pa], R the universal gas constant, M the molar mass of water, T the absolute temperature [K].

On the basis of the diffusion coefficient D, the water vapor diffusion resistance factor μ (which relates the diffusion in the air to the diffusion in the porous system) was determined:

$$\mu = \frac{D_a}{D} , \tag{7}$$

where D_a is the diffusion coefficient of water vapor in the air.

The water sorptivity was measured using a common experimental setup. The specimen was water and vapor-proof insulated on four lateral sides and the face side was immersed 1-2 mm in the water, constant water level in tank was achieved by a Mariotte bottle with two capillary tubes. One of them, inside diameter 2 mm, was ducked under the water level, second one, inside diameter 5 mm, was above water level. The automatic balance allowed recording the increase of mass. The water absorption coefficient *A* [$kgm^{-2}s^{-1/2}$] was then calculated using the formula

$$i = A \cdot \sqrt{t} , \tag{8}$$

where *i* is the cumulative water absorption [kg/m^2], *t* is the time from the beginning of the suction experiment. The water absorption coefficient was then employed for the calculation of the apparent moisture diffusivity κ [m^2s^{-1}] which is defined as

$$j_w = -\kappa \; grad\rho_v , \tag{9}$$

where j_w is the liquid water flux [$kgm^{-2}s^{-1}$] and ρ_v the partial density of water in the porous body [kgm^{-3}], in the form (Kumaran, 1994)

$$\kappa \approx \left(\frac{A}{w_c - w_0} \right)^2, \tag{10}$$

where w_c is the saturated moisture content [kgm^{-3}] and w_0 the initial moisture content [kgm^{-3}].

The samples for determination of water and water vapor transport properties were as follows: the specimen size was 50 x 50 x 20 mm, and samples were on four lateral sides water- and water vapor-proof insulated with epoxy resin to ensure the one-dimensional transport.

3.3 Thermal properties

Thermal conductivity and specific heat capacity were measured using the commercial device ISOMET 2104 (Applied Precision, Ltd.). ISOMET 2104 is equipped with various types of optional probes, needle probes are for porous, fibrous or soft materials, and surface probes are suitable for hard materials. The measurement is based on analysis of the temperature response of the analyzed material to heat flow impulses. The heat flow is induced by electrical heating using a resistor heater having a direct thermal contact with the surface of the sample. In the experimental work 3 cubic samples 70 x 70 x 70 mm were used.

4. Experimental results and discussion

4.1 Basic properties

The basic properties of studied HPCs are shown in Table 2. The highest value of porosity achieved the material BM containing metakaolin and the lowest value the material BS with slag admixture. The difference between these two materials was about 34 %. The bulk densities of all materials differed only up to about 2% and matrix densities up to 5 %.

Table 2 Basic physical properties of the studied concrete mixtures

Material	Bulk density [kg m^{-3}]	Matrix density [kg m^{-3}]	Open porosity [% m^3 m^{-3}]
BM	2366	2691	13.0
BS	2334	2602	9.7
BP	2356	2717	12.5
BR	2380	2715	12.3

4.2 Mechanical properties

Table 3 shows the compressive and bending strength of the studied HPCs after 28 days. The results were very similar for all materials, only the material BP with fly ash achieved about 8 % lower values. The other differences were within the error range of the experimental method.

Table 3 Mechanical properties of the studied concrete mixtures

Material	Compressive strength [MPa]	Bending strength [MPa]
BM	86.95	11.93
BS	85.30	11.10
BP	80.52	10.64
BR	87.31	11.63

4.3 Water and water vapor transport properties

The results of measurements of water and water vapor transport parameters of the studied hardened cement mixtures are presented in Tables 4 and 5.

The measured data revealed basic information that the values of water vapor diffusion coefficient corresponding to the lower values of relative humidity (5/25 %) were always lower than those for higher relative humidity values (97/25 %). This is in accordance with the previous measurements on many other materials including concrete (Kumaran 1996). The main reason for this finding is coupling of water vapor transport with liquid water transport in a material with higher relative humidity where the capillary condensation takes place in a much higher extent than in the range of lower relative humidity (Černý and Rovnaníková 2002).

Comparing the data measured for the four studied HPCs, we can see that the values of water vapor diffusion coefficient of BM and BP were in the both ranges of higher and lower relative humidity about 2-3 times lower than for BS and BR. This does not agree very well with the open porosity data in Table 2; the material BS with the lowest porosity achieved the second highest water vapor diffusion coefficient. However, the reason for this discrepancy cannot be explained with the data available at the moment. The pore distribution should be measured, to get a better insight into the problem.

Table 4 Water vapor transport properties of the studied concrete mixtures

Material	97/25 %		5/25 %	
	Water vapor diffusion coefficient [m^2s^{-1}]	Water vapor diffusion resistance factor [s]	Water vapor diffusion coefficient [m^2s^{-1}]	Water vapor diffusion resistance factor [-]
BM	1.10E-06	21.0	7.09E-07	32.4
BS	2.61E-06	8.99	1.31E-06	17.7
BP	1.34E-06	17.2	5.23E-07	44.6
BR	3.63E-06	6.60	1.50E-06	15.8

The effect of alternative silicate binders on the liquid moisture transport parameters was pronounced for materials with ground granulated blast furnace slag and metakaolin. The water sorptivity values of BM and BS were about 30-40% lower than for BR. On the other hand, water sorptivity of the material with fly ash achieved nearly the same value as the basic mixture BR. Here the results were in better agreement with the open porosity data from Table 2 than for water vapor transport parameters. The material with lowest open porosity achieved the lowest water sorptivity value. A more detailed discussion in this respect, once again, would require the pore distribution measurements.

Table 5 Water transport properties of the studied concrete mixtures

Material	Water absorption coefficient [kg $m^{-2}s^{-1/2}$]	Apparent moisture diffusivity [m^2s^{-1}]
BM	0.0070	4.09E-09
BS	0.0057	3.77E-09
BP	0.0105	6.49E-09
BR	0.0099	7.15E-09

4.4 Thermal properties

The data in Table 6 show that the thermal conductivity of all materials was very similar. The differences were in the whole analyzed moisture range rather low, up to 10%. The highest thermal conductivity in dry state achieved the material BS which is in a qualitative agreement with the open porosity data in Table 2.

Table 6 Thermal properties of the studied concrete mixtures

HPC	Moisture content [% kg kg^{-1}]	Thermal conductivity [$Wm^{-1}K^{-1}$]	Specific heat capacity [$Jkg^{-1}K^{-1}$]	Thermal diffusivity [$10^{-6}m^2s^{-1}$]
BM	0.00	1.565	728	0.908
BM	2.87	1.760	738	1.052
BM	4.00	1.952	753	1.092
BM	4.66	2.085	762	1.155
BP	0.00	1.550	692	0.951

BP	2.00	1.750	715	1.039
BP	2.40	1.780	717	1.053
BP	3.80	1.940	747	1.102
BS	0.00	1.632	705	1.001
BS	0.72	1.760	719	1.030
BS	3.40	1.978	787	1.142
BS	4.17	2.077	800	1.190
BR	0.00	1.486	672	1.040
BR	2.53	1.690	703	1.070
BR	3.92	1.915	742	1.157
BR	4.77	2.085	766	1.252

The specific heat capacity of BR was slightly lower than for other materials in the whole range of moisture content. However, the observed differences were within the error range of the measuring method of ±10%. The values of thermal diffusivity were once again very similar for all materials in whole the moisture range. This reflects the low differences in both thermal conductivity and specific heat capacity data of the investigated materials.

5. Conclusion

The investigations of mechanical and moisture and heat transport and storage properties of high performance concretes containing metakaolin, ground granulated blast furnace slag and fly ash as partial replacements of Portland cement in this paper revealed that these materials may become a viable alternative to the HPC containing only Portland cement as binder. The mechanical properties of the materials with metakaolin and ground granulated blast furnace slag were after 28 days of curing the same as of the reference HPC, for the material with fly ash an 8% decrease was observed. This is a very perspective result because the rate of pozzolana reaction with water is lower than the hydration reaction of cement (Černý and Rovnaníková 2002); thus it can be anticipated that the strength of the materials containing metakaolin, ground granulated blast furnace slag and fly ash in long-term view will be higher than of the reference material with Portland cement only. The water transport properties of three studied concretes with alternative silicate binders were found to meet reasonably the basic requirements necessary to achieve such a durability which is expected for HPC; concretes with metakaolin and ground granulated blast furnace slag transported liquid water significantly slower, concrete with fly ash exhibited approximately the same water absorption as the reference material. Heat transport and storage properties were for the alternative materials very similar as for the basic material with only Portland cement. Therefore, it can be concluded that the use of alternative silicate binders as partial replacement of Portland cement can be considered as a perspective way for the production of high performance materials beneficial to the environment.

SUSTAINABILITY IN ROOF REHABILITATION

Ana-Maria DABIJA Prof. Dr. Arch.[1]

[1] 'Ion Mincu' University of Architecture and Urbanism, Bucharest, Romania, am.dabija@iaim.ro

Keywords: roof, rehabilitation, sustainability, mansard, green-roofs, BIPV

Summary

Sustainability and energetic performance of the buildings may be accomplished in more than one way; the process of refurbishment is a good opportunity for it. The walls, the windows, the roofs, the floor, each of them can be remodeled in order to ensure better comfort standards and to preserve energy in the same time.

In many situations the roof is subject to severe interventions, from the re-evaluation of the use of the space beneath the pitched roof (from a simple attic to dwelling) to drastic changes of the volumetry of the buildings (by creating new penthouses), in the case of the low sloped roofs, that deal ultimately with the functionality and aestetics of the building.

This paper focuses on some of the types of interventions for roof rehabilitation, carried out in Romania, taking into consideration cultural, environmental, technical and functional implications that they have on the built space or on the entire building.

Beginning with a brief presentation of the number and the state of the dwellings in Romania, the most current types of interventions on existing buildings are listed, according to what is expected to be achieved in terms of performances, after carrying out the rehabilitation work.

Abstract

The higher need of space in the urban areas led to the identification of buildings that can be refurbished, remodeled, even heightened, in order to accommodate people into the heart of the city.

The stock of existing dwellings in Romania is very important. Over 8 million dwellings. Most of them are located in blocks of flats (over 83,799 blocks). 52.5% of the dwellings are built in urban areas. Among them 15.3% were built before 1944, about 76% between 1944 and 1990, and the remaining of 8.7% after 1990 [1].

The existing stock of buildings in the cities – dwellings as well as public institutions - is subject of complicated activities of refurbishment and conversion that aim to accomplish higher comfort, efficient use of the energy resources as well as appropriate functionality of the existing space. In many countries the preoccupation to decrease the urban pollution and the urban heat island effect, to preserve and improve the environment by constructive means and to use new forms of energy has led also to the development of appropriate roof structures. Nowadays, although there are Romanian investors – home owners or institution managers – who are open to the use of non-conventional energy systems, and environmental preserving systems, we are still very much at the beginning with the implementation of the new technologies for producing green energy.

In Romania building consolidations, general repairs or refurbishment are frequent. In fact, the need of re-building after the major earthquake of 1977 (when 35.000 dwellings were destroyed, many of them in mass buildings), the aim to ensure dwellings for the population in the '80s, as well as the building activity of the past 20 years (changes of the political and economical conditions, that led to higher comfort exigencies and to the migration from collective dwellings to individual houses) shows that the building industry is very much active.

Taking advantage of the need of structural interventions over the existing buildings as well as of general repairing, the work of intervention aims not only to improve the overall hygro-thermal behavior, but also to ensure extra space for the users of the buildings.

The evaluation and the decisions for the most adequate means of overall interventions for rehabilitation are often made by bringing together specialists from different fields of activities: architects, engineers (structure, HVAC), urban designers, historians (in the case of patrimonial buildings), geologists and other experts (chemists, physicists, environmental specialists etc).

1. Types of roofs – types of interventions

The roof can be defined as a building component that fulfills the same functions as any other part of the building envelope. The traditional function of the roof is to protect the upper part of the building against weathering.

Roofs can be characterized from many points of view; in the following lines we present some possible classifications:

- by volumetry (or geometry): pitched roofs and low sloped roofs;

- by the features of the roof covering elements: continuous – watertight membranes or discontinuous – different types of shingles and tiles; obviously, the type of material dictates the roof structure and the geometric conformation of the roof;

- by the type of the materials that fulfill the protection (roof covering): “traditional” natural materials, like earth, straw, reed, wood, ceramics or metal shingles and “new” products, like all the waterproof membranes, different types of cement-based shingles, glass, PVC, metallic sheets, composite panels etc

- by the type and material of the structure of the attic, that supports roofing: wood, metal, concrete

- by the type of space that results beneath the roof (in the attic): technical or functional

- by the way the roof responds to other requests of the building envelope: hygro-thermal protection, acoustic protection, fire and wind protection, natural lighting, natural ventilation

In recent times, the demand to save the natural (and sometimes also the built) environment as well as the higher need to discover and use alternative forms of energy led to a new request that can be formulated for the roof as well as for the façade: to be an environment preserver or/and an energy generator.
The main types of approaches that can be emphasized, while deciding about the complexity of an intervention over an existing building, are presented in Table 1. Each of the actions has implications over the roof component. The structural interventions on the entire building are not to be discussed here; they may be or may not be applicable and therefore they are not mentioned in the table.

Table 1 Principles regarding the aims and means for intervention on existing buildings

	Aim	Means of interventions	Type of building on which it (generally) applies
I	Preservation of the original features of the building: volumetry, internal horizontal and vertical partitions, materials and technologies	replacement of the original building components with identical ones	• historic monument • architecture monument • traditional buildings • buildings for tourism, integrated in the local architecture • private, medium-low income owner
II	Preservation of the main original exterior features of the building while improving the comfort parameters and increasing the functions of the building envelope; some parts of the roof system changes due to the new exigencies imposed to the envelope. Internal horizontal and vertical partitions may be changed	insertion of thermal insulation structures as well as the conversion of the (technical) attic into a (functional) mansard; possible use of new systems or technologies for roofing (eco-technologies);	• private, medium income single owner • private, medium income multiple owners (mass dwellings) • historic building, • public institutions hosted in historic buildings (when applicable)
III	Accomplishment of a complex rehabilitation where, along with the structural and hygro-thermal new performances, the volumetry of the building changes significantly, by adding (a) new floor(s) on the roof top	interventions over the structure that take into account the new floor(s) that are built on the low sloped roof; possible use of new systems or technologies for the new roofing;	• private, medium income owner • mass dwellings with multiple or unique owners • public institutions

Considering the consequences of the interventions strictly in regard with the roof, some of the conclusions that can be drawn out generally link the type of approach with the type of the building and it’s functions.

2. Identical replacement of the roof system (I)

This is a main condition imposed in the case of historic buildings, cultural heritage etc, as a need to preserve the traditional building systems, materials and techniques. The replacement of the roof system with similar, identical or comparable products is currently used in the rehabilitation of traditional houses with thick earth, straw or reed roofing, with wooden shingles, or ceramic tiles.

Their performances are connected to the thickness of the roof (in the case of earth, straw or reed) and with the slope (in the case of wooden shingles, or ceramic tiles), as shown in Figure 1.

Figure 1 Traditional houses in the Village Museum in Bucharest; the original materials, structure and techniques for the roofs are preserved (as they are for the whole building)

The same principle may apply in the case of new buildings, in special locations, where the architectural style of the place dictates the integration in the landscape. It is the case of some buildings for tourism, in natural preserved areas, or where the architecture of the rest of the buildings is traditional and continuity is requested.

3. Identical volumetry of the roof (II)

In the case of an intervention that aims to improve the comfort parameters without altering the constructive features of the building, the interventions that are carried out should be compatible with the original roofing materials (ceramic tiles, metallic sheets). The structure of the roof may change, in order to accommodate the thermal protection system [2].

The overall image of the building remains the same, although interior modifications are often being made by changing the interior partitions or even by re-evaluating the position of the floors, in the case of important structural consolidation work.

In the case of the buildings with low sloped roof ("terrace roofs"), the possibilities of interventions are larger, from the simple repair or replacement of the waterproof membrane, with a similar one, having more or less the same characteristics, to the more energy saving type of waterproof system, which is the "green terrace roof".

