If a society is still based on agriculture, and not yet fully facilitated by infrastructure, there is no need for enormous investment for the establishment of infrastructure. Instead, individual energy self-sufficient units can, if it is required, establish an autonomous network. This approach is regarded to be promising not only in developing countries where the status of infrastructure is generally poor, but also in industrialized countries such as EU member states, especially in rural areas.

It is highly important to follow up the research results through practical applications. Therefore a series of pilot and demonstration projects are under development. In Austria, Italy, and Switzerland, a number of houses, and even small villages, are planned to be constructed.

4 Conclusions

The constantly rising energy consumption as well as increasing energy costs asks for radical instruments for reduction of energy consumption and for sustainable solutions. The Wireless House concept aims to create solutions for completely independent and energy self-sufficient housing. It rather focuses on the whole system of housing, integrating the demand side as well as the production side, than solely developing singular technical solutions. This approach will have far-reaching consequences in residential areas, both in industrialised and developing countries.

The concept is especially useful for remote areas or scattered geography. For these regions, the Wireless House can be a good solution for getting access to communication (e.g. media, mobile communication) and gaining comfort. Currently prototypes are under development to be tested and to be demonstrated in the first Wireless Houses. The concept will be further developed, expanded and put into practice in a number of Zero Carbon Village projects.

5 Acknowledgement

The idea for the Wireless House has been firstly developed within a strategic programme called ‘energy 2050’ initiated by the Austrian Federal Ministry for Transport, Innovation and Technology. This is a strategic programme with a focus on future energy supply solutions. It aims to figure out the way how we can safely and sufficiently meet our energy demands in forty years from now.

Summary

Existing assessment tools for the built environment have been designed for use in a reactive evaluation process rather than in a proactive decision process. Whereas current assessment tools generally catalog past decisions, the proposed decision-assistance [DA] tools focus on (1) guiding decisions when they are made and (2) directing relevant and timely information to specific decision makers. These proposed tools may better support the implementation of environmental strategies in the building industry.

The authors advocate:

A. The identification of topics within existing assessment tools for use in applicable decision categories.
B. The development of new DA tools tailored to specific decision makers.
C. An overarching framework to coordinate DA tools, track past decisions, and collect public contributions.

1. Current Use of Assessment Tools

Existing assessment tools for the built environment have been designed for use in a reactive evaluation process rather than in a proactive decision process. Although professionals in the building industry have accepted the use of building rating systems during project development, the existing assessment tools are not well designed to function as design aids. The proposed DA tools would guide decisions as they are made rather than document the decisions after they are made. The current assessment tools do not fit this intended purpose for the following reasons:

1.1 Current assessment tools present achievements categorized by physical components or environmental aspects, missing the opportunity to highlight a process of decision-making over time. Commonly, tools relate to a particular building typology and then group individual assessment topics by project components or environmental resources or impacts. By presenting the individual assessment topics all at once, the current assessment tools deemphasize decisions made at various stages of a project in terms of its timeline.

1.2 Current assessment tools stress the integrated approach of sustainable initiatives, inviting several disciplines to provide input in a holistic process. The emphasis on integration denies the assessment tools the opportunity to present clear directives for each decision maker. Because they include information that is applicable to so many participating entities, the assessment tools become diluted overall, failing as specific and thorough guides.

1.3 Current assessment tools tend to be ignored in the earliest stages of project development and do not address changes in the building throughout its lifetime. Often the owner commences the assessment services during the design phase; thus the assessment tools are applied to a project only after the site has been selected and the building program has been established - decisions that may have been guided, if at all, by only a vague understanding of the assessment criteria. Also, many of the earliest decisions will have been made by entities other than the owner, such as local, state, and federal governments, or international commissions. Current assessment tools are closely linked to the design and construction phases of a project, and building operations and renovations are addressed in subsequent, non-integrated rating systems, if at all. As a result, the produced ratings tend to become quickly outdated since they fail to reflect building modifications or fluctuations in life-cycle operations and maintenance.

1.4 Current assessment tools do not provide for clear interaction between project team members. Preferences by one team member may not be apparent to another unless expressed outside of the system.

1.5 Current assessment tools, in general, focus on one project at a time and cannot demonstrate associations between several buildings in a complex or portfolio. Thus they do not educate users about the cumulative effect of several buildings that rate well in the certification process. Nor can the current assessment tools aid the design team in developing a sense of greater environmental responsibility, such as for a region or the planet, outside of their desire to reach a higher rating level when their scope is limited to singular projects.

1.6 Current assessment tools also do not provide accumulated data from one project to another, or between rating systems. Because they fail to track and update information from the decision makers, assessment tools consider each project in isolation, and cannot be used to guide decisions in subsequent developments.

1.7 Current assessment tools can only indirectly affect the building industry. Through the advertising potential of positive ratings, these tools claim to affect the market by economically incentivizing environmentally responsible decision-making in the building industry. However, this market-driven approach appears somewhat circuitous and less effective than a direct method to affect change. Some of the current assessment tools do act as incentive programs, promising an award for a positive rating. A certification or plaque thus represents an opportunity to achieve broad market exposure, but requires very long feedback cycles to begin affecting the building industry's production methods. Furthermore, relying on entities like building product manufacturers, outside of the direct reach of building rating systems, to affect the market significantly weakens the argument that assessment tools assert pressure towards market-wide sustainability.

2. Proposed Objectives for Decision-Assistance (DA) Tools

Based on the above shortfalls in the current assessment tools, the authors propose the following objectives for DA tools:

2.1 Allow for a decision-making process over time

2.2 Provide clear guidance to each decision maker

2.3 Support the entire life-cycle of a building

2.4 Show input from project team members

2.5 Demonstrate the impact of decisions beyond a singular building

2.6 Track decisions in a public database

2.7 Affect direct change on the market

The proposed tools would each be directed at a particular decision maker, whether a developer, international commission, mechanical engineer or building operations vendor, and would be tailored to that entity's relationship to the project throughout its lifetime. These tools would help guide the decision makers through their range of choices in the built environment, and would be called decision-assistance (DA) tools.

3. Proposed Framework for DA Tools

In order to establish DA tools with thorough access to relevant and timely information, an open-source framework based on wiki technology is hereby proposed. Such a framework will ensure that the DA tools are available for use as design guides and that they contain publicly shared knowledge on topics relevant to each decision maker. In detail, the DA tool framework will:

3.1 Allow for a decision-making process over time: The framework will be made up of a number of DA tools. Each of the DA tools will focus on how to positively affect decisions when they are made rather than record decisions after they are already in place, allowing decision makers to actively take environmental impact into account. Rather than a single assessment tool that catalogs decisions made by different entities at various points in the lifetime of a project, one can imagine a set of several DA tools that each focus on a single responsible team member. The DA tools may be linked to form a greater system, a framework, or they may stand as individual options to be used as needed.

3.2 Provide clear guidance to each decision maker: Because each DA tool will focus on a single decision maker, the information provided will be tailored to that entity's specialized knowledge-base. Introducing sustainable options directly to the relevant decision maker will allow issues to be addressed very early in a development's progress, facilitating integration of sustainable policies from a project's initial stages.

3.3 Support the entire life-cycle of a building: The DA tools, each directed at one decision maker, will give guidance to the decision maker throughout their relationship with the project. From international commissions to architects to facility managers and demolition contractors, the combined DA tools will reach out to everyone throughout the entire life-cycle of a project. A framework of DA tools will therefore resemble an overlapping group of timelines, each timeline representative of a particular entity's involvement in a development, in contrast to the approach of current assessment tools in which all the decision makers are required to participate in the assessment during one brief period in the project development.

3.4 Show input from project team members: Although each DA tool will emphasize the needs of a particular decision maker, it will also allow the other decision makers or project team members in supplementary roles to offer advice or information regarding their preferences. For example, within an owner's DA tool, the architect may stress the aesthetic desirability and environmental benefit of underground parking, although the owner will ultimately make the choice.

3.5 Demonstrate the impact of decisions beyond a singular building: Each of the DA tools will identify and describe the greater impacts of any potentially applied development strategy, on a region or the planet for example, based on past facts and future projections - including differing opinions and the surrounding debates between politicians, scientists, special interest groups and others. The open-source capability of the DA tools will keep information current and abundant as it facilitates a democratic dissemination of knowledge to the decision makers from all sides of the debates, and the participation of the public will keep the maintenance of DA tools manageable.

3.6 Track decisions in a public database: Each DA tool will inherently include more data capture and tracking than is common with current assessment tools. A historical record of environmental choices could become a powerful political instrument and prove useful to public interest groups or consumer advocates that value transparency in government. Such a database will also provide researchers the ability to track common disincentives towards certain environmentally responsible decisions and may lead to the development of economic incentives.

3.7 Affect direct change on the market: By being specific to decision makers, DA tools will have an immediate opportunity to affect market change. Within the knowledge base associated with each tool, readily accessible information on incentives, such as financial benefits or marketing exposure, may directly influence decisions.

4. Content of DA Tools, as derived from Current Assessment Tools

The authors suggest thirteen DA tools, based on proposed major decision categories as shown in Table 1, where each category relates to decisions in the entire project development that can be assigned to a single type of decision maker. Current assessment tools were reviewed in order to determine what existing individual assessment criteria, "credits," may easily transfer into the proposed DA tools.

Table 1 Decision Categories

1. International Policies
2. National Policies
3. National Land Planning
4. Community Plan
5. Community Operations
6. Investment (ownership, location)
7. Building Property Design
8. Building Structure Design
9. Building Interior Design
10. Building Product Manufacturing & Distribution
11. Construction
12. Portfolio or Building Operations
13. Building Operations Vending

In order to identify which individual credits could become part of a DA tool based on an intended decision maker, the following current assessment tools were reviewed: LEED-NC 2.2, Green Star NZ - Office Design v1.2, CASBEE-NC, 2006 NABERS Office, SBTool version SBT07, and BREAAM: Offices 2006.

Because these reviewed assessment tools sort their individual credits into groupings based on the building systems affected or resources used, commonly including groups for water use, air quality and building materials, no entire grouping from these assessment tools may be easily transferred into a single DA tool. For example, the current assessment tools typically include credits for general location and context;

however, these credits may be mixed in with sustainable site design items and landscape design issues, requiring several decision makers to participate in the “Site” grouping of an assessment tool.

The focus of the research was on the most commonly used assessment tools; those not reviewed include rating systems specifically designed for building operations and community design. For example, the U.S. Green Building Council’s Leadership in Energy and Environmental Design program includes a rating system called LEED for Existing Buildings: Operations & Maintenance, whose assessment topics could be extracted for use in decision categories like “Portfolio or Building Operations” or “Building Operations Vending.” LEED for Neighborhood Development could also be useful for the DA tool, “Community Plan.”

The following analysis of each proposed DA tool describes the intended decision maker involved and gives examples of relevant topics from some of the reviewed assessment tools.

4.1 International Policies

International Policies related to buildings are addressed by ongoing international forums, potentially leading to the ratification of internationally accepted protocols. Environmental issues like climate change affect the entire planet; thus the evolution of international policies in regard to the building industry is critically important. Decisions regarding these policies are implicitly addressed in several building rating tools, such as:

The use of alternate refrigerants that are less depleting to the ozone layer and that create lower amounts of greenhouse gases, as addressed in LEED-NC 2.2 EA Credit 3, Enhanced Refrigerant Management.

The practice of sustainable forestry, protecting against the destruction of forests including rainforests and old-growth forests, and the encouragement of reforestation for carbon sequestering, as touched on by LEED-NC 2.2 MR Credit 7, Certified Wood.

The Green Star Credit Ene-2: CO_2 Emissions encourages the reduction of carbon dioxide, a contributor to climate change, by requesting descriptions and comparisons of a building’s energy sources in terms of predicted carbon dioxide emissions.

Recognizing the importance of reductions in harmful emissions from building energy use, BREEAM Credit P11 advocates the completion of a feasibility study in the use of local renewable energy. The credit further encourages the implementation of energy plans that incorporate a high percentage of the researched strategies.

4.2 National Policies

National policies related to the development of buildings are typically directed by national technical departments under the authority of a country’s political leaders. These technical departments look into curbing pollution; the discharge of waste into water, land and air; limiting energy use per capita; and developing principles for the protection of ecosystems and wildlife throughout the country. Strategies researched by the departments may translate into laws and regulations, or they may provide the basis for environmental tax incentives. Examples for how these policies are addressed in building rating systems include:

The prevention of soil erosion and stream pollution, addressed in LEED-NC 2.2 SS Prerequisite 1, Erosion & Sedimentation Control, for temporary measures during construction, and in SS Credit 6.1, Stormwater Design: Quantity Control and SS Credit 6.2, Stormwater Design: Quality Control, for permanent measures during building operations.

Air pollution and energy use are affected by transportation to and from buildings by its occupants. LEED-NC 2.2 SS Credit 4.3, Alternative Transportation: Low-Emitting & Fuel Efficient Vehicles incentivizes the use of hybrid and alternative-fuel vehicles.

Green Star Credit Tra-2: Small Parking Spaces recognizes the tendency for smaller cars to be more energy efficient, and rewards the incorporation of parking spaces for very compact vehicles in the general parking plan.

4.3 Land Planning

Land planning is also conducted by national and regional departments subordinate to political leadership. This large-scale planning frequently deals with land to be set aside for highway and train transportation or for the protection of natural or historic treasures; but it may also safeguard bodies of water or agricultural land. Government property may be allocated through these programs for military purposes and regional public transportation systems. Current assessment tools may likely address some of these planning criteria:

Sites should be selected to avoid prime land that may better serve other purposes and should be avoided as building sites. Previously developed land or brownfields may be more suitable for building sites. For example, LEED-NC 2.2 addresses some of these issues in SS Credit 1, Site Selection and SS Credit 2, Brownfield Redevelopment.

BREEAM Credit P11 requires that a project team hire an ecology professional to oversee the development and implementation of an ecological management plan, as well as to educate the relevant workforce on how to protect local biodiversity during the construction work.

The net improvement of a building site's local ecology over its previous condition is addressed in Green Star Credit Eco-4.

Recognizing the often negative environmental impact of removing soil or adding fill to development sites, Green Star Credit Eco-5 encourages the balancing of cut and fill on the site.

4.4 Community Operations

On a local level, community departments, sometimes in close relationship with private vendors, address operational services to the general public on a daily basis. These services include the routing and maintenance of public transportation and the management of landfill and/or recycling waste. Examples of how these operational policies are addressed by current assessment tools include:

LEED-NC 2.2 SS Credit 4.3, Alternative Transportation: Public Transportation Access encourages development within ½ mile from a commuter train station or within 1/4 mile of two stops for more than one roundtrip bus line.

BREEAM Credit T08 encourages the investigation of transportation issues at an early stage in the project. This credit addresses the development of a travel plan tailored to the specific needs of the building occupants and incorporating public transportation options where possible.

4.5 Community Planning

Community planning departments, frequently with public input, devise ordinances for the physical layout of both new and existing developments. The resulting zoning ordinances regulate lot coverage, building height, historic preservation, solar access, the protection and planting of trees, and the avoidance of exterior light trespass, for example. Individual credits that could become part of a Community Plan decision-assistance tool include:

Dense developments and mixed-use communities maximize opportunities for pedestrian circulation. For example, LEED-NC 2.2, SS Credit 2, Development Density & Community Connectivity provides some criteria for higher density and mixed-use areas.

An exterior light ordinance may regulate that no exterior light can fall on a neighbor's property. Such a requirement is addressed in LEED-NC 2.2 SS Credit 8, Light Pollution Reduction.

Achieving local continuity in desirable neighborhood character is addressed in Green Star Credit Mat-2: Re-use of Facades, in which building facades are preserved and reused.

4.6 Investment

A building venture is typically undertaken by a building owner or developer. The owner may be any combination of private (for profit or non-profit) and/or public entities, and may include a group of investors not directly linked to the design and building decisions. Thus, a bank, real estate investment trust, or several private investors may be linked to a project. Many decisions at the time of investment chart the course for the project, such as identifying the type of building, its intended use, its targeted tenants, tentative building area, and a general target location. Decisions at this level lock the project development into some crucial design parameters.

Decisions reflecting site selection are for example addressed in the earlier discussed LEED-NC 2.2 credits SS Credit 1, Site Selection; SS Credit 2, Development Density & Community Connectivity; and SS Credit 3, Brownfield Redevelopment.

LEED-NC 2.2 MR Credit 1, Building Reuse addresses the choice between renovation and the tearing down of an existing structure.

4.7 Building Property

Site plans are designed by the architect and/or civil engineer with direction from the owner or developer, who often aim to maximize the building area on the site. Within the permissible ranges of zoning requirements and other regulations, the site plans address how much of the property is covered by structures and what areas are designated as open space. Environmental goals at the property level include the minimization of the building footprint and of hardscape, the use of light-colored/ shaded surfaces, the reduction and treatment of stormwater runoff, and the preservation, restoration or establishment of vegetated, wetland, and wildlife areas. Existing individual credits relating to these issues are addressed in several tools.

LEED-NC 2.2 SS Credit 5.1, Site Development: Protect or Restore Habitat and SS Credit 5.2, Site Development: Maximize Open Space reward the incorporation of designated open space on a development's site and the restoration of that open space to native vegetation.

Recognizing the participation of low-albedo materials on local temperature increases, LEED-NC 2.2 SS Credit 7.1, Heat Island Effect: Non-Roof suggests alternative hardscape colors and materials to lessen the development's impact on local microclimates.

4.8 Building Structure

The design of the building structure is often the first phase in which an architect and a green building assessment consultant are involved. Many of the design issues at the structural stage are driven by the owner, who may draw on the recommendations of the architect and green building assessment consultant. A structural engineer also has an important role in the selection of materials and dimensions of the structural building elements. The design issues considered by all the players at this stage include: anticipated length of use and desired durability of the structure, available structural materials, building orientation, shape, configuration and height, floor-to-floor height, major vertical circulation elements, desirable views and solar access, floor plate size and depth, building envelope materials for the roof and walls, glazing, insulation, and air-tightness. In this phase, decisions as to the building area and volume per occupant are solidified and the energy use per occupant will largely be determined.

LEED-NC 2.2, SS Credit 7.2, Heat Island Effect: Roof considers the incorporation of vegetated roofs or high-albedo coatings to reduce local heat gain and reduce building cooling loads.

LEED-NC 2.2 EA Credit 1, Optimize Energy Performance incorporates the building's shape, materiality, orientation, and operational systems to determine the building's net energy savings over a baseline building.

Natural daylighting strategies contribute to energy efficiency as well as to the well-being of occupants, as addressed in LEED-NC 2.2 EQ Credit 8.1, Daylight & Views: Daylight 75% of Spaces, and EQ Credit 8.2, Daylight & Views: Views 90% of Spaces. These individual credits use the building envelope configuration and materials to reward access to daylight and views for a high percentage of occupants.

BREEAM Credit HW02 encourages shallow floor plates in order to locate desks in an office setting within a reasonable distance from exterior windows.

SBT07 Credit A2.9 encourages a building orientation that suits local climates and aids in energy efficiency through the potential for passive solar systems.

4.9 Building Interior

Following or concurrently with the structural decisions, the architect and/or interior designer prepares documents for the building's interior environment, including the mechanical, electrical, and plumbing systems designed by engineers. Design issues related to the building's interior systems and materials contribute to energy efficiency, water conservation, indoor air quality, and controllability of the systems. Decisions could be more guided if specific disciplines were addressed; they could be more integrated if considered by a small team and along with the building structure. Interior layouts and material selections may address the life-cycle of the building elements and contribute to the healthfulness of the interiors, a major environmental consideration for this decision phase.

Controllability of system is addressed in LEED NC 2.2 EQ Credit 6.1 for Lighting and in EQ Credit 6.2 for Thermal Comfort.

Healthfulness of materials is addressed in LEED NC 2.2 EQ Credit 4: Low-Emitting Materials, which caps the VOC content of paints, composite wood products, and adhesives.

Interior noise pollution can negatively impact the well-being of occupants, and its avoidance is recognized in both BREEAM Credit HW17 and Green Star Credit IEQ-12: Internal Noise Levels.

4.10 Building Product Manufacturing & Distribution

Independently from the building development and design process, the building industry, with its manufacturers, distributors, transportation providers, show rooms, sales representatives, and sales centers, makes many decisions contributing to the ratings reflected in green building assessment systems.

The decisions address recycled content, recyclability, and the sourcing of products. Renewable sources, regional availability/manufacturing, harvesting, ecosystems endangerment through harvesting/extraction, and earthcrust exploitation may be considered, but may also be previously be addressed by governmental policies and regulations. For example, sustainable forest practices are addressed in LEED-NC 2.2 MR c7, Certified Wood.

4.11 Construction

The contractor or construction manager in charge of constructing a building project makes many building purchasing decisions and construction site management decisions, within the parameters defined by the owner and the design team's documents and in cooperation with the subcontractors. Issues include the indoor air quality management of the building under construction, the management of construction waste, and the sourcing and delivery of purchased products. In the construction DA tool, the owner and designers could make their preferences visible regarding construction management.

Regionally manufactured and regionally extracted materials may be given preference, for example. In LEED-NC 2.2, this is addressed in MR C5 Regional Materials.

Construction site management issues as to waste and indoor air quality are addressed in several rating systems, for example in LEED-NC 2.2 MR Credit 2, Construction Waste Management, or EQ Credit 3, Construction IAQ Management.

4.12 Portfolio & Building Operations

Once the building is constructed, the facility managers will make many decisions for the building operations throughout its lifetime. Decisions are made for a single building or for a portfolio of several buildings, and may include the use of vendors for cleaning, landscape maintenance, pest management, consumer waste removal / recycling, and building consumables. Building operations may address the maintenance of systems affecting indoor air quality, energy efficiency, and water use, and the measurement and verification of utility costs through submetering. This monitoring of energy uses and costs may inform the facility managers of what improvements make sense for the continued energy efficiency of the project, providing data regarding energy use per occupant or per unit area of the building.

These decisions are somewhat addressed in assessment tools for new design and construction, but usually in more detail in tools specifically geared toward the operations of existing buildings.

LEED-NC 2.2 EA Credit 5, Measurement & Verification establishes parameters for periodic measurement and verification programs.

Recognizing the varying limits of human comfort, LEED EQ Credit 7.2, Thermal Comfort: Verification addresses input from the building occupants regarding their satisfaction with the building's thermal characteristics.

4.13 Building Operations Vending

Each vendor for building operations makes decisions that affect the environment. If the DA tools for these entities described the preferred operations and maintenance methods of the facility managers, vendors could tailor their services accordingly. The maintenance vendors may offer more environmentally sound cleaning, landscape management, pest control, consumer waste removal, and building consumables purchasing. Providers of utility services like electricity, gas, water, or communications, could also use the DA tools to track decisions related to the building operations and could suggest how different decisions may positively affect energy efficiency and what incentives may be available.

Many of these issues are addressed in assessment systems more geared toward the operations of buildings, such as LEED for Existing Buildings: Operation & Maintenance.

NABERS, a building rating system developed in Australia, deals primarily with post-occupancy environmental performance. This assessment tool addresses the relationship between a property owner and the utility companies that serve the project.

5. Summary and Recommendations

No easy correlation between current assessment systems and the proposed DA Tools was found. Existing assessment systems do not provide clear decision making paths toward more environmentally conscious built environments. If the need for new decision tools should become recognized and widely acknowledged, a large undertaking would be necessary to rework the existing assessment tools into DA tools. While the individual credits from current assessment tools used in the examples above may be suitable for some DA tools, they would require extensive modification to become user-friendly in such a new application. Also, the existing credits do not have the capability to forecast the greater environmental impacts of applied building strategies in an interactive format, or to track decisions. For now, existing assessment tools are primarily framed to document the results for singular projects, results of decisions that have already been made. The authors recommend:

5.1 To those developing current assessment tools: Relate assessment topics to decision categories. Existing credits may be suitable for integration in future DA tools specific to particular decision makers, and although credits would need further development to be user-friendly in such an application, identifying their decision categories now will ease a future transition. More specialized assessment systems, such as those for neighborhood planning or those for building operations, appear to be a better basis for DA tools; thus entire systems or parts of systems could be converted to decision categories.

5.2 To those developing DA tools: Consider specific uses and tailor the tools to a specific type of decision maker identified by a major decision category. Tools should be available to decision makers over the length of their relationships with a project, and should be capable of maintaining user accounts for a long time period.

5.3 To those developing all tools: Add a framework that coordinates assessment methods and supports both data tracking and a searchable public-knowledge database. Current assessment tools rate project characteristics with differing methods, and there appears to be little dialogue between systems. Coordination would more easily allow for the development of DA tools by providing quick access to the topics in existing assessment tools. Synchronize decision topics related to a global scale across systems, and add data, opinions, and other public information that support decision making. Consider adding the capability to track decisions and maintain a database of such recorded information.

Keywords: LEED® Certified, green building, occupant, behavior, sustainability, environmental stewardship

Abstract

This study has examined occupants' perspectives on adopting environmental behaviors as a result of their occupying or not occupying a green building. It has also determined that this influences their behavior at home, work or elsewhere. Additionally, it assessed that when occupants are given the opportunity and the necessary tools to act "environmentally sustainable" within green buildings, they eventually adopt environmental behavior, outside the location of employment. An interview survey was conducted at two buildings in the City of Ottawa, Canada: a LEED® Certified building and a non-certified building.

As a result, the occupants employed in the LEED® Certified building have become more environmentally sustainable than occupants employed at the non-certified building. A majority of occupants (82%) have experienced increased awareness and interest levels in sustainability issues such as green buildings and also have also accumulated more knowledge on living sustainable. Occupants also experienced a positive change in their environmental behaviors concerning transportation, energy consumption and household activities. Furthermore, occupants of the LEED® Certified building have become promoters and stewards of green buildings in addition to environmental issues such as sustainability.

1. Introduction

The greater outcome of this study will find out if green buildings can be marketed to influence social change. The goal of the interview survey used in the study, was to discover occupants' perspectives on adopting environmental behaviors as a result of either occupying or not occupying a LEED® Certified building and attempt to discern whether these behaviors have also changed at home, work or elsewhere. This study also assesses that if occupants are given the opportunity and the necessary tools to act "environmentally sustainable" within green buildings, will they eventually adopt environmental behavior, outside their location of employment. Additionally, the interview survey was reviewed by, and received ethics clearance in 2005 through the Office of Research Ethics at the University of Waterloo, in Ontario, Canada.

1.1 Methodology

The survey was administered to two groups of people that were employed and occupied two separate buildings. Two different locations were chosen in order to find differentiation in the employees responses by either occupying or not occupying a LEED® Certified building.

Participants first surveyed on January 28th 2005, were employed within the LEED® Certified building, Mountain Equipment Co-op (MEC), (hereto referred as the "LEED® building"), located at 366 Richmond Road, in Ottawa, Canada. This building was chosen for the survey because during the time of the study, it was the only building in Ottawa certified by the LEED® (Leadership in Energy and Environmental Design) Canada Green Building Rating System. Participants in the second group were surveyed on January 25th 2005 and were employed at Bushtukah, (hereafter referred to as the "non-certified building"), situated at 203 Richmond Road, in Ottawa, Canada. The two retail stores were chosen for the study because they have a similar "culture", in which they sell the same genre of products such as outdoor sporting equipment and apparel, and therefore will have comparable staff in which to assess differences from the study. Additionally, both buildings are located near one another, within the neighborhood of Westboro Village in Ottawa.

1.1.1 Sampling

The interview survey was administered to fifteen employees at the LEED® building and eleven employees at non-certified building during non-working hours. All participants were approached at random selection or by choice of the store manager. Participants were given the same standardized recruitment letter and consent form prior to administering the survey, explaining that participation in the interview survey was voluntary and should take less than ten minutes of time. All information provided was kept confidential and grouped with responses from other participants and later destroyed. Participants were also informed that they were permitted to decline answering any questions or withdraw from the study at any time.

The sample of participants interviewed was 22% of the total number of employees from each building. This high percentage minimized the sampling error as well as the difference between the sample and population size. The sampling error was also minimized due to the vast range of respondents working in different areas of both stores (Palys, 1997).

1.1.2 Interview Survey

The interview survey was chosen because of the opportunity for high response rates. There was also a form of social contact created between the researcher and respondent; any ambiguities or misunderstandings, were clarified immediately. The choice of survey was selected because the end result of the study was to discover change in behavior when dealing with sustainability. The level vocabulary was appropriate due to the requirement of an adult for the survey (Palys, 1997).

In the study, both qualitative and quantitative questions were used to discover behavioral changes in occupants. The qualitative questions administered in the interview survey were open and general ("In your most descriptive words, what makes a building green, environmentally sustainable or significant?") and were based on the ethnographic approach, derived from the theme of anthropology, which emphasizes examining a culture (Trochim, 2002; Palys, 1997). Three of the questions were of open-ended structure, which provided many opportunities for response.

The analysis of the qualitative data from the interview survey was based on the U.S. National Science Foundation's qualitative modes of data analysis. Qualitative data can be studied from many angles in a variety of approaches because there is no standardization when describing environmental behavior. (Sharp et al., 1997).

2. Results

2.1 Level of Interested in Green Buildings

When occupants at the non-certified building were asked if they were informed or interested about environmentally sustainable issues such as "green buildings", 27% were neutral on the topic, 54% were somewhat interested, and 18% were very interested. At the LEED® building, 6% of the employees were neutral on the subject, 50% of the participants were somewhat interested and 44% of participants were very interested in environmentally sustainable issues such as green buildings. In summary, within the LEED® building, there is a significantly higher percentage (94%) of occupants who are very interested and somewhat interested in green buildings than occupants in the non-certified building.

2.2 Ranking General Issues

When employees were asked to rank three general issues (health care, economy and environment), from one (1) to three (3); where one is the most important and three is the least important, 27% of the non-certified building occupants chose the environment first, 54% selected the environment as second and 18% preferred the environment as third importance. Of the total respondents at the LEED® building, 50% placed the environment first, 44% ranked the environment as second, and 6% ranked it last.

In general, most occupants of the LEED® building chose the economy as their least important issue. In contrast, at the non-certified building most employees selected either the economy or healthcare as the most important issue. When associating the two questions, those occupants at the non-certified building that were either somewhat interested or very interested in green buildings, ranked the environment as the most important issue. Additionally, non-certified building occupants that had a neutral level of interest in green buildings ranked the environment as their second or third choice.

2.3 Defining a Green Building

Occupants were asked to define a "green" or "sustainable building" in their own words. The LEED® building group provided a substantial array of words that described sustainable building structures, components, materials, building functions and occupant well-being. They also referred to construction techniques and environmental philosophies. No two answers in this group were significantly comparable.

At the non-certified building, 63% of occupants defined an environmentally sustainable green building by expressing "energy efficiency". Other common definitions included "minimal use" or "low impact". Further definitions expressed were more sporadic and described building operations. One employee did not know how to describe a green building.

While comparing the two groups it is clear that those occupying the LEED® building have been enhanced with green building awareness. By examining the definitions provided, there were more detailed and specific responses. This is also apparent because they also targeted aspects of a green building that would be noticed by an occupant, such as: human health, indoor air quality, level of low Volatile Organic Compounds (VOC), amount of natural light and tenant satisfaction.

2.4 Environmental Behaviors Outside Employment

Employees were prompted to write down the environmental behaviors and actions they carry out outside their location of employment. The majority of the LEED® building occupants responded that they make use of sustainable transportation such as walking, biking, busing and carpooling. Nearly all of the occupants claimed they apply energy efficiency techniques and use sustainable energy at home in order to save money.

When the non-certified building employees were prompted to provide the environmental behaviors they carry out outside their location of employment, 63% mentioned that they recycle, 81% revealed that they use alternative transport when possible, 46% attempt to consume less water or energy, and 18% said they participate or are involved in environmental awareness programs or activities. The responses provided by the non-certified building were comparable to average environmental behaviors as defined by the frequency categories in the *Pennsylvania Environmental Readiness for the 21st Century Report* (PCER, 2005). These average environmental behaviors included behaviors such as transportation choice, learning about current issues, participation in environmental initiatives and recycling (PCER, 2005).