3.1. Interventions on pitched roofs

While the rest of the building and the envelope withstand severe modifications, the roof covering remains, in general lines, the same (see Figure 2).

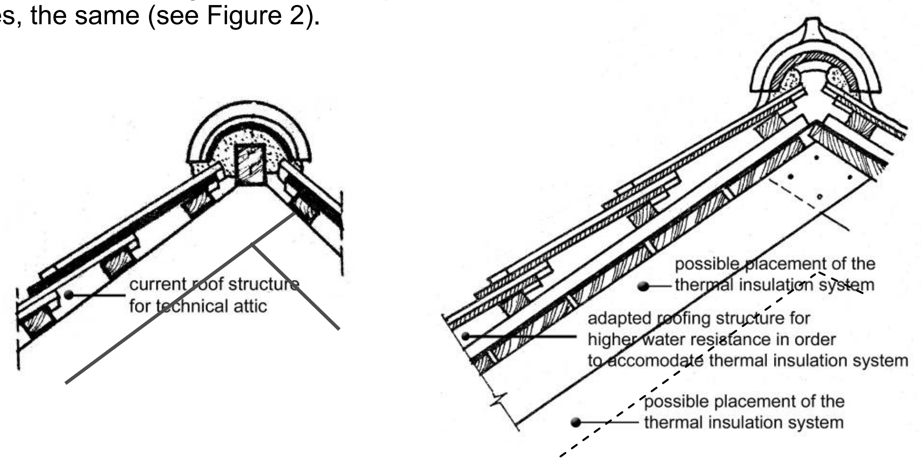

Figure 2 Roof structure with ceramic tiles for a traditional building with technical attic and the changes of the structure, for ensuring better water protection and thermal insulation, when converting the attic from technical to functional [3]

In the case of an intervention where the aim is to make a better use of the attic, the most important problems are to ensure the same hygro-thermal and functional conditions in the attic as in the rest of the building. Not the entire space beneath the roof can be used. The steeper the slope, the more space of the attic can be functional.

Providing an appropriate thermal insulated system on the roof (and walls) can be accomplished without major complications, there are structural, installation, functional and legal problems that have to be solved, in order to transform a technical space into a functional one [4].

Appropriate vertical circulation to the new functional space should be adapted. Sometimes this requests complicated interventions to be made inside or outside the building.

Also, the space conversion implies very careful evaluation of the height where the different objects are to be placed and – more than that – the relation between the user and the position of these objects so that the user may actually be able to reach to them (Figure 3)

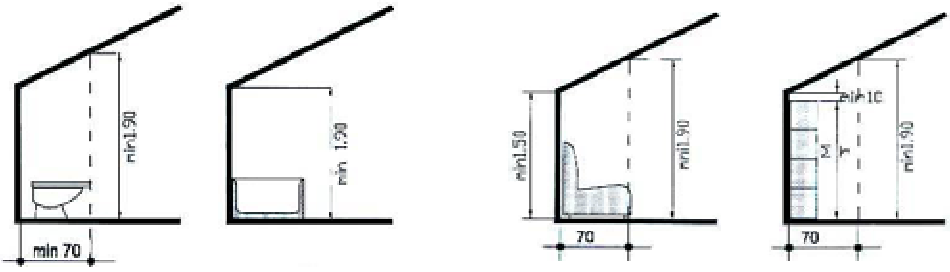

Figure 3 *recommended placement of sanitary or furniture objects, in a mansard; the height of the room at 0.70m from the mansard wall should allow an adult to stand comfortably [2]*

The heating, ventilation air conditioning and sanitation has either to be extended on the newly appeared floor, in case the system permits such an operation, or to be designed and carried out, independently only for the top floor.

In many of the cases of intervention on existing buildings that aim to convert the technical attic in a functional mansard, the replacement of the wooden structure of the attic is also required, due to the alteration of the original one.

The new structure is, usually, metallic, in order to accommodate the functional requirements (height, functional surfaces) as well as the hygro-thermal requirements (thermal insulation associated with the roof structure -rafters, roof boarding, laths – and the roof covering, while preserving the shape of the roof, the height and the type of roofing materials (see Figure 4).

Figure 4 *The attic of the School of Architecture, before the work of refurbishment and after; the volumetric and imagistic features of the building are preserved, by using the same type of roofing material (ceramic tiles), but the use of the interior space has changed, from technical to functional*

3.2 Interventions on low sloped roofs ("terrace roofs")

3.2.1 The replacement of the membrane with a new one may imply a major improvement of the performances of the roofing system as well as of the comfort conditions of the rooms beneath it.

Waterproof PVC membranes with PV coating are now available, so that the function of "energy generator" may also apply in the case of low sloped buildings, with no supplementary equipment installed on the roof (PV panels, frames, supporting structures) [6].

3.2.2 The use of green (terrace) roofs is another possibility of intervention on a low sloped roof structure, that leads to energy saving and heating costs reducing. By using these systems, the state of the exterior environment is at least preserved, if not improved. Polluted areas might even be thus rehabilitated (as we note the case of Linz in Austria where the politics of the "green roof" helped to "de-pollute" this industrial city).

Briefly, among the advantageous aspects of green (terrace) roof performance, the following should be noted:

- retention of an important quantity of the rain water (vegetation acts like an absorbent sponge), thus reducing the pressure imposed on water collectors placed on the terrace.

- reduction of the noise level felt by users who live on the top floor. This is due to the additional mass represented by the soil and the plants. In general, persons living near noisy environments such as airports, discotheques, parking structures, and industrial areas are better protected against noise with a rather non-expensive means.

- protection against electromagnetic radiations [9];

- achievement of a constant interior temperature with no heating peaks in the apartments situated on the top floor under the roof. This is due both to the additional thermal protection represented by the soil and plants as well as to the increased percentage of humidity produced by the breathing of the plants, that cool the air in the vicinity of the roof.

- preservation of the natural environment, as represented by these systems. As mentioned, in polluted industrial areas, the environment might be "healed" after the installation of green roof terraces.

3.3. Roof integrated photovoltaic systems as "clean" energy sources

In the past few years the possibility of integrating photovoltaic panels on the existing buildings – in particular, on existing roofs – gave the building envelope a new function: the energy generator [5], [6], [7]. Photovoltaic panels can be placed over the existing roof, or within the roof, acting also as skylights, with a minimum of constructive implications (the generator, represented by solar panels, the inverter, which converts the system's direct-current electricity to alternating current, batteries that provide energy storage and electrical components needed for installation).

While, in the case of new buildings, the specific aspect of a building that has a building integrated photovoltaic panel (BIPV) on the roof is acceptable, where historic buildings are concerned it is necessary to analyze whether the new envelope component is aggressing the image of the building or the neighborhood. Therefore it may be wise, in the given case, to proceed with a thorough study of the visibility of the pitched roof (and implicit, of the panels) [8] and install, for instance, BIPV on the slopes that are oriented to interior courtyards if the orientation and angle of these slopes are efficient for the performance of the panels.

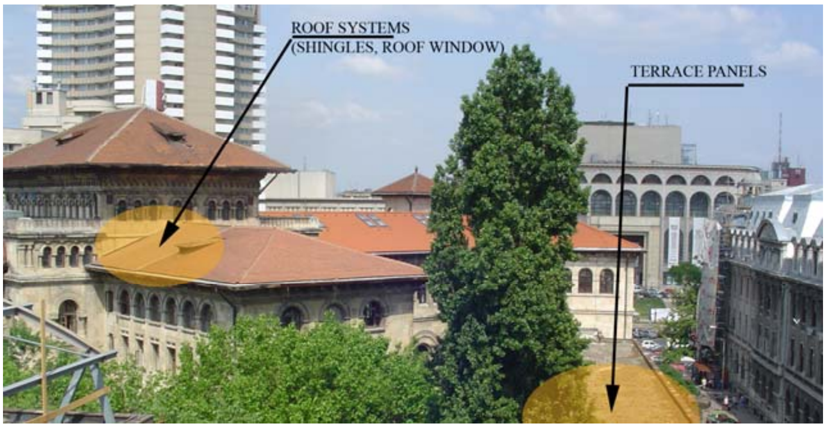

Figure 5 The roof of the School of Architecture in Bucharest, with the possible placement of PV panels on the South Western slopes of the pitched roof and on the terrace roof.

4 Overall changes of the roof – components as well as volumetry

Although the green roof system seems to be the most adequate for urban conditions, in most of the cases the possibility of adding a condominium on the roof seems to be more appealing. Like everywhere else in the world, the prices of houses in the center of the city are very high. In order to build in an expensive area, either some buildings are demolished or the existing buildings are heightened, by building condominiums (on top of the roofs of existing buildings).

The owners are presented the bright side of the problem: building a condominium, with a pitched roof, on top of a low sloped roof is an advantage, as it ensures

- better protection against water and snow (given strictly by the geometry of the traditional roof)

- a fairly rapid pay-off of the investment, once you rent the mansard that results.

The true colours are, however, not as radiant. Supposing the structure of the building allows the extra storey, there are legal problems as well as technical, design, structural, construction, economical other implications that are extremely complicated.

Some of the difficulties have been presented above (as the technical and design problems are more or less the same with the ones that appear when transforming a cold attic into a liveable place), but, due to the specific features of the mass dwelling, where each apartment is owned by a different person, legal, sociological, financial and juridical aspects rise: in multi-storey dwellings, where each apartment is owned by a different person, it is not a simple task to have everyone accept building a condominium.

The nuisance (debris, dust, noise, shocks) of demolishing the roof system (waterproof membrane, thermal insulation, slope, concrete) to reach to the reinforced concrete floor is differently felt by persons on the different floors: those who live on the floor beneath the roof are more exposed to noise; the dust and debris affects all the users of the building. Once the condominium is built, new problems appear: how and who gets the money, how is it spent, and so forth.

Last but not least, there are construction aspects that deal with the management of the site: while working on the condominium, extra costs have to be taken into account for protecting the building. Once the roofing membrane has been ripped off, it should be immediately replaced. There have been cases of buildings (at least one every year), when the rain destroyed from top to bottom all apartments and produced short-circuits, because the roof was not protected any more.

5. Conclusions

The sustainable roof system can be defined as a building component that conserves, recycles and helps renew natural resources. Where traditional materials are concerned, sustainability is given by the use of the same systems that are resulting as secondary products from other activities (straw, reed), are generally available (earth, wooden shingles) or are recyclable (ceramics).

Where waterproof membranes are concerned, the appropriate UV, IR or anti-oxidation protection can increase the service life from an average of 15 years to 25 years, provided that the system is appropriate for the specific use, well installed and accordingly protected.

In either case, the development of the roof integrated photovoltaic systems can – and should – be taken into consideration.

Building condominiums on existing roofs should be carefully considered, with all implications – constructive, technological, environmental. When it is a correct design option, the new roof system that covers the condominium can be designed as a part of the envelope of the building that, apart from the traditional characteristics, fulfills the task of environmental preserver and energy producer.

Keywords: wood, housing, envelope, overheating

Summary

The country shows a general absence of wood as a building material in architectural works and in the realm of housing. In Chile, wood production will grow significantly within the next five years. A research project that is being held in the Wood Innovation and Development Centre of our university tries to solve different pathologies, traditionally related to the wood construction in Chile through the development of a new skin. Improvements included in this envelope have been observed in some foreigner experiences, especially in northern Europe. Simulations by means of TAS software have been made to study the thermal behaviour of three housing prototypes in different Chilean climates, which have shown a good performance in terms of heating loads. However, overheating appears as an important drawback in summer, particularly in the case of Santiago, city with a Mediterranean climate. This study explores different solutions to avoid overheating in the prototype of Santiago tested through TAS. For this city, aspects such as thermal mass, ventilated roof and ventilation strategies have shown to be effective for improving the thermal behaviour of this dwelling for cooling periods. Additionally, the impact of windows over the internal thermal behaviour related to the ventilated air cavity of the panels was studied through a series of experimental models named “summer test”. By means of these models, the positive effect of the air cavity over the thermal performance is demonstrated, since it reduces internal temperatures in comparison with a model without air cavity (buffer effect). In this context, when the models are exposed to direct radiation (north facade) without solar protected, the positive effect of the cavity is eliminated, producing overheating. However, when the windows have complete opaque solar protections, diffuse radiation does not reduce this effect, buffering internal temperatures.

1. Introduction

Wood is an abundant Chilean raw material which has not been able to position itself at a national level corresponding to the country’s present state of development. This fact accounts of the massive absence of wood as a building material in architectural works, despite that historically, there were a lot of prefabricated systems that had used wood as main material. Just in the 60’s, in Chile we can find 31 prefabricated system. Between them, 28 were based in radiate pine, oak, aspen, plywood or another kind of panel. However, since the decade of 80’s, this material has been used widely to emergency solutions (due to earthquakes and other natural disasters) and social housing, producing a scenario which wood has been directly related to this situations (or with the second house, typically placed in the coast and used in holidays). Most Latin American countries share these difficulties and have no developed research and advanced technological transfers in this area.

According to the National Statistics Institute, in Chile, while house building reaches to 120,000 per year, only 12% represents timber housing. As it was explained, in Chile there is a negative image of wood as a building material also due to a deficient quality control and inadequate design solutions that have been used mainly in social housing construction. On the other hand, according to the statistics provided by the Instituto Forestal de Chile, the production of forest industry will be twice increased within the next five years, and nowadays, there are 1.800.000 hectares of plantations and 20,000,000 m^3 of annual harvesting. This growth makes imperative the incorporation of advanced technologies and specialized design, since national wood consumption for construction is still limited. For example, if the annual sawmill wood consumption per capita (m^3) is compared between different producing countries, Chile just reach 0.11 m^3 per capita, very far way to Scandinavian countries, with values between of 0,60 in Sweden and 1.02 m^3 per capita in the case of Finland.

Concerning to timber housing advantages, such as energy savings during heating season (due to the own construction process, which incorporates an interior layer of thermal insulation), no diffusion has been made in the country. This aspect is particularly appropriate to Chilean cold climates (which have an interesting wood construction tradition), similarly to the situation to Scandinavian countries, Canada or Germany, which have even more extreme climates in the heating season. However, some Chilean climates in Mediterranean latitudes, such as Santiago, present high temperatures and solar radiation in the cooling season associated to an important thermal oscillation (Figure 1). Therefore, overheating could appears as an important drawback in summer, since it is traditionally associated with timber construction, mainly due to a low thermal mass, which is not able to buffer internal temperatures (due to the principle of thermal lag absence).

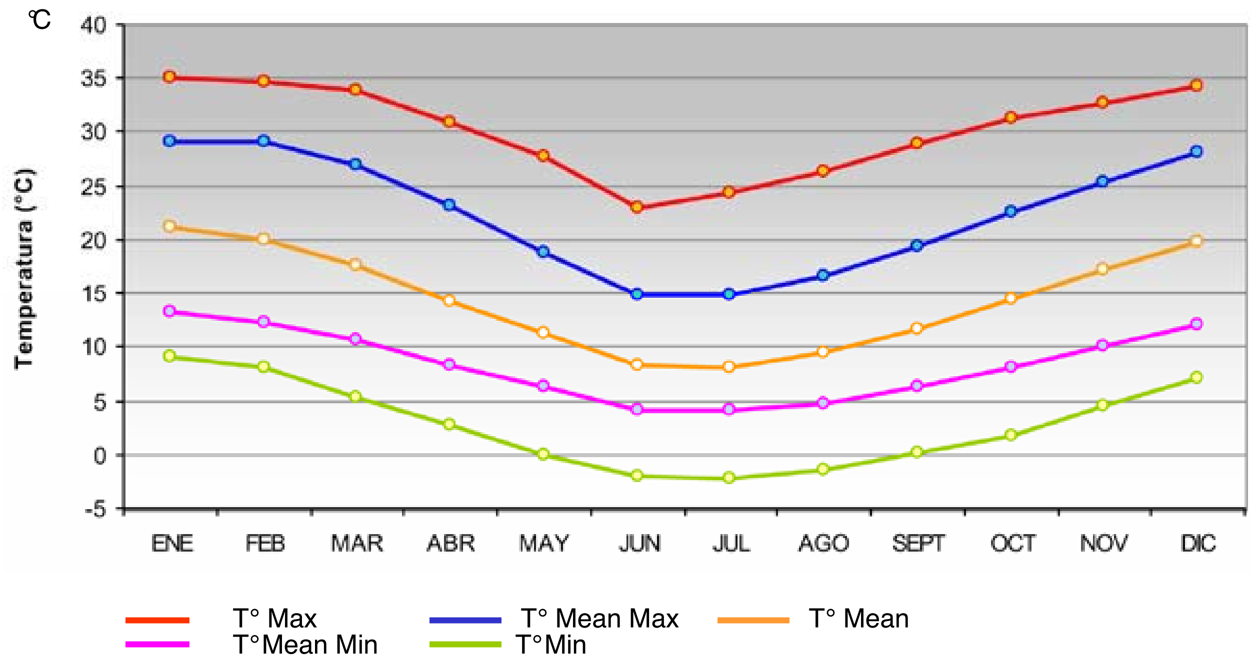

Figure 1. Mean and peaks temperatures city of Santiago

Different experiences have showed the positive effect that thermal mass may produce during cooling season in the internal conditions of a house in Mediterranean climates /1, 2, 3/. An experience carried out by the Fundación Chile in the 80's, that it was called "Viviendas Energitérmicas", showed both good thermal performance in winter and overheating in summer, this latter probably due to a inadequate orientation, lack of shading devices in eastern and western windows, limited ventilation in attics and low thermal mass to decrease thermal oscillation /4/, which affected severely the internal comfort conditions.

2. Methodology

2.1 Envelope design in timber housing

The research project FONDEF D03I1020 "Diseño por envolvente para la vivienda de madera: Innovación Tecnológica para fomentar el uso del Pino Radiata en Chile" (Envelope design for timber frame housing: technological innovation to promote Radiata Pine use in Chile) tries to solve different pathologies, traditionally related to the wood construction in Chile (humidity, acoustic, thermal insulation, termites and others). This applied research proposes to work within a Research and Development (R+D) scheme, supported by a joint effort of the State, universities, and private companies in the area of materials as well as building companies, in order to create new knowledge and open new fields for practical applications. The existent studies in Chile have rigorously searched for solutions involving specific parts and components, thus allowing for great advances in this area. Nowadays, however, it is necessary to start from that basis and develop the concept of "envelope", understood as a whole. Starting from this concept, new "skins" will be tested against the demands of the different Chilean climates.

Therefore, the mentioned project includes three different house constructions located in three different climatic zones of the country: central interior (Santiago 33º30’ S), southern coast (Puerto Montt 41º30’ S) and southern interior (Temuco 38º46’ S). These prototypes were tested before and after constructive process, in order to improve massive housing offer, increasing presence of wood housing construction in the national market. The research project produced a series of simulation to assess the thermal performance of these three prototypes, which was expressed through the heating demand and internal temperatures of the main rooms. In the two southern cases, results were completely successful for the heating season, reaching values of around 70 and 93 KWh/m^2 year in Temuco and Puerto Montt, respectively. In both of them, due to their climatic conditions, overheating does not appear as a particular critical problem, which on the contrary is one of the most important aspect to be considered as design criteria for Santiago (Figure 2). This study explores different solutions to avoid overheating in the prototype placed in this city (architects: Mario Ubilla and Rodrigo Cepeda), the most sensible location to this problem, tested through TAS software. For this latitude, aspects such as thermal mass, ventilated roof and ventilation strategies have shown to be effective for improving the thermal behaviour of this dwelling for cooling periods, which were assessed by means a series of thermal simulations.

Figure 2. Santiago Housing Prototype

The external wall framing of the house is composed by: Radiata pine studs 45x90mm every 600 mm, interior of gypsum board, vapour barrier, fibber glass of 90 mm filling the cavity, OSB and exterior envelope over a ventilated cavity of 25 mm. (Figure 3). Exterior envelope in the case of the house of Santiago is concrete stucco and OSB for exterior sheathing. The house also considers single glazing in windows and a ventilated attic with 100 mm of fiber glass over a gypsum board ceiling.

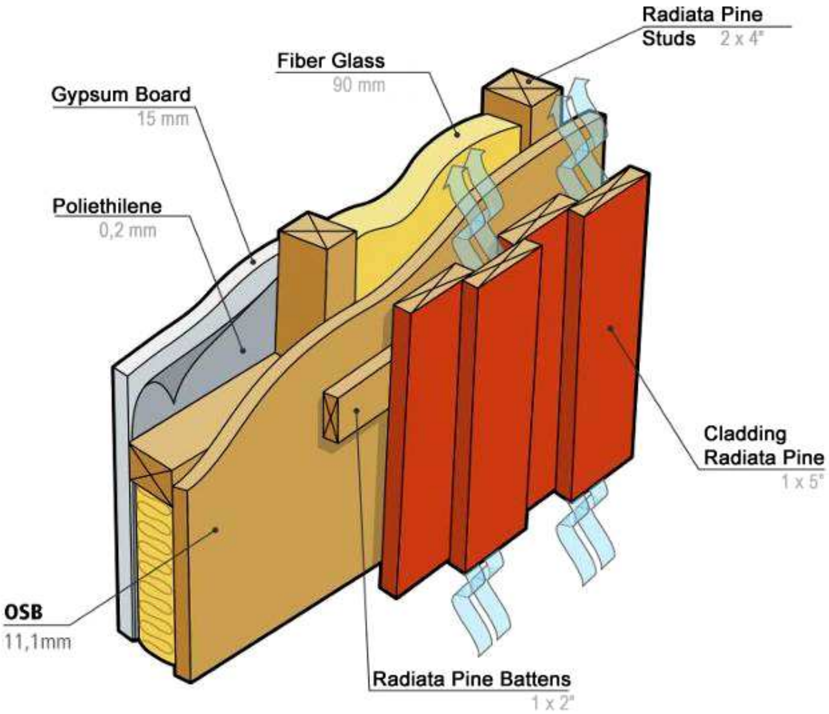

Figure 3. FONDEF D03I1020 Panel

2.1 Thermal modelling methodology

Evaluations content in this document were carried out from a modelling method of thermal performance in dynamic state. This one corresponds to a closer approach to the real behaviour of a building due to involving a great amount of variables (physical characteristics of materials, internal gains, occupation loads and other modelling settings) and complete climatic information (annual hourly values for temperature, direct and diffuse radiation, direction and velocity of winds, precipitations and cloudiness). In contrast to steady state estimations that assumes no variation between interior and exterior temperature through the time (and used mainly to specify HVAC systems from peak values).

This study was carried out by means of TAS software from the UK, and widely extended in Europe to expert environmental consultancies. TAS software lodges a series of modules, which are placed in a 3D modeller, a thermal-energetic analyzer, a climatic and control system simulator, and even a 2-dimentional module of CFD (computational fluid dynamics). Concerning environmental modelling tools, TAS has been catalogued as a tool of advanced level, in contrast to medium level ones (which are useful in architectural design owing to their fast answer and friendly interface), due to the fact that it considers greater entries of variables and delivering the necessary accuracy for an expert assessment.

Housing prototype designs have been evaluated by this software through thermal zone logic to distinguish the thermal behaviour per room and at the same time the heat transfer between them. It includes natural ventilation modelling, which is one of the most complex phenomenons to represent even with other specialized software.

2.3 Simulations of Santiago Housing Prototype

After the first simulations (made together with the southern prototypes), improved thermal models were considered, with the aim to assess the most realistic behaviour of the Santiago prototype, which finally was placed in the most unfavourable orientation from the point of view of the overheating. Therefore, this second series of TAS simulations was defined according to the following conditions:

2.3.1 The house modelled in the four orientations (N, S, W and E). It is chosen the best orientation considering the results in terms of heating and cooling loads. For these simulations, a steady ventilation of 1.0 air change rate throughout the year. Internal conditions for estimating the mentioned loads are:

Maximum temperature: 26℃

Minimum temperature: 20℃ (from 07:00 hrs to 23:00 hrs) - 18℃ (from 23:00 hrs to 07:00 hrs)

2.3.2 The chosen case of the previous simulations is assessed with variable ventilation through opened windows in the cooling season and trickle infiltration by windows and doors (with a value of 0.3 air change rate). The proposal ventilation is focused during morning and evening (after sunset). It is estimated the cooling load and the behaviour of internal temperatures in the rooms.

2.3.3 Shading external opaque devices were considered in eastern, northern and western facades (protecting windows) to assess their effect in the thermal performance of the house.

2.3.4 The effect of the thermal mass over the thermal performance was studied, considering internal partitions of concrete blocks.

Internal gains considered for all simulations reached a value of 115 Wh/m2day. These gains are mainly associated to occupancy, lighting, equipment and heat produced in kitchen and bathroom due to use of them. All simulations considered high attic ventilation (10 ach).

3. Results

3.1 Heating and cooling demand

Since heating demand was similar for the four different orientations (around 65 KWh/m^2 year), criteria for selecting the best orientation was the cooling demand. As it can be seen in Table I, the lowest cooling demand was experienced when the main façade of the house was assumed south oriented, being this one the case selected for the following simulations. Figure 4 shows plan of the first and second floor of the house with orientation considered in the following simulations.

Table I: Heating and cooling demand for the prototype for different orientations of the main facade. City of Santiago.

Orientation	Heating demand kWh/m^2 year	Cooling demand kWh/m^2 year
South	65.3	20.3
North	65.8	22.7
East	64.2	27.5
West	66.3	24.8

Figure 4. First floor (left) and second floor (right) plans for Santiago housing prototype

3.2 Temperature variation

Figure 5 shows simulated temperature variation in four different rooms of the house for a selected day in Santiago (5th January). This day shows a temperature variation which is typical of a summer day of the city. In this case light partitions and a steady ventilation of 0.7 ach and 0.3 ach for infiltrations and external opaque solar protection to avoid direct solar radiation to windows were considered.

Due to internal gains, we can observe high temperatures in bedrooms of the second floor (bedroom 1 & 2), where users concentrate their activities after 19 hrs. In order to decrease these temperatures, different simulation with different strategies were considered and the best performance obtained is shown in the graph of Figure 6.

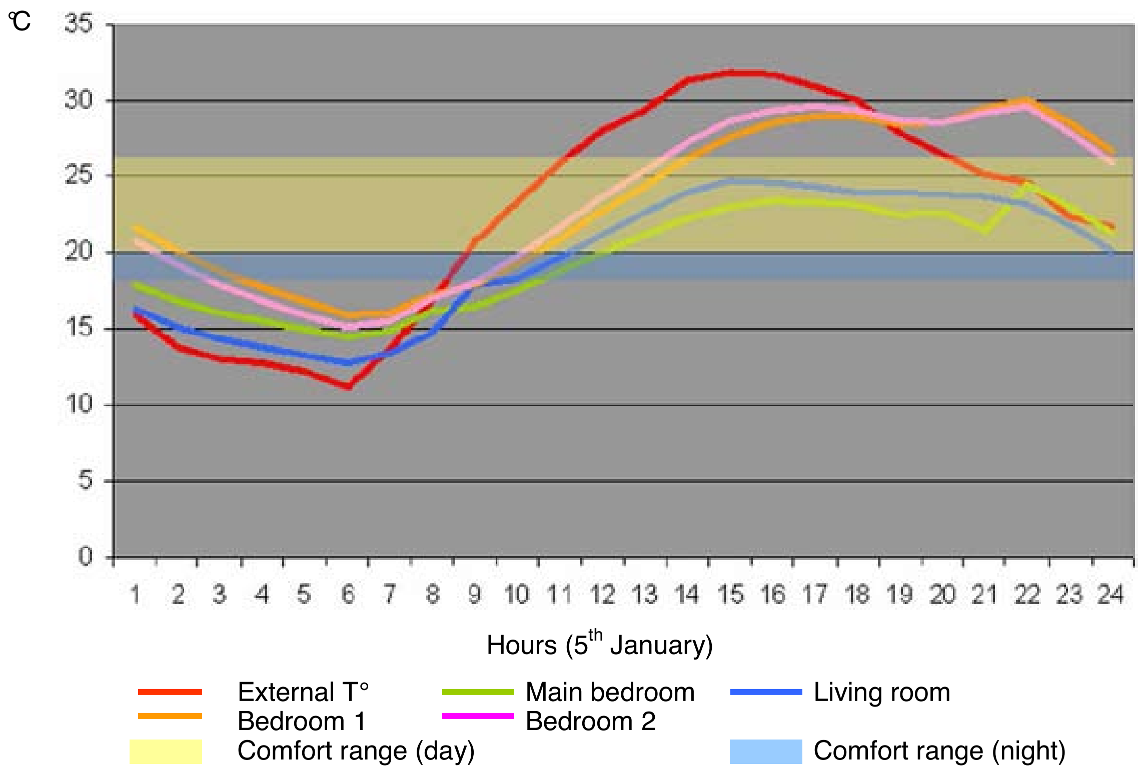

Figure 5. Temperature variation for timber frame partition walls and steady ventilation in different rooms for a summer day

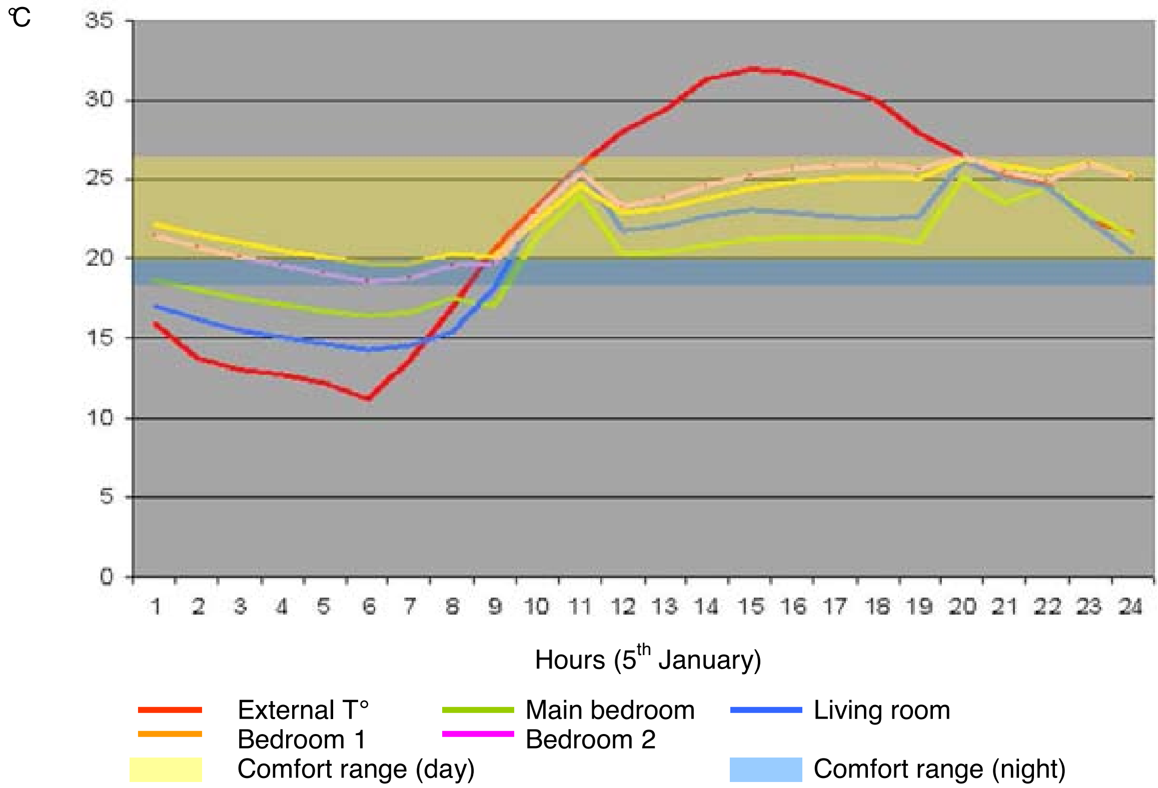

Figure 6. Temperature variation for concrete block partition walls and nocturnal ventilation in different rooms for a summer day

Figure 6 shows lower temperatures in rooms of the second floor. In this case, steady infiltration of 0,3 ach and nocturnal ventilation through partial opening of windows were considered. Solar protection was also considered.