In comparison, the LEED® building group alluded to more detailed environmental activities that were not mentioned by the non-certified occupants. These behaviors are: composting, purchasing products with no packaging or their life cycle analysis and location, and the type of food (i.e. organic, vegetarian, or locally grown). Additionally LEED® building occupants showed a higher level of stewardship in regards to their lifestyle, in terms of: living space (size, location, number of roommates) and household practices (non air-conditioned, lower temperatures, minimal lighting).

2.5 Change to Environmental Behaviors

Occupants were asked if their environmental behaviors have changed since being employed at their particular building. Most (90%) of non-certified building occupants believed that there has little or no change in their environmental behaviors outside the work environment. In contrast, 69% of the LEED® building occupants felt that their environmental behaviors have changed since being employed in the green building.

There is an array of responses from LEED® building occupants pertaining to environmental behaviors that have changed since being employed at the particular building. Most respondents stated that they have become more aware about their habits at home because of their work environment. Several respondents confirmed that they have become environmentally responsible and have developed into being promoters of reducing impact on the environment. In particular, one respondent mentioned that their behavior has changed by being around environmentally aware people. Furthermore, employees in the LEED® building have become more aware of environmental issues and more knowledgeable on aspects of environmental sustainability and many respondents said they have initiated new life style choices.

2.6 Location of Employment Initiating, Promoting or Enhancing Awareness

LEED® building occupants were asked if their place of work has promoted initiated or enhanced their awareness towards environmental issues such as sustainability. Eighty-two percent (82%) responded in detail that their place of employment in the green building has enhanced their awareness. Many felt that by frequently working in a green building, people have become more eager and interested to learn about the building and other environmental issues. Other occupants felt that due to the ongoing initiatives with their employer, Mountain Equipment Co-op (MEC), they have changed their environmental responsibility perspectives. Other respondents mentioned that since their employer, MEC, currently has high standards and is an environmentally ethical place, occupants have become more aware of their daily activities at work and outside work. Additionally, some employees believe that working in a green building has caused them to promote environmental awareness by educating friends and family on impacts and benefits.

Nearly 18% of the occupants of the non-certified building felt that their location of employment has initiated, promoted or enhanced their awareness or interest towards environmentally sustainable issues. Of those that responded that their place of employment has changed their awareness, one mentioned that they have become more aware of the outdoors for recreation.

3. Discussion

The next section discusses a few theories that complement and support the analysis that green or LEED® Certified buildings promote environmental sustainability among its occupants.

3.1 Influencing Environmental behaviors

Barr (2002) has examined the concept of what makes individuals act sustainable. He argues that there is a moderately strong relationship between stated intent and behavior. There are several motives that manipulate these two concepts. Public communication towards environmental action may be manipulated or persuaded by different previous circumstances to that of actual behavior. Additionally, there is some difference in environmental action with what is expressed and what is reality. These differences are symbolized by the attitudes of the public and their environmental actions. In recent years, the most publicized issue has become environmental degradation. Since sustainability is now institutionalized in every facet of the government, it is ironic that there are many movements to attain environmental awareness, and there is much publicity on the consequences of bad environmental stewardship. (Barr, 2002).

Another variable that influences green stewardship are situational characteristics. A study completed by Daneshvary et al. (1998) found that individuals involved in a household paper-recycling program were more expected to also be willing to participate in a clothing-recycling program (Danshvary et al, 1998). This study complements the idea that individuals who are involved one environmental action are more likely to be involved in other actions (Barr, 2002). This theory is demonstrated by the LEED® building occupants. Since they are actively participating in sustainable activities at work, they are more likely to participate at home. Moreover, knowledge will influence social norms and affect acceptance of the standard (Barr, 2002).

Schahn & Holzer (1990) conducted another study focusing on factors that influence recycling behavior. This analysis established that having access to services or technologies will cause usage due to its convenience and ease (Schahn & Holzer, 1990). It is demonstrated in this study that green buildings provide more comfort and ease to learn and participate in overall sustainability. Technologies within green buildings require little or no effort by occupants and establish how painless it is to participate.

Scott (2004), expresses that in order to achieve sustainability, interest and keenness concerning change must occur. Change has to be appealing to the individual and including incentives on an occasional basis will render it more attractive. However, if the resources or the means are taken away, than a behavior change cannot exist (Scott, 2004). It is apparent that several employees in the LEED® building have indicated interested in learning more about green buildings, and as a result have become advocates.

3.2 The Tipping Point in Environmentalism

Gladwell (2002) and his theories that make up the concept of the "Tipping Point", illustrate that in this study, green buildings can be tipped into a new way of living and working. The "law of the few", demonstrates that individuals in a green building can act as persuaders, connectors or mavens and promote green behavior. Green buildings can become like an adhesive. They "stick" to occupants by promoting sustainable behaviors, by proving the ease of sustainability and by creating a trend to occupants. Green buildings provide a context for occupants, and they create a sustainable environment to which become social norms. (Gladwell, 2002).

3.3 Fostering Sustainable Behavior

Mackenzie-Mohr (1999), explores fostering behavior change in order to conduct social based marketing. He argues that initiatives that will promote behavior change are the most forceful when they are undertaken at the community stage and encompass contact with people. Prompts like technologies with in a green building can cause a person to remember to act sustainable elsewhere. (Mackenzie-Mohr, 1999). At the LEED® building, occupants have had positive changes to their awareness and interest levels in areas of sustainability.

As a result of occupying a LEED® building, the standards and social norms are created by the knowledge that has accumulated by occupants. Some individuals felt that the environment has now become an interest and they are inspired to learn more and consequently are more aware. In relation to this concept, green buildings break the barrier between thought and environmental action, and provide the link to rhetoric and reality (Mackenzie-Mohr, 1999). It is apparent in the LEED® building, occupants have brought this sustainable vision to other parts of their lives.

4. Conclusion

Green buildings provide a context within which sustainable norms and values are created due to experience, awareness accumulation and environmental stewardship activities. Since being employed in the green building, 82% and 69% of LEED® building occupants felt that their environmental awareness has increased and their environmental behaviors have changed, respectively. The difference between the responses from the two buildings describes that occupants will adopt environmental behaviors outside their location of employment as a result of occupying a LEED® building. Green buildings will break conventional lifestyles and establish the creation of societal environmental change.

STUDY ON RESIDENT BEHAVIOR DURING CONSTRUCTION OF ENERGY-SAVING AND POLLUTION-REDUCTION COMMUNITY IN CHINA

F. YANG Ph.D Candidate
X. WANG Ph.D
Y. WANG Ph.D Candidate

School of Civil Engineering & Mechanics, Huazhong University of Science and Technology, Wuhan city, Hubei province, China, sylvia_0306@sina.com

Keywords: energy-saving and pollution-reduction community (EPC); resident behavior; behavior value; eco-efficient; survey questionnaire; complex adaptive system

Summary

Chinese government has taken many measures to promote the resources-saving and environment-friendly society since 2004, which is regarded as national strategy. For both urban and rural communities are basic living places, construction of energy-saving and pollution-reduction community is the foundation and crucial field for the national strategy. Residents are the primary systemic agent of energy-saving and pollution-reduction community and it's necessary to study resident behavior for better participation guidance in energy-saving and pollution-reduction way.

Firstly, this paper divides the cognition evolvement of energy-saving and pollution-reduction community in China into three stages and puts forward challenges that will face. Secondly, the paper takes resident behavior as the object during one project's life cycle among a series of construction projects for energy-saving and pollution-reduction community, and sets up the system of resident behavior, which is composed of time sub-system, space sub-system, available resource sub-system and behavior planning. Thirdly, the paper establishes the decision-making model of resident behavior though the following three steps: the equations of behavior value and behavior eco-efficient are the first step based on Value Engineering Theory and Complex Adaptive System Theory, followed by the design of the survey questionnaire, and finally comes the decision-making process. At last, the paper introduces the result of questionnaire of Yanhe village demonstration, which could help make resident participative policies and accomplish construction projects of energy-saving and pollution-reduction community in developing countries.

1. Energy-saving and Pollution-reduction Community (EPC)

Energy-saving and pollution-reduction community (EPC) is a new residential district model with high resource efficiency, low environmental impact and comfortable eco-health. Compared with traditional community, EPC focuses on energy-saving and environment-friendly factors during its whole life cycle and emphasizes resident participation in order to reduce emission and domestic waste, raise resource value, decrease operation and management cost with the principles of sustainability and human-orientedness, which is a new development trend of human settlement at the beginning of the 21st century.

1.1 Cognition Evolvement of Energy-saving and Pollution-reduction Community

In western counties the research and demonstration of sustainable buildings and green communities have been advancing from 80s of the 20th century. The latest development of relative theories and technologies in green community field is beneficial to China. With rapid economic growth and urbanization in past decades in China, it's urgent to find a new development way to harmonize environment with economy. Under these circumstances, the cognition evolvement of EPC construction could be divided into three stages in China:

Stage one (1976-1999): increase living space per capita; improve building environment quality; raise performance-price ratio of housing. Although the construction criterions of energy-saving building were enacted in the regions not only with hot summer and cold winter but also with hot summer and warm winter, there were few feasible indicators and assessment methods. Housing construction is focused on quantity rather than quality. Problems between environments and buildings attracted extensive attention.

Stage two (2000-2005): build the society of resources-saving and environment-friendly; issue energy conservation law and relative provisions, technical criteria and standards; demonstrate pilot projects in the fields of green building, eco-building and sustainable building. During this period, there are 1 billion M^2 newly-built housing p.a., and newly-built housing and existing residential building keep the ratio of about 1 to 44 according to the statistics provided by Ministry of Housing and Urban-Rural Construction, the People's Republic of China. Only 3% of existing residential building and 5% newly-built housing are in accordance with the national energy-saving standard. Housing construction was focused on buildings rather than communities.

Stage three (2006-present): promote public energy-saving and pollution-reduction activities for building the society of resources-saving and environment-friendly after a series of severe environment pollution events of Taihu lake in Jiangsu province, Cao lake in Anhui province and Songhua river in northeast China; put forward quantitative indicators and quantitative environment management procedures after the compulsory targets of reducing energy consumption per unit GDP by 20% and total emission of major pollutions by 10% compared with that of 2005 are set in the outline of 11^{th} Five-year Plan for National Economic & Social Development of the People's Republic of China. Housing construction in the way of energy-saving and pollution- reduction is focused on both governance and public participation.
At present, EPC is the major long-term foundational task for building the resources-saving and environment-friendly society. Unlike the old mechanism that the government acts as the only leading agent, a new mechanism is formed for the cooperation among social power including government, enterprise, NGO and residents. EPC construction is actualized by bottom-to-up and up-to-bottom management.

1.2 Challenge for Constructing Energy-saving and Pollution-reduction Community

Up to 2020, there will be 68.6 billion M^2 building in Chinese cities, towns and villages (26.1 billion M^2 in cities and towns; 42.5 billion M^2 in villages) and housing will exceed half of the amount of these buildings. The construction of EPC will face the following challenges:

Challenge 1: contradiction between the rigid demand of increasing living space per capita and the resource consumption and pollution of developing construction industry.

The demand of increasing living space per capita is rigid with population explosion in China. Now our construction industry have many problems in waste on construction material, low efficiency of reclaiming refuse, high consumption and poor utilization of construction energy, short life cycle of existing housing, durative pollution of chemical, physical emission and greenhouse gas, and inefficient investment.

Challenge 2: contradiction between the limited affordable cost of constructing EPC with the background of developing economy level and the accessible multi-function of improving human settlements

With deteriorating environment quality, the public pays more and more attention to man-made environment for better living conditions. Building and infrastructure is physical base of community as the man-made environment in order to supply the space of residential, recreational and working function. The energy-saving products and material, or equipments with new energy are usually expensive without the support of mature relative industry system. It's crucial to find the satisfactory multi-function of EPC for residents considering their economic level.

Challenge 3: contradiction between the participation willing of residents in EPC and the lack of leading mechanism.

Faced with more severe environment pollution, the ignoring attitude is abandoned. The voluntary environment management and preventing treatments are carried into execution. People realize their interactive effects in EPC. For example, the total energy consumption of household electric appliances, such as heating, lighting, refrigeration, cooker and so on has been rising year after year, which is determined by residents. However, there are few approaches and legal rights for residents to participate in final environment decision-making.

2. Resident Behavior System in EPC

Residents play an important role in the construction process of EPC. For example, residents' needs could guide the choice of materials and products, their behaviors could determine the eco-efficiency, and their knowledge could influence the operation and management. The resident behavior system in EPC discusses what residents could do for the construction of EPC. This system is composed of time subsystem, space subsystem and available resource subsystem.

2.1 Time Subsystem

The time subsystem refers to the life cycle of construction projects in EPC, see figure 1. EPC construction is composed of a series of energy-saving and pollution-reduction projects. Residents should participate in these projects and their behavior should help projects construction in adaptive and accessible way. Referring to LCA, a project's life cycle is composed of four stages: planning and design (T_1), civil engineering construction and decorating (T_2), operation and improvement (T_3), demolish or renewal (T_4). Resident behavior should be suitable for the characteristics of different stages during life cycle of project in EPC (Peter 2004).

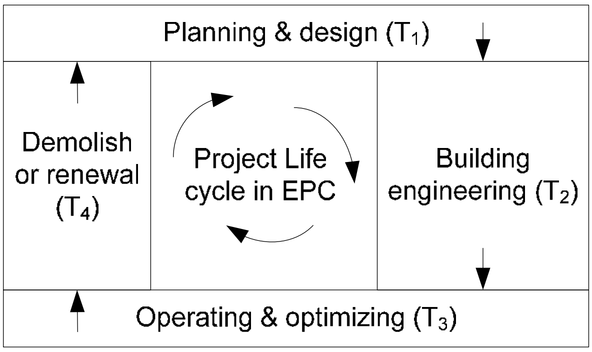

Figure 1 Life cycle of construction projects in energy-saving and pollution-reduction community (EPC)

2.2 Space Subsystem

The styles of building in China are mostly multistoried and high-rise, and residents have ownership and membership according to the Property Law and the land public-owned system of socialism of the P.R.China. Generally, the space of EPC could be classified into three types with the distinguished ownership of building:

Space 1 (S_1): private space of residents. Residents have integrated ownership of S_1 which is private space enclosed by wall, ceiling and floor.

Space 2 (S_2): common space of residents. All residents in EPC share S_2 with other members. S_2 consists of stairway, alley, corridor, common facilities and their chamber etc.

Space 3 (S_3): public space of residents. Residents in EPC and others outside EPC share the public ownership of S_3. Examples of S_3 are land, water, forest, mine, energy, biology, and climate.

2.3 Available Resource Subsystem

For residents in EPC, there are two kinds of available resources, natural resource and other resources from man-made factors including social, economic, environmental fields by labor. Available resource system is composed of natural resource, social resource, economic resource, and environmental resource. The major task of resident behavior during EPC construction is to enhance the function of environment resource with natural resource, economic resource and social resource. See figure 2.

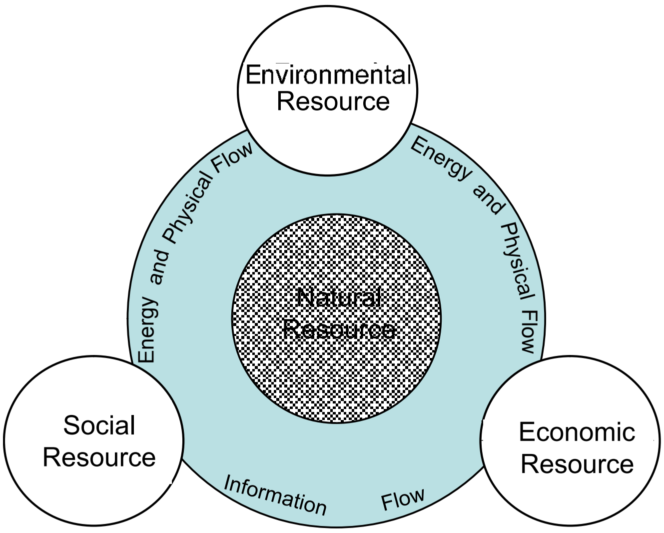

Figure 2 Four sub-subsystem of available resource subsystem for residents in energy-saving and pollution-reduction community (EPC)

Environmental resource sub-subsystem will reduce the quality and utility of living and result in uneconomical outputs if the eco-balance is destroyed. For residents in EPC, it should include outdoor and indoor water environment; air environment; noise, light and heat environment; green environment and sanitary environment.

Natural Resource sub-subsystem is the core and foundation of this subsystem. Residents in EPC should know the information about their resource occupation per capita and distribution, quantity, quality of natural resource.

Economic resource sub-subsystem takes natural resource transform with industry in order to form products and services that realize value by exchange. For residents in EPC, the stability and sustainable increase of their income should influence the utilization mode of natural resource, their understanding on cyclic economy and clean production should form information flow according to local natural resource and environment.

Social resource sub-subsystem affects human being in a nonmaterial way. This is the necessary support to ensure the transform from natural resource to economic resource. Natural resource is only pure natural substance and has no meaning for human being without social resources. For residents in EPC, it should include legal rights, cultural and customs, education and training, social welfare, and social equality.

2.4 Behavior Planning

The participative behavior, as shown in table 1, should be planned with resident's available resource responding to the time and space (F Yang et al. 2006).

Table 1 Behaviour Planning of Residents in EPC

Behaviors	S_1	S_2	S_3
T_1	Evaluate obtaining cost Analyze spatial form Belong to stratum	Make resource planning Enjoy open space Identify key environment factor	Assess resource occupation per capita Participate benefit distribution Harmonize whole social and environmental system
T_2	Develop new energy Choose recycled material Fix energy-saving facilities	Consume energy Survey infrastructure Implement green construction	Increase resource value Preserve culture and custom Operate living environment
T_3	Utilize Water, electricity, gas, heat and so on Clean pollution origin Make living water	Collect classified garbage Cooperate water recycle Integrate social organization	Appeal public service Maintain environment quality Educate and publicize Form social net and alliance
T_4	Recycle material Protect natural resource Endow legal rights	Assess environment risk Prevent pollution Keep health and safety	Keep social stability Claim protection and renewal Increase economic value

3 The Decision-Making Model of Resident Behavior

3.1 The Behavior Value of Resident

The behavior value of resident could use the following equation of function and cost referring to value engineering theory.

$$V = \sum_{i=1}^{n} V_i / n = \sum_{i=1}^{n} \frac{\sum_{j=1}^{4} \beta_j F_{ij}}{\sum_{j=1}^{4} C_{ij}} / n = \sum_{i=1}^{n} (\beta_1 V_{i1} + \beta_2 V_{i2} + \beta_3 V_{i3} + \beta_4 V_{i4}) / n \qquad (1)$$

Where:

V denotes average level of residents' behavior value in EPC including behavior value for environmental resource (V_{i1}), behavior value for natural resource (V_{i2}), behavior value for economic resource (V_{i3}), and behavior value for social resource (V_{i4})

n denotes the quantity of residents in a EPC, $i = 1, 2, \cdots\cdots, n$

β_j denotes the coefficient for corresponding function, and $\beta_1 + \beta_2 + \beta_3 + \beta_4 = 1$

F_{ij} denotes the function of one resident's behavior for one of four resource sub-subsystem, $j = 1, 2, 3, 4$

C_{ij} denotes the cost of one resident's behavior for corresponding resource sub-subsystem.

According to this equation, the behavior strategy of resident could be divided into three types, as is shown in table 2.

Table 2 Three Behavior Strategy of Resident in EPC

Behavior value	Behavior function	Behavior cost	Behavior strategy
V>0.6	increase	maintain or decrease	cooperation and participation
	maintain	decrease	
	decrease	substantial decrease	
	substantial increase	increase	
V: 0.4-0.6	decrease	decrease in same scale	In energy-saving and pollution-reduction way
	increase	increase in same scale	
	maintain	maintain	
V<0.4	decrease	Maintain or increase	nonparticipation
	maintain	increase	
	substantial decrease	decrease	
	increase	substantial increase	

Referring to the outputs of the National Key Technologies R&D Program of Tenth Five-Year Plan (2005BA807B08), which is named "Study and demonstration for construction techniques of eco-building in different areas of China", the following survey questionnaire for residents is used to assess their behavior value.

The survey questionnaire is composed of four parts with 45 items.

Part 1: satisfaction of environment renewal.

This factor consists of 26 items that focus on behaviors of indoor and outdoor environment renewal, which also displays that residents should participate in these emphases of EPC construction. There are 14 items for residents to assess their behavior value of indoor environment resource renewal as follows: building design, engineering quality, room arrangement, heat preservation, heat insulation, water supply, waste treatment, ventilation, window lighting, winter sunlight, energy for living, noise, new energy, and facilities. In addition, there are 12 items for residents to assess their behavior value of outdoor environment resource renewal including: community planning, transport arrangement, building characteristic, information construction, air quality, green place, pollution origin, sanitation, infrastructure, garbage collecting, new energy, and equipments.

Part 2: achievement of preserving natural resource.

This part has 7 items describing achievement of preserving natural resource by resident behavior including: land, water, forest, mine, energy, biology, and climate. Residents should understand the signification of natural resource first. Their attention determines the sustainable development of public space. The site testing data also help them acknowledge the problems and the progress before accomplishing these items.

Part 3: influence of improving economic resource.

There are 6 items in this factor that examine the influence of improving resident's economic resource after EPC construction including: employment, business, individual income, family income, family expenditures, and private investment. We should construct win-win EPC to replace the traditional community that wins economy and loses environment.

Part 4: ability of management and service.

In this part, there are 6 items including community management, service level, communication space, safety management, intercourse, and sense of place. There will be stronger links among EPC. This factor could guide resident behavior to partnering. Residents should share the information during the whole life cycle and join relative organization.

Every item is rated on a scale from 0.2, 0.4, 0.6, 0.8 to 1 as the representation of inefficacy, unobviousness, usefulness, obviousness and upgrade. Residents assess according to proposed indicators and give specific values. The preference of 4 factors is confirmed by resident willingness.

3.2 The Eco-Efficiency of Resident Behavior

According to environmental sociology, it's necessary to discuss the relation of resident and environment. We have looked at how to assess the behavior's value and the environmental impact together. As agents of EPC, residents' adaptive abilities to surroundings affect EPC sustainable development as complex system from bottom to top based on Complex Adaptive System (Stephen et al. 2002), see figure 3.

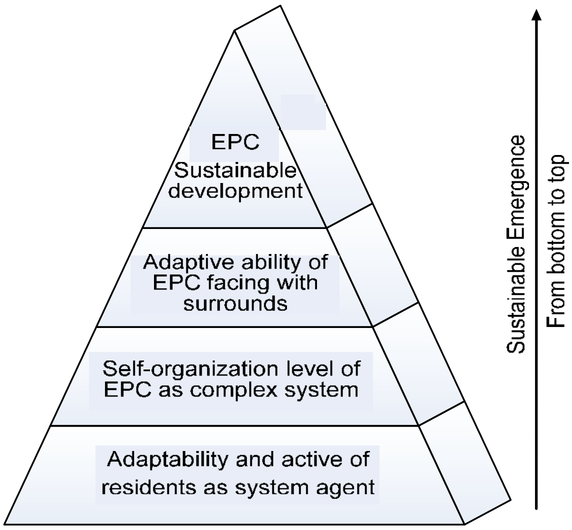

Figure 3 The sustainable emergence of EPC from bottom to top based on Complex Adaptive Theory

So far, BEE proposed "Eco-efficiency of Behavior = Environmental Impact / Behavior Value" for the basis of assess the eco-efficiency of resident behavior. This can be explained in the following equation:

Suppose $V \geq 0.4$, then

$$\text{BEE}=\sum_{i=1}^{n}\beta_1 V_{i1} / \sum_{i=1}^{n} V_i = \sum_{i=1}^{n}\frac{\beta_1 F_{i1}}{C_{i1}} / \sum_{i=1}^{n} V_i \quad (2)$$

The value of BEE is higher, and the contribution of resident behavior for their environmental resource renewal is more outstanding. The levels and comments of BEE are shown in table 3.

Table 3 Levels and Comments of BEE

Classification	BEE	Comments
1	>0.5	Alert level and residents must find new economic development way to sustain current environment
2	0.25～0.5	Good level and residents should pay enough attention on eco-education and information gain
3	<0.25	Worse level and residents ignore environmental resource value

3.3 The Decision-Making Process of Resident behavior

Benefit-oriented principle of resident behavior is the basic power to push EPC construction. The essential model of resident behavior is if something could do good to individual sustainable development, then residents enter project partnering system (Chan and Tam 1996). This principle and model show that the goal of resident behavior is to become adaptive agent facing with environment changed at every moment. In detail, the goals include: pursuing reasonable economic return, social return and environmental return. Residents could update the surrounding information and adjust behavior regular with accumulated and learnable information during the continual decision-making process.

For residents, the first phase is to learn and know the surroundings after gathering sufficient information by site exploring, questionnaire, interview, meeting etc., to analyze problems of EPC with arranging and comparing information; the second phase is to make behavior planning if problems are identified and observed. If residents ignore the problems considered by experts, residents wouldn't participate; the third phase is to renew environment by implementing behavior planning; the fourth phase is to assess their behavior value, their obtained function and their corresponding cost; the fifth phase is to enter project partnering system with owned resource if the ratio of function to cost is more than 0.4 (Eddie et al. 2002; Cheung et al. 2000); the sixth phase is to assess eco-efficiency of EPC and analyze new problems of next process if the previous process takes effect for upgrading eco-efficiency. However, residents will give up participation in EPC construction if there has no effect or downgrade eco-efficiency of previous process. See figure 4.

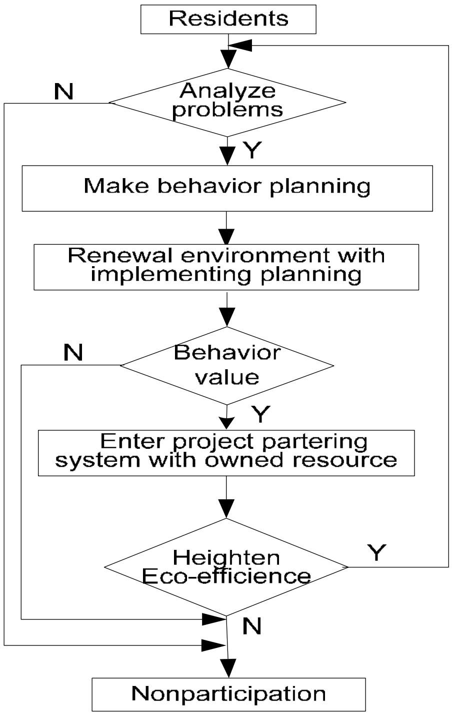

Figure 4 The decision-making process of resident behavior

4. Demonstration of EPC construction in China

4.1 Introduction of Demonstration Place, Yanhe Village

Yanhe village is located in mountainous area in Xiangfan city of Hubei province, China. It has 12 million M^2 land including 7.33 million M^2 forest, 0.64 million M^2 basic farmland, 0.66 million M^2 tea garden, 0.07 million M^2 construction land 0.01 million M^2 water area and other land. There are 242 families with 867 farmers. The main industry is agriculture, tea industry and eco-tourism. Yanhe village has developing economic level with a GDP of 10 million RMB.

Figure 6 Views of resident resource in Yanhe village (2008)

4.2 Making Behavior Planning

Combined with the result of site observation, interview and questionnaire, the behavior planning of residents is advanced with time subsystem and space subsystem, which is shown in table 4.

Table 4 Behavior Planning of Residents in EPC

Behaviors	S_1	S_2	S_3
T_1	Evaluate obtaining cost	Identify key environment factor	Harmonize whole social and environmental system
T_2	Develop new energy Fix energy-saving facilities	Consume energy	Increase resource value
T_3	Clean pollution origin	Integrate social organization	Maintain environment quality Educate and publicize
T_4	Protect natural resource Endow legal rights	Assess environment risk	Increase economic value

4.3 Assessment of Behavior Value and Eco-efficient with Questionnaire

In Yanhe, 50 questionnaires are delivered and 36 effective questionnaires are received. Then the numerical datum should be gained by above method, for example, n=36; the result of waste treatment item is 23.1% of 0.2 value, 7.7% of 0.4 value, 26.2% of 0.6 and 43.0% of 0.8. the value of this item is 0.826; what' more, 44% residents select environment resource as preference and then β_1 =0.44; in the same way, β_2 =0.13, β_3 =0.37 β_4 =0.06; then this paper accounts all 45 items of 36 residents with same way, behavior value is 0.572 and behavior eco-efficiency is 0.541. The results point out that Yanhe village is in energy-saving and pollution-reduction way and should find new economic growth power to sustain current environment in next behavior planning.

5. Conclusion

Residents' behavior should be conducted and enabled for long-term operation of EPC. This paper discusses the process, decision-making and eco-efficiency of resident behavior during EPC construction to find key factors, which help to make resident participative policies and accomplish construction projects. Resident's participation in EPC construction is significant both in developed countries and developing countries. Next, the following measures should be instituted: standard indicator of assessing behavior value has to be established by government or industry associations; the active participation of the community organization is encouraged; more education and training should be given to residents.

This paper is based on outputs of Chinese national key program "Study and Demonstration on Construction Techniques of Eco-building in Different Areas", and supported by Chinese national key program (2006-2010) on hand in Yanhe village, China.

LAND PROPERTY DISTRIBUTIONS AS A MEANS FOR ENHANCING SUSTAINABLE BUILDING.
THE LUNDBY COMPETITION IN GOTHENBURG, SWEDEN, AS AN EXAMPLE

Summary

This paper refers to an evaluation of a land property distribution competition arranged by the City of Gothenburg, Sweden. The competition aimed at combining high quality housing with energy efficiency, healthy indoor climate and cost efficiency proved in plans for management during ten years. About thirty-five firms showed interest in the competition and eight entries were delivered. The assessment was carried out in three steps. 1. An expert committee selected those entries that fulfilled the program goals. 2. The jury ranked these entries. 3. Following the order from the ranking, the jury assessed the financial and managerial capacity of the delivering firms. The outcome was that the two highest ranked proposals were delivered by serious developers. The results show that ambitious environmental qualities can be combined with economic goals. The dividing lines between the entries did mostly concern architectural qualities. Interviews have been carried out among a number of the competitors, the expert committee and the jury. The answers indicate that the competition process was well managed. A well-defined program and a transparent assessment are important instruments. Hence, the land property distribution instrument can be useful for municipalities for initiating sustainable building.

1. Introduction

The aim of this paper is to present a case in a larger research project about the impact of demonstration projects on the general practice concerning sustainable building (Edén et al. 2005). The case will be discussed in a governance perspective (Femenías 2008). Finally, the experience will be formulated in some advice for land property distribution competitions.

The background is that the building sector has been regarded as slow in the transition towards sustainable building. Some explanations are that the sector is heterogeneous and complex, consisting of a large variety of actors who work together in projects that are more or less unique. The built environment is one of the most long-lived artifacts in society and provides a most varying technical and cultural context. Hence, the uses of uniform legislative instruments have been found difficult to implement. However, the public sector can contribute to the development in many other ways. Authorities can act as large real estate owners, and managers of procurement. Municipalities can act through spatial planning but also as landowners. Land property distribution is a situation in which a city can negotiate with developers and, thus, by demanding certain qualities contribute to the implementation of new measures, for example measures about sustainable building (Stenberg 2006).

The city of Gothenburg made an open invitation for a land property distribution competition concerning sustainable building in the Lundby area in 2005. The result from this competition shows that the market has capacity to build good, cost-effective housing with much better energy efficiency and environmental qualities than what has been the general practice. This can be interpreted in one way that the sector is “slow”, but it also shows that the sector can act innovative in certain situations (Rubino 2007). Land property distribution processes can, therefore, be used as situations for better building practice, both on general level and is special, future oriented competitions.

2. Preparatory phase

2.1 A political initiative

The process started in 2003 with the submittance of a motion in the city council. The motion proposed that the city should complete an “urban eco-village” in order to set a learning example for the building sector. The motion was passed and the assignment was given to the property Management Office and the Town Planning Office. These offices invited Chalmers University of Technology for an open discussion about the project. The recommendation from the researchers was that the city should make an inventory of "ecological experiments in the city in order to get a platform for the ambitions in a new initiative.