The combination of the use of thermal mass and nocturnal ventilation permitted to decrease temperatures after 19 h and to increase temperatures during the night over 15℃ in occupied spaces during this peri od of the day, both in first and second floor.

4. Conclusions

First of all, this research shows that thermal behaviour of timber frame houses may be significantly improved for cooling for heating and cooling periods of the year.

For heating periods, the use of thermal insulation in the cavity of panels and in the ceiling of the house is effective to obtain an efficient thermal behaviour. In the case of cooling periods, for a Mediterranean climate such as the observed in Santiago, the use of external opaque solar protection in windows, high attic ventilation and strategies of thermal mass with nocturnal ventilation have showed to be effective to reach comfort in the inside.

Thermal mass combined with nocturnal ventilation allow a decrease in the internal temperature oscillation. This positive effect, that allows a temperature variation within the comfort condition in the inside, would completely disappear if no opaque solar protection in windows is used. However, this fact that was not completely demonstrate through the current simulations and by means of a series of experimental models could be tested. Indeed, a test related with the impact of the solar protection associated with the air cavity of the panel was made as part of a series of physical models with aim of assess precisely the effect of this air gap and other related variables (such as solar protection). These experimental models are presented as further research.

5. Further Research

The effect of ventilated air cavity in the panel could not be assessed by means of the thermal simulation, due to limitations of the model (the width of the gap is just 25 mm). However, the research team had the hypothesis that this cavity could improve the thermal behaviour of the prototypes during the cooling season, since the air gap could reduce the effect of solar gains over the envelope, removing the unwanted heat from the internal surface inside the cavity by means of buoyancy.

For this reason, four identical modules of 2.4 x 2.4 x 2.4 m were built, with ventilated attic, 100 mm of thermal insulation in the ceiling and external panels according to specifications (see Figure 3). All the modules have identical orientation and are placed in the courtyard of DICTUC laboratory that made the installation, calibration and collected the obtained registers. One of the four modules remained as patter during all the tests (without ventilated air cavity), with the aim to be compared with all the other modules (with ventilated air cavity), which suffer a series of changes depending on the kind of test (and the objective of the assessment). In all the modules, they were installed a series of thermocouples to register internal temperatures (in the centre of each module), exterior surface temperatures and temperature inside the cavity.

The first question to be solved therefore was about the effect that the ventilated air cavity has in the internal temperatures of the modules. Figure 7 shows the results obtained to the second test, which tried to assess the effect of different kind of envelopes in the internal temperatures. The curves have an almost identical behaviour to the three evaluated cases: radiate pine cladding, OSB for exterior sheathing and concrete stucco. However, when they are compared with the pattern (without ventilated air cavity), it was clearly demonstrated that the ventilated air cavity reduce internal temperatures of the modules by means of a buffer effect between 3℃ and 5℃.

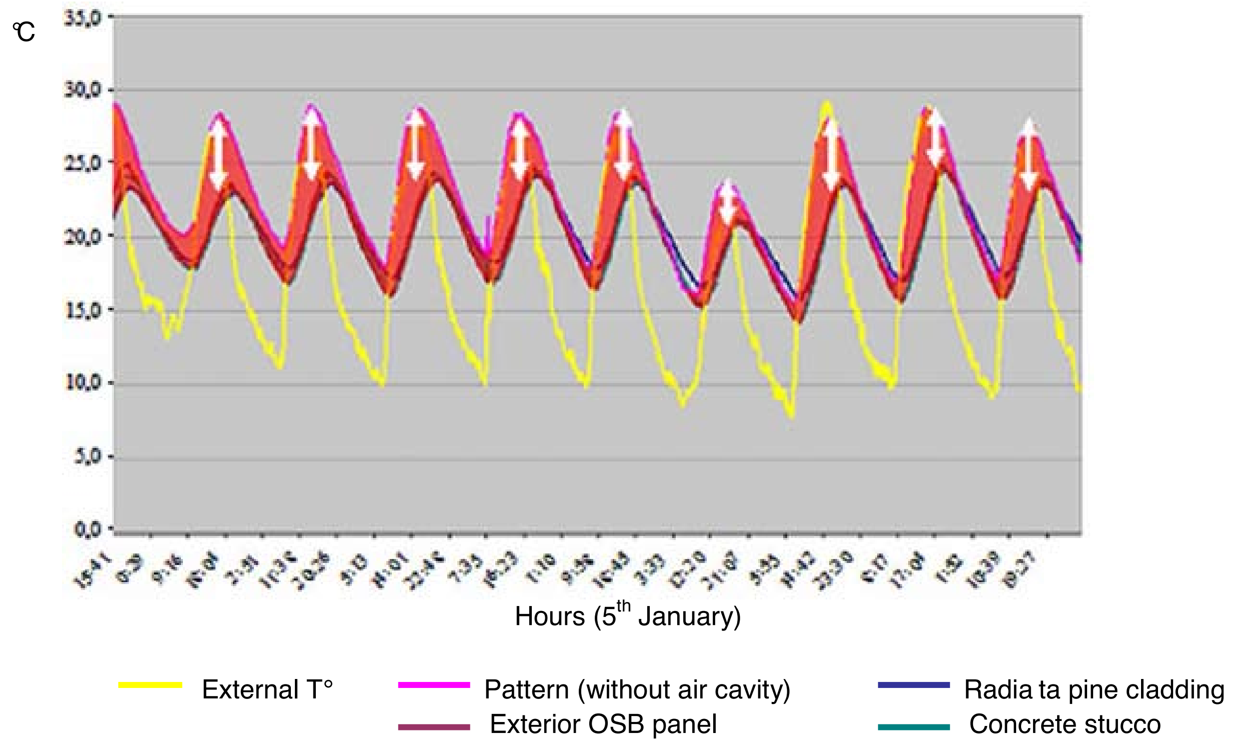

Figure 7. Temperature variation test two: different envelope materials

However, this positive effect would be reduced or even eliminated if solar radiation can penetrate inside the room through a window. In the case of the direct radiation, the result is obvious: greenhouse effect will generate overheating. Nonetheless the effect of diffuse radiation is more difficult to predict accurately from a theoretical point of view. Therefore, this problem was studied through a third test, which had the objective of assess the impact of windows and floor thermal mass over the internal temperatures of modules (and their relation with the air cavity). In consequence, they were tested:

[a] Module without air cavity (pattern)

[b] Module with air cavity (25 mm), covered window (north facade) and exposed floor (to assess the thermal mass efffect)

[c] Module with air cavity (25 mm), exposed window (north facade) without solar protection (including direct & diffuse radiation)

[d] Module with air cavity (25 mm), exposed window (north facade) with solar protection (including just diffuse radiation)

It can be observed that in the module [d] with solar protection (overhang), the positive effect of the air cavity remains, with a similar buffer that in the case without windows (second test, Figure 7). Therefore diffuse radiation does not reduce the effect of the air cavity in the thermal behaviour inside the modules. On the contrary, this one is clearly eliminated when windows do not have solar protection producing overheating (internal temperature curve is over the external one), such as in the module [3], which even shows a poor performance that in the pattern module.

Keywords: reuse, concrete, panel, masonry, wall, prestress, friction, damping

Summary

The objectives of this paper are to propose a sustainable connecting method between wall and frame of structure, and to clarify the frictional damping effect of the connection. Walls and frames are not bonded to each other at the proposed connections, making it possible to disassemble members once assembled, so that they can be easily reused or recycled. And the proposed connection absorbs the energy of external force, such as seismic force, by slip with friction between wall and frame.

High-speed horizontal loading tests were conducted on the proposed connections between walls and steel frames. Types of walls are precast concrete panel, SRB-DUP (Steel Reinforced Brick based on Distributed Unbond Prestress theory) wall, which is a kind of dry-masonry wall proposed by this authors, and reinforced concrete block wall. As a result of the experiments, it was found that precast concrete panel is the most suitable for the proposed connecting system.

The horizontal load-displacement relationship of the connection between SRB-DUP wall and steel frame was applied to static load incremental analysis and time history response analysis of the structure, revealing that the frictional damping effect of SRB-DUP wall is high, even the case where low prestress is given to the structure at each connecting point between wall and frame.

1. Introduction

Reduce, Reuse and Recycle are recognized as effective in reducing environmental impact. Especially, Reuse does not require any remanufacturing processes needed in the case of Recycle and therefore achieves a large reduction in environmental impact. However, the current system of building structural engineering is built on stress transmission mechanisms using bonds, such as adhesives (wooden structures), welding (steel structures), and rebar-concrete bonding (reinforced concrete structures). And this fact can often make it difficult to easily reuse building materials. For making Reuse of building materials easy, the different materials should not be bonded together. Frictional connection attracts attention as one of the connecting methods advantageous to Design for Disassembly, because it keeps construction element whole during removal (2006). In this paper, a disassemble-able connecting method by friction between wall and frame is proposed.

Generally, stiffness of wall is higher than that of frame. Therefore shear force loaded into the structure composed of walls and frames concentrates into walls. And it causes shear failure unless the strength of the wall is sufficient (2005a). In the country and area where an earthquake occurs frequently, if the serious damage by the earthquake occurs, great energy and cost will be spent on restoration, and environmental load will increase. The proposed connection absorbs the energy of external force, such as seismic force, by slip with friction between wall and frame.

2. Outline of the Proposed Frictional Connecting Method between Wall and Frame

As for type of wall connected by the proposed method, precast concrete panel, SRB-DUP wall, and reinforced concrete block wall, etc. are assumed. And as for type of main structure of a building connected by the method, steel frame, and wooden frame, etc. are assumed. Figure 1 shows the connection of the

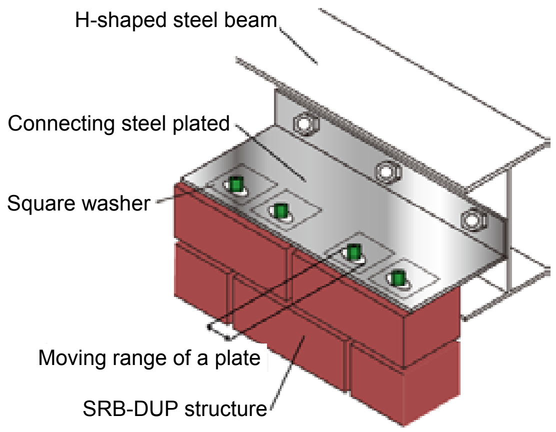

Figure 1 Overview of the Proposed Frictional Connecting Method between Wall and Frame (1)

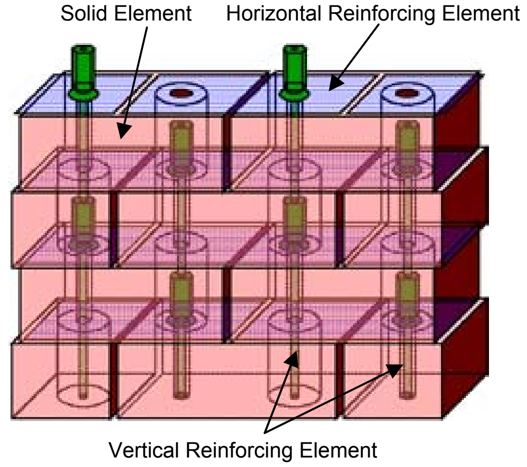

Figure 2 Overview of the SRB-DUP structure

steel frame used as the main structure of a building and the SRB-DUP structure that is used as a damping wall. Connecting steel plates are used for connecting damping walls to the main structure. They are mutually connected using bolts. The bolt hole of the connecting steel plate used for connecting the SRB-DUP damping wall takes the form of a long hole along the length of the plate. Dead load, live load, and inertia force by the earthquake, etc. are loaded into the structure composed of walls and frames. However, since rigidity of the steel frame is comparatively low, much of horizontal force is transmitted to the SRB-DUP wall panel whose rigidity is higher. When the horizontal force becomes larger than frictional resistance between the wall and the main frame, slip occurs there. After it, frictional sliding is induced at the connecting point between the SRB-DUP wall panel and the main frame to absorb external energies. And since the horizontal force exceeding the value at the time of slip occurring is not loaded into the SRB-DUP wall panel, the damage on the wall panel is controllable to the minimum.

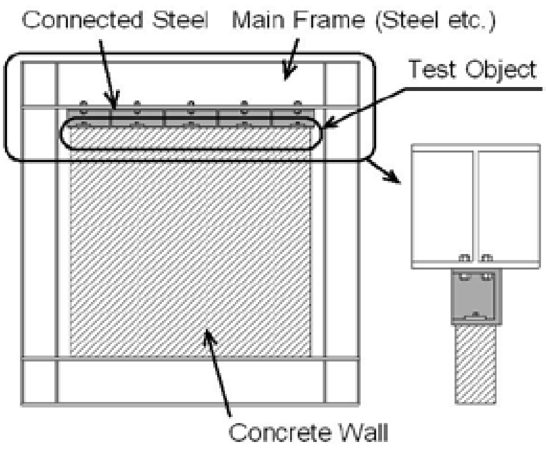

Figure 3 Overview of the Proposed Frictional Connecting Method between Wall and Frame (2)

The SRB-DUP structure is developed by the authors (2007). It is a dry-masonry structure, which has a friction-resistant type of stress transfer mechanism. Overview of the SRB-DUP structure is shown in Figure 2. By making a whole assembly where its constituting elements are not bonded with one another, assembled members can be disassembled, and later can be utilized for Reuse or Recycle. The SRB-DUP structural members demonstrate high vibrating energy absorbing capacities in their strong axes, and demonstrate resiliencies in their weak axes, using positively the voids which exist between their constituting elements. Furthermore the SRB-DUP wall can be used not only as the main load bearing structural member of a building, but also as a frictional damper for controlling vibration of the building with other main structural system as shown in Figure 1.

A damping wall panel of concrete or SRB-DUP etc. can be placed in the plane of the steel frame as shown in Figure 3. However, in order to design so that the wall may not support vertical load like general damping wall, the shape of the connecting steel needs to be devised.

3. Loading Test for the Connection of the Damping Wall and the Main Structure

3.1 Outline of Loading Test

In this research, horizontal loading tests were conducted by inducting frictional sliding between the wall and the connecting steel mounted on the wall after extracting a part of the proposed damping wall to clarify the frictional damping characteristics of the connection. Types of walls are precast concrete panel (curtain wall panel and ALC panel), reinforced concrete block wall, and SRB-DUP wall. A total of 9 types of test pieces, PCe to BCe shown in Table 1, were assembled by varying the material of wall and the type of plating for the connecting steel.

Table 1 Types of Test Pieces

Type	Material of wall	Coat type of connecting steel	Prestress (kN/bolt)
PCe	Precast concrete curtain wall panel	Electrolytic zinc-coated	4.0, 8.0, 12
PCd	Precast concrete curtain wall panel	Hot dip zinc-coated	4.0, 8.0, 12, 16, 20
ALCe10	ALC panel (thickness: 100mm)	Electrolytic zinc-coated	4.0, 6.0, 8.0
ALCe05	ALC panel (thickness: 50mm)	Electrolytic zinc-coated	2.0, 3.0, 4.0
RCBe	Reinforced concrete block wall	Electrolytic zinc-coated	4.0, 8.0, 12, 16, 20
BGd	Brick (ground)	Hot dip zinc-coated	4.0, 8.0, 16
BGe	Brick (ground)	Electrolytic zinc-coated	4.0, 8.0, 12, 16
BCd	Brick (covered with FAS mortar)	Hot dip zinc-coated	4.0, 8.0, 12
BCe	Brick (covered with FAS mortar)	Electrolytic zinc-coated	4.0, 8.0, 12

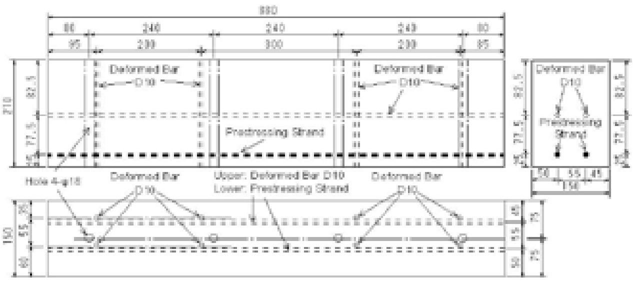

Figure 4 Test piece of PCe and PCd type

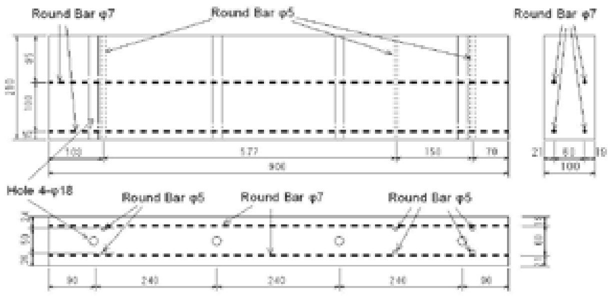

Figure 5 Test piece of ALCe10 type

PC (precast concrete) curtain wall panel, whose size was 1,000mmx1,000mmx150mm, was cut by the concrete cutter so that 2 header sides and the underside might be form, and so that its height, length and bar arrangement might become as it is shown in Figure 4. And 4 circular holes with a diameter of 18mm were opened for the loading test. The specified design strength of concrete was 50N/mm^2. The mold side of the PC curtain wall panel was used for the contact surface with the connecting steel.