2.2 A pre-study

The inventory showed that there were quite a few projects in Gothenburg and its close neighborhoods dealing with sustainability issues. However, all of them had not been evaluated, and the overall knowledge about them was poor.

The aim of the inventory was to spread information abut existing projects and to learn from them and use the learning as input in forthcoming projects. One important finding was that many projects were diffuse regarding the goal settings and evaluations. Some could be characterized as "green catalogues" with a lot of innovative devices but without any plan for evaluation of the experiments. Others were focused one, limited aspect, only energy or only materials for example, and also not very innovative. In order to find a platform for new, both "realistic" and "innovative" projects the author needed to formulate a framework, consisting of three "ambition levels" The levels were used both concerning technologies and processes. Among the projects some represented available technologies in experimental design processes while others represented innovate technologies in ordinary deign and procurement processes ((Thuvander 2004, Femenías 2004).

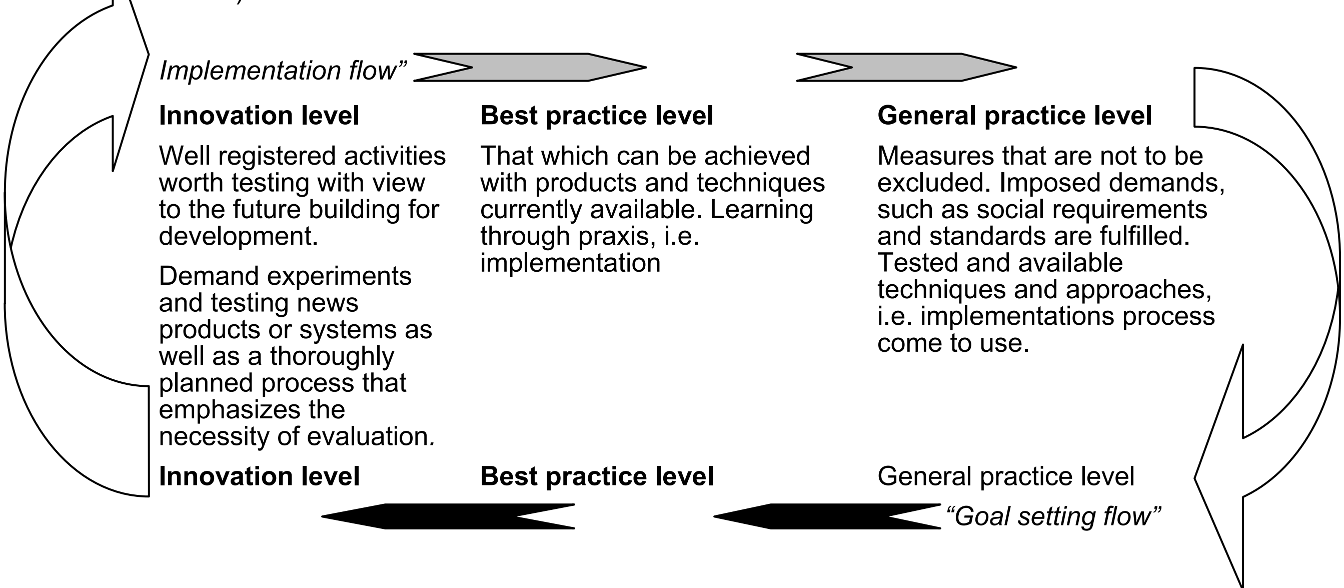

Figure 3 Ambition levels in a project There are two important "flows" from projects. The "implementation flow" (grey arrows) means that acquired knowledge from experiments will develop the sector, first in demonstration projects and when these are evaluated become general practice. The "goal setting flow" (black arrows) means that if the general practice is insufficient you need demonstration projects to begin with in order to develop better practice. If there is a lack of products or systems for necessary problems experiments need to be carried out. Both "flows "can be present simultaneously. The bows indicate that the boundaries between the "ambition levels" are changing over time. Hence, some of the projects in the report were innovative when they were accomplished, but represent "best practice" or even "general practice" today.

In figure 3 you can see that there is a general practice with more or less self evident qualities that should not be neglected. The best practice level contains measures that are available on the market, but in one way or another needs extra efforts to be accomplished. The innovation level consists of un-tested measures that have to be designed as parts of a regular experiment, with clear aims and a plan for evaluation. One important difference between "best practice" and "experiment" is that an experiment is allowed to fail, while a best practice project should have goals that can be reached and with the aim to demonstrate that what can be reached without the risk of failure. The conclusion of the pre-study was that if the city should launch a competition with the aim to set a learning example for practitioners the level should at least be "best practice" but also with elements of controlled experiments (Thuvander 2004).

2.3 Writing the competition program

When the report was published, City officials and a consultant started to formulate a competition program. The general aims of the competitions were said to be:

- Proposals for good dwellings with "reasonable" rental costs and a commitment from the proposer for a long term management.

- Proposals for healthy buildings with low environmental impact and contributing to sustainable development.
- Proposals that use experience gained in previous projects, mainly corresponding to the best practice level but allowing defined innovations adaptable to the chosen site. Some of the important features in the program are presented in tables 1-3. (Program 2005)

Table 1 DWELLINGS

Exploitation	No minimum or maximum levels of dwellings were formulated. The reason was that since the proposer should own and manage the area, the proposer had the overview of the total economy. The distribution of flats was, however, set to: 1 room dwellings – 20% 2 room dwellings – 40% 3 room dwellings – 20% 4-5 room dwellings – 20 %
Design	The design shall mirror the special prerequisites in the site and in the project aims
Functions,	The buildings codes shall be followed
Accessibility	The special codes shall be followed
Safety	The guidelines from the police in shall be followed
Use	The systems and the structures shall be robust and easy to maintain. Special attention shall be paid to community activities

Table 2 ENVIRONMENT

Health, indoor environment	The dwellings shall be certified according to the “P-mark” system. The P-mark is defined by SP, the Technical Research Institute of Sweden and comprises: Thermal comfort Air quality Emissions from materials Ventilation Moisture safety Air tightness Acoustics Light Water quality Management and control (P-mark 2008)
Materials – waste	Smallest possible impact
Energy	Not more than 90 kWh/m^2 year The proportion between heat and electricity shall be showed in “e-norm” calculations A plan for following the energy use during the management shall be presented
Water	The systems shall be deigned to ensure a resource efficient use of Drinking water Storm water Water for sewage

Table 3 ACCOMPLISHMENT

Commitment	The area shall be a part of the company’s normal housing stock for ten years. During this period the “P-mark” features shall be maintained
Costs/rental costs	The yearly costs shall be presented for year 1 and year 10 concerning Capital costs Energy costs Water costs Maintenance costs Other costs
Documentation – evaluation	The proposer shall formulate a program for following: The use of energy and water The usability Costs for management and maintenance

3. Competition phase

3.1 Interest

The competition gained interest from about 35 companies. Of these, 8 delivered entries

3.2 Jury

The jury consisted or the political board of the Property office. The jury appointed an expert committee for detailed analyses. The committee consisted of officials from the Town planning office assessing the dwellings; researchers assessing the energy calculations and indoor climate; consultants assessing the cost calculations and program for management. The committee also made a joint, holistic assessment of each entry. The authors of this paper were all members of the expert committee.

3.3 Assessment structure

The environmental, technical and economical assessments followed an elaborated matrix with about 50 different checkpoints. The architectural assessment used 18 aspects. The analyses were grouped into three main themes.

3.3.1 Area/dwellings

The area and its relation to the surrounding urban patterns
The buildings and efficient use of space and volumes
Standards and functionality of the flats
Standards and functionality of common spaces and outdoor functions
Design and function of the outdoor spaces
Accessibility, safety and usability

3.3.2 Environment

Health, indoor environment
Materials/ waste in relation to resource efficiency and ecocycles
Energy use in relation to resource efficiency and ecocycles
Water use in relation to resource efficiency and ecocycles
Adaptation to local conditions

3.3.3 Accomplishment and management

Rental levels and annual costs
Documentation and evaluation
Quality assurance and environmental work during the productions phase
Rental levels and annual costs
Quality assurance and environmental work during the use phase

3.3.4 Overarching aspects

The basic requirement is well designed dwellings and buildings with efficient use of plans and volumes. Proposals that are possible to accomplish will be selected, those that are assessed to contribute most to sustainable development will be ranked.

3.4 Two steps

The first step consisted of the selection a ranking of anonymous proposals. Before announcing the result the jury opened the envelopes following the ranking list in order to test the proposers' ability to fulfill the requirements for at least ten years of management. The procedure can be described as an architectural-technical competition in step 1, while step 2 is a test of the capacity of the owner.

3.5 Results from assessment step 1

In general, the entries were well worked out and comparable. Some characteristics are shown in table 4. Table 4 also shows some of the difficulties in the program. One was the varying exploitation, which still did not seem to have had too much impact on the final rental cost. All rental levels could be said to be “normal”. The second was that the tool for energy calculations could be interpreted in more than one way. The developer of entry H made the effort to demonstrate this for the jury.

Table 4 SUMMARY OF ENTRIES

Entry	Exploitation (flats)	Calculated Rent (SEK/m^2 year)	Energy (kWh/m^2 year)
A	70	1100	81
B	120	Not shown. Annual cost 1337	Not shown Ambition 105
C	72	1270	67/88
D	75	1160	67
E	59	1195	64
F	45	1150	Not shown
G	64	1095	Two calculations one with faults. Own system 83
H	101	1250	Two calculations 99/113 or 59/67

Very soon the entries could be divided into three main categories. A "top", consisting of two proposals, A and D, which fulfilled all qualities. A "middle", consisting of three proposals in with just one or two weaknesses that needed improvement, C, E and H. A "bottom" consisting of entries that did not fulfill goals or with severe weaknesses in the architectural approach, B, F and G. In this stage the discussion mostly touched architectural matters, since the technical and economical conditions were more or less solved or solvable in the proposals. The expert committee delivered their ranking as in table 5.

Table 4 RANKING OF THE ENTRIES

Category	Entry	Comments
Top	A	An experimental ventilation system, but since the developer accepts the P-mark, the system will be tested
	D	Prepared for PV:s and alternative sewage system.
Middle	C	Nice scale but a problematic high rise building, probably included in order to raise the exploitation
	E	A scale that was a little awkward on the site and lack of landscaping details
	H	The exploitation has lead to a parking garage and a density that gives unacceptable shade conditions in the outdoor areas.
Bottom	F	Almost a "middle grouper" with a nice scale and functional flats. However lacking important information about energy and details
	B	Weaknesses in the gardening design and in interior plans. Important calculations are missing. The energy ambition not sufficient.
	G	Lack of architectural qualities in both outdoor and interior deign. Calculations not credible

From tables 4 and 5 it becomes evident that there has been no contradiction between "soft" architectural - environmental qualities and "hard" technical – economical qualities. The pattern is evident, the top category consists of the entries that are in fulfill all qualities and where the final ranking depends on the differences in the architectural design. The middle category consists of entries that fulfill most of the important goals, and that can be adjusted concerning some weaknesses in he architectural design. The third category consists of entries that need to elaborated concerning both "soft" and "hard" aspects.

3.6 Final assessment

The jury accepted the categories delivered by the expert committee. In the final ranking the jury prioritized proposal A because the urban approach was judged to be the most appropriate according the urban qualities in relation to the surroundings. After the all envelopes were opened following the ranking order. Both entry A and D were found to be delivered by developers with sufficient managerial capacity. Entry A was, therefore, received the right to develop the site. The prize sum was after that given equally to all the delivered entries.

4. Evaluation phase

4.1 Interviews

After the competition most of the participators, also some of those who did not deliver a proposal have been interviewed (Skuflic' et al)

4.2 The report with prior projects

The report has been said to be both informative and inspiring. Some competitors interpreted it as a signal that the competition had its focus on environmental aspects.

4.3 The program

The main tendency is that the program was very clear. The goals were reasonable, although they were ambitious and required lots of work. Some participators meant that the mixture of sometimes fixed and sometimes open goals provided difficulties. Open aspects were the lack of goals for exploitation, the formulation "normal" rental costs and only "sustainable" material choices. Fixed aspects were the P-mark, energy balance, safety, accessibility etc. One pattern in the answers is that the architects appreciated the openness concerning the exploitation.

4.3.1 Energy

The target value of 90 kWh/m^2 year is by some regarded as too tough and by others too generous. As a comparison you can mention that the building code allows 110 kWh/m^2 year, while the best examples in the pre study had reached 50 – 80 kWh/m^2 year. Furthermore. the building code does not include energy for domestic electricity use, while the measured use in the examples include all use of energy. One participant would have liked division between use of heat and use of electricity. The calculation method were questioned by many, even if they understood that it is a common tool, which is fairly easy to use.

4.3.2 P-mark

Not all were familiar with the method. Those who are used to it means that it functions well and ensures quality. The P-mark harmonizes with the building code; the only difference is the demand for annual controls. For those who were unfamiliar the requirement meant efforts in learning. Some entries did not show how the P-mark was met, only made a statement that it should be reached if they got the opportunity to continue their project. One meant it that it was so self-evident that it did not need to be mentioned in the entry.

4.3.2 Rental costs

Some participators asked for more precise target values, but it has not seemed to be an important issue.

4.3.3 Management

The requirement that the company should own and manage the area for ten years was appreciated by most of the respondents. Some architects appreciated it very much, since the requirement calls for long term thinking and makes it easier to argue for the use of life cycle cost instruments. The requirement meant more work for both architects and developers, but many appreciate that documentation was required, because that had made the competition into learning project. It had, however been easier to deliver the documentation if some kinds of common guidelines had been introduced

4.4 Learning

The pre-knowledge among the competitors differs. Two architects belong to the pioneer generation in Sweden, and have completed several experiments and demonstration projects since the 1980-ies (entries C and D). Three managers have experience from energy efficient projects (entries D, E and H). Neither the manager nor the architect behind entry A had worked with sustainability issues before, but engaged a engineer with an overall environmental experience as a partner.

With the exception of small remarks all participators have shown confidence in the expert committee and the jury. The assessment and the ranking have been accepted. On the other hand, many wanted more feedback. The written assessment and the prize ceremony resembled an ordinary judgment in an architectural competition. The assessment document should have given more thematic comparisons. One respondent would have liked weights to difference aspects.

4.5 Economy

It costs to participate in a land property distribution competition. The respondents still claimed that the prize had no importance; the learning and the opportunity to market the company towards the city were the main reasons for participation. A prize gives legitimacy to a competition and in this case it gave at least some pay-back to the participators, roughly half of the costs. Also, the assessment procedure has been costly for the city, with about eight specialists working at least one month each in the assessment.

4.6 Those who not fulfilled

And what happened with the other 27? The reasons for not fulfilling the competition are mainly two, lack of time and, for consultants, difficulty to find a developer. Some answers indicate that an ambitious competition like this one is impossible for Small or Medium sized developers. Those people would have preferred a procedure with an architectural competition as a first phase. One of these SME:s put a lot of work into a proposal, but came to the conclusion that the program was too conventional and meant the experts in the committee represented conservative thinking.

5. Discussion and conclusions

Four questions will be discussed: First of all, a more general one, about the obstacles for implementing sustainable building. Secondly, competitions as means for learning. Thirdly, land property distribution competitions as governance. Fourthly, the relation between "hard" and "soft" measures.

5.1 Obstacles for sustainable building

From the Lundby competition you can draw the conclusions that "costs" or that "it costs" is not an obstacle for sustainable building. At least not as long as the investments are made by managers with a long term perspective. Lack of knowledge and experience is a more credible obstacle. Many of the participators, including the winner, had never before been asked to fulfill goals similar to the Lundby program, but had managed to fulfill the goals. There is a threshold in the sector, which is that many firms have to make a first time investment in learning. Any project can be the base for learning, as long as someone sets goals and the project team together work to reach the goals.

5.2 Land property distribution competitions as means for learning

The land property distribution process has many possibilities to initiate such investments in learning. If a city formulates conditions for the distribution that are proven to be achievable, also the inexperienced developer is willing to learn in order to stay on the market. The learning can, thus, be imposed on the consultants, but the efforts and costs can also be shared by a team. Land property distribution competitions represent a costly procedure for all participators. On the other hand, such a competition results in a "real" and "realizable" project and can, therefore, be used regularly in order to push the market a step further from ingrown routines. The "ordinary" land property distribution can, of course, also contribute to learning, if there is a policy or similar instruments that contain certain qualities that shall be reached.

5.3 Land property distribution competitions as governance

The "governance" perspective can be said to consist of three elements, governance, standardization and visibility (Femenías et.al. 2008, Gram-Hanssen 2008). The Lundby competition is interesting in all perspectives. 1) Governance: It represents a new kind of cooperation between public and private stakeholders. 2) Standardization: It contains new standards and tools for assessment, although on a local level. The process also legitimizes the concept of sustainable building as a "general" and not "special" practice. 3) Visibility: Finally it contributes to visibility, both in measuring performance data but also by building new examples of sustainable housing.

5.4 Competing on "hard" or "soft qualities?

An interesting feature in the Lundby competition was that the competitive ingredients mostly touched architectural matters. When it came to costs or energy the figures were fairly similar and if the calculations were correct there was not so much more to discuss. Some respondents were a little disappointed; they had expected a "competition in ecology". This question is of course crucial but has not given answer. Architecture always is an "open" matter and will always be a dividing line in competitions. But how do you compare a brilliant architectural entry with sufficient energy balance with a conventional architectural entry with an excitingly low energy balance? Can you put weights as one respondent asked for? No! Or – do not try to put weights that compare qualities from different worlds. A system for ranking energy balances and costs could be developed, and criteria for assessing architecture can be developed. But, since weights only can be attached to already familiar features, and since one of the aims with competitions is the birth of unexpected solutions, it seems meaningless to advertise weights in advance, or even use them at all.

5.5 Conclusions – how to use the land property distribution competition instrument

The technical contents can be said to be generic for all building, while the architectural qualities are bound to a local context. A program ought to be clear regarding the differences in these aspects. The Lundby program worked well, but the assessment criteria could have been advertised a little bit more in advance, especially that you cannot compensate lack of basic architectural qualities with low environmental impact, or vice versa. The goal is to unite the "hard", generic qualities with "soft", local ones into one integrated design concept.

The difference between a land property distribution competition and an "ordinary" architectural competition is the aim to create realizable projects without further development of an idea. It means that the goals ought to be possible to reach with available products and techniques; that is the "best practice" level. Demands for innovations and experiments passes a boundary in which research needs to be integrated in the project. The request that entries could contain elements of experiments did not fall out well in the Lundby competition. It might be that the authors were not skilled enough to make relevant suggestions, or it might just as well be an ambition that shall be saved for other types of competitions or assignments.

The conclusion is that the "normal" land property distribution can very well be used in raising the qualities in "general practice". In Gothenburg, the Property management committee has used the experience from the Lundby competition in a policy for all coming land property distribution processes.

The competition form should be used when there are good reasons to renew a policy or to set examples for new standards on the "best practice level." Currently, two years after the Lundby competition there is almost an explosion of passive house projects in Scandinavia, with an energy use down to 50 kWH/m^2 and year. These projects are so many that they very soon could represent a "general practice level". (Passivhus Norden 2008). So, from an energy point of view, there are motives enough for a new land property distribution competition, for example introducing passive standards or even "0-energy" housing. There are more reasons, such as the environmental impact from the material use, new systems for sewage and water treatment, just to mention a few aspects for which a new "best practice" level needs to be visualized and legitimized.

Keywords: Life cycle inventory, forestry, wood products,

Summary

Sustainability imperatives are starting to drive business decisions and government policies. As solutions are sought to growing environmental assessments, it is important to know how much energy, water or chemical has gone into manufacturing a product, and what greenhouse gas emissions or other emissions to the environment have been released in the process. The first national rigorous Life Cycle Inventory (LCI) of representative Australian forestry and wood products and processes was developed to allow the environmental impacts of the production of common engineered timber products and systems to be quantified and evaluated from cradle-to-gate. The Life Cycle Inventory database covers five categories of forestry and wood products: softwood plantation and hardwood native forests; softwood framing and hardwood timbers; veneer and plywood, and LVL; particleboard and MDF; and glulam and engineered I-beams. The coverage target was to obtain data on at least 50% of Australian production in the defined categories to create a Life Cycle Inventory for a wider range (over 60) of commercial forestry and wood products. This paper outlines the development of the Life Cycle Inventory of Australian forestry and wood products and provides some results and benefits.

1. Introduction

Over recent years there has been a growing recognition that consumption of manufactured products affects both resources and the environment (RMIT Centre for Design 1997) and that the production of a product impacts the environment, beginning with the extraction of raw materials, through processing, subsequent manufacturing, use and disposal, as well as all necessary transportation. Business decisions and government policies (Australian Government, Business Roundtable on Sustainable Development 2008) are starting to be driven by such sustainability imperatives. Governments are increasingly incorporating consideration of environmental impacts and sustainable development in policy decisions and are also increasingly holding product manufacturers accountable for their actions. Environmental assessments of products require details of how much energy, water or chemical has gone into manufacturing a product, and what greenhouse gas emissions or other emissions to the environment have been released in the process.

There is little verified life cycle information available on forestry and wood products; and Life Cycle Inventory (LCI) information for wood products is the least well defined in any current Australian Life Cycle Inventory database. Thus, wood products are at a distinct disadvantage compared to other products, such as steel and concrete, as there is no detailed database to provide strategic insight for use in pro-active environmental marketing, process improvement, comparison for product substitution, and, importantly, supply of information for building evaluation tools.

Organisations such as CORRIM in North America have worked with a variety of stakeholders over several years to produce an extensive publicly available Life Cycle Inventory of forestry and wood products in the United States (Wilson 2005). Of the available Life Cycle Inventory data for wood products used in Australia, few are based upon detailed analysis of the Australian forestry and wood products industry. The Life Cycle

Inventory database will ensure the content is compatible with international standards and with an Australian National Life Cycle Inventory Database whose specifications are currently being determined.

A thorough and detailed approach to a LCI for forestry and wood products was undertaken to provide a LCI database of representative wood products and processes used in Australia. Direct detailed input from forest managers, distributors and product manufacturers was obtained to confirm the processes and values used in creating a LCI database of forestry and wood products. This paper outlines the development of the Life Cycle Inventory of Australian forestry and wood products and provides some results and benefits.

2. Life cycle assessment

Life Cycle Assessment (LCA) is described as an objective process to evaluate the environmental burdens associated with a product or process over its life cycle by identifying and quantifying energy and materials used and wastes released to the environment, to assess the impact of those energy and materials uses and releases on the environment, and to evaluate and implement opportunities to effect environmental improvements (Consoli et al. 1993). "Life cycle" refers to all activities from acquisition of raw materials through to product manufacturing, and to the end use of these products and their eventual disposal or recycle, i.e. from "cradle-to-grave". Thus, Life Cycle Assessment quantifies the flow of materials and energy into and out of a system, as shown in Figure 1.

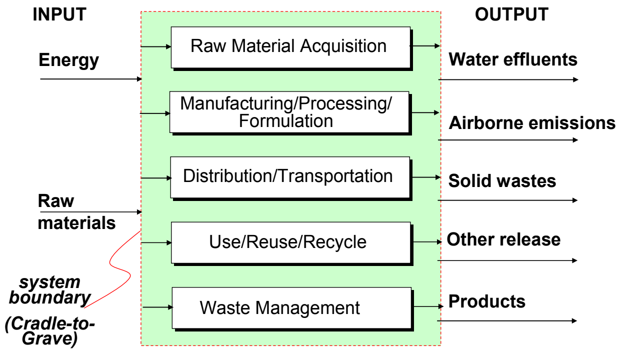

Figure 1 Life cycle assessment flow diagram showing indicative inputs and outputs

According to the ISO 14040 guidelines (ISO 14040 1998) to the Life Cycle Assessment methodological framework, a Life Cycle Assessment shall include four elements: goal and scope definition, inventory analysis, impact assessment, and interpretation of results. The key component is the inventory (known as a Life Cycle Inventory) which contains the values of all the inputs and outputs for relevant activities undertaken to produce a product. It is this information which provides a quantitative basis for comparison of the environmental impacts of building products.

The scope of a typical Life Cycle Inventory includes the inputs and outputs up to the factory gate, i.e. up to when a product is produced for a market as the consequent inputs and outputs depend on the application of that product. In addition, the development of a thorough forestry and wood products inventory results in the industry benefiting through a more advanced understanding of the life cycle of its products and processes.

It is most important to create a Life Cycle Inventory for wood products thoroughly for each type of product to ensure a quality database both for the forestry and wood products industry and for the industries which produce products which compete with wood products. There are established guidelines for creating a Life Cycle Inventory database in the form of the ISO 14040 series of standards (ISO 14040 1998). Currently there is work on setting standards for a wide-ranging Australian National Life Cycle Inventory database (AusLCI) (Tharumarajah, 2005) and all activities on a Life Cycle Inventory for wood products are compatible with this approach.

3. Life Cycle Inventories

Countries in Europe and North America have completed detailed analysis of forestry and wood products in close collaboration with industry and timber research organizations (e.g. Wilson 2005) as have Asian countries such as Japan (e.g. Tsuda et al 2006). Major international research studies conducted on the forest resource (*i.e*. production of logs) and major wood products relate principally to the timber framing of houses and wood building construction (e.g. Seppala et al. 1998 and Kakita et al. 2006)]. Many other counties have adopted their own national standards, as well have developing guidelines for specific industries, an example of which is the American Forest and Paper Association user's guide for the US forest industry (American Forest and Paper Association 1996).

In Australia, there have been a few Life Cycle Assessment studies undertaken for construction and packaging materials. Moreover, these studies did not so much include a full Life Cycle Assessment of wood or timber products but focused on embodied energy for timber products (e.g. Lawson 1996). Todd and Higham (1996) reviewed Life Cycle Assessments of forestry and wood products. Some researchers have tried to compare environmental impacts of wood products with other alternatives using a Life Cycle

Assessment method (e.g. Taylor and van Langenberg 2003). However, these Life Cycle Assessment and Life Cycle Inventories have had very limited work on the detail of forestry and wood products.

One of the key distinctions between Australian and international Life Cycle Inventory efforts has been the lack of coordination, the minimal representation of industry and the insubstantial detail of the final output in Australian databases, almost all of which are held in-house and not made public so that the data collection processes lack coordination and documentation is variable. In other countries, the process of effectively engaging industry has not only led to a comprehensive Life Cycle Inventory database, the process of data collection has also informed industry of the value and use of a Life Cycle Inventory database. As a result the Life Cycle Inventory database becomes a useable resource for industry.

4. Australian Life Cycle Inventory of forestry and wood products

The overall objective was to create the first national rigorous Life Cycle Inventory (LCI) of representative Australian forestry and wood products to enable evaluation and benchmarking of the environmental impacts of wood products for comparison with selected competing products.

4.1 Overview

A Life Cycle Inventory database for forestry and wood products aimed to be of high quality, contain a range of representative products, and be consistent, credible, and demonstrably independent. Practicalities such as focusing on a limited but representative range of wood products, availability of resources, and availability of data meant that many decisions were made on what would constitute a satisfactory Life Cycle Inventory database. The content was compatible with international standards and with an Australian National Life Cycle Inventory Database (AusLCI) whose specifications were being determined concurrently.

The underpinning principle was to obtain substantial industry input into a forestry and wood products life cycle inventory (LCI) database to confirm the processes and values used in creating a LCI database of timber products. The target was to obtain data from those producing between them at least 50% of Australian production in the defined categories. The range of data collected was, of necessity and lack of unlimited resources for its collection, restricted by what data industry had available or was willing to provide or what could be obtained from existing sources. The cooperation of the industry was excellent and resulted in good quality data and desired industry coverage but data collection was slower than anticipated.

The Australian Life Cycle Inventory database covers the following categories of forestry and wood products: softwood plantation and hardwood native forests; softwood framing and hardwood timbers; veneer and plywood, and LVL; particleboard and MDF; and glulam and engineered I-beams.

The data collection was up to the consumption phase for the wood products when sold to a consumer (known as a cradle-to-factory-gate study). This provides an accurate database of Australian wood products for various users to examine a wood product and consider its production history. Most importantly, it provides industry with a reference of production practices and the ability to benchmark and monitor performance over time. A cradle-to-gate study is a practical point to collect data for a Life Cycle Inventory database. For example, beyond this point, the useful life and maintenance requirements of wood products used in a building will depend upon a number of factors, including the exposure to various elements and the use and type of preservatives and paints, all highly variable and not within the responsibilities of producers and manufacturing plants.

While the original aim was to develop Life Cycle Inventories for generic wood products, the detailed data was sufficient to provide information on common categories of the generic products. Table 1 shows the original categories of products and the expanded (more specific) range of products developed for the Australian timber products Life Cycle Inventory database.

Table 1 Products in the Life Cycle Inventory database

Category	Products
Logs - Softwood	Peeler log, High quality saw log, Low quality saw log, Pulp log, Chips
Logs - Hardwood	Peeler log, Saw log, Pulp log
Sawn timber - Softwood and Hardwood	Rough sawn green timber, Rough sawn kiln dried timber, Planed kiln dried timber, Bark, Chips (as sawmill co product)
Plywood	Veneer, Interior Plywood, Exterior Plywood, Formply, T&G Flooring, Structural Plywood (each 3 thicknesses)
LVL	LVL (3 thicknesses)
Particleboard	Raw and Decorated (each 3 thicknesses)
MDF	Raw and Decorated (each 3 thicknesses)
Glulam	Pine, Hardwood
I-beams	OSB web and pine flanges, Plywood web and LVL flanges

4.2 Guidelines, documentation and quality assurance

It is most important to create a Life Cycle Inventory for wood products thoroughly for each type of product to ensure a quality database both for the forestry and wood products industry and for the industries who produce products which compete with wood products. There are established guidelines for creating a Life Cycle Inventory database in the form of the ISO 14040 series of standards (ISO 14040 1998), including ISO 14044 Life cycle assessment — Requirements and guidelines (ISO 14044 2006) and ISO/TS14048 Life cycle assessment — Data documentation format (ISO/TS 14048 2002).

CORRIM generally followed these guidelines in developing a Life Cycle Assessment methodological framework for their studies, but found it is essential to provide very detailed information on every aspect of data collection and process modelling to ensure consistency, compatibility and credibility in meeting the objectives of a Life Cycle Inventory database. Thus, the plan for developing a Life Cycle Inventory database included a preliminary step where standards are set and strict guidelines developed. The development of the Australian Life Cycle Inventory for forestry and wood products was no different.

ISO 14044:4.2.3.1 clearly states that the scope of a Life Cycle Inventory study shall specify the following items: product system to be studied; functions of the product system; functional unit; system boundary; allocation procedures; data requirements; assumptions; limitations; data quality requirements; type of critical review, if any; and type and format of the report required for the study. A quality assurance plan was put in place and data documentation spreadsheets developed in spreadsheet form with accompanying checklists to ensure documentation met ISO standards. Documents setting out the specific guidelines, quality assurance and documentation procedures and the Life Cycle Inventory database relating to the development of the Australian Life Cycle Inventory were prepared. An example of the detailed specifications is the system boundaries as shown in Figure 2.

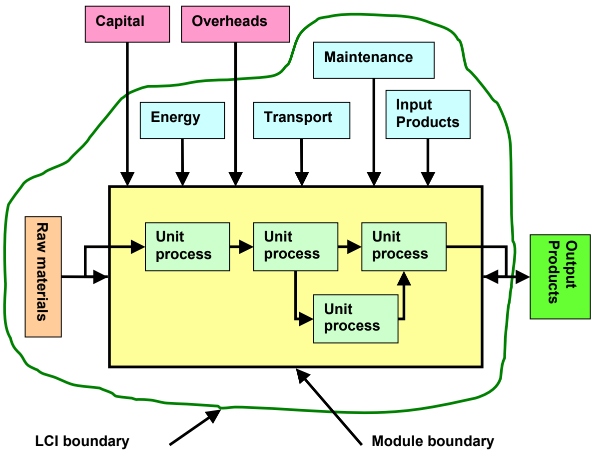

Figure 2 System boundaries for the LCI Timber project

The raw materials in Figure 2 are the materials obtained directly from the environment. The inputs between the Life Cycle Inventory boundary and the module boundary are common or pre-defined processes which can be called upon by any of the inventory product models. The common processes include logs from forests, glues, imported products and materials (glues and timber products such as oriented strand board), energy supplies (electricity, gas, etc), transport modes (ships, aeroplanes, rail, trucks, cars etc) and equipment. The output products include the main product, by-products and wastes.