ALC (autoclaved lightweight concrete) panel, whose size was 900mmx600mmx100mm, was cut by the concrete cutter so that the underside might be form, and so that its height and bar arrangement might become as it is shown in Figure 5. And 4 circular holes with a diameter of 18mm were opened for the loading test. ALC panel, whose size was 900mmx600mmx50mm, and in which the metal lath had been arranged in the center of the thickness direction instead of steel rods, was cut by the concrete cutter so that the underside might be form, and so that its height might become 210mm. And 4 circular holes with a diameter of 18mm were opened in a similar position to Figure 5. The top surface in the state where the each ALC panel was shipped from a factory was used for the contact surface with the connecting steel.

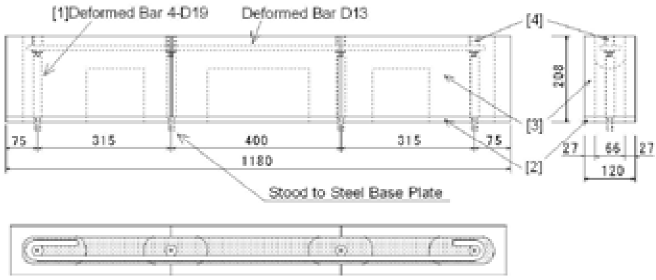

Figure 6 Test piece of RCBe type

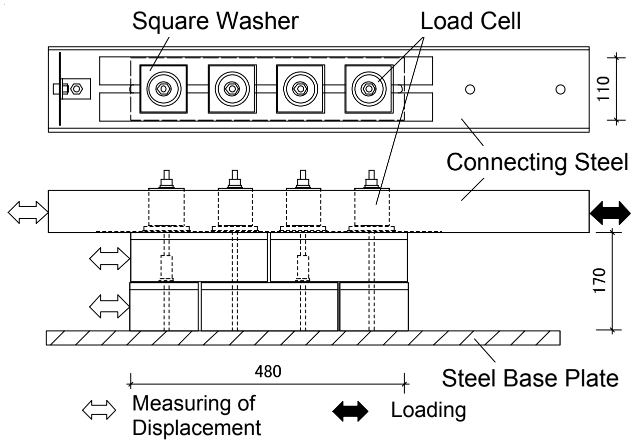

Figure 7 Test piece of BGd, BGe, BCd and BCe type

The details of a RCB (reinforced concrete block) wall test piece are shown in Figure 6. Odd-form concrete block for building, type C in JIS A 5406 was used for the loading test. The screw of M12 type (ISO metric classification) was cut at one end of deformed reinforcing bar of D19, and the screw of M16 type was cut at the other end (Figure 6 [1]). M16 side of it was stood to the steel base plate with a thickness of 25mm. Cement mortar with a thickness of 20mm (Figure 6 [2]) was laid on the steel base plate, and four blocks (Figure 6 [3]) were laid in a single row on it. A 40mm long nut (Figure 6 [4]) was stood to the M12 side of each deformed bar. Then a horizontal reinforcement was arranged at the upper part of the wall, and it filled up with cement mortar. Compressive strength of cement mortar is 40.5N/mm^2, and Young's modulus is 2.42x10^{4}N/mm^2. The about ±1mm unevenness of the top surface of the wall was finished flat and smooth with the polymer cement mortar whose compressive strength is 29N/mm^2 (catalog value).

The details of a SRB-DUP wall test piece are shown in Figure 7. The test piece was a brick wall, whose size was 480mmx170mmx110mm, and which was constructed by the SRB-DUP dry construction method. Elements of a SRB-DUP wall test piece are shown in Figure 8. Bricks with punched-out holes were 2 types of clay bricks meant for SRB-DUP method, and their top and the bottom surfaces were ground or covered with fly-ash slurry mortar to make them smooth and parallel, as well as to keep their height-dimensional precision. The standard deviation of their heights was 0.12 mm. Horizontal reinforcing plates were made of 1.0mm thick and 80mm wide steel. As the vertical reinforcing element of the SRB-DUP method, steel bolts of M12 type were used with 40mm long nuts, circular cut washers and spring washers. Both the bolt and the nut have ordinary strength.

In the loading test, channel steels of hot dip or electrolytic zinc-coated SS400, whose sectional size was H150×B75×tw6.5×tf10, fitted to the length of each tested wall was used as the connecting steel. They are shown in Figure 9. As for the PC curtain wall panel and ALC panel, steel headless bolts of M12 were stood to the steel base plate with a thickness of 25mm through the circular holes with a diameter of 18mm in the tested wall. As for the RCB wall, steel headless bolts of M12 were stood to the long nuts embedded in the wall. As for the SRB-DUP wall, steel headless bolts of M12 were protruding from the top of a tested wall. Through the headless bolts, a channel steel, a square washer, a circular cut washer, a load cell, a circular cut washer again, a spring washer and a nut were arranged in order on each tested wall and fixed as it is shown in Figure 7.

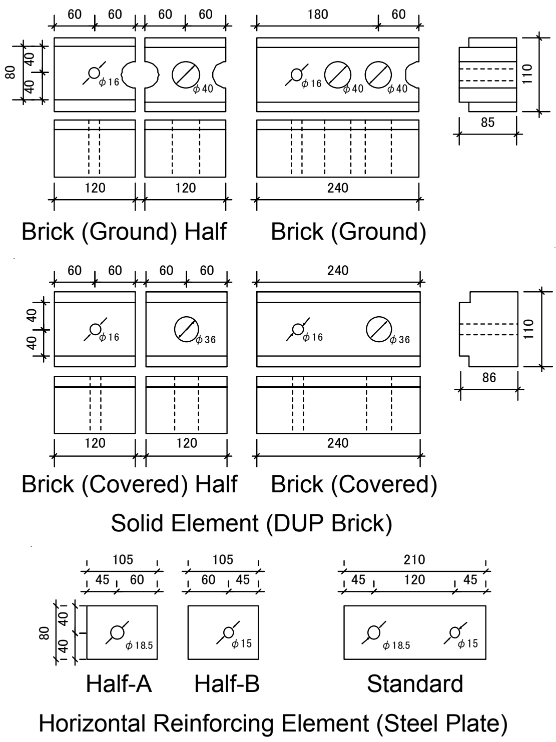

Figure 8 Elements of SRB-DUP wall

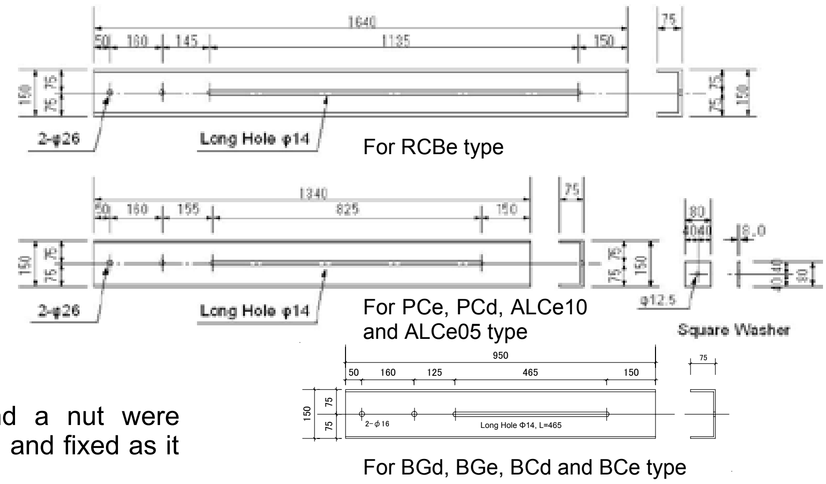

Figure 9 Channel Steel for Connecting

The magnitude of prestress (tensile force) given to the bolts of each tested wall was set as several steps shown in Table 1. First, small tensile force was given to the bolts, and the loading was conducted. After the loading, tensile force of the bolts was increased to the next setting value, and the next loading was conducted. Figure 10 shows the status of the test. Forced displacement of 10mm, 20mm, 30mm, 20mm, and 10mm in the single-sided amplitude of vibration with frequencies of 1.0Hz, 0.5Hz, 0.33Hz, 0.5Hz, and 1.0Hz were applied alternately from one end of the connecting steel in the given order for five cycles each. The total slide distance per load reached 1,800mm.

Figure 10 Test Status (PCe type)

3.2 Results of Loading Test

Figure 11 and Figure 12 show the relation between the horizontal displacement of the test piece and the horizontal load applied to the test piece. This figure shows some typical results of the loading test.

As for the test pieces of the PC curtain wall panel, the stable hysteresis characteristics near rectangular

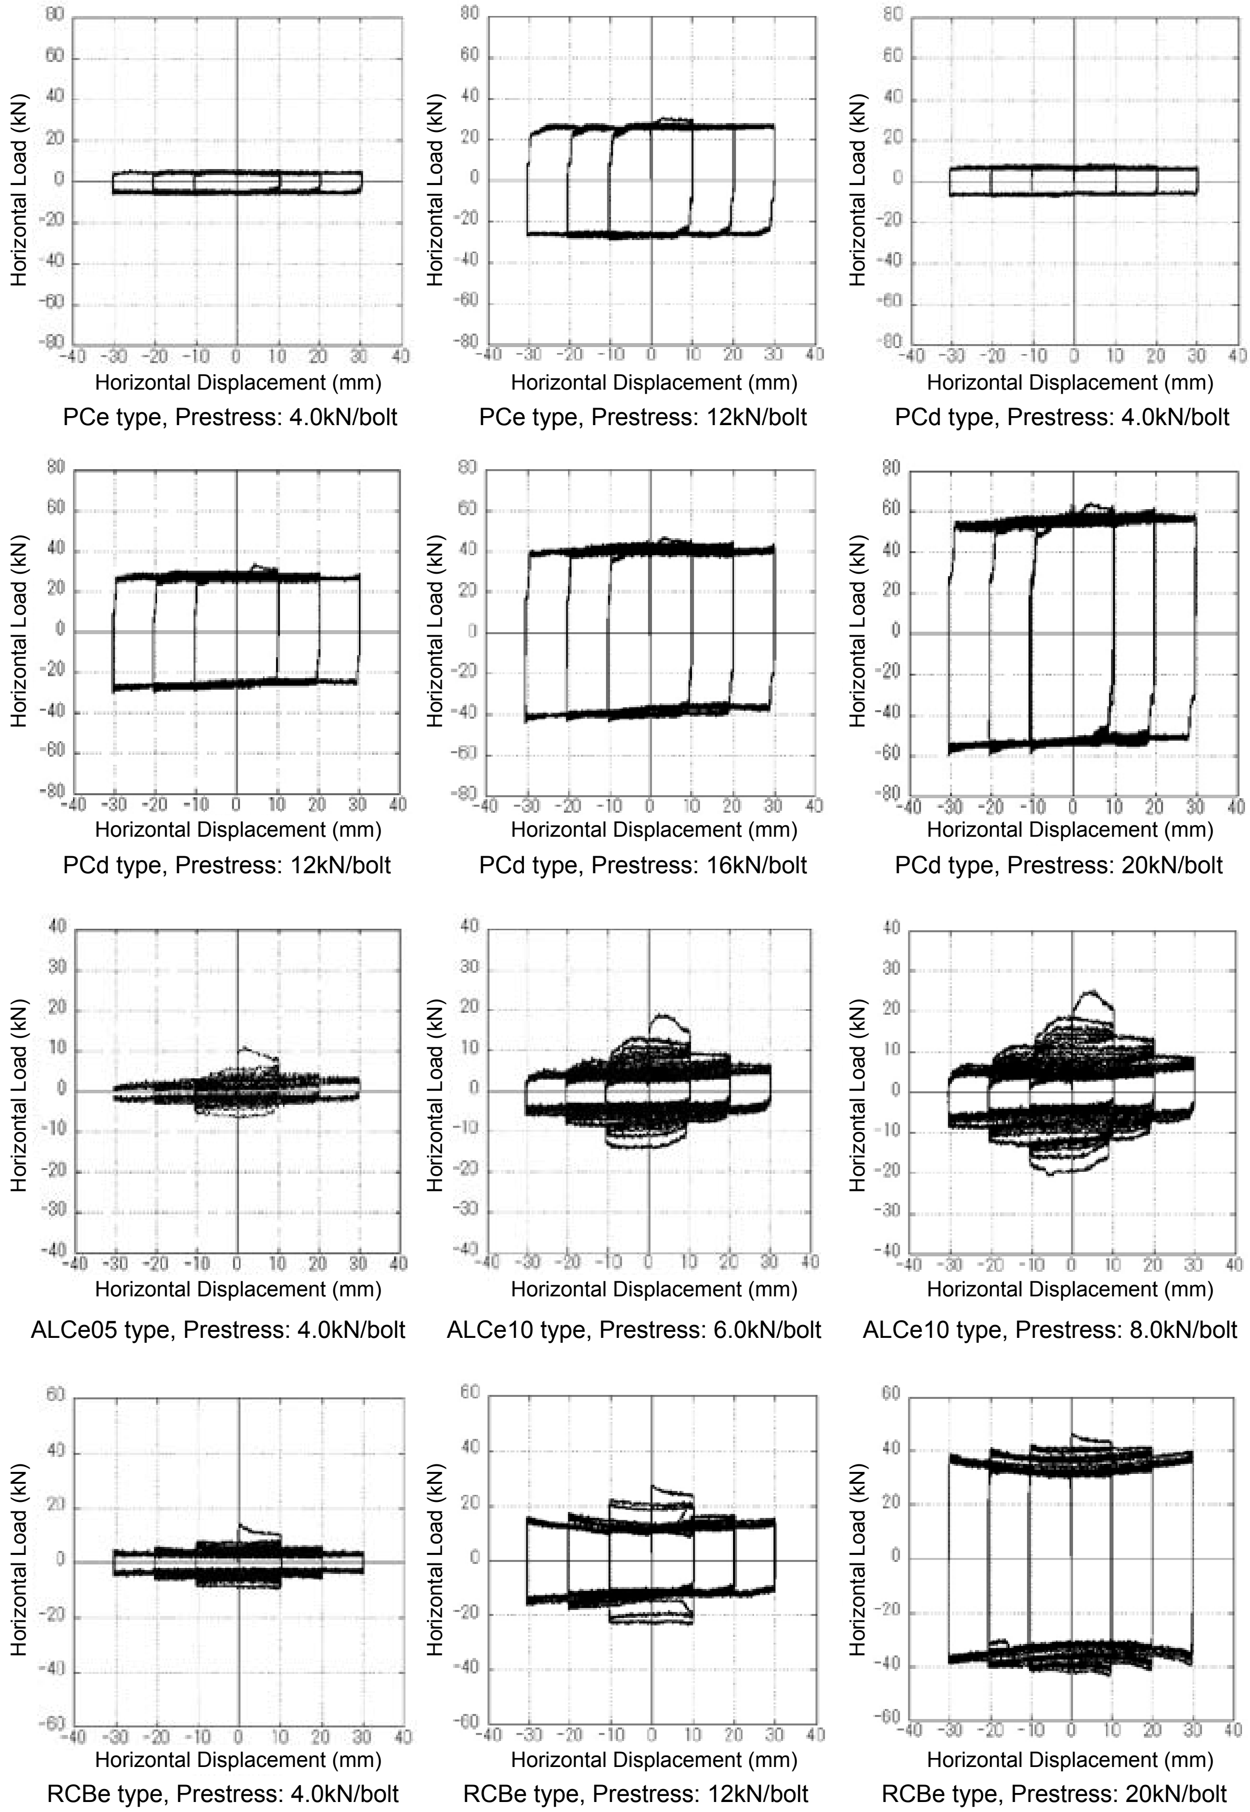

Figure 11 Relations between Horizontal Load and Horizontal Displacement (1)

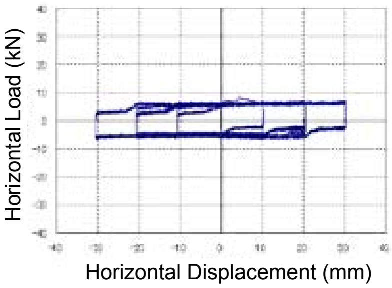
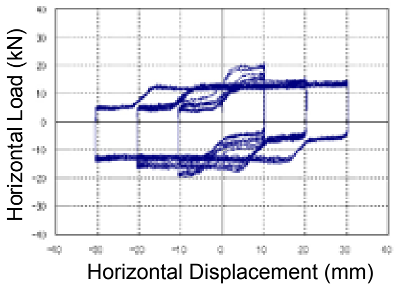
(b) BCd type, Prestress: 4.0kN/bolt



(c) BCe type, Prestress: 4.0kN/bolt



(d) BCe type, Prestress: 8.0kN/bolt

Figure 12 Relations between Horizontal Load and Horizontal Displacement (2)

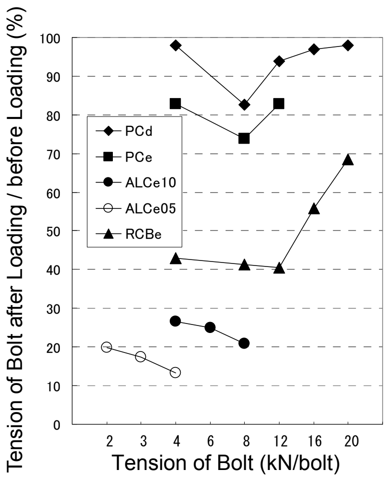


Figure 13 Relaxation of Tensile Force Given to Bolts about Test Pieces of Concrete Wall

shape were acquired. Horizontal resistance while the slide had occurred between the wall and the connecting steel was larger than the case of other test pieces. The resistances of the PCe type and PCd type did not have a conspicuous difference mutually, and the influence on the horizontal resistance by the method of zinc plating was not so large.

As for the test pieces of the ALC panel, the top surface of the panel was ground by loading, and tensile force given to the bolts and horizontal resistance decreased remarkably.

As for the test pieces of the RCB wall, when tensile force given to the bolts was low, reduction of the horizontal resistance while the slide had occurred between the wall and the connecting steel was large. However, when the tensile force of 16kN/bolt, or 20kN/bolt was given to the bolts, the rate in which level resistance decreases while the slide had occurred became small. This phenomenon has appeared also in Figure 13 having shown relaxation of tensile force given to the bolts about the test pieces of concrete wall. It is considered to be the cause that the influence of grind became small by repetition of loading although the portion of the polymer cement mortar which had finished the top surface of the wall was ground by early loading.

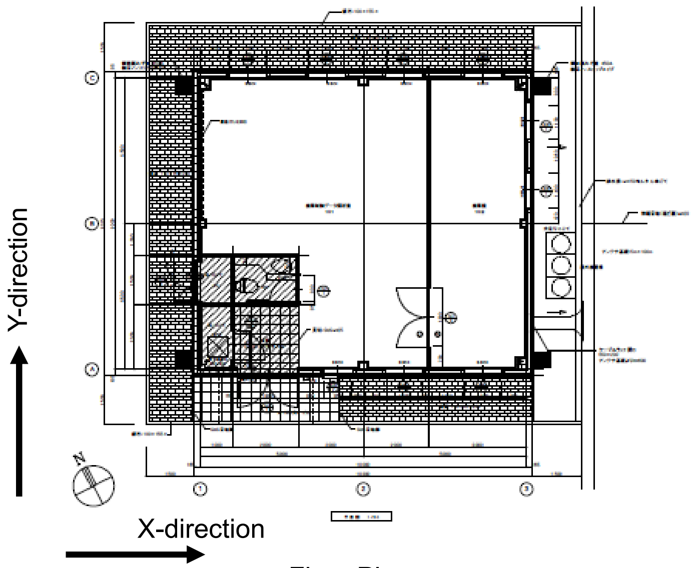
As for the test pieces of the SRB-DUP wall, in the case of Figure 12 (d), where the prestress is large, the horizontal resistance of the test piece changed stepwise, while in Figure 12 (c), where the prestress is small, an almost rectangular curve was observed as the relation between the horizontal load and horizontal displacement. It is considered to be the cause by which the horizontal resistance changed stepwise that the slide occurred also in positions other than the top surface of the SRB-DUP wall. And the influence on the horizontal resistance by the method of zinc plating or the kind of brick was not so large.

4. Vibration Analysis of a Building Using SRB-DUP Damping Walls

4.1 A Building Using SRB-DUP Damping Walls and Outline of Vibration Analysis

Figure 14 and Figure 15 show the Satellite Communications Laboratory (a single story structure, height: 3.97m, main structure: steel frame) of Kyushu University, Ito Campus, Fukuoka, Japan, that uses SRB-DUP damping walls. Vibration analysis was performed for this building.

For the purpose of comparison, vibration analysis was performed for the same shaped building with ALC panels used as non-structural wall instead of the SRB-DUP structure as well as with the SRB-DUP structure used as non-structural wall. The analysis procedure was as follows. A model of the connection was developed for the relation between the horizontal load and the horizontal displacement obtained by the test (shown in Figure 12 (c)). Then, a static load incremental analysis was performed by using hysteresis characteristics of the SRB-DUP wall considering the performance of the connection and the SRB-DUP beam to find the relation between the story shearing force and the story deformation angle of the building. Based on the obtained results, a model was established for the hysteresis characteristics of the building in the form



Floor Plan

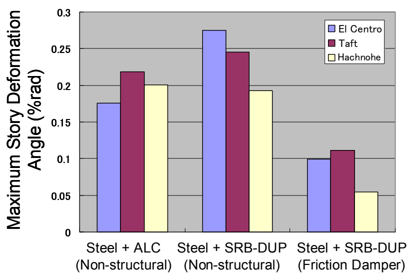
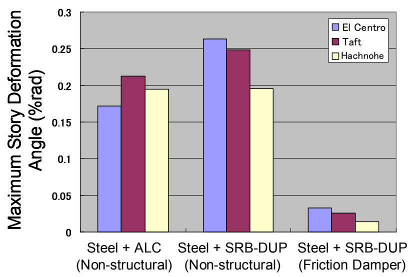
of a trilinear skeleton curve, and then time history response analysis was performed to find the building's response to the input vibrations. The earthquake waves inputted in this analysis were three waves of El Centro-NS, Taft-EW, and Hachinohe-NS. Each earthquake wave was normalized the PGV (peak ground velocity) to 25cm/s and 50cm/s, and was applied to the analysis.



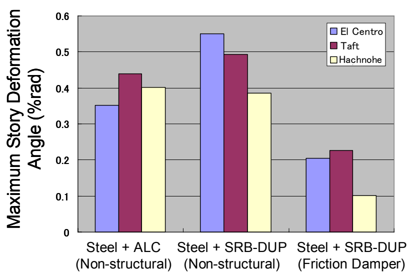
PGV: 25cm/sec, X-direction



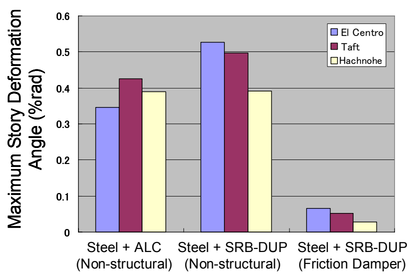
PGV: 25cm/sec, Y-direction

4.2 Results of Vibration Analysis

Figure 16 shows the results of the analysis. This analysis was based on the assumption that a relatively small prestress was applied on the connection between the SRB-DUP structure and the skeleton of the steel structure. Even in such cases, the maximum story deformation angle of the building in the case where the SRB-DUP structure was used as damping wall decreased greatly compared with the case where it was not used, and the damping effect of the SRB-DUP structure was clearly observed.



PGV: 50cm/sec, X-direction



PGV: 50cm/sec, Y-direction

5. Conclusions

In this study, a disassemble-able connecting method by friction between wall and frame was proposed. The proposed connection absorbs the energy of external force, such as seismic force, by slip with friction between wall and frame. Horizontal loading tests were conducted by inducting frictional sliding between the wall and the connecting steel mounted on the wall to clarify the frictional damping characteristics of the connection. The horizontal load-displacement relationship of the connection between SRB-DUP wall and steel frame was applied to static load incremental analysis and time history response analysis of the structure to find the building's response to the input vibrations. The results are as follows.

(1) Precast concrete curtain wall panel is the most suitable for the proposed connecting system.

(2) It is necessary to devise the usage in consideration of the ALC panel being ground as the slide with friction between wall and frame occurs.

(3) As for the reinforced concrete block wall, the contact surface with the connecting steel must be made not to be finished later if possible. When finishing up the contact surface unavoidably, the kind of finish material must be taken into consideration.

(4) By the vibration analysis, the damping effect of the SRB-DUP structure was clearly observed, even a relatively small prestress was applied on the connection between the SRB-DUP structure and the skeleton of the steel structure.

Life cycle energy (LCE) and life cycle CO_2 ($LCCO_2$) of wooden, reinforced concrete and SRB-DUP housing were compared in a series of study on SRB-DUP structure. And it was found that the SRB-DUP structure, in which bricks are reused, is effective in reducing LCE and $LCCO_2$ (2005b). Future research will include estimating the environmental impact of changing from conventional solution to the proposed frictional damping system. This connecting method could contribute to improved earthquake-resistant capabilities in buildings as well as improved reusability of building materials.

SWARM PLANNING: DEVELOPMENT OF A NEW PLANNING PARADIGM, WHICH IMPROVES THE CAPACITY OF REGIONAL SPATIAL SYSTEMS TO ADAPT TO CLIMATE CHANGE

Rob Roggema Ir.[1]
Andy van den Dobbelsteen Dr. Ir.[2]

Keywords: Regional design, climate change, spatial planning, complexity, swarm planning, climate mapping

SUMMARY

Climate on earth is changing. Due to these changes mankind is forced to adapt as well as to produce energy, which minimises the effect on global warming. The question is how spatial planning is capable to contribute to realise these aims. The changes in society - which becomes increasingly complex and two-sided – may be used as a chance. In order to adapt and produce energy the potentials in a region should be used. They can found by mapping the energy and adaptation potentials of the region. Once they are mapped they can be integrated in climate proof designs, which are able to make regions more resilient. The realisation of these designs should be conducted by starting processes instead of define an end-plan. The processes are started by creating the right impulses and realise the right enduring patterns in the landscape. Both are able to influence the entire regional system. To create impulses - which are able to start a process of realising integrated climate proof designs - a new planning paradigm is required: swarm planning.

1. Climate Change

Global warming develops slowly, but continuously. The most recent 150 years show a clear, yet extreme, warming. Trying to stop this process will take a long time – decennia or more. Warming of the atmosphere enhances a slow warming of the oceans, which react – due to their large warming-capacity – very slow. The emissions of greenhouse gases of recent decennia, combined with current emissions, lead to a warming, which will continue for the next decennia. Beside the reduction of emissions, aiming to reduce climate change, mankind has to adapt to the upcoming changes in climate [IPCC, 2007a+b, Gore, 2006, Stern, 2006].

Table 1.2 Two scenarios (2050) for Groningen [Roggema, 2007a]

	Royal Dutch Meteorological Institute (KNMI) - scenario	Accelerated Melting Land Ice-scenario
Precipitation spring and autumn	+ 20%	+ 30%
Precipitation summer	- 20%	- 40%
Precipitation winter	+ 15%	+ 30%
Temperature	+ 1,5	+ 3,0
Sea level rise	+ 35 cm	+ 150 cm

The province of Groningen [Roggema, 2007a] developed two scenarios. The first scenario is based on a combination of the four KNMI-scenarios [KNMI, 2006]. For the second scenario, an accelerated

[1] Ph.D Technical University Delft, Faculty of Architecture and Wageningen University, Earth System Sciences & Manager Strategy and Regional Planning, Province of Groningen, r.roggema@provinciegroningen.nl
[2] Assistant Professor, Technical University Delft, Faculty of Architecture, a.a.j.f.vandendobbelsteen@tudelft.nl

melting of the land ice masses of Greenland and Antarctica is taken as the base. Both scenarios are defined for 2050. In table 1.2 parameters of these scenarios are summarised. Both scenarios were developed to show the broad range of possible futures. If policies are developed – which is the purpose in Groningen – future adaptation policies can be developed in a robust way, making use of the range described in these scenarios.

In every era the climate changes. The speed is mostly subject of debate. It is expected that the aim to freeze the rise of temperature on a level of +2°C by the end of the century is difficult to achieve and that a rise with 3°C is more likely to happen. The sea level might have risen by then with at least one metre and – if ice-sheets of Greenland and the Western Antarctic are melting more rapidly – even more. Furthermore, it is impossible to fixate the emissions of greenhouse gasses immediately. Even if this might be possible, temperature on earth and the sea level will continue to rise for the next decades. There is a multiple urgency: on the one hand side mankind is forced to adapt to the consequences of climate change and on the other hand mankind is obliged to produce energy in a way that minimises the effect on global warming.

2. The incorporation of adaptation in planning

The timeframe of changes in climate is spread out over a long period. Starting now, it will continue for the next century and beyond. This means that it has approximately the same time span as building houses. They are supposed to last also 100 year or more. And it certainly has the same resonance as the design of urban and other spatial structures and patterns, which will last over centuries. Theoretically it must be easy to combine long-term changes and developments with spatial planning. But in practice spatial planning mostly fixes its horizon on a period of ten years (figure 2.1). By doing so an unnecessary difficulty is introduced. Although it is rather simple to incorporate long-term changes in the spatial planning system, it is seldom done in practice. If we look at the new spatial law in the Netherlands [Staatsblad, 2006, Schoot, 2007] and the current practice of development planning, the issues can hardly be found in plans. A more anticipative planning system needs to be developed, which connects more to recent and future societal developments.

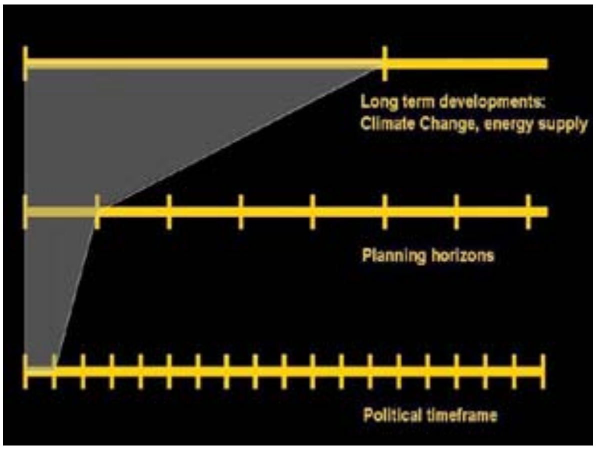

Figure 2.1 Connection of long- and short-term [Roggema, 2007c]

3. A changing society

In the Internet society, one is not only a consumer of news, adds or products, but also generator of information and able to deliver to the Internet in order to share it with others. This free space of exchange, where every consumer is also a producer, might influence the spatial design of regions. Adaptation to climate change and the sustainable supply of energy are issues, which might lead to serious problems on the long term. These changes are fundamental and irreversible. Therefore, it is important to take measures now. These measures need to encourage desired longterm developments at short notice. Existing planning methods – which try to fix the future on a term of max 10 years – and the regular political focus of four to eight years, need to be connected with a further future (see figure 2.1). This requires a new design paradigm. This paradigm needs to enclose the characteristics of the transition to the Internet society [Toffler, 2006] and Web 2.0 [Eye, 2007, NRC Next, 2007].