4.3 Data collection

Survey forms identifying all required data were developed in collaboration with relevant industry input from each of the five areas: forests, sawmills, veneers and plywood, particleboard and MDF, glulam and engineered I-beams. From a comprehensive list of Australian forests, sawmills and wood product manufacturing plants, a list of the industry providers of forestry and wood products who would be sufficient to achieve a target of 50% of Australian production was drawn up and approached for participation in the surveys. Typical forests, mills and plants were visited for visual inspection, initial data collection and identification and understanding of processes.

Six case study regions – softwood plantations in the three States of Australia; and hardwood native regrowth forests also in three States of Australia became the representative sources of forest data. A seventh softwood plantation area was added later in a different State of Australia.

Because of the large number and hugely varying scale of sawmill operations, a sampling procedure was set up to capture data from as many as possible of the larger sawmills (approximately 22 softwood mills and 66 hardwood mills) using detailed data surveys. A simplified data form was sent randomly to a large number of the small sawmills to ensure that data from a full cross section of sawmills were included.

For the remaining plants manufacturing wood products in Australia, in any one category, there are less than ten producing almost all of the production in Australia so plants producing up to 80% of Australian production were approached. Where clear differences in processes among the competing plants could be identified, effort was made to include representatives of each identified type. The resulting coverage is shown in Table 2 for each category of forestry and wood product. Cooperation levels were generally very high and some very detailed data was made available thus ensuring a thorough understanding of the processes, their inputs and outputs and comprehensive maps of the processes.

Table 2 Coverage of Australian production

Category	Proportion of Australian production (approx %)
Forests - softwood plantation areas	60
Forests - hardwood regrowth forest areas	30
Sawmills - softwood	40
Sawmills - hardwood	30
Veneer and plywood manufacturing plants	90
LVL plants	50
Particleboard manufacturing plants	60
MDF plants	80
Glulam plants	53
I-beam plants	65

4.4 Environmental impact modelling

The data inputs and outputs per reference unit (e.g. usually m^3 or m^2 of a standard product) were then averaged for input into models developed in the SimaPro life cycle assessment software (PRé Consultants 2008) for all products except logs from forests where seven individual models were created.

From the visits to forests, mills and plants, comprehensive process maps were drawn up and then related individual processes were aggregated into a small number of processes which became the unit processes required of a life cycle inventory. The selection of unit processes was based on clearly defined steps in the process of producing the output products and influenced by the availability of data (or lack of being able to disaggregate available data). These unit processes were modelled in an integrated Simapro model to calculate the resulting inputs and outputs per reference unit (e.g. cubic metre of log or sawn timber or square metre of a plywood or particleboard) including all raw materials from growing forests and common processes such as Australian energy sources. The result is a Life Cycle Inventory of all inputs and outputs for the products listed in Table 1.

5. Some outcomes

5.1 Forestry

The Forestry process includes the establishment, growing and management of forests, harvesting of trees and transportation of logs to processing facilities.

Inputs considered in the forest production systems included: land, water, fuel/energy, chemicals and other materials (other resources, consumables and infrastructure). Averaged over the production cycle, land use efficiencies ranged from 0.05-0.08 ha m^{-3} for softwoods and 0.11 ha m^{-3} to 0.98 ha m^{-3} for hardwoods. Estimated water-use ranged from 0.3 to 0.7 Ml m^{-3} for softwoods compared with 1-10 Ml m^{-3} for native hardwoods. These differences were largely a result of the lower management and harvesting intensity of native forests compared with plantations.

Direct energy use varied from 198 MJ m^{-3} in softwood plantations to 464 MJ m^{-3} in hardwood native forests. Virtually all (>99%) energy use was associated with combustion of diesel in vehicles and machinery. The greater energy usage in hardwood native forests was largely due to greater fuel usage during harvesting. For softwood plantations, the largest contributor to energy inputs was haulage (51%), followed by harvesting (28%) and management (18%). For hardwoods, the highest contributor was harvesting (61%) followed by haulage (25%) and management (10%).

Assumed CO_2 sequestered by the forest and stored in wood products averaged 756 kg m^{-3} for softwood products and 1013 kg m^{-3} for hardwood products.

Direct emissions include both CO_2 and non-CO_2 emissions from operations under the control of the forest owner or contractor (e.g. this from fertiliser, burning or vehicle and machine use). Direct CO_2 emissions averaged 10 kg CO_2 m^{-3} for softwood plantations and 21 kg CO_2 m^{-3} for hardwood native forests. Major non-CO_2 emissions included CH_4, N_2O and NO_x. Using IPCC emission factors of 23 for CH_4 and 196 for N_2O, these non-CO_2 greenhouse gasses (GHGs) effectively contributed 7 kg CO_2-e m^{-3} from softwood plantations and 21 kg CO_2-e m^{-3} from hardwood native forests. Thus, total GHG emissions were 17 kg CO_2-e m^{-3} from softwood plantations and 42 kg CO_2-e m^{-3} from hardwood native forests.

SimaPro modeling was used to estimate total direct plus indirect (associated upstream processes such as fuel, energy and fertiliser production and transport) arising from wood production. Preliminary results for total GHG emissions associated with growing, harvesting and hauling an average log were 26 kg CO_2-e for plantation softwood compared with 60 kg CO_2-e for native hardwood logs. For softwood plantations 37% of total GHG emissions were due to burning and fertiliser application, 32% to log transport, 24% to timber harvesting, and 7% were due to forest management operations. For native hardwood forests 50% of total GHG emissions due to burning, 13% to log transport, 31% to timber harvesting, and 6% were due to forest management operations.

These emissions were allocated to wood products based on the total value of each product. For products from softwood plantations, total GHG emissions varied from 17 kg CO_2-e m^{-3} for pulplogs to 30 kg CO_2-e m^{-3} for large sawlogs. These represented between 2 and 4% of the total CO_2 sequestered in the logs. For hardwood logs, there was wider variation in allocation of CO_2-e emissions as a result of the greater variation in product value. Thus, CO_2-e emissions varied from 38 kg CO_2-e m^{-3} for low quality sawlogs and pulplogs or 3% of the total CO_2 sequestered to 146 kg CO_2-e m^{-3} for other logs (poles pile and girders) or 13% of the total CO_2 sequestered. Thus, the net amount of CO_2-e sequestered in plantation softwood products varied from 726 kg CO_2-e m^{-3} for large sawlogs to 740 kg CO_2-e m^{-3} for pulplogs and that for native hardwood products varied from 911 for other logs to 1017 kg CO_2-e m^{-3} for pulplogs.

It is thus critical that there is recognition given to the longer-term storage of carbon in forest products. If this occurs forestry will be reflected as a long-term sink for carbon in terms of net carbon storage in the logs harvested, otherwise forestry will be accounted as a small source of carbon emissions.

5.2 Softwood framing and hardwood timbers

The data collection provides a new benchmark for sawn timber building products in Australia. The results presented draw upon data collected from 24 sawmills from across Australia. In comparison, CORRIM collected data from eight sawmills for its data collection for sawmills. The data collection covers all Australian States and captures a significant proportion of total production.

The recovery rate reported for softwood primarily relates to dried and dressed radiata timber building products, with a particular focus on timber house framing, which is the dominant building product. The recovery rate of 45% for softwood building products fits in the middle of a wide range of rates previously reported, 45% (Pöyry 1999) and 47% (Ximenes) as well recovery rates reported by CORRIM of 42% (hemlock) and 58% (douglas fir) (Milota 2004).

The fuel mix in the softwood sample shows a very high reliance on wood residues for the kiln drying process. Approximately 80% of the heating energy in the study is from wood residues compared to approximately 58% in CORRIM (Milota, 2004) and this is reflected in the emissions profile reported.

Water use for the kilns was higher in Australia than in CORRIM. However, CORRIM reported high water usage in the log yards for sprinkling logs with water during storage. As a result the water usage in Australia for softwoods was much lower.

5.3 Veneer, plywood and LVL

Data for veneer, plywood and LVL has been collected from 80% of Australian plywood and LVL mills making this the most comprehensive analysis of these products undertaken, providing a new Australian benchmark. The plywood and LVL processes were compared and considered similar which enabled the use of plywood data in the LVL model. The results were generated by a single server version of the SimaPro software using the updated FWPA data libraries. The results are for average Australian veneer, plywood and LVL. The veneer process has four unit processes within the system boundary (Preparation, Conditioning, Green Veneer, Dry and Finish). The plywood and LVL processes both have three unit processes (Manufacture, Finish, and Packaging). There is also a separate boiler process and a glue-mixing unit process which have been detailed as separate unit processes, but secondary data created for LCI Timber was used.

The main inputs to manufacture 1m^3 of structural plywood include: 80 kg A-bond glue (which includes resins, flours, fillers, catalyst, etc.); 0.43 m^3 of hardwood veneer; 0.84 m^3 of softwood veneer; 0.0039 kg AACQ preservative (there are other inputs but in non-registering quantities). It takes 2.1 m^3 of logs to produce the veneer to make 1m^3 structural ply. The average results show that the yield of veneer from logs is approximately 40% compared to 50% estimated by CORRIM but varied between mills, with small labour intensive mills reporting higher recovery rates. The main source of energy is the boiler (3.6 GJ) which is mainly used in the veneer drying process. The electricity input is 165 kwh m^{-3}; LPG is 3.37 ltrs; and natural gas 0.351GJ. These energy sources are mainly used in the drying process (40% in drying). 640 ltrs of water is also consumed. Preliminary results for CO_2 emissions show that veneer drying accounts for the significant proportion. CO_2 emissions are broken down into 3 categories: CO_2 (1 tonne); CO_2 Biogenic (1 tonne); and CO_2 Fossil (67tonnes). This is a significant CO_2 release. 70% of CO_2 release is estimated to derive from the pressing process in plywood manufacture, and of this only 10% is down to the actual pressing process with over 30% originating from oil and gas production, and 30% from diesel production.

5.4 Glulam and engineered I-beams

Australian average glulam requires 501 MJ of energy to manufacture 1 m^3 of glulam. To manufacture 1 linear metre of I-beam, OSB web and pine flanges requires 9.3 MJ and 8.9 MJ for plywood web and LVL flanges, respectively. Table 3 shows an example of the timber and energy used in Australia in comparison to the CORRIM values for glulam. As seen in this table, to manufacture of 1 m^3 of glulam in Australia, 668 kg of sawn timber is required and 64.8 kg of shavings and trimmings and 63.4 kg of sawdust including wood waste are generated respectively. Wood recovery for glulam in terms of wood input as sawn timber and output as glulam was estimated at 81%, the rest being shavings and trimmings and sawdust (Table 3), which is similar to CORRIM's data (82% for PNW and SE).. Manufacture of Australian glulam consumes a little more electricity, requiring 364.6 MJ comparing to CORRIM's 304 MJ for PNW and 356 for SE, but the balance of other energy sources such as natural gas, or diesel are considerably much less for Australian glulam. The data collection for glulam and I-beam products provides a new benchmark for glulam and I-beam building products in Australia.

Table 3 Glulam product yields comparison

Wood Mass Balance (weighted average)	FWPA*	CORRIM (PNW)**	CORRIM (SE)***
Input (kg/m^3)	668	592	676
Output - Glulam (kg/m^3)	540	483	551
Output – shaving, trimming & sawdust (kg/m^3)	128+	89	119
Output - wood waste (kg/m^3)		20	6
Recovery of wood (%)	81%	82%	82%
Energy consumption (MJ)	501	893	1420

*Australian glulam weight averaged; **CORRIM (Pacific North West Area); ***CORRIM (South East Area)

6. Benefits

A major benefit of the Life Cycle Inventory of forestry and wood products for the industry is to have a credible quantitative basis for comparison of competing timber products and non-timber alternatives. Collection, enhancement and verification of data provide the industry with reliable environmental impact information to improve the environmental bottom line as well as providing data for assessing choice in building products on the basis of environmental impacts. The future potential in obtaining this information for the forestry and wood products industry means greater acceptance of wood as an environmental material choice, give wood products a greater prominence in evaluation tools, and greater understanding by the industry of future growth areas, such as recycling opportunities, service provision potential, and take back schemes, which would greatly add to the bottom-line in the future market place.

The project has produced the first national Life Cycle Inventory database on Australian forestry and wood products production with benefits including:

- The compilation of a common database for the wood industry,
- An objective and quantitative basis for comparison of competing wood products and non-wood alternatives,
- An objective and quantitative basis for comparing systems which incorporate wood products to those systems which use alternative materials, for example, complex composite products or whole houses,
- A method of comparing the environmental impacts of wood products from improved production processes,
- A database for use with Life Cycle Assessments of wood products and the buildings in which they are used,
- Provision of up-to-date credible industry based life cycle inventory information for life cycle assessment of wood products from Australian manufacturers,
- Support to manufacturers on environmental performance and impact assessment measures so environmental improvements can be addressed,
- Facilitating communication of environmental information to customers and other stakeholders,
- Setting a benchmark for carbon sequestration in wood products, and
- Setting an industry standard for handling of environmental data.

7. Conclusions

The development of a Life Cycle Inventory for Australian forestry and wood products is a major step forward in the provision of quality data on the environmental impacts of wood products used in building. The quality assurance procedures, in following the ISO Standards procedures and documentation, have set a high level for all following contributions to the developing Australian Life Cycle Inventory database (AusLCI). The wide forestry and wood industry coverage also makes the resulting Life Cycle Inventory very representative of Australian wood products and an excellent basis for assessing the environmental impacts of any application of wood products.

8. Acknowledgements

The work reported in this paper was part of a research project conducted for, and substantially funded by, Forest and Wood Products Australia in collaboration with CSIRO, Ensis and RMIT. A wide range of forestry and wood products industry participants cooperated and willingly supplied the data necessary for the development of the Australian forestry and wood products LCI database.

Keywords: heat loss; overnight shut-off; lumped heat capacity; energy demand

Abstract

A new method is introduced for calculating heat loss in buildings while the heating system is off. Developed from the mass and physical properties of the materials as a starting point, it determines the temperature distribution under variable flow rate conditions in exterior walls in contact with the outdoor air or bounded by unheated premises, as well as in partition walls, furniture, household appliances and so on. The data on overnight temperature variations are then entered in the Lumped Heat Capacity model to obtain the temperature variation and heat loss in the solids inside the flats studied. Knowing the temperature distribution in outside walls, the heat loss across these walls can be calculated. Lastly, the heat loss resulting from the inflow of outdoor air is calculated as specified in legal standards. In the case study – three flats on a cold day 21-22 December 2006 – used as an example, heat lost was seen to constitute a significant fraction of each flat's daily demand and depend on its location in the building are discussed. The overnight loss generated in the top storey flat came to an additional 48.4% over and above daily demand; in the second and third storey flats the additional loss was 19.18% and 40.24%, respectively.

1. Introduction

Given the moderate climate prevailing on the Iberian peninsula, Spanish homes can be kept at a comfortable temperature with a maximum of 12 hours of heating daily, from around 11:00 a.m. to 11:00 p.m. As a rule then, the heating is off from 11:00 p.m. to 11:00 a.m. the next day. During this period buildings cool down, with heat transferred by convection across the enclosures in contact with the outdoor air or bounded by unheated premises. Air exchange and infiltration contribute to the decline in indoor temperatures. When the indoor air cools, the temperature of partition walls, furniture, household appliances and so on also drops. The following day, when the heating system begins to warm the building, partition walls, furniture and so on absorb heat from the surrounding air, raising their temperature to a comfortable level.

Scant literature can be found on this subject, for researchers and engineers have paid insufficient attention to this heat loss, which depends on building inertia and is replenished the next day. Standards in place in Spain, such as European standard EN 832:1998 and the more current international and European standard ISO-EN 12831, dating from 2003, can be used to evaluate this heat. The ISO-EN standard includes a simplified method for residential buildings based on the general assumption that indoor temperature declines by 3 ºC. Such assumption is imprecise, however, for the decline in indoor building temperatures depends on the outdoor temperature, wall composition and orientation, relative location, use and so on.

This paper introduces a method for determining heat loss in a three-storey building with an underground garage during the hours when the heating system is disconnected. Account is taken of the additional cooling caused by air exchange and infiltration. First, building heat loss is calculated on the basis of its heat capacity and air exchange rate to obtain the indoor temperature decline from 11:00 p.m., when the heating is turned off, until the next day. This information can then be used to determine the temperature decline in furniture, partition walls, household appliances and so forth. Knowing the variation in both the indoor and outdoor temperatures, the temperature distribution can be found for outside walls and walls bounded by unheated premises. Lastly, the total heat lost during the hours the heating system is off is calculated: this is the heat that needs to be replenished the next day. The results for three flats on a particularly cold day are discussed. While the method introduced is designed for general application, the wide variations in building conditions and flat use made it unfeasible to address all these factors in the present study. Consequently, the results obtained refer exclusively to the type of building analyzed.

2. Description of the building

Located in the city of Madrid, the building studied is an apartment complex consisting in three storeys and an underground garage with a total area of **584 m²**. Each storey has two flats with a built area of **70 m²** each. The floor plan for the standard flat studied, which is the same on all three storeys, is shown in Figure 1. The surrounding environment for each flat depends on the storey.

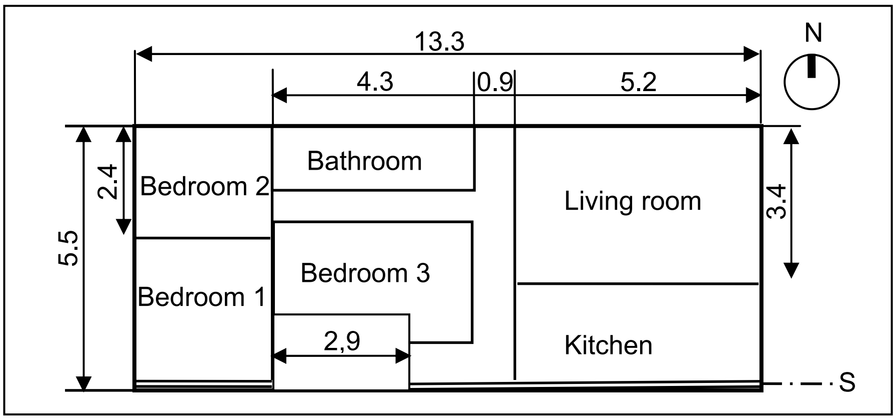

Figure 1. Flat A floor plan (dimensions in metres)

All the flats have outdoor walls facing east and west. The party wall on the north is bounded by unheated premises. The enclosures bounded by other heated housing are regarded to be adiabatic. The flat located on the third storey is exposed to the outdoors across the roof, while the first storey flat is exposed to the unheated garage, across the floor slab.

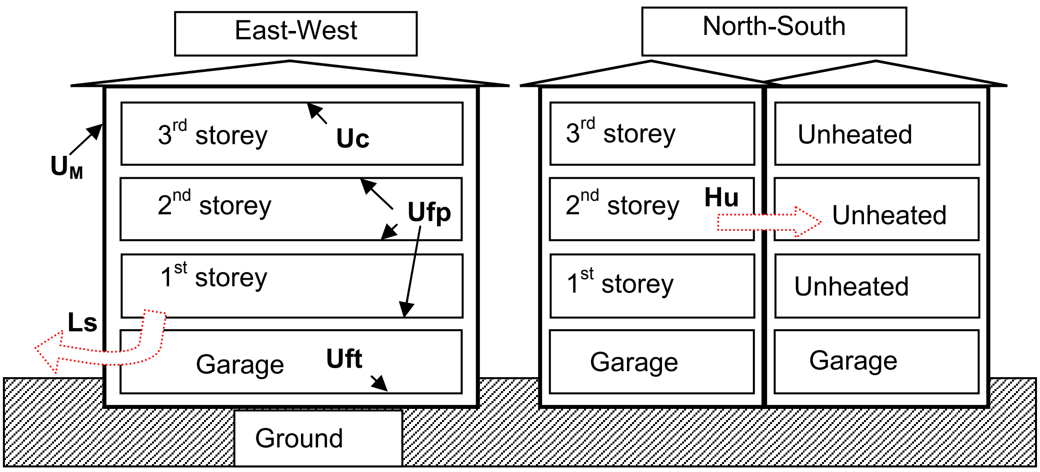

Figure 2. Cross-sections of the building

2.1. Enclosures in contact with the outdoor air

The enclosure characteristics shown in Table 1 were taken from the Technical Building Code (Spanish initials, CTE) while the physical properties, thermal transmission coefficients and so forth were taken from Spanish and European standard *UNE-EN 10456*.

Table 1. Heat transfer coefficients and specific heat capacity

	1st storey	**2nd storey**	**3rd storey**
C (KJ/kg°C)	34230	34230	34030
UA roof (W/°C)	---	---	33.49
UA wall (W/°C)	8.95	8.95	8.95
UA windows (W/°C)	27.85	27.85	27.85
Hu (W/°C)	9.4	8.8	9.6
Ls (W/°C)	---	---	21.12

2.2. Partition walls and furnishings

The flats are divided into rooms and premises by partition walls. The furniture is made of wood and the household appliances of a variety of materials. The partitions are *2.5 m* high and have a total length of *30 m*. They consist in 5-cm face brick plastered on both sides (1 cm each). For the intents and purposes of the present thermal calculations, this wall is replaced by another with equivalent density, specific heat and thermal conductivity (Table 2).

Table 2. Properties of wood and equivalent partitions.

	ρ (kg/m^3)	Cp (KJ/kgºC)	K_m (W/mºC)	V (m^3)
Wood	600	1.52	0.14	1.4
Equivalent partition	1.086	0.854	0.415	5.67

2.3. Enclosures bounded by unheated premises

2.3.1. Floor slab bounded by unheated garage

Further to European and international standard EN-ISO 13370, which contains the heat transmission coefficients for construction elements in or on the ground, the thermal coupling coefficient is **Ls=21.12 W/ºC.**

2.3.2. Party wall bounded by unheated premises

European and international standard EN-ISO 13789 explains how to determine the heat transmission coefficient across unheated premises, **Hu**. This coefficient takes account of the heat exchange between the unheated space and other indoor areas on the one hand and outdoors on the other. The air exchange rate in the unheated space is similar to the exchange rate inside the flats, namely 0.5 exchanges per hour. Table 1 gives the thermal transmission coefficients, **Hu**, for the three flats studied (layout as in Figure 1).

3. Variation in the indoor temperature in the flats

The study aimed to determined temperature variations inside the flats from the time the heating is turned off at 11:00 p.m., when the temperature was 21 ºC, until it is turned back on the next day at 11:00 a.m.

3.1. Equations used for the calculations

Heat losses in the flat are assumed to be due to heat transmission across enclosures and the entry of outdoor air as a result of air exchanges and infiltration, i.e., disregarding internal sources. Using an energy balance, the interior temperature **Tin** can be found with equation (1). The **UA(Tout-Tin)** member quantifies heat transmission across the enclosures, while the **ρCpV(Tout-Tin)** member assesses the cooling of indoor air due to the entry of cold exchange air and infiltration.

$$C \cdot \frac{dT_{\text{in}}}{dt} = UA \cdot (T_{out} - T_{\text{in}}) + \rho C_p V \cdot (T_{out} - T_{\text{in}}) \qquad (1)$$

In this equation, **ρCp=**0.34 Wh/ºC, **V** is the volume of exchanged air and **C** is the effective heat capacity of the heated volume. In other words, **C** corresponds to the variation in the amount of heat stored by the building structure when the indoor temperature variation is 1ºC during a given period. This parameter can be found with equation (2), defined in European standard EN 832:1998 as the sum of the effective heat capacities of all the indoor elements in the building in thermal contact with the indoor air.

$$C = \sum_j \sum_i \rho_{ij} c_{ij} d_{ij} A_j \qquad (2)$$

Where ρ_{ij} is the density of the layer i material in wall j, Cp_{ij} the specific heat of the layer i material in wall j, d_{ij} is the thickness of layer i on wall j, and A_j is the area of wall j located within the space studied. The temperature of the unheated premises is found from equation (3), in turn obtained from a heat balance resulting in thermal equilibrium.

$$T_u = \frac{\phi + T_{\text{in}} \cdot H_{iu} + T_{out} \cdot H_{uo}}{H_{iu} + H_{uo}} \qquad (3)$$

Φ is the heat flow generated in the unheated area (solar gain, internal sources and so on) and **H** is the heat transfer coefficient. Subscript **i** means indoor, **o** outdoor, and **u** refers to the unheated premises.

3.2. Calculating the indoor temperature in the flats

Adapting the calculations to the specific circumstances of flat type A yields a system of equations (4) from which the indoor air temperature can be determined in terms of the surrounding conditions, which in turn depend on construction components, weather conditions, the relative position in the building and so forth. The unheated premises considered are the premises bounded by the party wall, $\mathbf{T_{premises}}$ and the garage, $\mathbf{T_{garage}}$. Table 1 gives the effective heat capacity, **C**, of the flats and the heat transfer coefficients for the enclosures.

$$C\frac{dT_{in}}{dt} = UA(T_{out} - T_{in}) + \rho C_p V(T_{out} - T_{in}) + Hu(T_{premises} - T_{in}) + Ls(T_{garage} - T_{in})$$

$$T_{premises} = \frac{T_{in} \cdot Hiu + T_{out} \cdot Huo}{Hiu + Huo}$$

$$T_{garage} = \frac{T_{in} \cdot Hiu_g + T_{out} \cdot Huo_g}{Hiu_g + Huo_g} \qquad (4)$$

Figure 3 shows the temperature variation in third storey flat A from 11:00 p.m. on 21 December to 11:00 a.m. on 22 December.

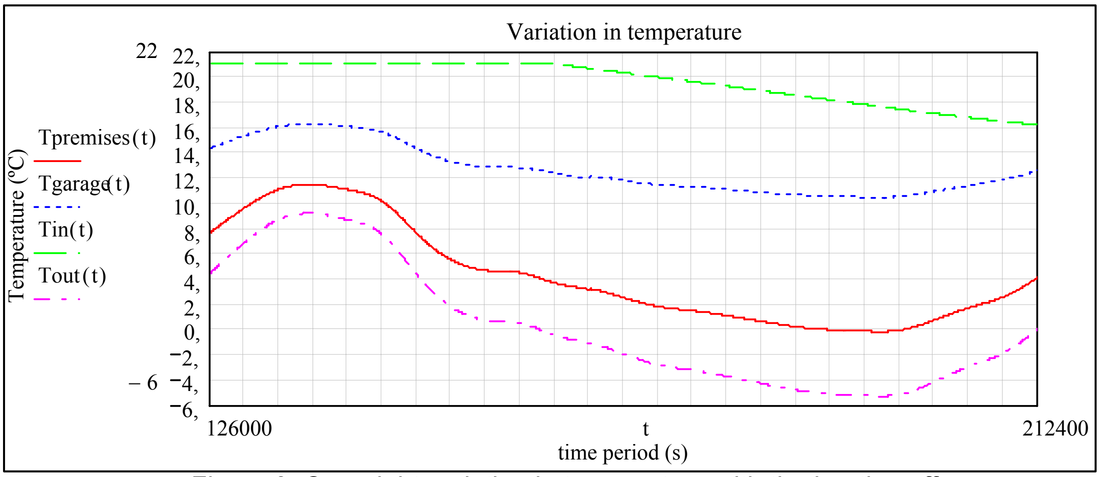

Figure 3. Overnight variation in temperature with the heating off

The indoor air temperature distribution during the hours the heating is off is obtained by repeating the calculations for the three vertically aligned flats and varying the number of air exchanges per hour from 0.5 to 1.5. Table 3 gives the final temperature at 11:00 a.m.

Table 3. Indoor temperature at the end of the period

	Final temperature (° C)		
	3rd storey	**2nd storey**	**1st storey**
n= 0.5	17.24	18.35	18.05
n=1	16.2	17.26	16.97
n=1.5	15.21	16.22	15.95

4. Heat loss in furnishings and partitions

The variation in the indoor temperature sets off convection heat transfer in the partition walls, furniture and appliances inside the flat. The temperature of these solids as the building cools is found with the Incropera and De Witt (1990) lumped heat capacity method. The dimensionless Biot number, equation (5), is first determined for wood and the equivalent wall to determine the applicability of the method,

$$Bi = \frac{h_i L_c}{K_m} \qquad (5)$$

where L_c is the characteristic length of the solids : the thickness of the equivalent wall or mean thickness of the wood; K_m is thermal conductivity; and h_i is the surface convection heat transfer coefficient. Since the Biot numbers found are less than one, as **Table 4** shows, the lumped heat capacity model can be used in both cases.

Table 4. Physical and geometric properties of the solids.

Material	h_i (W/m^{2}ºC)	L_c (m)	K_m(W/mºC)	Biot
Wood	2	0.025	0.21	0.238
Equivalent wall	2	0.07	0.415	0.337

4.1. Heat transfer equations

The heat transferred from the solids (wood, equivalent wall and so on) to the indoor air is found with equation (6).

$$q_{conv} = h_i A_s (T_{solid} - T_{in}) \qquad (6)$$

Where T_{solid} is the temperature of the solid, T_{in} the temperature of the indoor air and A_s the area of the solid exposed to heat exchange. The amount of conduction heat transferred inside the solid at a variable flow rate, which depends on time **t,** is the product of mass times the temperature variation, equation (7). Equation (8) is the energy balance.

$$q_{cond} = \rho V C_p \frac{dT_{solid}}{dt} \qquad (7)$$

$$-\rho V C_p \frac{dT_{solid}}{dt} = h_i A_s (T_{solid} - T_{in}) \qquad (8)$$

To facilitate the calculations involved in equation (8), a constant, β, is defined, and equation (10) is obtained:

$$\beta = \frac{h_i A_s}{\rho V C_p} \qquad (9)$$

$$\frac{dT_{solid}}{dt} = \beta (T_{in} - T_{solid}) \qquad (10)$$

The parameter defined in equation (9) for wood and the equivalent wall adopts the values of ***$1.7510^{-5}s^{-1}$ and $6.1610^{-5}s^{-1}$***, respectively. Equation (10) can be adapted for application to all the various materials. When the indoor temperature dips to 16.2 ºC, with **one** air exchange per hour, the equivalent wall cools to **17.58 ºC**, and the wood to **16.66 ºC**.

4.2. Heat transmitted from solids

The heat transferred from the solids to the indoor air between 11:00 p.m. and 11.00 a.m. the next day is found with equation (11).

$$Q_{tpp} = \sum \rho V C_P \Delta T_{mx} \quad (11)$$

Where Δt_{mx} is the difference between the peak temperatures of the solids during the period. Using equation (11) and assuming one air exchange per hour, the heat transmitted by the solids is as shown in Table 5. The thermal and geometric properties of the solids are given in Table 2.

Table 5. Heat transmitted by the solids

	Heat transmitted by the solids (kWh)		
	3rd storey	**2nd storey**	**1st storey**
Wood	1.348	1.049	1.128
Wall	4.765	3.697	3.981

5. Heat losses across enclosures

The building also loses heat across the enclosures in contact with the outdoor air or bounded by unheated buildings or flats. The heat transferred by an enclosure with an area of $\mathbf{A_{en}}$, once $\mathbf{T_{in}}$ its calculated from equation 1 and the outdoor temperature $\mathbf{T_{out}}$ has been measured, can be found with the following equation.

$$q_{ce} = U_{en} \cdot A_{en} \cdot (T_{\text{in}} - T_{out}) \quad (12)$$

The flow per unit of area:

$$\frac{q_{ce}}{A_{en}} = U_{en} \cdot (T_{\text{in}} - T_{out}) = U_i \cdot (T_{\text{in}} - T_i) \quad (13)$$

Equation (13), which gives the surface temperature for each component, **i**, in the wall,

$$T_{i+1} = T_i - R_i \cdot \frac{q_{ce}}{A_{en}} \quad (14)$$

may be re-written as follows:

$$\Delta T_i = R_i \cdot \frac{q_{ce}}{A_{en}} \quad (^{\circ}C) \quad (15)$$

5.1. Enclosures in contact with the outdoor air

Figure 4 shows the temperature distribution in the materials comprising the outside wall, obtained from equation (14), where **ti** is the initial temperature and **tf** the final temperature during the interval when the heating is off, obtained from the system of equations (4).

Given the indoor and outdoor temperatures, the difference for each material in the wall is obtained by applying equation (15). The heat lost across the wall is obtained by adding the heat lost by all its component materials, based on their known temperature differences and physical properties, equation (11). The heat loss for the third storey flat is **4.78 kWh**, while the values for the second and first storey flats are **3.67 kWh** and **3.97 kWh**, respectively.

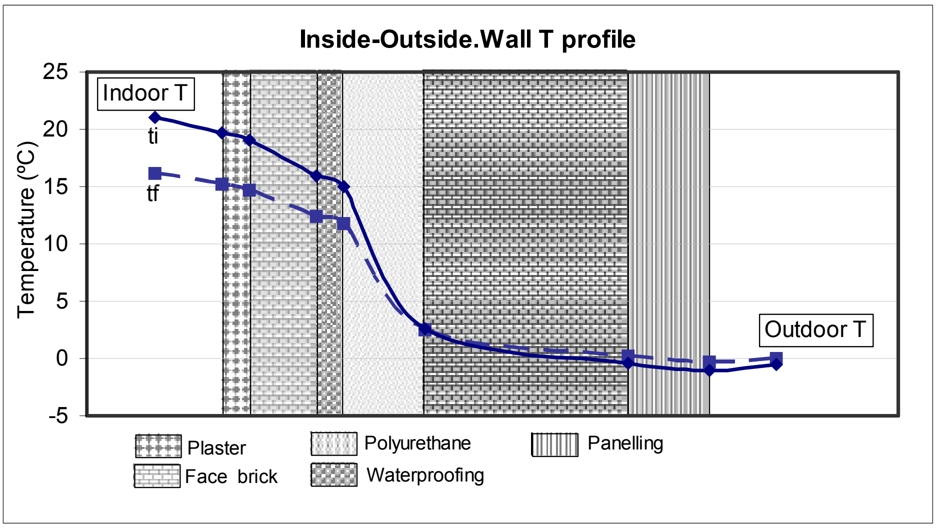

Figure 4. Inside-outside. Wall temperature profile.

5.2. Roof in contact with the outdoor air

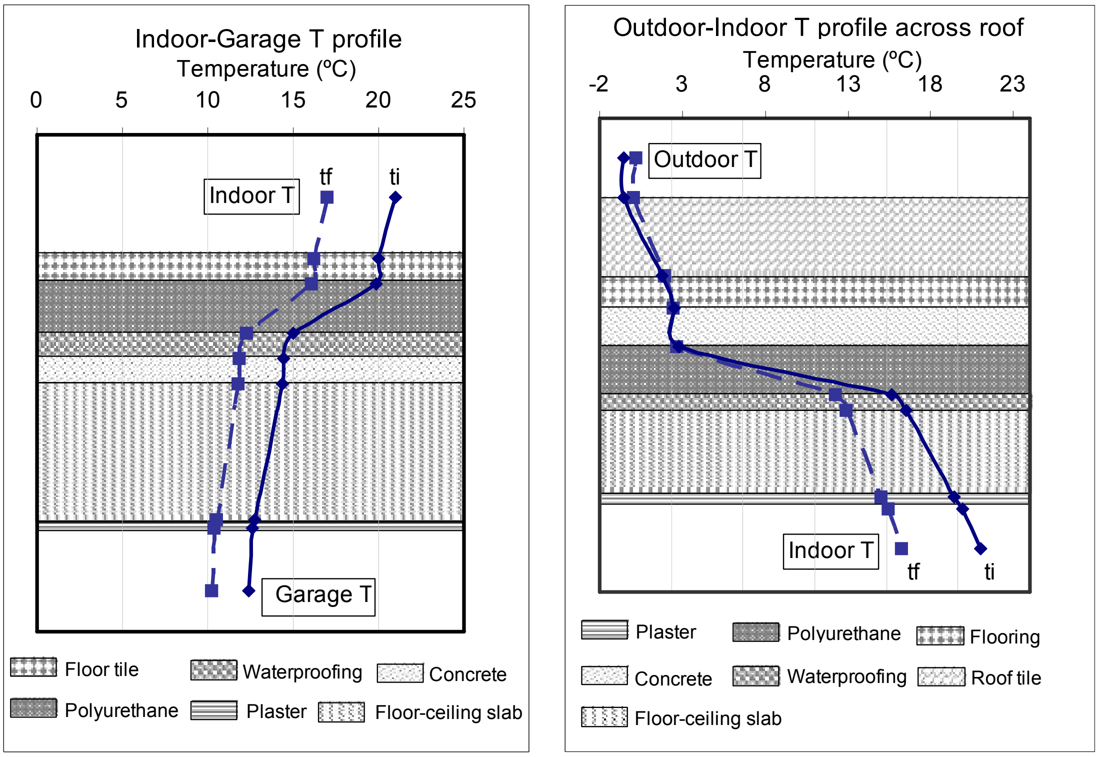
The method for calculating temperature variations in the roof is similar to the methods described in the preceding section for the outside wall. In this case, only the third storey is impacted, for its ceiling is in contact with the outdoor air across the roof slab. **Figure 5** shows the temperature in the roof materials. Using equation (11), the heat transmitted is found to be **21.9 kWh.**

5.3. Slab bounded by the garage

In this case only the first storey, whose floor is bounded by the unheated garage, is impacted. **Figure 6** shows the temperature in the slab materials. The value found when equation (13) is applied is **15.35 kWh.**

5.4. Party wall bounded by unheated premises

The heat required to raise the temperature of the materials in the party wall to the initial values is **9.97 kWh**, **8.2 kWh. y 8.41 kWh** for the third, second and first storeys, respectively.



Figures 5 and 6. Temperature profile for the slabs over the garage and third storey.

6. Total losses

Table 6 shows the total energy balance for the three flats. The heat demand for each flat, excluding the heat lost while the heating is off, is 75.7 kWh, 61.86 kWh and 68.91 kWh. The heat lost during the off period is 36.66 kWh, 11.86 kWh and 27.73 kWh, or an additional **40.24%** for the first storey, **19.18%** for the second storey and **48.4%** for the third storey flat.

Table 6. Energy balance for the three flats

	Heat transmitted (kWh)		
	3rd storey	2nd storey	1st storey
Wall	4.77	3.67	3.97
Party wall	9.97	8.19	8.41
Slab	**	**	15.35
Roof	21.90	**	**
TOTAL during the off period	**36.66**	**11.86**	**27.73**
Heating demand excluding losses	75.7	61.86	68.91
Total heating demand	**112.36**	**73.73**	**96.64**

7. Conclusions

The method introduced for calculating building heat loss when the heating is off constitutes an improvement over existing models. It consists in finding the temperature distribution in outside walls and walls bounded by unheated premises, as well as in partition walls, furniture, household appliances and so on.

The heat lost per flat between 11:00 p.m. on 21 December and 11:00 a.m. on 22 December 2006 was found to depend on the location of the flat in the building and to constitute a significant fraction of the daily demand. The additional loss generated in the top storey flat came to 48.4% over and above daily demand. The additional heat loss for the second storey flat was 19.18%, while the value for the first storey unit, bounded by the garage below, was 40.24%.

DEVELOPMENT OF A DAMAGE-BASED SYSTEM FOR WEIGHTING ENVIRONMENTAL IMPACTS FROM BUILDINGS

Keywords: Buildings, Weighting, Life Cycle Assessment, DALY

Summary

Weighting is applied to aggregating and communicate a large amount of information to stakeholders. Often the subjectivity involved in weighting leads to a diminished reliability and acceptability.

Different basis for weighting like monetarisation, damages, expert panels, questionnaires, etc have been applied in different assessment systems. However, after comparing different approaches, the use of the consequential implication of emissions and depletion of natural resources on human beings was considered to be the most relevant basis for a new system of weighting external impacts from buildings. A major simplification used is that damage to nature is transferred to endpoint problems on human beings. The principles of the Disability Adjusted Life Years system are adopted to qualify damage and annoyance to man. This was further complemented with a development of the European Quality of Life Scale system for facilitating setting new disability weights covering issues like loss of employment. Overall, the weighting system for each impact category includes different steps from defining endpoint problems to calculating a damage value, used to calculate the weights. Climate change is used as an illustration. Current lack of data poses a problem. The method is transparent and open for updating with improved data availability and quality.

1. Introduction

Almost all kinds of environmental assessments need to be interpreted for practical applicability. However there is still no consensus about how to perform this. The Standard for Life Cycle Impact Assessment (LCIA) stresses that normalisation; grouping and weighting are optional elements of an LCIA (ISO 2000). It further outlines that normalization employs baselines and/or reference information while grouping and weighting employ value-choices. Environmental assessment of buildings is no exception. In the area of environmental assessment of buildings, a large number of tools have been developed with no relation to any standardised methodology. Environmental indicators are chosen freely, quantitative and qualitative information is mixed and aggregated (weighted) into one or a few final scores.

Weighting is the heart of all assessment since it dominantly affects the overall performance score of the building being assessed (Lee et al 2002).

Contemporary weighting attempts are based on the rating of environmental performance of buildings by awarding credits and assigning performance points. The awarded points or credits are used in establishing scales for the different aspects or indicators being assessed.

Credit-scales bring the result to the same unit and enable the next step of weighting. However, so far there is no common basis for how the number of points which could be gained for individual indicators are set (Ding 2007). Working with whole point values for both qualitative and quantitative issues makes the system very crude and the result difficult to comprehend.

It is quite obvious that environmental assessment systems to a large extent are value based since indicators credit-scales and weighting are chosen in a subjective way. On the other hand, there are many common ingredients in these tools and a consensus will hopefully be reached in the future. The perspective of this contribution is the recognition of the importance of contributing to more similar and less subjective assessment tools regarding especially all these three factors. This paper presents an attempt of making weighting systems less value based. The context for this system was the EcoEffect method for environmental assessment of buildings developed by a group of researchers in Sweden. In this development work, weighting was recognized as a major problem and hence great efforts to develop a less subjective weighting process have been made.

2. Different basis for weighting

There are different starting points for establishing weights. Weights can, for instance, be calculated on the basis of quantitatively specified environmental goals or damages. The process of setting environmental goals renders them value-based but taken in a broader political context they have a legitimacy that can't be gained by a tool designer using votes from stakeholders as a basis for weights. Referring to national or international environmental targets for the weights the tool designer can claim that these weights are not subjectively set.

But the most common way to set and defend certain weights is to refer to votes from a group of “experts” or stakeholders. Such weights will reflect opinions in a certain area and time. Although looking objective at the time they may become obsolete from another perspective or at a different time.

Our point of view is that damage-based weights are the least subjective. The difficulty here is that the knowledge regarding future damages often is poor. On the other hand, this knowledge improves continuously and can be utilized without jeopardizing the method. It will instead strengthen it.

3. Damage-based weighting

With external environmental impact from a building is here meant impacts generated from building activities or use of buildings that contribute to environmental problems elsewhere, i.e. not affecting or targeting the building users specifically. It applies mostly to regional to global scale problems like climate change, acidification, toxicity etc.

The way to calculate contribution to external impacts is generally taken from the methodology of life cycle assessment (LCA), i.e. from inventory of emissions through out the life cycle of the product considered and knowledge about the potential contribution to each impact category from these emissions. Since one emission may have a larger impact per unit than another this is taken care of by factors representing these differences. The procedure ends up in an amount of equivalents that represents the potential impact. For instance, energy use in a building creates emissions corresponding to 1600 CO_2-equivalents/m^2, yr which is a way to measure contribution to climate change. If an overall judgment of the energy use in the building is asked, the significance of these equivalents compared to other equivalents for other kind of impacts has to be sorted out. The need for weighting thus arises. But to make aggregation possible first all equivalents have to be brought to the same unit to make weighting and addition possible. This is normally done by normalisation, i.e. dividing with a reference value with the same unit, for example the total amount of emitted equivalents of the same kind per capita in the country.

3.1 Defining and expressing damage

The motive of defining damage is uncovering the difference in significance between impact categories. From the damage point of view it could be defined as the difference in damage to people, ecosystems and resources caused by the different kinds of impacts. Since the external impacts are large scale problems, the difference in significance preferably should be compared on a global level. If impact category A is found to potentially create x times larger damage than impact B on the global scale, a unit contribution to A from a building should also be valued as x times worse than a unit contribution to B.

Damage to people can be measured in DALY (Disability Adjusted Life Years) developed by WHO (Murray and Lopez 1996). It is composed of two parts, one representing the inability to live a normal life when affected by a physical or physiological impairment, YLD (Years Lived Disabled), in this case caused by an environmental impact. The other part represents the theoretical suffering by an early death calculated as number of lost years compared to normal life length, YLL (Years Lost Life).

DALY [Years] = YLD+YLL

The YLD part has two components, one is a disability weight expressing the degree of disability the impairment causes and the other is the duration of the impairment.

YLD = dt * dw

dt: duration of impairment

dw: disability weight

Disability weights have been established by WHO for a large number of well-known diseases through a procedure of expert voting. These are both of physical and psychological type. For a population with groups of people with different kinds of impairments, DALYs can be calculated for each group and the sum indicates the magnitude of the total problem for the population. Once it is possible to find or establish disability weights for impairments caused by environmental impacts, one could determine the difference in significance through DALY calculations.

Each of the different impact categories includes a number of human problems. Although it might be impossible to tell all future potential human problems associated with different environmental impacts, there is broader awareness on a number of them. Tracking them down to individual human beings enables discussion at the level of endpoint problems for people. So the first step is to exhaustively identify as many endpoint problems related to each impact category as possible. An illustrative way of doing this is to draw cause-effect chains for each category, fig 1.

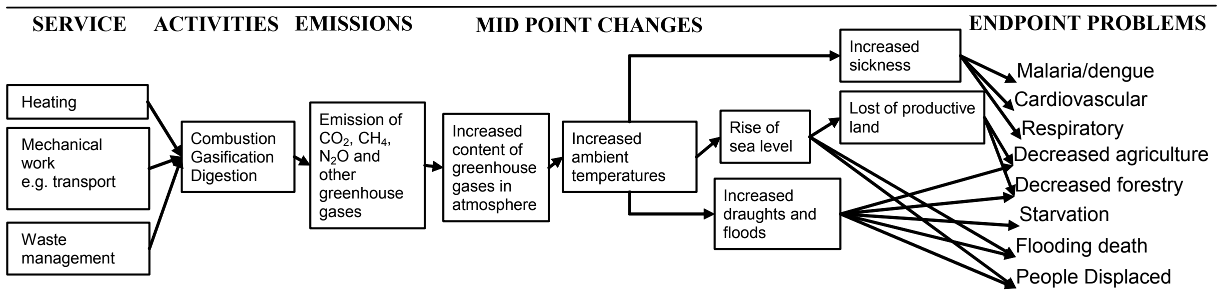

Figure 1 Example of a cause-effect chain for climate change

The endpoint problems identified for climate change are shown on the right side of the figure above. For malaria, dengue, cardiovascular and respiratory diseases, it is possible to find disability weights from WHO (Murray and Lopez 1996). The remaining endpoint problems are not particularly related to diseases and WHO gave no guidance on them. However, as they are problems affecting humans, it should be possible to express a disability weight to each of them in order to use the DALY system.

Glaumann et al (2005) presented a way to estimate disability weights for any human problem based on extension of the EuroQol system EQ 5D+system. This is a health classification system based on six aspects of quality of life; mobility, self care, usual activities, pain, anxiety and cognition. All kind of human problems can be associated to one or several of these aspects. Through a more elaborated problem definition and a clear score system, it is actually possible to set disability weights also on the remaining endpoint problems depicted above using this methodology.

Table 1 A procedure to arrive at disability weights

	Mobility	Self care	Usual activities	Pain/discomfort	Anxiety/depression	Cognition	**Mean value**	**Disability weight**
Malaria		Murray and Lopez (1996)						0,19
Starvation	0	0	2	2	3	2	1,50	0,38
Flooding		No disability weight						-
Drownings		No disability weight						-
Dengue		Murray and Lopez (1996)						0,19
Cardiovascula		Murray and Lopez (1996)						0,32
Respiratory		Murray and Lopez (1996)						0,10
People displaced	0	1	1	0	3	0	0,83	0,21
Decrease forestry - loss of job	0	0	0	0	3	0	0,50	0,13
Decrease agriculture - loss of job	0	0	0	0	3	0	0,50	0,13

0=no problem, 1=insignificant problems, 2=some problems, 3=large problems, 4=very large problems

4. Global damage per endpoint problem for each impact category

The bottom-line of this approach is estimation or calculation of the total number of DALYs associated with each endpoint problem through out the duration of endpoint problem caused by each impact category. Once disability weights have been established, there is also a need to estimate an average duration time per year for those who have been affected. At last the potential number of people that might be affected but will survive and those who die should also be estimated. The former number is used for calculating an average YLD value per year and the latter an YLL value per year. The sum of these multiplied by the total duration (years) for the impact under consideration finally gives the total damage for each endpoint problem. And the sum of all DALYs for the endpoint problems, i.e. future DALYs, within an impact category gives the basis for the category weight.

The calculation starts in estimating the number of affected today. Often figures are not available for the global situation but for a single country. Then this figure has to be extrapolated to the global situation. Some endpoint problems have been present long before the environmental impact occurred but have been accelerated due to the impact. In this case, the percentage of the existing problem that might have been caused by the impact should be established.

Since resource depletion and damage to ecosystems in the end will harm people as well we can try to reformulate those problems in terms of damage to people. For instance, acidification will harm people due to decreased incomes from forestry creating unemployment; acid lakes will decrease fishing harvest and maybe decreasing the value of the land next to the lake etc. Also it is possible to find disability weights and then calculate a damage value for such problems.

5. Calculating DALYs

To make this description more concrete the calculations for the climate change impact category is shown in the tables below.

Table 2 Estimation of number of people affected by environmental impact

Endpoint problem	Fatal cases/year	Non fatal cases/year	Reference/Remark
Malaria	52 500	30 000 000	Steen (1999)
	196 000		Goedkoop and Spriensma (2000)
Starvation	1 800 000	50 000 000	Steen (1999)
Flooding	15 000	150 000	Steen (1999)
Dengue	4 620	-	Goedkoop and Spriensma (2000)
Cardiovascular	350 000	-	Goedkoop and Spriensma (2000)
Respiratory	42 000	-	Goedkoop and Spriensma (2000)
People displaced	14 000	140 000	Goedkoop and Spriensma (2000)
Decrease forestry-LD	-	10 500 000	3% loss and 350 000 000 employed
Decrease agriculture-LD	-	60 000 000	5% loss and 1 200 000 000 employed

For each endpoint problem, different levels of data can be used to calculate the total DALY over the total duration of the impact.

At the detailed level where YLD values are missing, the following types of data are used:

Percentage of production loss or nuisance, A

This is where aspects such as decrease in agricultural production or forestry etc are accounted for.

The maximum number of potentially concerned per year locally today, B

Following the same example of agriculture or forestry, the total number of people working in the sector in a given geographic area can be used as a starting point.

Number of people affected directly at local level, C= A*B

Factor of conversion from local to global scale, f

This factor is meant to scale up from national and regional data to global data and it can be based on GDP or energy, population relationships etc.

Number of people affected at the global level, D=f*C

YLD per person and year, E

These values are either obtained from the literature or can be calculated as mentioned above.

Total YLD per year, F =D*E

The calculation of YLL is relatively shorter:

Number of deaths per year, G

Literature and expert estimations can be used in combination as a source of these figures.

YLL per person per year, H

There are literature sources providing YLL values for a number of diseases that constitute fatal endpoint problems.

Total YLL per year, I=G*H

Once the YLD and YLL, DALY for each

Total DALY per year, J=F+I

If and when the aforementioned calculations are based on a certain year which is different from the year of maximum effect or point of culmination, there is a need to introduce a factor of conversion and recalculate the DALY value:

Factor of conversion from current figure to the point of culmination, f_c

Total DALY per year cumulating point, $J_c= f_c*J$

More often the data on endpoint problems is available at aggregated level without discriminating what is related to environmental impacts and other causes. This aspect is taken care of by another parameter namely, *percentage of DALY caused by the environmental impact under consideration,* K.

In order to calculate the total DALY value for the endpoint problem, the duration of impact is required.

Duration of impact, d

For example, the duration of the climate change impact have been estimated to at least 500 years (Bernes, 2001). This means that after minimum 500 years has a new steady state climate been established on earth.

Total DALY over the duration of impact, $L= K*J_c*d/2$

Once the total DALY values are calculated for all endpoint problems associated with a given impact category such as climate change, their sum gives the total number of DALYs for that category.

The calculations and estimations outlined above can be seen as an extrapolation of the situation today, into one of the many possible scenarios. The same methodology opens up for the possibility of testing other scenarios and analyzing the associated consequences.

6. From DALYs to Weights

As can be seen in Table 3, the total number of DALYs calculated for climate change over the duration period is a very large number. The corresponding values for other impact categories are shown in same Table .

Table 3 DALYs calculated as basis for impact category weights.

Impact Categories	Total DALYs	In relation to climate change
Climate change	54 727 898 958	1,0000
Ozone depletion	23 713 561	0,0004
Photochemical ozone formation	2 315 091	0,0000
Acidification	156 899 640	0,0029
Nutrification	170 331 633	0,0031
Toxicity	37 188 697 118	0,6795
Ionising radiation	1 084 988 333	0,0198

As can be seen from the table above, there is large difference between values of the total number of DALYs for the different impact categories.

From a global human point of view, the climate change problem dominates all other categories except from toxicity emanating from synthetic chemicals and metals spread all over the world. From a local point of view, where fish harvest is affected, woods are dying etc the picture is another. While recognizing the significance of climate change, the more locally relevant problems have to be tackled at the same time. Local action may also be very efficient for solving local problems and often it would rather be irresponsible not to tackle them before putting all attention and resources on reducing contribution to climate change. It will always be important to combat local environmental problems in addition to the global ones.

A more balanced and reasonable picture from the point of view of a local or regional decision maker can be achieved through a discounting in time and scale.

In other words, the *Total DALY over the duration of the impact* (L) at the level of endpoint problems or at the impact category level is recalculated using a defined discounting function, f(di)

*Total DALY Discounted, M=L*f(di)*

Such a discounting function f(di) should be able to capture time frames from as short as a life time of man to the most long-lived impacts which are those associated with radioactive waste. Different exponential functions have been tested for the discounting purpose but in the end a natural logarithm seemed to fit the demands quite well. These values are shown in the end of the Table 4 below.

Table 4. Discounted DALYs and Relative weights

Impact Categories	Total DALYs	In relation to climate change	Discounted =ln	Relative weights
Climate change	54 727 898 958	1,0000	24,73	0,18
Ozone depletion	23 713 561	0,0004	16,98	0,12
Photochemical ozone formation	2 315 091	0,0000	14,65	0,11
Acidification	156 899 640	0,0029	18,87	0,14
Nutrification	170 331 633	0,0031	18,95	0,14
Toxicity	37 188 697 118	0,6795	24,34	0,17
Ionising radiation	1 084 988 333	0,0198	20,80	0,15

7. Conclusions

The method of estimating total DALYs for all endpoint problems is quite laborious. However, once it is done for the first time, there is only a need for updating. The weights can be used in different contexts as long as the principle is accepted. Apart from being an accepted the methodology, it is not value-based and it is easy to understand conceptually. If additional endpoint problems are identified they can easily be added to the existing ones.

Relatively the role of those who are involved in developing the method has nothing to do with what they think is relatively important as is often the case with most of other weighting approaches. On the contrary it is synthesis of existing knowledge and data that is processed and brought about the weights.

With regard to the data use, since estimations are also involved, critical reviews and improvements of the calculations are desired. Discussions around the size of different endpoint problems and alternative scenarios are certainly fruitful for legitimacy of methods like this. The number of estimations involved might look too much but the very large differences obtained between different endpoint problems shows that even large inaccuracies don't change the final result. Such inaccuracies do not change the ranking of the impact categories rendering the influence of uncertainties resulting from rough estimations invisible. Preliminary sensitivity analysis done internally on the weights showed that their relationship is fairly robust. Nevertheless, the specific data used to arrive at the weights needs improvement and scrutiny with increased knowledge and data availability. Certainly along with new data and knowledge, the calculations can and will be improved.

The future work in this area should focus both on using and testing such weighting methods. Besides, a parallel effort is required in terms of not only generating data but also enhancing access to what is available.

With regard to the limitation of the method, the linear model of the damage-based approach adopted here has the shortcoming of simplifying the cause-effect relations embedded in the environmental mechanisms that lead to the different endpoint problems. In reality the environmental mechanisms are non-linear and more complex than what can be captured using a linear model. The linear model dictates that the damage is proportional to the cause or "dose". This linearity at all doses implied implicitly in this weighting method deviates from what happens in natural systems where for a given environmental impact there is often a threshold, and no damage is caused until the threshold is overridden.

Keywords: indicators, health, comfort, safety, accessibility, indoor environment, sustainability

Summary

Under the ambitious acronym PERFECTION a new European coordination action has been launched. The project aims, via the development of an interoperable framework for performance indicators, at enabling the application of appropriate building design and technologies to improve the impact of the indoor built environment on health, comfort, feeling of safety, accessibility and positive stimulation.

A review of performance indicators currently used in design, construction and use will be undertaken. Areas where new indicators for health and safety (including accessibility and indoor environmental quality) should be developed will be defined. Recommendations for building design and technologies will be formulated in line with European directives on construction products and on energy building performance of buildings, the European environment & health action plan, the European green public procurement policies and the recently launched Lead Market Initiative on Sustainable Construction. A support tool should guide the use of correct indicators for a given context.

The project is carried out at an EU scale and the project results will reach every EU country. Next to 11 key partners, a great number of so called network partners representing industry from SMEs to LSEs, academia and research, will actively contribute to the common goal.

1. The PERFECTION Objectives

In the recent years, several approaches have been developed in the EU as regards the assessment of the indoor environment and building sustainability and the establishment of respective indicators. It is exactly because of the many activities and elaborations in the area of indoor environment and building sustainability that the potential of a co-ordinated activity is maximized. Learning from each other and setting a common agenda and a common roadmap constitute the obvious reasoning for this.

The aim of the PERFECTION coordination action is to help enable the application of new building design and technologies that improve the impact of the indoor built environment on health, comfort, feeling of safety and positive stimulation. In order to reach this objective, the project will deliver:

- a repository of good indoor performance indicators for health, comfort and safety
- a repository of state of the art environmental technologies that appear to have the potential for an important impact on the indoor performance and sustainability of the built domain
- an interoperable framework for performance indicators qualifying the indoor environment, allowing the successful life cycle management of sustainable buildings and stimulating the exploitation of appropriate technologies
- a decision support tool for different user groups applicable to different building types
- findings from selected pilot cases of the use of the indicators framework and the relevant indoor performance indicators
- recommendations on policies and the future research agenda: a roadmap including incentives and barriers for the application of building design and technologies to improve the quality of indoor environments

- knowledge and good practices on performance indicators for health, comfort and safety in the indoor environment.
- a wide dissemination of findings through an extensive expert network and the organisation of a series of events.

Figure 1 presents the PERFECTION framework, its mission statement and expected impacts and the main tasks to be executed in the 36 month project duration.

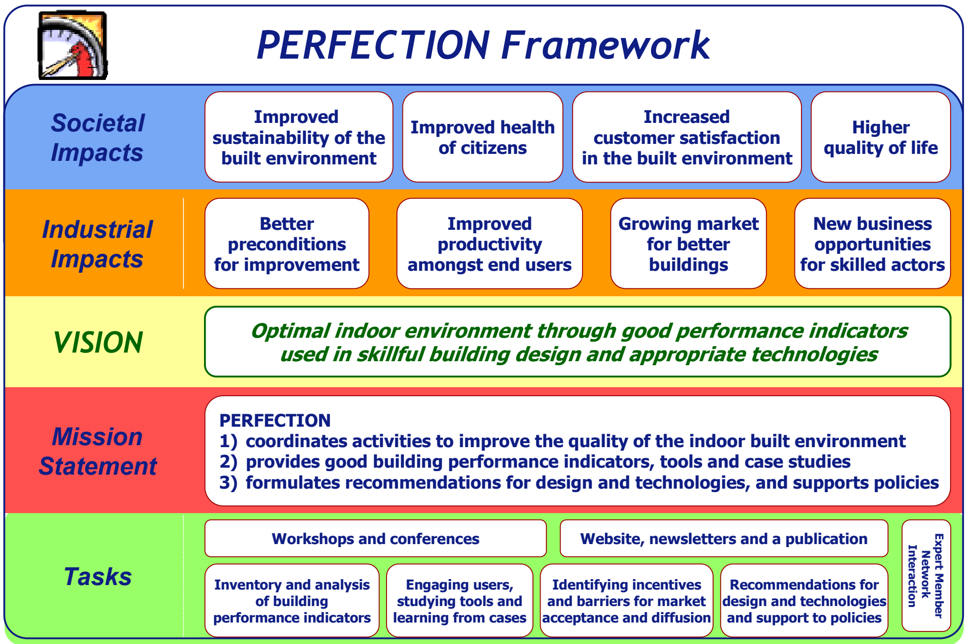

Figure 1: The PERFECTION Framework and its expected impacts

2. Towards a PERFECTION Building Performance Indicator Inventory and Framework

A number of the PERFECTION partners have been involved in the compilation of different performance and sustainability indicator systems in the immediate past (e.g. CRISP, ECOServe, Hope). However, the lack of a strong contextual element is what we see as one of the drawbacks in assessment methodologies, and related metrics and indicators. The indicator framework in PERFECTION will position not only health, comfort, safety and accessibility indicators, which in the LEnSE-project have been categorized in the Social Sustainability Theme. It should also include other important indoor performance indicators that touch on the sustainability aspects, such as adaptability or usability in a form that designers can communicate to clients. In this direction we will take into account the results of the LEnSE, ManuBuild, PeBBu and TISSUE projects to further detail or reformulate the core performance indicators and actively engage the end user considerations (Foliente et al. 2005; Huovila et al. 2004). The following figure 2 illustrates this approach.

Performance indicators for health, comfort and safety of the indoor built environment	
Indicators named in the ENV 3.1.5.2 Call	**Potential supplementary indoor performance indicators**
• Health • Comfort • Feeling of safety • Positive stimulation • Accessibility • Indoor environmental quality • Sustainable, low-energy built-environment	• adaptability / flexibility • service life • usability • life cycle costing • environmental pressure

Figure 2: Performance indicators covered by PERFECTION

CIB has produced an internationally accepted Compendium of Building Performance framework including the categories of safety, comfort, health & hygiene, service life, and usability and maintainability. CIB has also an active Working Commission W077 on Indoor climate and its recent large EC funded Performance Based Building Thematic Network (2001-2005) included a domain for Indoor Environment (ISO, 1984; Lützkendorf et al. 2005). An example of a practical tool containing a database of performance indicators for e.g. indoor conditions, comfort, safety and accessibility is shown below in figure 3.

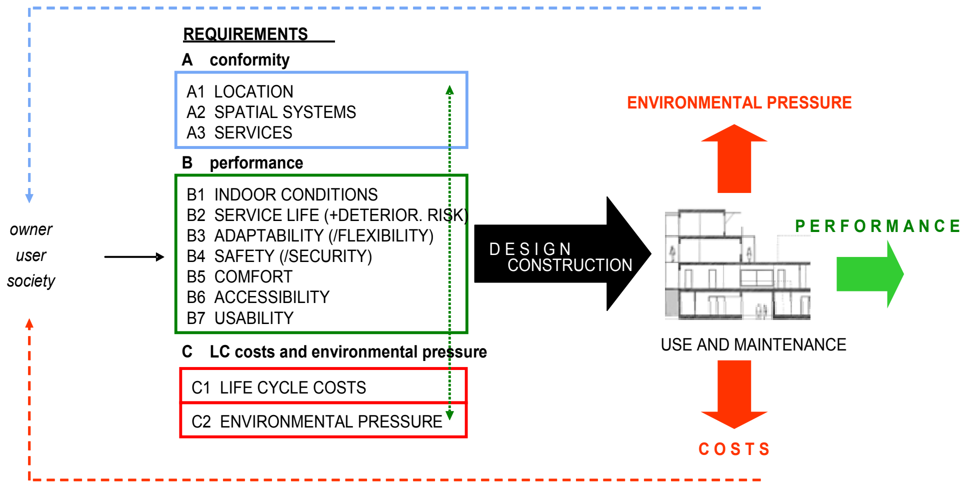

Figure 3: VTT's EcoProP tool[1] for design briefing and systematic requirements management.