3.1 Serious changes

Serious changes are ahead of us. They can be summarised as follows:

- The make-ability of the world or a society is an idée fixe;
- Climate change is an illustration of how an increasing series of complex interactions lead to visible problems. The exact relations between interactions and effects are impossible to overview by individuals;
- Required measures need to encourage desired longterm developments at short notice. This requires a new design paradigm, which needs to enclose the characteristics of the transition to the internet society and Web 2.0;
- The new economy is a connection of people, ideas and information. In this new economy flexible network organisations take over. In this new world it is more important to be a contributor and connector than owner of knowledge or goods. Not the possession is the key factor, but the immaterial, virtual additions to the net and the exchange of information is;
- If we sustain the Internet development on the developments in climate change new landscapes lie in front of us. It is no longer only possible to consume, but also to deliver climate resiliency to the spatial environment.

The changes in society offer a chance to adapt more easily to climate change, because large groups of people intend to work together, not in a power based way, but by contributing values. This state of mind opens views to a stronger build society than the hierarchical one, because people are no longer only consuming energy or political messages, but they start to produce them theirselves and start contributing. Instead of a one-way society a both ends-society is emerging. The only thing is that these large groups need to be steered to start those processes, which enhance the resiliency of a region and thus make it a more adaptive one.

4 Mapping climate potentials

We know that the climate is changing and that it is hard to integrate this in regular planning systems, but that there are chances based on the emergence in a both-ends-society. If these chances are to be taken seriously, the knowledge of this fuzzy future needs to be available. To get this information available a method of mapping the potentials may be used [Dobbelsteen et al. 2006, Roggema et al. 2006]. This mapping method can be used for the energy as well as for the climate issues.

The key-factors in climate knowledge, which are crucial for spatial functions, are precipitation and sea level rise.

4.1 Precipitation

The future changes in precipitation are shown in figure 4.1. The maps show for Groningen and Drenthe provinces the possible changes in 2050 in two KNMI ’06 [KNMI, 2006] scenarios for both the winter and summer period.

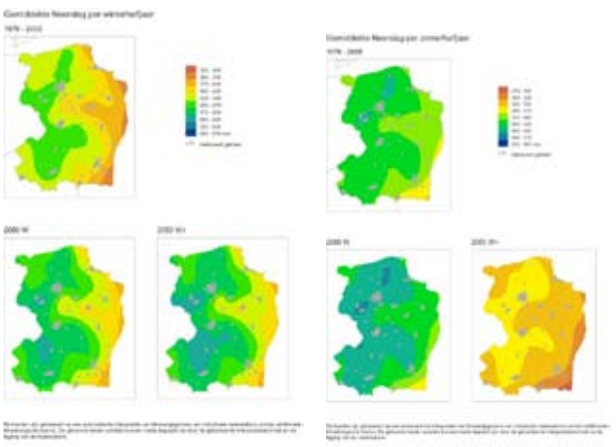

Figure 4.1 Precipitation in the winter and summer six-month period (1976-2005, W-scenario and W+-scenario) [DHV et al. 2008]

Main outcomes of the analysis of precipitation maps are:

1. In the summer period drought will probably increase. In the 'dry' scenario of the KNMI (W+) in the peat colonies the drought will become the biggest problem. In this area the water shortage is at this moment already a problem – partly solved by the inlet of IJssel lake water from outside the area - and this problem will increase. Another development, not visible on the maps, is the increasing intensity of severe rain showers.
2. According to the KNMI '06 scenarios, autumn, winter and spring become wetter. Although a dry summer will have its 'drying' effects, which will lead to average dryer autumns, the total amount of precipitation in the winter period shows an increase.

4.2 Sea level rise

The sea level rise as a result of global warming will continue the next centuries. To what extend depends on the speed of melting processes of land ice. Even if we stop today with the emissions of CO2, the melting processes will continue in this period. Therefore, we must adapt to the rise of the sea level. The maps (figure 4.2) show the impact of the rise of the sea level for Groningen in two scenarios and compared with the current altitudes (+50 and +150 centimetres) if the sea could enter the land undisturbed. In reality the landscape contains several obstacles (roads, little dikes), which prevent the sea from flooding the land without barriers.

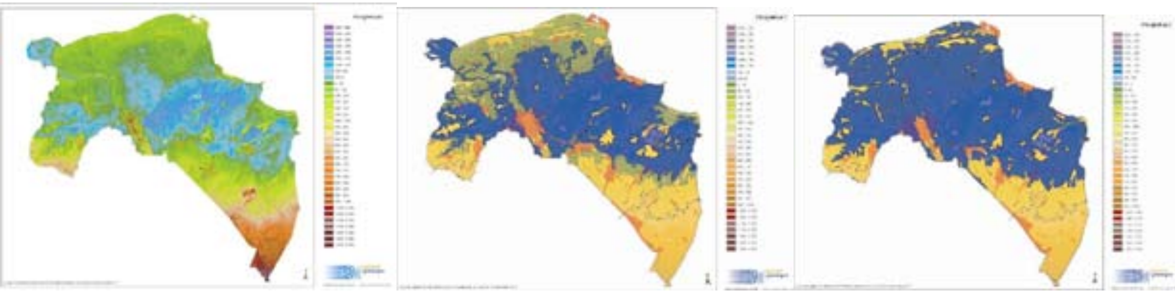

Figure 4.2 Flooding according to altitude lines (current situation (left), 50 cm sea level rise (middle) and 150 cm (right), [Roggema et al. 2007a]

The maps show an illustrative and theoretical image based on altitude lines. The maps are not taking into account the circumstances in which a breakthrough takes place, namely when the sea level is much higher than normal (spring tide) and heavy rain and wind is appearing. The map is not showing the meaning of maintenance of dikes in order to keep them strong and a breakthrough is less likely to happen. But the impact of a much faster melting land ice, leading to a sea level of maximum + 3 metres above the current level in 2100, is also not visualised in the maps.

4.4 Idea-map Climate Adapted Groningen

Climate analyses and notification of the effects on existing functions lead to an Idea Map of adaptive Groningen (figure 4.3), in which the adaptation principles are spatially translated. The map can be read as a spatial image of climate design ideas.
The Idea Map shows the spatial design of the principles. In the lower zones water is collected. This lower area plays also a major role in a main robust wet ecological connection between Dollard and Lauwers Lake. Existing brooks discharge their water towards this wet zone. A robust ecological network emerges, which offers space for existing as well as colonising species. Because these area is located at the lowest parts of the area the water can flow naturally towards this zone. The surplus of water in autumn and spring can be collected here. Nature has the best chances to survive in these areas in dry summers. The reservoirs are also functioning as the source to provide of agriculture especially in the Peat Colonies, by making use of the, partly existing, canal system under the condition that this is economically feasible. This makes it possible to continue the potato starch production. The

supply with clean water is necessary, because the groundwater level will drop and becomes saline in the 'dry' KNMI scenarios, which decreases the availability of water in summer.
In front of the Northern Coast new Wadden Islands are created to facilitate protection, nature development, living and recreation.

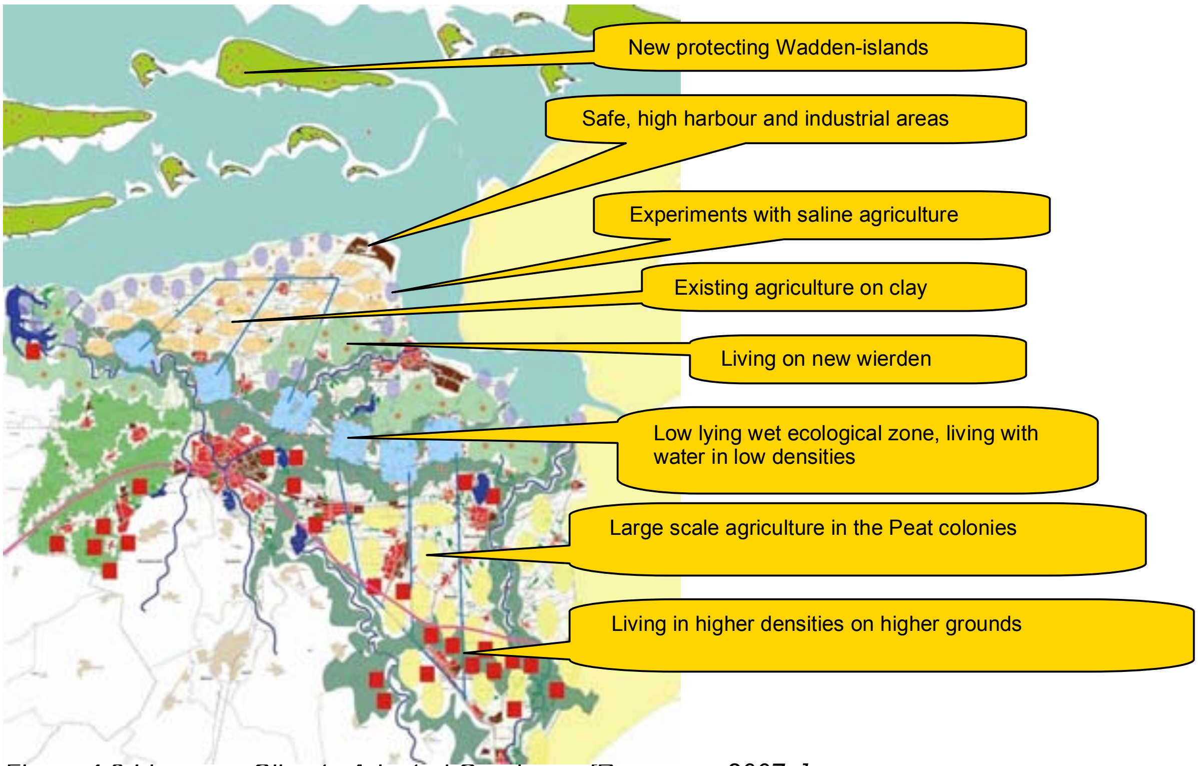

Figure 4.3 Idea-map Climate Adapted Groningen [Roggema, 2007a]

5. Swarm planning

The next step is to define those kind of measures which are coherent with the adaptation aims and fit in the future society. The way this climate-resiliency can be improved may be found by comparing the spatial system of a region with a self-organising system and the way these systems increase their overall fitness [Homan, 2005] (or become more resilient) and reaching a higher level of complexity. Tipping point offer insights in the way these kind of changes can be enhanced. The possibility of sudden change is at the centre of the idea of the tipping point. Big changes occur as a result of small events. The situation is similar to the phenomenon of an epidemic. Epidemics follow three rules [Gladwell, 2000]. By applying these rules to planning and design, the question when a design becomes a success and reaches required changes, can be understood. First of all the law of the few tells us that a successful design will originate from a small group of individuals. The design is not what the common people expect. To change things the design will be away-from-the average [Ridderstråle and Nordström, 2004, Roggema, 2005].
Secondly, the stickiness factor suggests that a successful design sticks in ones heads. Once having seen the image of the design it is not forgotten. A good example of this is the design for Almere Poort, the Wall (figure 5.1) [MVRDV et al, 2001].
Finally, the power of context in relation to design processes tells us that a design with huge impact provides the solution to a commonly felt problem. If a fundamental change is required, a widely shared context of deep trouble improves the chances of change. A sense of real urgency is required for fundamental change. If the existing system dissatisfies, a crisis is required to jump to the next level of complexity required to upgrade the system (figure 5.1) [Geldof, 2002, Timmermans, 2004]. These crises can be seen as the tipping points in design processes.

Figure 5.1 The Wall in Almere Poort, MVRDV, 1999 Crisis enforces the jump to a higher level, Geldof, 2002

5.1 A new design paradigm

In this paradigm the role of spatial design is seen as introducing essential impulses to influence the whole system, like a swarm of birds is reshaping itself constantly under external influences. Spatial design will no longer be concerned with the whole picture, but will focus on those essential design interventions that enforce the region to reshape it self. The metaphor is not any longer the blueprint, but acupuncture.

Thus, for a swarm planning approach [Roggema et al, 2006, 2008a+b] to be successful, two aspects are essential: the (spatial) characteristics of the region and the availability of extraordinary ideas. Complex systems theory suggests that the swarm paradigm will work where the following conditions are met:

- A large group of individual elements (people, buildings)
- Many connections (virtual, roads, rail, water)
- High quality of relations (fast, intense)
- High quality network (flexibility, intensity)
- Enough, but not too much, diversity (neighbourhoods, groups)
- Several co-existing patterns (patches)

If these circumstances pertain idea-mergers between different elements will lead to creative jumps, and new structures and information is created. A small group of extravagant idea creating people will enforce this and transform it into a sticky idea, which influences and shapes large parts of the region. If the sense of urgency is there -climate change for instance- a suitable trigger brings the idea to a tipping point and collective patterns emerge out of co-evolution of local systems, leading to an increased overall fitness of the system [Homan, 2005], which is able to adapt more easily to climate change.

5.2 Kwelderworks Eemsdike and blauwe stad examples

The project Building on structures [Meliefste et al, 2008] shows several interesting interventions, aiming to anticipate on future climate change. The propsed intervention is dealing with the rising sea level and the upcoming shortage of drinking water. The proposal is to store fresh water in the Lauwers Lake and adjust the water level there up to the level of the risen sea (figure 5.2). By doing so it is possible to let the water flow into the sea without pumping. But more important, the entire water system (the swarm in this example) of Groningen is forced to adapt itself. The risen water level in Lauwers Lake implies also the rise of water level in Reitdiep and other small canals and brooks. The result of this will be that the capacity to store rainwater is increased dramatically. And this helps to solve the problem of heavy rain showers and potential flooding in villages and towns. In other words, by solving the first problem and intervene in the Lauwers Lake, the entire region is challenged to adapt to the effects of climate change: the swarm reshapes. The same kind of analysis can be made for the planning process of the Blauwe stad.

Figure 5.2 Proposal for fresh water storage in Lauwers Lake [Meliefste et al, 2008] (left) and Blauwe stad (right)

5.3 Steer the Swarm

Because of the inability of traditional spatial planning to create and reinforce effective interventions, capable of changing the regional system, a new steering principle needs to be developed. In the environmental spatial plan of the Province of Groningen [Roggema et al, 2007] this issue is explored in some depth, leading to the decision to develop a range of approaches to influence the spatial system (figure 5.8). In doing so it is hoped that the best regime to realise a satisfactory outcome will emerge. The aim is to end up with a regime that is able to change the direction of the 'swarm' towards a high standard of spatial quality and resiliency. The most appropriate approaches may differ from area to area, depending on their identity, and the availability of a number of approaches to choose from in combination with the unique characteristics of the area will make it possible to retain the flexibility to make the area adaptive to uncertain future developments.

6. Conclusions and discussion

If the future society wants to deal with changes on the long term, like the adaptation to climate change, it should organise its planning system according the rules of the future society. Swarm planning, in which the contribution of large number of people are used to change the form of its spatial order and the people are steered in the direction of resiliency by the introduction of a certain well-defined impulse, makes use of the new rules in society. These rules include an increased two-sided exchange of values and collective attributions. In order to make use of these new rules, swarm planning needs to adjust the characteristics of complex adaptive systems. By doing so, swarm planning may be able to increase the overall fitness of the system, i.e. increase the resiliency. The following characteristics are important:

1. A large pool of genes (measures, inhabitants, functions), some simple rules and enlargement of trails (improving impact) is the start of changes on the long-term
2. The genes of regions, the trails and the simple rules, which may be successful in turning a region into a climate-proof one, are yet to be found. The elements, which play in the future society a major role in interconnecting, are not clear yet. In history, the sidewalks in a neighbourhood functioned like the interconnection platform, but today and in the future interconnections are made in a different way and at different places. The transport system, the sidewalk, the stranger (the away-from-the-average) and the ‘city’ of our time is yet to be discovered;
3. Swarm planning (large pool), with a well-defined (simple rule) impulse (which is able to enlarges the trail/impact) may be able to steer a region into the desired direction

If decision-makers in a region decide on the required interventions, which can be discovered by mapping the energy and adaptation potentials of a region, it is well possible to incorporate them in the spatial planning system, which is lied down in the new spatial law in the Netherlands. Far more difficult is it to realise a climate proof region by using development planning as it takes longer times and tends to be compromisional.