2.1 Comfort related indicators

Review of comfort (and health, see the next paragraph) related indicators is based on existing publications, regulations and standards on the subject, e.g., EN 13779:2004, EN 15251:2007, NBN EN ISO 7730:2006, NBN EN 12464-1, FMA-LNE (2007), CEN TC 350 on sustainability of construction works and CEN TC351 on hazardous substances in construction products. Based upon earlier work a first subset of indicators has been established as the starting point.

- Hygrothermal comfort
  - Thermal conditions in winter and summer, as characterized by thermal comfort indices PMV-PPD[2], temperature and/or air velocity variations.
  - Local thermal discomfort, such as draught, radiant temperature asymmetry, vertical air temperature differences and floor surface temperatures.
  - Indoor air humidity
- Ventilation conditions
  - Ventilation rate/air flows
  - CO_2 concentration[3]
- Acoustic comfort
  - Acoustic insulation performance for airborne noise and structure-borne noise
  - Façade insulation performance
  - Background noise from indoor sources
  - Reverberation time and acoustical absorption

[1] http://cic.vtt.fi/eco/ecoprop/english/EcoProp_brochure.pdf
[2] The PMV-PPD index (EN ISO 7730) takes into account the influence of all 6 thermal parameters (clothing, activity, air and mean radiant temperature, air velocity and humidity).
[3] CO_2 concentration may be used to characterize air quality in buildings where people are the main pollution source (see EN 12251:2007).

- Lighting comfort (natural and artificial lighting)
    - Daylight factor
    - Maintained illuminance and uniformity
    - Distribution of luminances and reflection coefficients
    - Glare (as characterized by UGR (Unified Glare Rating))
    - Color Rendering Index and color temperature
- Vibrations
- Access
    - Access to adequate external space such as gardens, parks, squares, etc.
    - Access to indoor facilities related to the building
    - Access to parking/storage facilities

2.2 Health and Indoor Environment related indicators

The standardization work by e.g. ASHRAE, ASTM, CEN (TC156W1, TC264WG7, TC350, TC351), EC (CPD 89/106), EOTA (PT9), ISO (16000/TC146SC6, 16814/TC205) and WHO, without even mentioning all, gives extensive references on indoor health related indicators. Also legislation such as the Flemish Decree on indoor environmental quality, includes indoor environment and health related indicators. A first list of indicators has been defined and will be further elaborated:

- Indoor air quality
    - Quality of the Air Intake (especially relevant in urban and industrial areas)
    - Concentration of CO
    - Dust (Particulate Matter PM2,5 and PM10)
    - Total Volatile Organic Compounds (TVOC)
    - Formaldehyde, benzene, toluene, tetrachloroethylene, trichloroethylenen, ozone O_3, acetalaldehyde, other aldehydes
    - Asbestos
- Electro-magnetic Fields
- Biotic factors
    - Guanine
    - Cockroaches
    - Micro-organisms
    - Mites
    - Rats and mice
    - Mould
- Quality of drinking water
    - Microbial water contamination
    - Water pollutants

2.3 Accessibility and positive stimulation related indicators

Accessibility may be defined as a comfort-related issue, but is so specific that it probably should be dealt with in a specific category. The work of CIB Working Group 084 on building comfortable environments for all is particularly relevant with regard to indicators on accessibility and positive stimulation. Other interesting sources are amongst others UN Enable, the World Bank, Agenda 22, the European Concept for Accessibility, the European Institute for Design and Disability, ISO TC 59 SC16 "*Accessibility and Usability of* *the Built Environment*" and the recent EC funded RTD project POLIS - Decision support tools and policy initiatives in support of a universal design of buildings (2004-2006)[4].

Defining indicators which can be used to measure and/or monitor the accessibility or quality of the indoor environment is not an easy task. As most countries define detailed criteria in legislation, standards or guidelines, and work with consultants and checklists to guide and evaluate designs and buildings, the risk is high that the number of indicators will become too important to stay manageable. It will therefore be necessary to define broader categories, probably based upon the needs of the users, such as:

- Disabled Access. An important element here will be whether we categorize the users or not. As a matter of fact, the needs of wheelchair users, blind or deaf may be entirely different. However, as universal design starts from the point of view that the design should respect the needs of all users, the disabled users do often not like to be categorized. When defining indicators, it may be easier or even necessary to categorize.
- Children Access
- Pram Access
- …

Accessibility and positive stimulation are also closely linked. An accessible built environment is essential if one has the ambition to have an inclusive society where everyone is able to participate in normal daily activities, such as work, leisure, shopping, etc. On the other hand, the built environment and the buildings may be so that they stimulate people to move, to communicate, to look, to feel, to participate in society, etc. A target group which comes immediately to mind in this context is the ageing population, but also other groups, e.g., children, disabled, stressed and depressed, may profit from positive stimulation.

2.4 Safety and security related indicators

Safety and security have been dealt with in projects such as the EC-funded projects PRESCO (5FP European Network for Practical Recommendations for Sustainable Construction) and LEnSe (6FP STREP Methodology Development towards a Label for Environmental, Social and Economic Buildings). Also the work of CEN TC 325 on the Prevention of Crime by Urban Planning and Building Design is particularly interesting. This TC has in the recent year published a series of standards and specifications:

- NBN EN 14383-1:2006 – Prevention of crime - Urban planning and building design – Part 1: Definition of specific terms
- NBN ENV 14383-2:2004 – Prevention of crime - Urban planning and design - Part 2: Urban planning
- NBN CEN/TS 14383-3:2005 – Prevention of crime - Urban planning and building design - Part 3: Dwellings
- CEN/TS 14383-4:2006 – Prevention of crime - Urban planning and design - Part 4: Shops and offices.

However, safety includes also other indoor risks such as falling, electrical dangers, explosions, etc. In our views indicators should be defined for:

- Structural stability
- Flood risks
- Fire safety and alarms
- Fire fighting provisions
- Provision and Quality of Escape routes
- Lightning safety
- Prevention of crime – burglar proof provisions in the planning or design phase
- Static electricity
- Personal safety (slipperiness, risks of collisions, falling due to unexpected differences in height, etc.)

3. Other PERFECTION Objectives

3.1 Use of Technologies and Designs

Creating an indicator framework is merely the fist step of the PERFECTION coordination action. An important work package will focus on the use of indicators and the way they could stimulate the development and the uptake of new designs and technologies (Huovila 2007a; Huovila 2007b) In that regard a PERFECTION user decision support tool will be developed. It should comprise 2 modules:

- an evaluation module of specific technologies, services, etc. against metrics and benchmarks defined in the indicator framework.
- a promotional module where solutions that are related to the PERFECTION scope and achieve a building enhancement mark above a certain level will be publicised against a defined template

3.2 Policy Recommendations

PERFECTION has also policy related objectives. As a matter of fact, PERFECTION hopes to be able:

- To formulate a set of recommendations to the EC and the Member States with regard to incentives and barriers to new designs and technologies. As a matter of fact, the application of new and innovative designs and technologies allowing ameliorating the quality of the indoor environment is hindered by existing standards and regulations or by the conservatism in the sector. On the other hand, the uptake of such designs and technologies may be accelerated by incentives developed by the authorities such as green procurement or pilots at government associated buildings.
- To formulate a set of recommendations to the EC, the Member States and Industry with regard to the needs and priorities of the future. Reference is essentially made to the urgent technological needs in the short and medium term. As an example one could for instance name the need for sensors, technologies and designs to make sure the indoor CO_2 concentration is always below the threshold values, taking into account the human interaction.

Figure 4: The PERFECTION team covers various areas of expertise.

- To deliver a Policy Support Paper with regard to the CPD, EPBD, EEHAP, standards and regulations. This Paper will be based upon the work realised in WP1 and WP4, and will amongst others deal with the lack of knowledge and the lack of uniformity around Europe.
- To describe an Indoor Core Performance Indicator Roadmap that describes various development paths towards the desired future state taken cognisance of different time frames, technology maturity and relevant policy action plans (barriers and incentives). . The roadmap will be validated by an extensive network member group containing knowledge from different industrial and scientific domains.

3.3 PERFECTION Dissemination Activities

The project is carried out at an EU scale and the project results will reach every EU country as is illustrated in Figures 4 and 5. More than 40 experts from over 30 countries were carefully selected to the PERFECTION team to ensure the necessary depth and width. As figure 4 shows the network consists of experts from various domains focused within the ENV.3.1.5.2 call; such as indoor health issues, acoustics, universal design, performance metrics and tools, sustainable design and construction, etc. Clear project yardsticks are the following:

- Engaging in the project roll-out partners or subcontractors from all EU-27 countries and securing a networking effect, extending well beyond the project lifetime. Next to 11 key partners, a great number of so called network partners representing industry from SMEs to LSEs, academia and research, from all over the EU and the accession countries, are actively contributing to our common goal.
- Organizing five events all across Europe (North, East, South-East, South-West, Central), two with a policy focus, two with a research focus and one business focused. A sixth smaller-scale event will be organized for EC officers and will be focused on EC policies in the areas of environment, enterprise, transport and energy, employment, social affairs and equal opportunities.

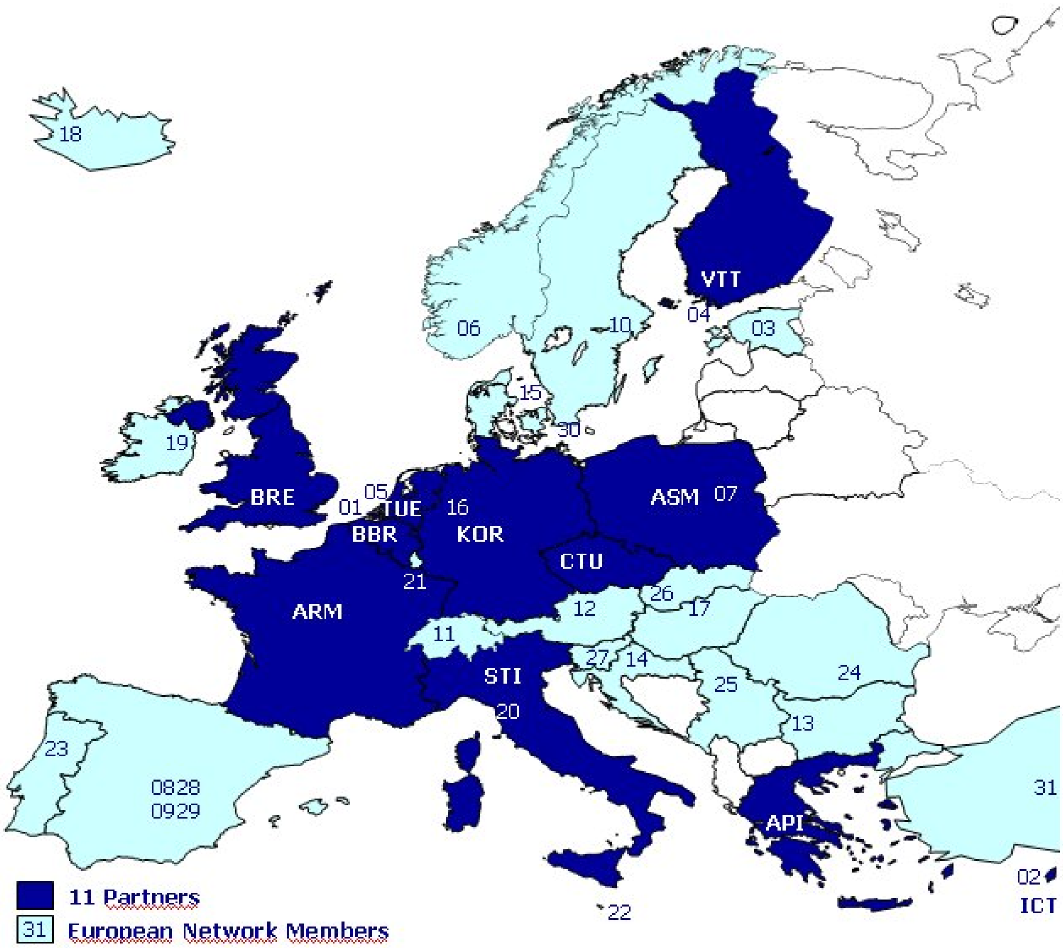

Figure 5: The PERFECTION Network encompasses well the European dimension.

- Producing a quality publication - showcase of a number of case studies across all EU-27 countries, whereby the impact of innovative and well defined technologies as well as policies on specific buildings will be presented in a user friendly way.

4. Conclusion

The PERFECTION coordination action just started in the middle of 2008 and runs over a period of 36 months. Contract negotiations were not yet finalised when submitting the paper. As such, not more than the project objectives and a first, premature subset of indicators could be presented in this paper. However, numerous initiatives will be taken in the coming months and years. This is an open invitation to participate and contribute whenever feasible. PERFECTION will inform you about progress.

5. Acknowledgement

PERFECTION is a coordination action that will be supported by the European Commission within the 7th Framework Programme Environment Calls as soon as contract negotiations are successfully terminated.

DEVELOPING THE SUSTAINABLE BUILDING ASSESSMENT TOOL FOR STADIA

Nosizo SEBAKE[1]

[1] CSIR, Built Environment, Architectural Sciences. P.O. Box 395, Pretoria, 0001. ssebake@csir.co.za

Keywords: Sustainable Building Assessment Tool, SBAT, sustainability performance, FIFA 2010 World Cup, South Africa.

Summary

South Africa will, in 2010 host the continent's first FIFA World Cup, and in so doing attempt to continue the legacy of the Green Goal, developed for its predecessor, Germany, for the FIFA World Cup 2006. In preparation for the event, South Africa's Department of Environmental Affairs and Tourism (DEAT) aims to ensure that like the German stadia, South Africa stadia are environmentally sustainable, particularly in terms of water, energy and waste aspects.

A framework, specific to stadia, is required in order for the sustainability of each stadium to be rated. The Sustainable Building Assessment Tool (SBAT) has an existing structure; however its indicators are focused primarily on the assessment of commercial buildings.

The paper investigates a selection of indicators relevant for stadia and undertakes the development of an SBAT for Stadia for the environmental assessment of the 2010 World Cup stadia.

1 Introduction

South Africa will host the FIFA 2010 World Cup in three years' time and in keeping with the legacy left by the FIFA 2006 World Cup, the Department of Environmental Affairs and Tourism (DEAT) green status of the 2010 soccer stadiums is being reviewed.

1.1 Relevance

The review team proposed the use of the existing SBAT framework/methodology with adaptations to reflect the stadium building type. Table 1Table 1 outlines some differences between commercial buildings (for which the SBAT was originally intended) and stadium. This brief comparison shows that the two building types cannot be compared and therefore a tool targeting one building type (i.e. commercial building) cannot be used to measure the sustainability performance of the other (i.e. stadium) without being biased to the other (i.e. stadium).

Table 1 Comparison between a commercial building and a stadium

	BP Building, Cape Town	Green Point Stadium
Definition	A commercial building is a building type that is used for commercial use, including office buildings, warehouses, or retail (Wikipedia contributors, 2007).	A modern stadium is a predominantly outdoor place used for sports, concerts or other events. It consists of a field that is partly or completely surrounded by a structure designed to allow spectators to stand or sit and view the event (Wikipedia contributors, 2008).
Users	540 employees are accommodated in the building. At maximum capacity each employee has a space of 16,26m^2/occupant	50'000 spectators will seat on a structure that is open to most external element. Each spectator has a space of 1,97m^2
Occupancy	Approximately 260 days/year for a minimum of 12 hours/day	A minimum of 30 days/ year for a minimum of 4 hours/event
Area Analysis	More than 50% of the floor space is used for commercial purposes.	More than 50% of the floor space is used for spectator seating, VIP and media facilities.

1.2 Scope of Research

The research will present the development and use of the SBAT for Stadia assessment tool.

1.3 Research Aim and Questions

The aim of the research was to find an appropriate tool to assess the sustainability performance of the stadia for the 2010 FIFA World Cup.

The research question derived from this are:

- Can the SBAT be adapted to reflect the stadia building type?
- How will this new assessment tool be used?

1.4 Structure of the Paper

The paper is structured under the following headings; background, literature review, methodology, discussion and conclusions.

2 Background

2.1 South African Context

The Republic of South Africa is considered to be the most developed and modern country on the African continent. Since 1994, when the first democratic government was elected, South Africa has had positive economic growth (Knight, 2006). However, on the other side of these positive aspects, is a country which still has major social and economic problems, including poverty, inequality, unemployment, HIV/Aids and property and personal insecurity (Beall, et al, 2005).

It was in light of these socio-economic problems that South Africa's bid campaign for the 2010 Fédération Internationale de Football Association (FIFA) World Cup promised that it would ensure *"a lasting social legacy through the event and"* leverage "*the event to spread economic and social benefits beyond the borders of South Africa"* (DEAT, 2006). In May 2004, South Africa was awarded the rights to host the 2010 FIFA World Cup event. Ten stadiums will be constructed, upgraded or reconstructed for the event (FIFA, No date).

South Africa's hosting of the 2010 event presents an opportunity not only to run a successful event but also to achieve the political and social promises on which South Africa's bid campaign was based (Cornelissen, Swart 2006). In addition to fulfilling the promises made, South Africa will take on the challenge of upholding the standards set by Germany during the 2006 FIFA World Cup event, which was carried out in an environmentally accountable way.

South Africa's Department of Environmental Affairs and Tourism (DEAT) has addressed this challenge by setting up the Review of the Greening Status of the Stadia for the 2010 World Cup in South Africa project which is currently undertaken by Green by Design (GbD), Paul Carew Consulting (PjC) and the South African Council for Scientific and Industrial Research (CSIR). The project aims to review the sustainability initiatives that have been included in the host stadia, identify gaps and where appropriate provide recommendations.

2.2 SBAT framework

The SBAT framework includes criteria in all three sustainability aspects, namely, economic, environmental and social as outlined below (Gibberd, 2003):

- Economic: local economy; efficiency; adaptability and flexibility; ongoing costs; capital costs.
- Environmental: water; energy; waste; site; materials and components.
- Social: occupant comfort; inclusive environments; access to facilities; participation and control; education, health and safety.

Each of the 15 criteria has a set of five sub-criteria linked to indicators that are used to measure the sustainability performance of a proposed design or existing building (see Table 2).

Table 2 The Structure of the Sustainable Building Assessment Tool (SBAT)

Sustainability aspect	Criteria	Sub-Criteria	Indicator
EC ECONOMIC	EC1 Local Economy	EC1.1 Local Labour	Use of local (from within 50km of the site) labourers
		EC1.2 Local Materials	Building material sourced from within the country
		EC1.3 Local Materials and Components	Material and components sourced from within the country

		EC1.4 Local Furniture and Fittings	Furniture and fittings sourced from within the country
		EC1.5 Maintenance	Maintenance and repairs can be undertaken by local SMMEs (turnover of <R5m)
Total: 3 aspects	Total: 15 criteria	Total: 75 sub-criteria	Total: 75 indicators

Source: Sebake and Gibberd, 2008

3 Literature Review

3.1. Greening of sporting events

The concept of sustainable development has been defined by the World Commission on Environment and Development (WCED) in their Brundtland Report as meeting the needs of the present without compromising the ability of future generations to meet their own needs (WCED, 1987). This was recognized as a balance between the environmental protection, economic growth and social development dimensions in 1992 at the Rio Declaration by the United Nations NGO Committee on Sustainable Development (UN, No date a).

Table 3 Chronology of global commitments to Sustainable Development and the Incorporation of Sustainability principles in the Olympics and FIFA

Sustainable Development	Year	Incorporation of Sustainability in the Olympics and FIFA
Brundtland Commission defines "sustainable development"	1987

Formation of the South African Green Building Council	2007	FIFA Technical Requirements adds 'Green Goal' chapter

Source: Sebake and Gibberd, 2008

Of the largest global sporting organizations, the International Olympic Committee (IOC) was the first to respond to the global concern on environmental concern. This was done by the Local Organising Committee (LOC) who incorporated environmental practices in the implementation of the Lillehammer 1994 Winter Games. Subsequent LOCs followed this example including the Nagano 1998, Sydney 2000, Salt lake City 2002, Athens 2004 and Torino 2006 (IOC, 2007). The most recent Olympics Games stand out because the Torino Organizing Committee (TOROC) pioneered the move to sustainability reporting based on the Global Reporting Initiative (GRI) guidelines (TOROC, 2005). This ensured that planning, implementation and monitoring incorporated the three sustainability dimensions recognized at the 1992 Rio Declaration which went beyond focusing on environmental issues.

It is evident from the preparation of the following three Olympic Games events, namely Beijing 2008, Vancouver 2010 and London 2012, that the respective LOCs have been influenced by the sustainability practices undertaken in the Torino 2006 Winter Games and will be addressing sustainability as a major concern (IOC, No date).

The 2006 FIFA World Cup LOC were inspired by the successes of Australia for the 2000 Summer Olympics in Sydney and submitted a chapter called Environmental Concept for the stadia as part of their bid campaign even before FIFA required any commitment to Environmental Protection or Sustainable Development.

The Green Goal initiative was developed by the 2006 LOC who worked with the Öko-Institut and the World Wildlife Fund (WWF) to develop guidelines and objectives for the event. Implementation of the initiative was difficult, mainly because construction of the stadia had already begun. The programme therefore only had a limited impact on the stadium planning (Öko-Institut, 2006).

Following Germany's successful hosting of the 2006 World Cup, FIFA (like the IOC following the Lillehammer Games in 1994) showed its support for environmental protection by adding a Green Goal chapter in its Football Stadiums: Technical Recommendations and Requirements (FIFA, 2007) manual and the incorporation of Environmental Protection in the host city agreement with the 2010 FIFA World Cup LOC and the host city (CoCT, 2006, pp 3). The host cities have been bound by this agreement to plan, implement and operate the 2010 stadia in an environmentally sustainable manner. South African legislation (which has been guided by global priorities encapsulated through documents like the Agenda 21, Millennium Development Goals and the Johannesburg Plan of Implementation (DEAT, 2006)) has provided additional guidance.

3.2 The use of Assessment tools for Sporting events

Table 4 Assessment tools used

	Tools used
Sydney 2000	Green Star
Torino 2006	SEA GRI guidelines
Vancouver 2010	LEED
London 2012	BREEAM Bespoke

4 Methodology

4.1 Background of the Review Project

The Review of the Greening of the Stadia for the FIFA 2010 World Cup project was initiated by the Department of Environmental Affairs and Tourism (DEAT) to review the sustainability initiatives that have been included in the host stadia, identify gaps and where appropriate provide recommendations. The project commenced in July 2007 and is undertaken by Green by Design (GbD), Paul Carew Consulting (PjC) and the South African Council for Scientific and Industrial Research (CSIR). To date two stadia (Moses Mabhida Stadium and Green Point Stadium and one training venue (Athlone Stadium) have been reviewed.

The original terms of reference (ToR) for the proposal received from DEAT included environmental assessment of water, energy, waste and transport issues as outlined in the Green Goal Report (iSeluleko Consulting 2007). The review team's successful proposal to DEAT responded to these issues and included the suggestion that the SBAT be used to address some of the broader social and economic issues rather than solely focusing on environmental issues.

The review project widened the scope from a purely environmental focus and acknowledged South African local concerns, by assessing the social and economic issues. The use of the SBAT, which has been found to be the most suitable tool for a developing country context (Kaatz, et al, 2002) was therefore appropriate for use for the review project.

4.2 The Development of the SBAT for Stadia

The existing Sustainable Building Assessment Tool (SBAT) was adapted to create the SBAT for Stadia through the development of a set of indicators and targets/benchmarks that would support the assessment of the sustainability performance of the 2010 FIFA World Cup stadia.

The development process of the SBAT for Stadia is reflected in Diagram 1 (Sebake and Gibberd, 2008). The process is described below:

- The first stage (A) requires the review of relevant literature subsequent to the completion of the first SBAT version in 2003.
- From the review, an assessment framework is developed (B). This will be used to assess the appropriateness of new indicators to global trends.
- In the third stage (C), a review of the SBAT and the relevant building type is undertaken. Indicators not relevant to the building type are removed.
- Building specific indicators are added to the amended list of indicators (D). This stage is best undertaken in conjunction with the development of related targets / benchmarks where they exist (E).
- The indicators are then prioritized using the assessment framework developed in B above to ensure that each criterion has five indicators (one per sub-criteria) (F).
- This prioritization and elimination of indicators results in the first draft SBAT for Stadia (G).
- The SBAT for Stadia should ideally be piloted before being published on the website for public use (H). The field testing was with the first stadium.
- The piloting of the first draft SBAT for Stadia assessment tools will require input from relevant professional experts (I), and may lead to indicator – target / benchmarks set (J).

- Using this feedback and field testing, revise the SBAT for Stadia accordingly (K).
- Publish the revised version of the SBAT for Building Type on the www.sustainablebuilding.co.za website (L) and request user feedback over a three month period.
- Use the feedback and comments received from the users (M) to revise the tool before publishing a third and final version SBAT for Stadia online (N).

4.3 Assessment Process using the SBAT for Stadia

To date two stadiums and one training venue have been appraised. For the purposes of this paper, the focus will remain on the stadia for the event, not on the training venues. The two stadia will be referred to as stadium A and stadium B in order of commencement.

The review of the stadium was undertaken in three stages. The three stages are described in the following sections, which also highlight how the SBAT was used.

4.3.1 Stage 1: The Initial Workshop

The objective of the first stage was to review the existing sustainability initiatives and undertake an appraisal of the possibilities and opportunities that had not been explored.

During this stage, a full day workshop with the stadium authority and individual professional team members was held. This provided the review the sustainability initiatives currently being implemented in the stadium design. These included energy, water, waste, transportation, urban design and material selection.

Following the workshop, additional information was requested from the professional team, including technical documentation (i.e. a site plan, plans of all the levels, sections along both axes of the stadium) and any available and appropriate reports.

The information gathered from the workshop and from the professional team following the workshop is used to develop the first SBAT appraisal and the first draft of the stadium review report. The report consists of two parts; namely the general information and the stadium review.

The general information presents the host city's activities regarding and provided a contextual introduction of the stadium. The stadium review shows the results of the first SBAT appraisal and describes how the stadium design performs in terms of the sustainability review criteria defined in the TOR (i.e. water, energy, waste, transport). Possibilities and opportunities At the end of this stage, gaps in information were highlighted, particularly with regard to the SBAT, which could not be finalised without the missing data. The report, including the incomplete SBAT appraisal, was sent to the stadium authority, who shared this with the professional team.

4.3.2 Stage 2: The Interim Workshop

The objective of the second stage was to assess the feasibility of each of the possibilities and opportunities identified in the first draft report. Both of the stadiums reviewed have reached this stage, however the stadium A has had an additional visit, because processes have been improved.

During this stage, a half day workshop with the stadium authority and selected professional team members was held. This provided the review team with an opportunity to present the first draft report. The first stadium visited provided valuable feedback; however too much time was spend discussing the SBAT rating defeating the objective of the workshop. Following the feedback session, the shades of green decision-making matrix, developed by GbD, was drawn up to assist in allocating resources for the possibilities and opportunities identified.

Following the workshop a SBAT questionnaire was designed to capture missing information. This specifically sought information that was not easily accessible from drawings or reports. The SBAT questionnaire was sent to the stadium authority who forwarded it to the professional team. The SBAT questionnaire was then completed as far as was possible by one or more professional team members. Where information was readily available in a report or other documents not already submitted, this was requested in order to assist the review team and lessen the work load on the professional team.

At the end of this stage, gaps in information were highlighted, particularly with regard to the SBAT, which could not be finalised without the missing data. The report, including the incomplete SBAT appraisal, was sent to the stadium authority.

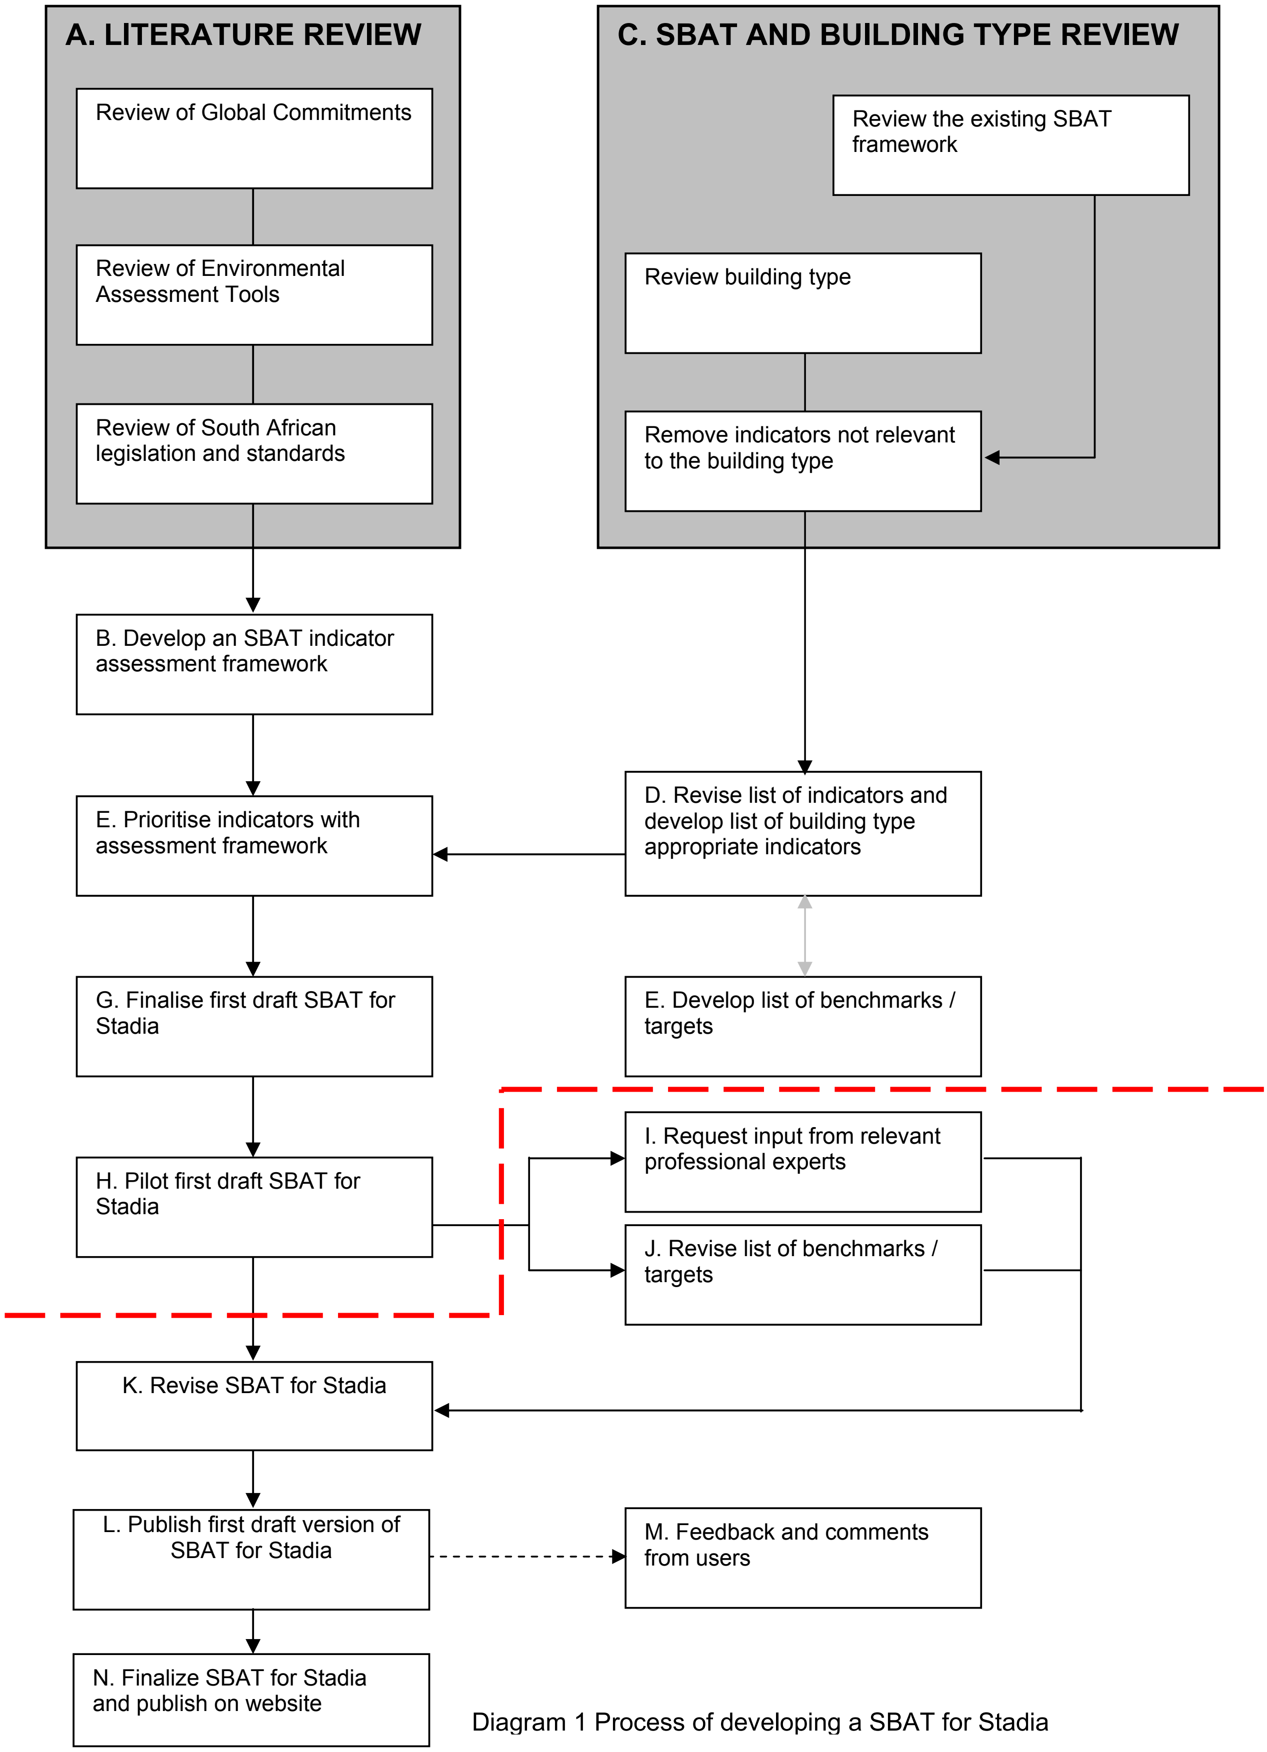

Diagram 1 Process of developing a SBAT for Stadia

4.3.3 Stage 3: The Final Workshop

The objective of the third and final stage is to finalize and present the final report to stadium authority and selected professional team members, and to submit the final report to DEAT. Only one of the two stadia currently under review has reached this stage, however the presentation still needs to take place.

During this stage, a half day workshop with the stadium authority and selected professional team members will be held. This provided the review team with an opportunity to present the final report with incorporating all the comments received from the stadium authority and professional team.

The final report consisted of a completed SBAT appraisal with information used from the SBAT questionnaire sent to the stadium authority. The SBAT diagram (see Figure 1) for the first and currently only stadium to reach this stage was incorporated in the report without the rating figures and final score.

4.4 An Overview of the SBAT Performance

The SBAT report above indicates that the overall sustainability performance of the stadium is good and fairly well balanced across the three different sustainability areas. Relatively poor performing areas include efficiency, water and site rated just under a score of 3 (Average). Areas that appear to perform well include the local economy, adaptability, materials & components, spectator comfort rated well over 3 (Very Good).

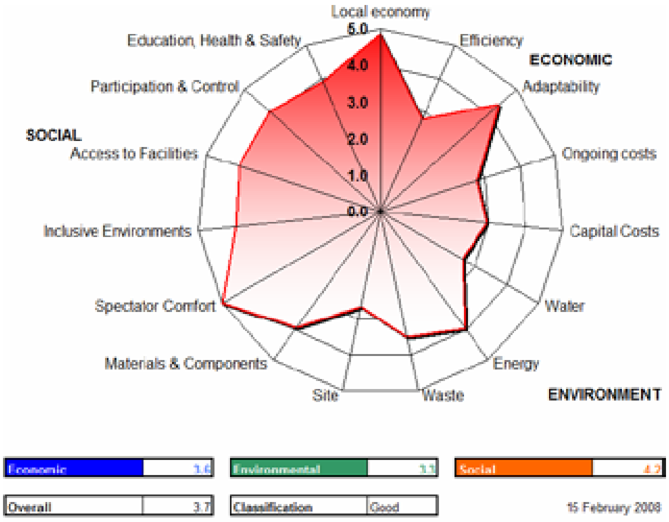

Figure 1 SBAT Radar Diagram Report

The overall rating is “Good” (score between 3.1 and 4) indicates that the approach taken is robust and may lead to a “Very Good” sustainability performance. The balanced performance (ratings vary from 3.6 to 4.2) within the three sustainability areas confirms that there has been an even and effective handling of the performance objectives and that one area (such as environmental issues) has not been allowed to eclipse the others. This balance is likely to have been achieved as a result of the experience of the professional team, the procurement policy and other policies being applied to the project.

5 Discussion

The 6th principle of the Rio Declaration on Environment and Development states that the *“special situation and needs of developing countries…shall be given special priority…”* (UN, No date). This suggests that as a developing country, South Africa needs to ensure that its social and economic issues are addressed before the environmental ones. Although this was aptly highlighted in the bid campaign the planning of the 2010 event has *“...unlike other World Cups … been burdened with near-extreme expectations about what it can in fact achieve with regard to social and … regional economic integration”* (Ndaba, 2007).

The review project widened the scope from a purely environmental focus and acknowledged South African local concerns, by assessing the social and economic issues. The use of the SBAT, which has been found to be the most suitable tool for a developing country context (Kaatz, et al, 2002) was therefore appropriate for use for the review project.

6 Conclusions

The development of the SBAT for Stadia has resulted in a set of indicators and targets which have not been previously available. The development of the tool will be useful for the construction of new and major refurbishment and possibly assist with the monitoring of existing stadia.

Keywords: non-residential sector, carbon management, transition, socio-technical system, low carbon society, simulation

Summary

In this paper, we address the changes needed to realize a substantial reduction of carbon dioxide emissions from the non-residential sector. We try to expand our consideration by focusing beyond technological change and looking instead into the socio-technical system, which refers to a system providing a societal function—a shelter for business and services in case of non-residential sector buildings, consisting of not only technologies but also a cluster of other elements, for example, the building industry, standards and regulations, energy utilities and infrastructure, and cultural and local contexts. The questions addressed in this paper are:

(1) Whether or not achieving a low carbon society requires a structural change in the building system (seen as a socio-technical system)? and
(2) If so, what kinds of change must be addressed in the building system to obtain a substantial reduction in carbon dioxide emissions?

In order to answer these questions, we first identified several carbon dioxide management concepts. We then conducted a case study in which we applied these concepts to the non-residential sector of the city of Osaka, Japan, as a case study to estimate the potential reduction in carbon dioxide emissions. The results show that achieving a substantial reduction requires a structural change in the building system. We finally derived some key challenges to identify possible pathways toward achieving a low carbon society.

1. Introduction

The transition of the building stock and infrastructure toward low carbon emissions is an emerging challenge. This is mainly due to the increasing pressure of global warming and the threat of depletion of fossil fuels. The Japanese residential and non-residential building sectors currently accounts for 32% of the national carbon dioxide emissions, and their emissions increased by 37% and 44% from 1990 to 2005, respectively. A clear gap exists between the current increasing trend in carbon dioxide emissions and the reduced emission level required to achieve a low carbon society. While it is true that a large number of “green” buildings have been constructed in Japan, they only occupy a small portion of the total building stock. The increase in the number of green buildings is offset, for example, by an increase in the total floor area of buildings and the level of services provided in buildings.

Recently, an increasing number of studies have been conducted on estimation of potential reduction in carbon dioxide emissions derived from the building sector with a long-term perspective. Previous research implied that a significant reduction of carbon dioxide emission is achievable in the building sector by a strategic implementation of carbon management concepts. Such studies are relevant not only for developing a shared vision of how the sector should function in our society, but also for searching for possible transition pathways that lead to the envisioned future. In such studies, however, little attention has been paid to the difficulties that must be overcome to realize the changes proposed in the study. Some changes might be of an incremental kind, for example, an improvement in the energy efficiency of appliances and an increase in the share of green buildings in the market. Some changes might be of a more radical kind, in tandem with a structural change in the system providing the societal function of housing and shelter for business and services. A system that provides a societal function such as transportation, health care, education, and energy supply is called a “socio-technical system” (Geels, 2005). The building system (i.e., the socio-technical system providing the societal function of housing and shelter for business and services) consists of a cluster of elements including land ownership and land owners, occupants/residents, appliances/equipment, building engineering systems (ventilation, air-conditioning, lighting, etc.), regulations and standard elements of the building industry such as the construction company and/or the maintenance and operation networks. The socio-technical system also includes all local contexts, energy utilities, and urban form and community.

Researchers studying innovations in the socio-technical system have pointed out that although substantial improvements in efficiency may still be possible with innovations of an incremental kind, larger jumps in efficiency will only be possible with radical innovations; these will require changes from, for example, one building system to another (Geels et al., 2004). If the results of this research are true, a transition of the building sector toward a low carbon society might require integral innovations leading to a structural change in the building system. They also pointed out that leading and managing a structural change in socio-technical systems is very difficult because the elements comprising a socio-technical system are interwoven with multiple societal processes and rooted in our societal structure (Rotmans et al., 2003).

The building system might share the nature of socio-technical systems. Indeed, the building system has evolved through more than a hundred years of history, and the elements of the system listed above are mutually interwoven. Any single factor of the system cannot achieve its purpose without using the resources of the others. There are shared explicit (e.g. regulations, standards, codes) and implicit rules (e.g. expectations, common practice) have been developed in the system throughout history. These rules stabilize the system. Sources of structural change tend to be pushed out from the system even though small changes and technological innovations occur in the system due to the rules.

How do we recognize whether an assumed change in a socio-technical system is of an incremental or a radical kind? The former fit the rules existing in the system, generally leading to an improvement in the system as well as strengthening its stability. On the other hand, a radical change means that a structural change occurs, and consequently, the elements of the system and the correlations among them are reconfigured. For example, in the case of the building system, technological advancement in the existing energy consuming appliances/equipment (e.g., heat source machine) can be said to be an incremental improvement. It is unlikely that such a technological improvement results in a structural change in the building system. On the other hand, dissemination of distributed generation technologies (e.g., micro turbines and fuel cells), for example, could possibly lead to a structural change for the following reasons: the electricity utility must adjust its generation capacity and tariff in accordance with a substantial change in the electricity demand. City gas utilities would increase their supply capacity and strengthen their distribution network. Design of heat source systems will therefore be different because utilization of waste heat generated by distributed generators results in energy and expenditure savings. Urban energy flow might vary considerably. Standards and codes would be developed to assure safety and quality of service provided by the system. These are examples of possible changes resulting from the dissemination of new technologies. The elements and correlations among the elements will be reconfigured through the transition process in this case. It is obvious that leading and managing such a structural change is difficult.

In this context, two questions arise:

(1) Does achieving a low carbon society require a structural change in the building sector?

(2) If so, what kinds of changes must be addressed in the building system to spearhead a substantial reduction in carbon dioxide emissions?

Japanese society tends to pursue a development model of a somewhat incremental kind that relies on developing individual technologies and pursuing partial improvement in the elements of a system. Thus, it is important to make sure that such an incremental development will really assure the sustainability of our building sector. The aim of this paper is to answer these questions as a preliminary study on the transition pathways of the Japanese residential and non-residential building sectors.

In this paper, we first try to understand the elements consisting of the building system (as a socio-technical system) and their connection to energy usage. Based on this understanding, we specify several concepts for managing carbon dioxide emissions applicable to the building system. We qualitatively evaluate if applying these concepts to a large extent must accompany a structural change in the building system. We then develop scenarios combining the carbon dioxide management concepts, and then estimate to what extent carbon dioxide emissions from the building stock of Osaka City in Japan can be reduced until 2050 by introducing the carbon dioxide management concepts addressed previously. We obtain the answer to question (1) based on the results of the case study. We also derive some key challenges as an answer to question (2).

2. Understanding the building system using spatial hierarchy

In this section, we identify key elements of the building system that provide the societal function of shelter for business and services, in order to specify the options available for managing carbon dioxide emissions. For classification purposes, we use a spatial hierarchy consisting of the nation/region, city, district/neighborhood, building and appliances/equipment. We then analyze the correlations that exist between the elements identified in each layer of the spatial hierarchy and energy usage in buildings. Finally, we qualitatively evaluate whether the implementation of each of the carbon dioxide management concepts identified in a particular layer of the spatial hierarchy is likely to accompany a structural change in the building system.

2.1 Spatial hierarchy and carbon dioxide management concepts

Figure 1 lists the elements involved in each layer of the hierarchy. We identified physical properties that represent the links between the elements listed for each layer and energy usage in non-residential sector buildings. Based upon the understanding of the structure, we identified the following five carbon dioxide management concepts applicable to each layer of the spatial hierarchy:

(1) Improvement in the efficiency of energy-consuming appliances/equipment

(2) Dissemination of energy-saving measures for buildings, such as improvement in the insulation performance of a building's envelope
(3) Local energy planning, i.e., optimization of the local energy generation and distribution systems, including the development of district heating and cooling systems, and the adoption of renewable technologies at a local level
(4) Management of land usage and urban form (Jaccard et al., 1997)
(5) Improvement in the carbon dioxide emission factor of the electricity grid by improving the generation efficiencies of power plants, switching fuel, adopting carbon dioxide sequestration and storage, and increasing the share of nuclear power and renewable energy sources.

Spatial layer	Elements	Physical property	CO_2 management concept	Key actor
National/Regional 	Population, economic activity National and Regional Planning Utility (Electricity, City gas)	National/regional building stock Population CO_2 emission factor of the grid electricity	Improvement in the CO_2 emission factor of the electricity grid	National government, Energy utility
City 	Urban planning, Urban form, Land use	Distribution of building stock	Management of land use and urban form	Local authority
District/Neighborhood 	Local context (history, land ownership, area), Community-scale energy generation & distribution system (e.g., DHC)	Density, function (usage), gross floor area, distribution of size and configuration, total number of buildings	Optimization of the local energy generation & distribution	Local community Developer
Building/Building system 	Building structure, principal usage, insulation performance, building systems (air-conditioning, ventilation, lighting, etc.)	Number of energy saving measures adopted in buildings Share of heat source systems	Dissemination of energy saving measures	Building owner Building industry National/local government Residents/occupants
Appliance/Equipment 	Lighting, OA, pump, fan, heat source machine Alternative technologies (e.g. LED)	Energy efficiency	Improvement of energy efficiency (stepwise improvement, technological substitution)	Manufacturers National government Users

Figure 1 Elements comprising the building system and classification of carbon management concepts.

2.2 Linkages of the elements involved in each spatial layer with the energy usage in buildings

2.2.1 Appliances and equipment

Technological advancement in energy-consuming appliances and equipment that is currently used in buildings might directly contribute to reducing energy demand and carbon dioxide emission. The key players in this layer are the manufacturers of appliances/equipment. In Japan, manufacturing companies tend to deliver the most energy efficient products to the market, because energy efficiency is one of the most important buying factors for customers. National standards (e.g., energy efficiency standards) have been implemented to influence the pace and direction of technological advancement.

In this study, we survey information on lighting and heat source machines as examples of key technologies. Table 1 lists the energy efficiency of these appliances/equipment, extrapolated to the year 2050 based on a number of roadmaps and technical reports on the technologies, in addition to discussions with experts in this field. The column titled "Baseline" in the table lists the efficiencies of these appliances/equipment, which is assumed to be the average level of the stock. We will estimate potential reductions in carbon dioxide emission from the non-residential sector of the city of Osaka in Section 3 using the values listed in Table 1.

2.2.2 Building and building system

Buildings are constructed to serve a particular function or purpose. Building engineering systems (e.g., ventilation, air-conditioning, and lighting systems) are designed and operated to maintain an appropriate

Table 1 Efficiency arising from lighting and heat source machines.

Technologies		Baseline	Year 2050	Note
Lighting	Technology	Fluorescent	LED	
	Luminous efficiency	70 [lm/W]	150 [lm/W]	
Absorption chiller [high heat value]	Cooling COP*	1.00	1.65	
Compression chiller	Cooling COP	4.5	8.0	Inverter technology will be introduced to improve part-load operation
Air-source heat pump	Cooling COP	2.9	5.0	
	Heating COP	3.1	5.4	
Room air-conditioner for commercial buildings	Cooling COP	2.6	4.0	
	Heating COP	3.1	5.0	

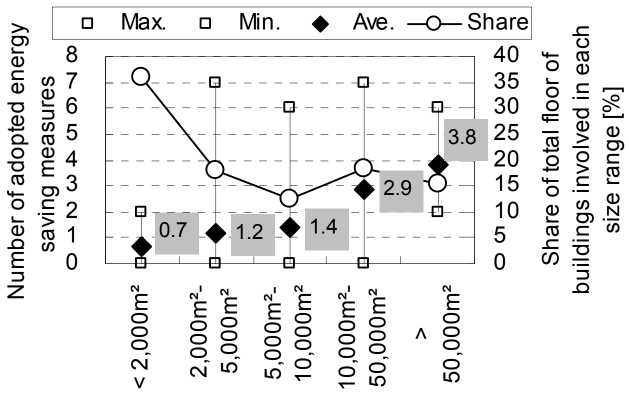
* COP (Coefficient of performance)

indoor environment and to fulfill a particular function. The key players in this layer are building owners and the building industry (e.g., construction and maintenance companies).

We identified a number of energy saving technologies adopted in buildings and the share of heat source systems as physical properties representing the link between elements involved in this layer and energy usage in buildings. We performed statistical analysis on these data and found that there is a trend indicating that larger buildings with more energy-intensive usage (e.g., hospitals) are equipped with a larger number of energy saving measures. Figure 2 shows the average number of energy saving measures in office buildings. For the analysis, we classified the building stock by size. As shown in the figure, larger buildings are equipped with a larger number of energy saving measures. A similar trend can be found in other principal usages—larger buildings with more energy intensive usage have higher energy efficiency. However, small buildings, which account for a large portion of the total building stock in Japan, have been equipped with only a small number of energy saving measures (see Figure 2).

Building regulations and standard (e.g., the Law Concerning the Rational Use of Energy, Japan) has been gradually enforced due to growing pressure for climate protection and higher energy prices. Subsidy programs and different policy initiatives have also been promoted to enhance new business and practices that promote energy saving, such as those of Energy Service Company (ESCO). However, the progress in the energy efficiency of buildings has so far been very slow.

Integrating a large number of energy saving measures makes building design, construction process, and maintenance activity more complex. One needs to fully take into account the local conditions of a specific site. Dissemination of energy saving measures means that conventional norms practiced daily will be no longer be applicable. Thus, although full dissemination of energy saving measures seems to be an extension of the currently slow progress, it also requires a structural change in the building system itself.



The bars show the maximum & minimum number observed in the sample. The number shows the average number of adopted measures.

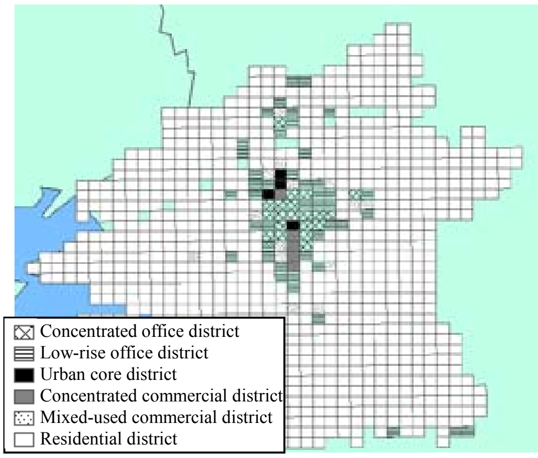


Figure 2 Average number of adopted energy saving measures. *Figure 3 Result of classification of grid cells.*

2.2.3 Neighborhood to district

The carbon dioxide emission management concept in this layer consists of local energy generation and distribution planning. In particular, we focus on the development of energy generation and distribution systems that fit local conditions. District heating and cooling systems in a district with high building density may be considered as examples. Another example is to promote renewable technologies in districts with low building density. There is no question that a radical change is necessary to introduce a energy generation and distribution systems appropriate every local conditions.

Regarding this layer, we would like to focus more on the correlations between energy usage in buildings and the elements of this layer, the local context, and the urban form. These correlations are often ignored in technological studies. However, these elements have a significant influence on energy usage, even in the building sector. This is because these elements predetermine size and configuration, as well as principal usage of buildings located in a given district or neighborhood[1]. A district or neighborhood has a certain function that is defined in the city plan or which has been established through history. This global function determines the amount of building stock accumulated in a district/neighborhood and the function of the individual buildings in the district. The accumulated building stock is realized in a specific local context, with its own history and within its piece of land. These local contexts, in addition to zoning codes and standards, will significantly influence the form and configuration of buildings. This, in turn, means that similar buildings are likely to be duplicated in a district or a neighborhood over the course of time because the local context and urban from do not vary much over a span of a few years.

This implies that a district/neighborhood has certain characteristic in energy demands. In order to quantitatively analyze the influence of local context and urban form on energy usage in buildings, we performed a simulation study. We first developed a grid cell dataset using 500 × 500-m grid cells for the elements that represent the properties of this layer, as listed in Figure 1. The grid cells were classified into six district categories, as shown in Figure 3. We then selected a representative district for each district category. All buildings in the representative districts were surveyed to perform an energy demand simulation. The district-level energy system simulation model developed in this research was applied to the representative districts in order to quantify the energy demand per unit floor area (Yamaguchi, 2007a). The space heating and cooling, hot water, and electricity demand profiles for each building were simulated on an hourly basis. The total end-use energy consumption in buildings was then simulated taking into account the specific configuration of the energy generation and distribution systems. The end-use energy consumption per unit floor area was then quantified by dividing the total end-use energy consumption of all the buildings by the total floor area. Figure 4 shows the procedure of the simulation.

Step 1
Clustering of districts (500 × 500-m grid cells) into several district categories according to the characteristics of building stock (resulting in 6 district categories)

Step 2
Selecting representative districts each representing a district category and developing a database on buildings in the district to perform energy demand simulation

Step 3
Performing district-level simulations to quantify energy consumption per unit floor area in each representative district (the result of this step are used in section 2.2.2)

Step 4
Aggregating the total end-use energy consumption by using the representative end-use energy consumption determined in Step 3 for each *district category* (the result of this step are used in section 3)

Figure 4 Procedure for quantifying the end-use energy consumption

Table 2 shows values of the parameters indicating the characteristics of each district category. Table 2 also shows the energy demand characteristics (measured as a proportion of the total end use of electricity and city gas of the consumption and peak demand for electricity), and the carbon dioxide emission per unit floor area of non-residential sector buildings. The values in the table encompass the influence of the distribution of size, configuration and usage of buildings, predetermined by the local context and urban from, as well as the reality in adoption of energy saving measures and heat source systems explained in 2.2.2. The table shows that each district category has different characteristics with regard to energy usage and carbon dioxide emission. This result clearly shows that local context and urban from have a strong influence on the energy usage in non-residential sector buildings.

Table 2 Characteristics of district categories and energy demand profile.

District category	Gross floor area	% in total floor area	Principal usage		% of buildings with total floor area		
			Office	Others (retail hotel, etc.)	< 5000 m^2	<10000 m^2	> 10000 m^2
Concentrated office	210%	19%	83%	17%	26%	15%	59%
Low-rise office	56%	14%	64%	29%	51%	16%	34%
Urban core	345%	14%	31%	69%	11%	5%	84%
Concentrated commercial			20%	79%	34%	6%	59%
Mixed-used commercial	146%	10%	58%	38%	38%	13%	49%
Residential	16%	43%	52%	31%	91%	9%	0%

District category	Share in secondary energy		Indicator	
	Electricity	City gas	CO_2 [kg-CO_2/m^2•y]	Peak electricity demand [W/m]
Concentrated office	71%	29%	62.2	60.3
Low-rise office	69%	31%	69.4	65.6
Urban core	61%	39%	83.8	61.9
Concentrated commercial	64%	36%	84.1	58.6
Mixed-used commercial	69%	31%	72.8	63.8
Residential	77%	23%	67.8	85.2

[1] Size, configuration, and principal usage mainly determine the characteristics of energy usage in the following manner:
- Size and configuration (shape, zoning adopted) of buildings, which affect the thermodynamic characteristics of buildings and efficiencies of heat distribution systems
- Usage of spaces in buildings, which determines the scale and pattern of heat gains and electricity loads from spaces and operation hours of HVAC systems
- Adopted energy saving measures and heat source systems, which generally depend on the size and usage of buildings, as mentioned above

2.2.4 City

The carbon management concept identified in this layer refers to the management of urban form. The physical property representing this layer is the distribution of building stock. Management of urban from is very important as we have already shown in Table 2. Jaccard et al. (1997) suggest a group of policy instruments as community energy management (CEM) to promote management of the urban form and adjustment of the local context. However, management of urban form is not easy to achieve because it means the demise of the structure explained in 2.2.3. It should be noted that opportunities must be created to implement management of urban form when a change in the social environment occurs, such as a change in demand for business and services potentially due to a decreasing and aging population. It is also important to adjust the spatial distribution of building stock so that carbon emissions derived from buildings are minimized on integration of all the carbon management concepts.

2.2.5 Other elements

It should be noted that the carbon intensity of the electricity grid and occupant behavior/lifestyle are important factors that might have a strong influence on energy usage in the building sector. This study does not adequately take these factors into account.

3. Potential reduction in carbon dioxide emissions by implementing carbon management concepts

In this section, we present a case study that investigates the technological potential for reduction in carbon dioxide emissions from the non-residential sector of Osaka City, Japan, which has a total floor area of 54 million m^2 in the non-residential sector. It annually emits approximately four million tons of carbon dioxide. In this study, we consider the year 2000 as the starting point and 2050 as the projected end point.

Five scenarios were designed to meet each management concept, as shown in Table 3. We qualitatively evaluated whether changes assumed in these scenarios require a structural change in the building system based on the analysis presented in Section 2.

Table 3 Description of CO_2 abatement scenarios.

Scenario	Management Concept	Description	Incremental or radical?
Scenario 1	Advancement in technology	Table 2 shows the efficiencies of the technologies considered for baseline estimation and those extrapolated for the year 2050. We assumed a 40% decrease in electricity consumption of office equipment in addition to the change listed in Table 2.	Incremental
Scenario 2	Dissemination of energy-saving measures	Energy saving measures available at the building level are fully incorporated into buildings. The available energy-saving measures are assumed to consist of improvements in insulation performance, advanced lighting control, outdoor air intake, and variable speed control in heat distribution systems.	Radical (being an extension of the current trajectory of incremental change)
Scenario 3	Optimization of heat source systems	The configuration of heat source systems in the buildings is replaced by new systems that minimize CO_2 emissions using available heat source machines. We assume the introduction of district heating and cooling systems in districts with a gross floor area of more than 100%. For districts with a gross floor area less than 100%, we assume that optimization leads to heat source systems being replaced with those using heat pumps (air-source heat pumps and room air-conditioner for the non-residential buildings listed in Table 2) operated using electricity.	Radical
Scenario 4	Management of the form of urban building stock	Implementation of spatial management methods, such as growth control and restrictive zoning codes, to manage the form of the building stock at the neighborhood level, such that the building stock will be accumulated in a form with a lower CO_2 emission per unit floor area. It was assumed that a scheme to replace small buildings with large buildings will be applied throughout the city. It was also assumed that district heating and cooling systems will be developed in districts with a relatively high density.	Radical
Scenario 5	Improvement in the CO_2 emission factor of the electricity grid	The CO_2 emission factor of the electricity grid is currently 238.4 kg-CO_2/MWh in Osaka City. For Scenarios 1 to 4, we have assumed it remains at the same level until 2050. In this scenario, it is assumed that the value is improved by 20% to 190.7 kg-CO_2/MWh. This would be realized by changing fuels, adopting CO_2 sequestration, and increasing the contribution of nuclear power generation and renewable energy sources.	-

3.1 Simulation model

In order to quantitatively evaluate the measures considered in this study, we developed a simulation model. Most of this procedure has already been presented in 2.2.3 (see Figure 5). The feature of this model is to deal with a district as a unit. We classified districts into several district categories. The clustering of districts aims to indicate connections between the spatial building stock pattern and a strategy to manage energy usage and carbon dioxide emission in the districts. We then selected a representative district for each district category and performed simulations to quantify the end energy consumption per unit floor area for each representative district. We finally quantified the total end-use energy consumption and carbon dioxide emission from the non-residential sector in Osaka City by multiplying the total floor area of the building stock in the districts by the end-use energy consumption per unit floor area; this was calculated for each representative district. We call this modeling approach "district clustering modeling approach"; a detailed explanation of this modeling method is given elsewhere (Yamaguchi et al., 2007b). The bottom-up structure of the model allows it to seamlessly take into account the performance of energy-consuming appliances/equipment, building systems, and local energy generation and distribution systems.

3.2 Results

Figure 5 shows the estimated potential reduction in carbon dioxide emissions. This was calculated based on the baseline emission (3650 thousand ton-CO_2/year), and a detailed decomposition of each scenario's carbon dioxide reduction. Scenario 1 assumes only the reduction in carbon dioxide emission due to the advancement of the technologies listed in Table 1. If the carbon dioxide emission factor of the electricity grid remains at the current level of 238.4 kg-CO_2/MWh for the city of Osaka until the year 2050, technological advancements in lighting, office equipment, and heat source machines alone would reduce the carbon dioxide emissions by 18%. Scenario 2 assumes that the energy saving measures at the available building level were fully incorporated into the buildings. A complete dissemination of the energy saving measures would contribute to a further reduction in the carbon dioxide emission of 19%.

Scenario 3 assumes that each building will replace their heat source systems with those that minimize carbon dioxide emissions using the available heat source technologies listed in Table 1. We also considered development of district heating and cooling systems in the minimization process for districts with a gross floor area of more than 100%. The replacement of heat source systems by those using compression chillers and heat pumps driven by electricity and the development of district heating and cooling systems in densely constructed districts would account for approximately 12% of the carbon dioxide emission reduction.

Scenario 4 assumes the implementation of spatial management methods, such as growth control and restrictive zoning codes, to manage spatial building stock patterns in such a way that the building stocks are accumulated in an urban form with lower carbon dioxide emission per unit floor area. Based on the simulation results of Scenario 3, changes in the urban from were designed as shown in Table 1. Management of the urban form examined in Scenario 4 would contribute to an increase in the carbon dioxide emission reduction potential by 6%. The increase in the carbon dioxide emission potential of Scenario 4 compared to Scenario 3 is relatively modest. However, this does not mean that management of urban form will be less effective in the reduction of carbon dioxide emissions. It is difficult to realize the situation assumed in Scenarios 2 and 3, in which all buildings, including small ones, would fully install available energy saving measures and highly efficient heat source systems. Management of urban form would contribute considerably to reducing the carbon dioxide emissions by assisting in the transition of the urban energy systems toward those assumed in Scenarios 2 and 3.

Scenario 5 assumes improvement in the carbon dioxide emission factor of the electricity grid by 20%, which would lead to a further reduction in carbon dioxide emissions by 8%.