Several subjects and questions raised in this paper require further research:

a. The way the complexity can be used in spatial terms

b. The exact effects of interventions on the resiliency of the region and the level of adaptation and energy supply
c. The way the interventions are put together and chosen.

Keywords: sustainable development, retrofitting strategies, environmental, commercial buildings, urban regeneration, revaluing property, Bristol, UK

Summary

This paper presents tentative results from a study of retrofitting activities in the commercial property sector in Bristol, the UK. The study is part of on-going research on the theme 'Retrofitting the city' that explores the adaptation of existing built environments to deal with climate change and objectives for sustainable futures. From the Bristol study two concepts related to retrofitting becomes especially apparent: 'commercial' and 'community'. Results indicate that we might be experiencing a shift where the UK property sector is gaining conscience of the risk of having 'unsustainable' property as part of their portfolios. This change is induced by occupier demands, increased costs for energy and waste management etc., and a more complex process for planning permission. Environmental ambitions have to be balanced with commercial viability, but strengthened policies are to be expected. The study shows that retrofitting of single buildings often includes visions for regeneration of urban areas and the involvement of the local community. This agenda seems partly to be pushed by new planning permission procedures. The study points to a number of fields in which contributions are needed to facilitate future sustainable retrofitting activities including: the archaeology of site, rewiring of the city, and the socioeconomic and environmental benefits in a revaluation of existing property.

1. Introduction

The starting point for this research project is the increased pressure on the urban built environment related to growing urban populations, environmental protection and visions for sustainable development. In 2008, statistics show us that we have reached the tipping-point when half the world's population became city dwellers (www.un.org). From a European perspective where almost 80% of the population lives in urban areas, and cities are changing slowly there are important work to be done to existing, obsolescent and deteriorating urban structures. The UK building stock is renewed by no more than 2% per year through new construction and major renovation. As for the next 50 years the majority of the stock will be comprised of building that exists already today, it is generally perceived that initiatives to address goals for carbon reduction in new buildings will have relatively little impact on the stock as a whole.

1.1 Scope, Definitions and Limitations of the Study

The aim for this paper is to identify and understand the commercial framing of retrofitting activities of existing buildings and the mediation of these issues in current development and regeneration processes. Focus is on non-domestic buildings, an area that has been less studied than the dynamics of the domestic building sector (Bruhns *et al.*, 2000). In addition, the potential for carbon savings in the commercial building stock is seemingly large. The rate of growth of energy use in the commercial sector in the UK has since the 1970s been three times greater than in the domestic sector (Scrase, 2001). The study includes mixed use development (residential, work space and leisure) which is increasingly part of contemporary commercial property development.

As regards definitions, Flourentzou and Roulet (2002) state that the concept of ‘renovation’ can be divided in two sub-categories: retrofit and refurbishment. The concept of ‘retrofit’ identifies actions to upgrade a building to new requirements while ‘refurbishment’ refers to actions to bring back the building to its original state. We use the term retrofit as it conforms to a necessary environmental upgrading and it also highlights the act of revaluing property. Retrofitting actions will also include strategies in new design to facilitate adaptation to future demands for energy reduction etc.

1.2 Methodology

An extensive literature review has been carried out in order to understand the dynamics of the commercial property sector in a UK perspective regarding retrofitting strategies as well as its ability to respond to the sustainability agenda. This paper sums up the research field based on the literature review and tentative results from on-going empirical studies, setting out a range of issues to be examined and that might become hypotheses for the continued work. The paper has three main parts: a review of knowledge regarding environmental issues and non-domestic buildings; a review of knowledge regarding the dynamics of the British commercial property sectors; and a short presentation of the four case studies and their outcomes.

The empirical material consists on the one hand of interviews with senior representatives in the Bristol commercial property sector, and the other hand of four evolving cases of retrofitting of non-domestic buildings in Bristol city centre. At present 14 qualitative and open-ended interviews (length from 1 hour to 1 hour and a half) have been carried out with 16 actors including architects, developers, estate agents and planning officers. Additional interviews have been made for the case studies. The choice of the four cases reflects problems when addressing different categories of non-domestic buildings. This includes obsolescent 1960s and 1970s office buildings, industrial buildings and listed buildings. The choice of cases also shows varying approaches to address the sustainability agenda from basically ‘green’ projects to more commercially pragmatic approaches.

2. Addressing the Non-domestic Building Stock

During last years, major work has been done to develop a UK national database on non-domestic buildings (NDBS) (e.g. Environment and Planning B, 2000 vol. 26; Bruhns *et al*, 2000). Compared with the domestic stock, the non-domestic building stock is very diverse, complex and heterogeneous. If the housing stock can be effectively represented by 1000 dwelling types, the non-domestic stock would need maybe 100.000 building types (Pout, 2000). Many non-domestic buildings have mixed use and mixed construction, coming in a huge range of shapes, size and materials. In addition, the boundary between domestic and non-domestic is not always clear.

2.1 Age and Lifecycle

The majority of non-domestic buildings in the UK were built before the 1980s (Bruhns *et al*, 2000). Just over half of the stock is more than 30 years old. Old buildings (pre-1939) dominate in retail and offices while newer stock is found in factories and warehouses. Over 50% of all office space was built prior 1939 but only counts for 30% of the total floorspace. The old age of the UK office stock indicates a great potential for energy efficient retrofitting or refurbishment activities.

In general, non-domestic buildings have been found to have a higher replacement rate than domestic buildings, one important factor can be that they more often change ownership than domestic and in each ownership change the question of demolishing or recycling will appear (e.g. Bradley and Kohler, 2007). Non-domestic buildings are also to a higher degree exposed to changes in use and have a high rate of change of tenants/users. The service life of a building can be prolonged through regular maintenance and refurbishment and does not automatically mean the physical life of the building. The economic life is established by taxes, legal requirements and accounting standards and is not necessarily related to the likely service life or physical life. The ‘effective life’ of buildings, in general, seems to be much higher than different assumptions of service life and economic life. Some parts of buildings, like the foundation and structure, will probably have a technically longer life than other parts and longer than the assumed service life. Internal replacement cycles in for example office layout and leisure decoration, is higher than external or structural replacements (Ball, 2003). This indicates that subsystems should be controllable and replaceable and that certain design criteria such as floor heights could be provided in the perspective of a possible 'second service life' (e.g. Bradley and Kohler, 2007).

2.2 Carbon Reduction

Non-domestic buildings in the UK are responsible for almost 20 % of the UK's energy consumption and carbon emissions (Communities and Local Governments, 2008). Even if less in total numbers than domestic buildings, several categories of non-domestic buildings have the highest energy use per square meter as for example office buildings. The repatriation of energy use in UK offices is: 58% for heating, 15% for lighting, 7% for IT equipment, and 5% for water heating (Mortimer *et a*l., 2000). The remaining 15% is used for cooling, fans, small power equipment etc. The Carbon Trust (2006) claim 15% of the office electricity use to IT services a figure that is expected to rise to 30% by 2020. In addition, HVAC – heating, ventilation and air conditioning (AC) – uses 20-30% of the total space in commercial buildings (Wagner *et al*, 2005).

Last years rapid growth in commercial energy use reflects expansion in floor space where offices occupy twice as much floor space in 1994 as in 1970 (Scarse, 2001). Between the mid-eighties and mid-nineties, the use of AC increased by a factor of three in the UK. This increase has various reasons (EOF, 1995): client demand, institutional requirement and market perception; deeper plan constructions; increasing external pollution and noise; high density of occupancy; higher internal gains principally from small power loads (poor efficiency of lighting and IT equipment); excessive solar gain due to poor design but also hotter summers. The heavy dependence on electricity for AC, lighting, IT equipment etc. is one major contribution to natural deterioration from the commercial property sector as in UK, electricity production emits twice as much carbon dioxide emissions than for example gas heating due to inefficiencies in power stations (Toke and Taylor, 2007). The situation will be different with new energy efficient lighting and IT equipment. For example, the use of energy-efficient lighting can reduce the overall energy use by 4 to 10% (McAllister and Sweett, 2007). Another problem is related to occupancy and the importance of energy efficient behaviour. One architect office in our study claim that 60% of their energy use is outside office hours (this energy is used for IT services, heating and some cooling).

2.3 An Inclusive Sustainability Perspective

Several studies point to the relative environmental advantage of retrofitting existing buildings compared to demolishment and new construction. In their comparative study, the British Research Establishment BRE (Andersson and Mills, 2002) suggests that the re-construction option (based on lifecycle of 60 years) has a higher environmental impact when using the same method of ventilation or cooling, even though the uniqueness of every site could influence results. The comparative evaluation is based on: embodied impacts (including transport, maintenance and disposal), cooling and ventilation energy, heating and lightning energy, capital costs, whole-life costs, rental values (lettability and manageability), buildability (speed of construction and disruption). The higher environmental impact of the re-construction option is attributed to the demolition and materials involved in the new construction (40-50% of the environmental impact).

The BRE study points to the necessity to expand the scope of environmental considerations beyond embodied energy and energy in use. However, few studies focus on the inclusive 'ecological footprint' and the sustainability agenda regarding socio-economic aspects of building activities (e.g. Building Research & Information, 3/36 2008). For example, location, e.g. accessibility by low carbon transport means will be of importance. A few models under development include other environmental measures in commercial property valuation such as water, waste, material and biological diversity (Ellison *et al*, 2007; McAllister and Sweett, 2007).

3. Addressing the commercial property sector

Generally the 'greening' of the commercial property sector is perceived as "tense and uncertain" and the "idea of 'development' appears anonymous with environmental degradation and unsustainable development" (Guy, 2000). Different actors in the commercial building sector have differing values and wishes concerning what they want to achieve from development of property. In a 'vicious circle of blaim' (Cadman, 2007) occupiers would like sustainable buildings but there are few available; constructors can build them but are never asked; developers would ask for them but investors will not pay for them; and finally investors would found them but nobody asks for them. The circle is further reinforced by the agents that can not see any market demand. However, there are witnesses of an emerging awareness regarding the consequences on investment portfolios of neglecting social and environmental issues and a perceived risk for future or 'anticipatory' legislation (Pivo and McNamara, 2005; Lützkendorf and Lorenz, 2007; Scarse *et al*, 2007; Cadman, 2007). This development is supported by new property rating systems capable of expressing the relative advantages of sustainable measures through the treatment of 'unsustainability' as additional risk (downside risks such as environmental hazard, increased rates of obsolescence and value depreciation) and the inclusion of sustainability for the calculation of credit and mortgage. In addition, sustainable building has been acclaimed to bring countless win-win situations as they are not necessarily more expensive to build and their ownership results in financial benefits including lower operating costs, improved marketability, longer life-spans, reduced exposure to increasingly stringent legislation, and increased occupant productivity and well-being.

Other internal market drivers are for example changed conditions for occupiers with shorter leases and opportunities to negotiate space based on functional demands, and more flexible and healthy workplaces (Guy, 2000; Sayce et al, 2007). However, the strongest pressure for sustainable and energy efficient commercial property does not seem to come from occupiers. Observations made by Cadman (2007) is that developers has led the way since the late 1990s and more recently, also investors have taken a shift and started to shape good practice.

External enablers to adapt more sustainable property management comes from strengthened legislation, taxes as for example The Climate Change Levy, The Aggregate Levy and land fill taxes, as well as raised energy costs. Several political documents addressing carbon reduction has been published last years, e.g. the Climate Change programme (2006), the Climate Change Bill (2007) and the Sustainable Energy Act (2006). The government has set out a progressive tightening of Building Regulations. The 2006s revision to Part L on Conservation on Fuel and Power of the Building Regulations is set to reduce carbon emissions for new built and refurbished non-domestic buildings. Another key measure is the Energy Performance of Buildings Directive, i.e. energy labelling of buildings. Furthermore, the government supports sustainable property management through VAT reduction on renewable energies; the English Partnerships, the regeneration agency, that focus on sustainable urban regeneration; and the Carbon Trust that supports private and public organisations in reducing energy use and carbon emissions. Launched in 2007, the UK Green Building Council sustains a new partnership between government, industry and other stakeholder groups that facilitates dialogue and sets up objectives on the road to more sustainable futures.

Except from cutting-edge buildings the raised awareness for sustainable property has not led to large market transformations. Despite rapidly increasing energy prices it is difficult to create a business case on cost reduction from environmental property even when adopting a whole-life approach (Sayce *et al.*, 2007). In the hand of the occupier, energy costs only represent a fraction of total business costs. Several authors state that a market-led shift to sustainable property is unlikely to happen within the time-frame set out by the current political agendas, proposing more fiscal measures if the market fails (Scarse, 2001; Toker and Taylor, 2007; Sayce *et al.*, 2007).

4. Case studies of Retrofitting Projects in Bristol UK

In early 2007, Bristol council launched the action Bristol Green Capital. Together with Bristol Partnership they seek to establish joint public-private and voluntary actions to reach the Community Strategy target to cut carbon dioxide emissions in Bristol by 60% by 2050.

At present the local authority's possibilities to push the environmental agenda in planning permissions is weak, but strengthened policies are expected in the end of the year. Changes to planning permission procedures have through for example the introduction of the 'section 106 agreement' set restrictions on the developers for the benefit of the local communities.

4.1 Hamilton House – The Pioneering Environmental Retrofitting Project

Hamilton House project is the retrofitting of a 1970s office block in central Bristol for mixed use including residential, offices, retail and a café. New light-structure penthouse apartments are added on the roof and a new residential building to the back of the block. Built in 1974, Hamilton House is currently only partly occupied as offices for the owner, a commercial developer. The owner approached the Bristol City Council with a proposal for a redevelop to housing which was refused. Instead, the city council proposed them resubmit an environmentally focused proposal.

Bristol based architects White Design work on the project now subject for planning permission. One of the challenges is the building being set back from the street with 5 metres, a space that quickly dilapidated. In the new scheme this space is turned it into an atrium, approaching the façade to the street, creating a place for a café and art exhibitions (the building has a Banksy mural), and providing a noise screen that will enable the building to be naturally ventilated. A new façade will be set up with super-insulated panels and floor to ceiling full height glazing. The whole block is heated with a biomass boiler and there will be solar heaters for domestic hot water. The architect has experienced problems as the original structural data of the building can not be retrieved. The structure will be reinforced for wind loads to comply with contemporary regulations.

The architect is convinced that the retrofitting project is the best sustainable solution and works on convincing the developer that this project would not only increase the market value of the property but also support the regeneration of the area, a great story in which they would take part. In their negotiations with the planners, they put forward that the project would add public value in terms of environmental quality, mixed use living, the attractive atrium space and a public garden.

4.2 Lake Shore – The Commercial Green Regeneration Project

In 2004 the award winning developer Urban Splash (South West) bought the 4,5 hectare site with the former Imperial Tobacco head quarter (HQ) building in Hartcliffe, an area that suffers from problems which characterise a socially excluded community. The HQ building from 1973 is a modernist structure of Cor-ten steel sitting on an artificial lake. In 1991, the factory was closed and HQ building was left derelict. In 1997 the building was listed by English heritage.

Urban Splash has a long record of approaching difficult and run down sites and successfully regenerating them in commercial terms. Their vision for the Lake Shore project is to retrofit the listed building and add a new building to create 406 apartments, live and work space, and some commercial space. They wish to attract people offering high quality architecture in an environmentally green area to comparably low prices. The success of Urban Splash can be linked to their niche market of approaching derelict and unwanted sites that they have been able to buy to low prices (and sometimes with additional grants from governments) leaving them resources to focus on their passion for architecture and design and now recently on the green agenda.

Initially Urban Splash aimed at an excellent level of BREAM rating Eco Homes (now Sustainable Homes). They are actually on level 4 (of 6) due to changes in the assessment model. Prerequisites of the site allowed them to use geothermal heating combined with a biomass boiler, local waste water management. They have plans for solar collectors and wind turbines and the lake has been decontaminated. Their work with the local community has brought together a job initiative where 10 trainees work on site. Furthermore, a social enterprise scheme matches local skills with enterprises. The architect is Acanthus Fergusson Mann (see 4.4).

4.3 Broad Quay and A Few More Cases – The Commercial Projects