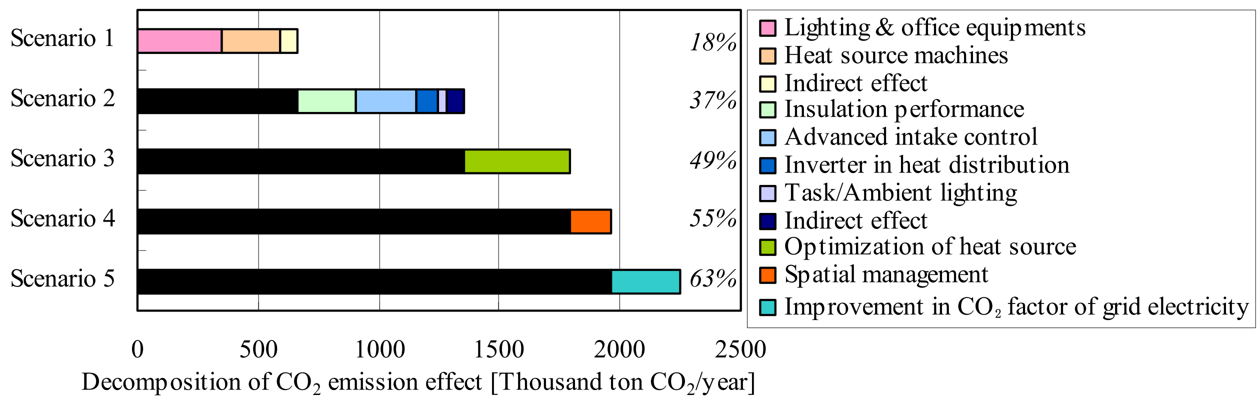

Figure 5 Carbon dioxide emission reduction under carbon dioxide abatement scenarios and its decomposition

4. Implications

(1) Does achieving a low carbon society require a structural change in the building sector?

Any single carbon dioxide management concept cannot achieve a substantial reduction in carbon dioxide emissions. This result implies that achieving a substantial reduction in carbon dioxide emission in the non-residential sector requires a structural change in the building system and providing the societal function of shelter for business and services.

(2) What kinds of change must be addressed in the building system to lead to a substantial reduction in carbon dioxide emissions?

Advancement in technologies and complete dissemination of energy saving measures into buildings are necessary challenges that should be addressed when considering a long-term scenario for the non-residential sector. Here, we only considered common technological options currently in practice, meaning that we assumed the changes were only an extension of the current practice. In order to lead to a substantial reduction in carbon dioxide emissions, more radical changes might be incorporated, for example, incorporation of a "zero emission" concept in the building design.

Implementation of the other carbon dioxide management concepts will require more radical changes in the building system. The implementation of local energy generation and distribution planning and management for the urban form are also relevant and should be addressed in the long-term scenario; this implementation is comparable to that due to an improvement in the carbon intensity of the electricity grid. Further reduction in carbon dioxide emission could be attained in several ways, although these pathways require a structural change in the building system. One possibility is the use of highly efficient, distributed generation technologies (e.g., solid oxide fuel cells) and renewable sources. An important challenge is to establish synergy among the actions in each layer of the spatial hierarchy. For example, management of urban form should be applied to maximize the benefit of implementing local energy generation and distribution planning.

5. Conclusion

This paper presented preliminary results on the transition of the Japanese non-residential sector toward a low carbon society. The questions addressed in this paper are as follows:
(1) Does achieving a low carbon society require a structural change in the building sector?
(2) If so, what kinds of change must be addressed in the building system to lead to a substantial reduction in carbon dioxide emissions?

In order to answer these questions, we identified several carbon dioxide management concepts based on our analysis of the elements that are relevant to energy usage in buildings. We tried to understand these elements and their correlations as a socio-technical system that provides the societal function of shelter for business and services. We then conducted a case study in which we quantified the potential reduction in carbon dioxide emission of the non-residential sector of Osaka City, Japan, due to the strategic implementation of the carbon dioxide management concepts identified above. The results of this case study showed that achieving a low carbon society requires radical changes that do not fit to the current dominant practice in the building system (e.g. complete dissemination of energy saving measures, appropriate implementation of local energy generation and distribution planning and management of urban form). In other words, the transition requires larger, more integral innovations in the socio-technical system consisting of a cluster of elements, including land ownership and land owners, occupants/residents, appliances/equipment, building systems (systems for ventilation, air-conditioning, lighting, etc.), buildings, regulations and standards, the building industry (e.g., construction companies and maintenance and operation networks), local infrastructure and energy utilities (electricity, gas, etc.), as well as urban form and local community.

Summary

Connected. Viable. Livable. Sustainability is flowing into the mainstream. As part of this cultural awakening the suburbs will be reinvented on a massive scale. Their potential to model the triple bottom line at community scale has already begun to be realized.

In the late 19th century electricity held potential for global change. But it was the distribution of power and subsequent opportunities for connecting innumerable inventions that transformed this newly harnessed energy source into a cultural necessity. From the internal combustion engine to Model T, binary code to laptop, and radio wave to PDA innovation integrated through infrastructure continues to transform the mainstream.

Sustainable technologies will be introduced through innovative infrastructure to transform the viability and livability of the suburbs. This process will also realize the potential for giving back to the earth and reducing greenhouse gas emissions.

Over forty million homes make up suburbs in North America alone. Their design, delivery and servicing has remained unchanged for over fifty years. Buildings are designed independent of their sites and connected to centralized municipal services. Infrastructure replacement backlogs are escalating, funding is diminishing and warming weather trends are dramatically increasing the amount of storm related damage. Suburbs represent a huge liability environmentally, socially and economically.

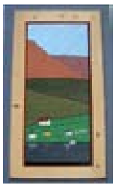
Five strategies are evolving to address these challenges:

- Integrated design process: consensus-based mixed use communities
- Conservation – greenbelt boundaries, retrofit rather than replace
- Reintegrating building + site systems: garden roofs, intensified native plantings, shading, absorptive pavements, high performance envelopes
- Renewable energy technologies combined with conventional building systems
- Decentralizing intelligent site servicing: plug-in energy + waste systems

Smart communities will replace centralized aging infrastructure with on-site modularized components managed with offsite wireless intelligence. The suburbs represent a huge opportunity for introducing these strategies to address climate change.

1. The Burbs Are Alright

Tofino, Vancouver Island. Western tip of Canada, in sight of Meares Island in Clayoquot Sound, a UNESCO World Heritage Site where two thousand year old red cedars stand and the Nuu-chah-nulth First Nation originated ten millennia ago. This is the home of Laura. She runs eco-tours along the northern Pacific Rim where fishing once flourished. People and dwellings are rooted in these irreplaceable islands.



Woody Point. Newfoundland. East across the continent to Gros Morne National Park, a World Heritage Site where the ochre rock of the earth's mantle towers above the landscape. Enduring proof of tectonic plate theory. Home of Charlie Payne, folk musician, artist and builder. His family fished the Grand Banks here for 300 years. But the cod are gone. Charlie now recycles buildings. His gallery is a former fishing gear shed moved inland to display local art celebrating the spirit of this place along with the traditional island jigs and reels he performs and records.

Laura and Charlie are worlds apart in the Canadian hinterlands. Yet they share the passion and urgency of experiencing parts of the planet that are fragile and unique. The sense of place in their communities endures through the connections they have crafted with the environment.

Cobourg. A town of 20,000 midway between these two worlds on the north shore of Ontario, one of the Great Lakes, the largest reserve of fresh water on the continent. Settlement is just over two hundred years old. Suburbia has sprawled beyond the historic core of the community in just over fifty. This is where the rest of Canada lives, in housing detached from the natural and historic sense of the place.

To the north is the Oak Ridges Moraine, a vast, rolling glacial deposit. Now protected as the primary source of fresh water for hundreds of inland communities, it serves as a natural boundary to suburban sprawl. Here in Northumberland County indigenous tall grass prairie is slowly being reintroduced and thousands of acres of forest have been reestablished after being stripped a century ago for the British fleet. Some old growth hemlock and pine have endured for over 350 years.

Community facilities in suburban Cobourg and similar towns are now being designed to connect with such local natural features and to optimize energy use and environmental performance. As learning centres, they are also serving as mentors for suburban dwellers and inspiring green transformations in local backyards. Sustainability is beginning to transform the Burbs.

The Suburbs include more than forty million homes in North America, over five million in Canada (1, 2). Design, delivery and servicing has remained unchanged for over fifty years. Generic buildings are installed and connected to centralized aging municipal infrastructure. Repair backlogs are escalating and funding diminishing. In Canada, average house sizes have doubled to 1900 square feet in the past 30 years (3). Development densities are in the order of six detached dwellings per acre (4).

From the first subdivisions of 750 square foot dwellings built to accommodate families following the Second World War, the Burbs have been informed by the automobile. In recent years the most frequent car trips have reduced to less than 2 miles and the numbers of vehicles per household have grown as younger generations stay longer at home. Home improvements account for nearly $40 billion CAD annually in local business (5). Yet energy conservation improvements have been a low priority in consumer spending. Air quality is diminishing, energy consumption continues to rise and neighbourhoods lack a sense of place. The Burbs must be connected to the environment on several levels to be engaged in efforts to address climate change.

The auto industry is being transformed by efforts such as Google's Automotive X PRIZE competition (6). It is engaging innovative minds in the development and delivery to market of a sustainable car at scale. The winning vehicle is required to attain 100 mpg, meet existing safety standards, and be deliverable through mass-production. Technologies now also exist to enable Burb houses to be made net energy producers, and properties redesigned to lighten their burden on municipal infrastructure and the environment.

Viable solutions for car and house are now shifting from unique, inspiring showcases to workable, reliable applications integrating locally serviceable, affordable technologies. Ford advanced the Model-T in this way by designing a flex-fuel engine that would allow farmers to produce and use their own ethanol (7).

Education, awareness and engagement are necessary for mainstream uptake of this shift. In the case of the Burbs, resident buy-in is essential. However, the suburbs have been disconnected from sustainable settlement principles and benefits since inception. Like the car in the driveway it is the model with which three generations have become increasingly comfortable. However, as Canadian folk singer Bruce Cockburn laments, "The trouble with normal is it always gets worse" (8).

What are beginning to take shape are a series of events engaging the Burb resident as part of local solutions that are making their communities more viable, livable and connected. The following strategies are emerging.

- Consensus and Mentor Buildings
- Conservation, Boundaries and Opportunities
- House and Park
- House as Platform
- House as Portal
- Both/And…Balanced Solutions

1.1 Consensus and the Mentor Buildings

Residents give sense of place to their communities through their recreation, work, purchases and votes. Yet while the urbanite and hinterland resident have generally been more engaged with the environment, those in the Burbs less so. A generation ago urban activists championed resource conservation, alternative energy initiatives and air quality restoration in light of industrial disasters laying waste to their back yards. Three Mile Island, a flaming Lake Erie and the Sydney Tar Ponds come to mind. With kindred urgency, those in the hinterland have rallied to prevent similar disasters such as the clear cutting of old growth forest at Meares Island. The suburban experience, buffered from these realities has helped to preserve the viability and profitability of these same industries. This consumer cohort with lawn, car and home has stoked the economy at the expense of the environment. However, a consensus on the need for action on climate change that also engages the Burbs appears to be building. Recent regional events in Ontario appear to have assisted in advancing this phenomenon.

The Ice Storm of 1998 destroyed thousands of trees and left hundreds of communities without heat and power, in some cases for weeks. Neighbours volunteered firewood, generators, food and water. Ad hoc disaster relief centres were set up. Municipalities were overwhelmed and advised residents to be prepared to wait for assistance for up to 72 hours. The need for local emergency preparedness plans became immediately apparent. Residents woke up to the need to be more self-reliant in their own back yards.

The Walkerton Water Crisis in 2000 resulted in several deaths as a result of inadequately treated water from the municipal system being distributed to local residents. Confidence in municipal infrastructure and provincial safety standards was shaken. Government inquiries and the overhauling of Ontario drinking water regulations followed.

In 2003 a massive power failure shut down distribution grids across the north eastern US and Canada. Summer cooling demands had exceeded infrastructure capacity. Again, hundreds of communities were without power for several days. A pending Ontario initiative to deregulate power supply was cancelled. It was now apparent to elected officials that aging infrastructure was increasingly becoming a liability. Residents were more frequently being put at risk and costs for repairs and ongoing insurance coverage were escalating. Officials became determined to renew confidence in their constituencies as places to live and invest.

Communities are now focusing infrastructure renewal projects on ways to increase the energy and environmental performance of their aging centralized plants. In the order of 40% of the operating costs shouldered by communities in Ontario is directly related to maintaining water and sewage treatment and distribution systems. Residential resource conservation programs are also being introduced. Low flow plumbing fixture installations, compact fluorescent lighting retrofits, waste and recycling programs are examples.

One of the most visible emerging strategies is Mentor Buildings. These sustainable design learning centres are situated in high profile locations in communities. Open to the public they provide hands-on education about green building and site technologies that can be introduced into residents' homes and back yards.

The Northumberland County headquarters completed in Cobourg in 2007 was designed to administer community programs and also serve as a post-disaster response command centre. The facility and site have been made sustainable through an integrated design process. This approach built on the consensus-based cross-departmental decision making culture that characterizes the County organization, a contrast to the more traditional "silo" approach to public administration.

The headquarters demonstrates the role public buildings can play in communities as mentors in sustainable design. Site features include local vernacular dry stone walls, native drought-resistant plantings and a planted south canopy. Sustainable technologies also include a geo-thermal system designed to use off-peak electrical power. It will also accommodate adjacent County facilities as their HVAC systems come due for replacement. The 40,000 square feet building is set into a hill so that the lower level is able to benefit from the moderating effect of the surrounding earth. The advanced envelope is designed to assist in reducing energy demand by an estimated 30% compared to the Canadian Model National Energy Code for Buildings. This results in a reduction of annual energy costs in the order of $15,000 AUD.

Millwork, wall and floor finishing include light colours to maximize light diffusion. Council chamber millwork also combines four local wood species – ash, cedar, birch and maple – acknowledgement of the reverence the local Ojibway First Nation has traditionally placed in these woods and their abundance along Lake Ontario's north shore. Today, this tradition continues with the Eastern Ontario Model Forest administering one of the largest tracts of sustainably managed forest on public and private lands in North America.

The above measures were conceived, developed and combined through an integrated design process to provide a community facility that is serving to educate and empower local residents to introduce similar measures into their homes.

They demonstrate the "soft path" approach to sustainable design pioneered by Amory Lovins – combining the efficient use of resources with renewable energy technologies (9). The initial public open house was attended by 300 residents.

The design for the Lake Simcoe Region Conservation Authority administration centre in Newmarket, Ontario completed by TSH in 2006 is the result of a similar process and performs a parallel function in the community. As a regulating agency reviewing new development applications, it was essential to the Conservation Authority that the design demonstrate their commitment to sustainable design, showing that they "walk the talk".

In 2008, TSH will complete for the Ganaraska Region Conservation Authority a new Forest Education Centre north of Cobourg on the Oak Ridges Moraine. It will build on the theme of the forest as classroom. Storm and grey water recycling, solar pv, in-floor radiant heating and planted roof technologies will be exposed for learning. In-line water and electrical meter read-outs will be positioned for visiting groups to measure conservation efforts through eco-challenges while in residence. The facility will be a sustainability classroom.

As with the Northumberland County Headquarters, each of the above projects is designed to engage, inspire, educate and motivate individuals and communities alike to action. Through consensus-built design solutions they are demonstrating viable, affordable commitments to the soft path, the route to healthy, financially sound resource efficient projects. With several local public models of investment in green technologies in their back yard as learning centres, residents are beginning to have the local means and confidence to integrate aspects of sustainable design into their homes.

1.2 Conservation, Boundaries and Opportunities

Perhaps the most successful Canadian example of linking sustainable community leadership with suburban development is Okotoks, Alberta (10). Here municipal leaders faced a dilemma with a local population boom on the horizon and the natural resources extraction and processing industries in full swing: unlimited growth and economic wealth or a more balanced, sustainable triple bottom line future. Consensus was reached on the latter and today Okotoks is growing based on the carrying capacity of the river running through it which is the sole source for potable water and sewage treatment. Current population is 18,000 and the sustainable growth cap has been set at 30,000. The community will be built out within twenty years.

Okotoks is unique in Canada geographically. It benefits from one of the highest solar intensities in the country. Working with the federal government the suburban development of Drakes Landing proposed within the community the design of homes heated, cooled and powered by solar thermal/photo-voltaic systems. Homes are fitted with collection equipment and a central energy sink stores and redistributes energy. The initial development sold out and subsequent phases are in progress. Managed growth based on the carrying capacity of local resources has resulted in a community being able to give back to the environment through the application of soft path principles. Home owners have already experienced healthy returns on investment. As a win-win for nature and human settlement, Okotoks is an excellent example of both/and thinking as a community realizes the benefits of the environment and economics working together.

North of Cobourg, Ontario the Oak Ridges Moraine is a similarly unique phenomenon formed at the end of the last ice age. Extending across the province this winding deposit of granular material serves as the purifier and repository for fresh water for hundreds of inland communities.

The province has enacted a Green Belt to conserve the moraine and provide a boundary to urban growth which is expected to double to six million people in the next twenty years. This regional conservation initiative is underpinning local efforts to introduce sustainable design initiatives.

(11- photo credit - H2OMES)

As an example, TSH alternative energy expert Michael Hubicki conceived and constructed *Unter den Birken* a model for sustainable residential design north of Cobourg (11). The project is recipient of provincial and federal awards for leadership in energy and environmental performance. The house features a two level configuration settled into a natural slope to take advantage of the moderating effect of the earth's temperature. A radiant in-floor heating system is fed by a solar thermal collector and biomass boiler. A tracking solar photo-voltaic array is coupled with a wind turbine, inverter and battery bank to provide electricity. Generated power is sold to the provincial energy utility to help offset the investment in alternative energy technologies. Electrical and water consumption readouts are located prominently in the house to keep resource use top-of-mind. The project champions *soft path* thinking, the inspired link between resource conservation and renewable energy technologies.

(12 – photo credit – Sentinel Power Systems)

Under the H2OMES program, *Unter den Birken* also serves as a green learning centre visited by individuals, community and school groups interested adopting aspects of the project in their homes and facilities. Most recently it served as a springboard for East Northumberland Secondary School students to put forward a proposal to erect a wind turbine and use the power to energize computers at the school in Brighton, Ontario. Working with Sentinel Power (12) the students are raising the funds for the project in partnership with local community groups.

TSH continues to evolve the concepts of *Unter den Birken* into larger community projects. These include the Lake Simcoe Region Conservation Authority administration centre, the Northumberland County headquarters and the Ganaraska Region Conservation Authority forest education centre profiled above.

As these projects come on stream each provide another learning centre, a portal, a wellspring for actual experience with sustainable design applications. Innovative technology solutions for buildings and sites are now working and available in the community backyard. Residents are motivated by the leadership such projects are providing and are gaining confidence that such working models have affordable applications for their homes.

1.3 House and Park

As with the solar intensity in Okotoks and the fresh water reserves of the Oak Ridges Moraine suburban developments hold their own latent environmental resources and infrastructure that can serve to transform consumer based realms into sources of production and renewal for energy and climate restoration. These transformations are beginning to occur as the result of growing awareness among suburban residents of the opportunities they have with their lands and buildings to address climate change by going green. 2007 has already been cast as the year sustainability went mainstream.

In the Next Sustainability Wave, Bob Willard notes one to five percent of corporations are estimated to now be pursuing sustainable products and services (13). This percentage continues to trend upward and is anticipated to reach a secured, committed market demographic within the next five years.

The same shift is apparent elsewhere at the corporate level. Katrina, Iraq and Enron have broadsided the mainstream consciousness. Corporate sustainability reporting is now becoming de rigueur as a means to enhance the credibility of companies with respect to their communities (shareholders and workers), ecological footprint and economics (profitability in the short term, and increasingly, goodwill in the long term).

For those in the Burbs, the $40 billion CAD spent annually on home improvement now includes a full range of green options. Home Depot now offers their eco-products line including alternative energy technology solutions in partnership with BP Solar. Lowes features LEED Gold stores to show they walk the talk. Walmart is investing millions to increase energy efficiency, integrate planted roofs and increase daylighting because market research has determined that greener stores yield substantially higher sales per square foot. Competitors are following suit. The green consumer has emerged as a market force. The Burbs have been engaged through their purchasing power to address climate change. They also have an increased awareness of local sustainable solutions with community mentor buildings and the efforts of pioneering neighbours.

For the Burbs the reforestation of sites is paramount. This applies equally to property owners and municipalities which own and maintain lands. Each have the opportunity to introduce massive amounts of carbon absorption with tree foliage. The canopy created in ten years or less also provides a moderating effect for buildings, outdoor recreational areas and planting to reduce water consumption. At the 43rd north parallel the solar angles are such that positioning of a mixture of deciduous and coniferous species – both of which are native to the region – allow for solar gain into buildings in cooler seasons and shading opportunities when the sun is higher. The use of coniferous trees on north elevations as wind breaks also assists with reduction in heat loss due to the protection afforded from prevailing winter winds. The benefits vary with the existing positions of buildings on sites. However, the amount of property typically provided around houses allows for planting solutions that can be adjusted to maximize benefits for several orientations.

Planting material is regional and drought resistant. In several jurisdictions the use of potable water for irrigation of Burb properties is now banned. For others watering schedules and quantities are being gradually reduced. Where grasses are used, slow growth mixtures are recommended to reduce the amount of lawn cutting. In several US jurisdictions site planting without traditional lawns are required in order to minimize mechanical maintenance and conserve water.

For planting strategies and species the municipality can play a key role by including the resources in site plan reviews. Performance criteria for water consumption, carbon absorption, growth rates and cross-pollination opportunities can also be listed so that alternatives meeting the criteria can be submitted for review. In this way innovation in planting is ensured while guidelines for front yards can afford a degree of consistency along streets and boulevards. Municipal property also affords the opportunity to lead with robust, long-term mixed tree planting. The results of such investment are compelling. Premier neighbourhoods in Toronto including the Kingsway and Leaside are prime examples demonstrating the benefits of extensive boulevard tree planting for nearly a century.

Perimeters of Burb properties also provide opportunities to introduce hedge rows. In addition to providing habitat for birds and small mammals, the planted perimeter provides for areas to reintroduce composted material.

Water conservation measures include management of stormwater and recycling of potable water. Building strategies include introduction of water meters with remote readouts in prominent locations in each residence to increase awareness of consumption. Fixtures are low consumption type and water reused through grey water recycling systems. On-site treatment of grey water is also available seasonally in Ontario using multi-tiered vegetated filtration systems. Year-round use requires the incorporation of such systems as water and plant features in solariums.

Stormwater management on site is accomplished with infiltration galleries, deposits of clear stone placed below the frost line – 4 to 5 feet below grade in Ontario – to which surface drains can be used to return stormwater to ground sources. The water can alternately be directed to cisterns for combination with grey water recycling systems, for use in on-site irrigation and for evaporative cooling systems. For homes with level or low slope roofs extensive (light-weight) vegetated systems are also available to incorporate to absorb precipitation and enable it to be reintroduced into the atmosphere. Light-weight approaches are appropriate particularly for retrofits where opportunities to increase the structural capacity of loadbearing systems are limited. It is primarily the added load of stored moisture that needs to be factored in when considering the overlayering of planted systems on existing roofs.

Surfaces on properties for vehicles also represent opportunities for increasing environmental productivity. The use of pervious pavement systems using recycled concrete, granulars and reinforced turf are being implemented. Conventional asphalt material can now be taken up and distributed to civil project involving road resurfacing. Pervious asphalt pavements are also being developed to increase local absorption of stormwater. Of course, municipalities need to also introduce new dimensional criteria when retrofitting aged roads, With general reductions in vehicle sizes and increased movement toward enhancing the walkability of communities, street widths are being reduced where not needed for collector or arterial functions. Again, reduced impervious area adds greater opportunity for local return of stormwater to the ground water source.

As stormwater is increasingly retained and reused on site the burden on municipal pipes lightens. This prompts the opportunity for Town works groups to consider introducing infiltration galleries in public boulevards. Such localized stormwater management solutions, in concert with aggressive tree planting hold the potential to radically reduce the amount of run-off from the parks that suburban developments are being transformed to become.

1.4 House as Platform

With the house reconnected in the renewed park environment the buildings also represent opportunities to be evolved beyond shelter to become platforms for generating energy. Following the examples of green community mentor buildings, the Burb property and house become an energy garden. Home owners can choose to store energy in on-site back-up systems, be independent suppliers of energy to the power distribution grid or participate in new partnership models to garner the collective benefits of delivering the energy they generate from renewable sources on site. Okotoks is an excellent pioneering model for this last opportunity.

As houses are increasingly improved through conservation measures the need of energy at home for heating and cooling is reduced. The revenue opportunity for the home owner grows as available energy output from each site grows.

Whether it be wind generator, solar photo-voltaic collector and inverter, battery bank or other emerging technology the opportunity to "plug-in" alternate energy technologies to the grid via the house will grow. And with local community examples available residents will have the confidence to participate in such initiatives and harvest new sources of income from their properties.

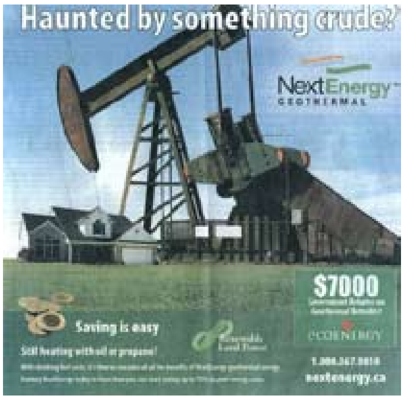
1.5 House as Portal

Community leadership involves renewing streets, boulevards, pipes in the ground, power lines and maintenance processes with innovative solutions that reduce the burden on traditionally centralized infrastructure plants. Municipalities already expend in the order of 40% of their annual energy budget on operating water and sewage processing facilities. Cost increases are expected to accelerate with rising energy prices and the added costs of carbon taxes on conventional power generating systems upstream.

To address these trends, municipalities are increasing their awareness of their carbon output as a result of providing infrastructure and services to their constituents. In Cobourg, the GHG emissions of municipal facilities and services are now being measured to establish a baseline model upon which can be developed alternate models for operation and service delivery. In co-ordination with this type of effort the provincial electrical generating utility Ontario Power Generation (OPG) is providing net metering for residents. The intelligence of this system enables the utility to alter the rates at which residents are billed throughout the day to be able to manage demand more effectively with variable rates to assist in tempering energy use peaks. The province is also actively promoting a culture of conservation to assist residents with practical ways to even out energy consumption. Introducing compact fluorescent lights and arranging energy audits are examples.

At the Northumberland County building an ice storage facility is planned to use off-peak (overnight) power to charge a cooling sink that will then provide interior cooling over the following day when power rates and demands are at their peak. The overall energy demand has been tempered, the costs to the County and constituents have been lowered and the use of the on-site geo-thermal system has significantly reduced GHG output. The building energy systems are also designed to provide real-time data on systems operations and performance. This enables facility status to be continually monitored and adjusted to optimize performance. In the four months since opening the facility data has already confirmed the building to be primarily providing heat by harvesting and recycling of energy from occupants, equipment and lighting. As the cooling season approaches, systems adjustments will again be made and monitored. The data can be made available as part of the mentoring role to increase the understanding of how such systems perform.

(14 – photo credit – Next Energy Geothermal)



In the Burbs, residents will be able to interact with utilities in similar ways. For example, an on-site geo-thermal system for a 1,900 square foot home will require in the order of three 100' deep vertical wells or an equivalent linear footage of horizontal piping on the property to provide heating and cooling. Add to the system an ice storage battery and cooling is economically available using the same power purchasing strategy as the County. The technologies are proven and available off-the-shelf. Regional organizations such as the Canadian Geo-Exchange provide installer knowledge through workshops. On-site training is increasing monthly to meet the rapidly increasing demand for this alternate approach to providing energy at home. As residents in more mature Burbs begin to experience increased maintenance with traditional fossil fueled heating and cooling appliances that are reaching the ends of their useful life cycles, such alternate approaches with working local examples will become increasingly affordable.

As energy demand from homes decreases municipalities will be able to adjust long-term forecasts for centralized infrastructure upgrades and expansions.

The geo-thermal solution is an excellent example of integrating local natural resources on the house property to create a micro-system that services heating and cooling on site. And it is just a start. Consider for example the integration of a solar photo-voltaic system. The property and house now become a portal for outgoing power to the community. Combined with a well insulated, sealed envelope and heat recovery ventilation system the house demands can be reduced to downsize the geo-thermal / solar thermal or biomass system. Using the heat energy of occupants, IT equipment and appliances as the primary heating source for the dwelling the house now converts to a multi-functioning power plant and shelter.

The economics of these residential solutions are compelling. Alternate energy approaches are emerging to make subdivisions more sustainable and marketable. Marshall Homes in Oshawa west of Cobourg, and Rodeo Homes in Newmarket are examples. After securing their own energy demands residents may soon alos have the opportunity to partner to contribute the latent heat energy in the ground or solar exposure on their property for a negotiated, renewable rate of return. The subdivision becomes an energy garden that contributes to the local community or regional power distribution grid in much the same way as a district energy system or wind farm. Equipment can by owned and maintained by residents or by the alternate energy utility in the same way as conventional gas fired hot water heaters are provided and serviced in Ontario.

This arrangement is not unlike increasingly intelligent wireless infrastructure for voice / data systems being introduced by developers as subdivisions are opened up. Strategically located servers within developments provide secure two-way communication access throughout the community. The house is evolved to set-top box or PDA interfacing with centralized utilities to convey energy and data about environmental performance. The Burbs become connected on a new level to the community in the movement to local interconnected micro-energy solutions.

This decentralization of infrastructure is also evident in emerging technologies addressing on-site sanitary systems. In lieu of effluent being piped through increasingly aged pipes to centralized processing plants, local solutions are available and being considered for residential developments. Containerized peat cassettes are used to accept effluent and process it on site. When the peat mixture has reached uptake capacity the cassette is replaced and the peat distributed to farms for fertilizer. Such applications are being pioneered in rural locations in Ontario.

1.6 Both/And … Balanced Solutions

To engage the Burbs, both/and solutions are required and are emerging. Economics is becoming increasingly balanced with environmental priorities. Products are also becoming value-added through their environmental benefits. For example, consider the replacement of a conventional natural gas fired hot water storage tank with an instantaneous heater. Energy is used to heat water only when needed, space is gained with a smaller heating appliance, costs for heating are reduced and greenhouse gases are also reduced by using less energy. Taking this example a step further and integrating it with a solar collector and electronic inverter to power the heater effectively eliminates GHG emissions through the integration of a renewable alternative energy source. Canada currently offers funding for assessing baseline energy use and also provides assistance for incorporating the solar photo voltaic system. Green auditors are also emerging providing comprehensive door-to-door assessments of waste, water energy and transportation performance and recommendations for improvements with paybacks. For a family of four this can amount to monthly savings in the order of $500 AUD.

To continue the mentoring role of community buildings and municipalities TSH is also developing the greenscreen tool. This web-based software will provide a multi-disciplinary overview of the issues that are encountered with buildings and developments at the project initiation stage. The tool allows projects to be assessed and a baseline scenario generated and adjusted to determine measures that will move the project toward a more sustainable solution.

Also in the early stages of development is the greenleaps program. This networking tool is intended to link municipalities so that mentor building project information can be shared. This would include links to real-time date streams from operating facilities. The intent here is to link each municipal participant with both a community that is more advanced and another which is in the early stages of development. In effect, the links provide means for participants to leap forward with more readily available sources for technologies and built solutions by learning through direct partnerships with those having the applied experience.

The rural Ontario homestead summarizes well the re-emerging concept of house integrated with renewed working parkland. Masonry structure and envelope served to provide a moderated interior environment. A central fireplace warmed the building mass in a radiant heating system application. Surrounding trees were planted for shade and as wind breaks. Gardens were tended to produce food and receive composted material. Drives and parking areas were gravel to allow for natural percolation of surface water. Inside the dwelling, a cellar cistern collected rainwater captured from the roof. Piping arrangements in the house included for hot, cold and non-potable water to each fixture. A root cellar and larder were incorporated to store dry goods and preserves over winter.

Several of these features were carried to town dwellings and properties as migration to urban environments grew through the early part of the twentieth century. In addition to the comforts and practicalities of the residence the walkability of the town also afforded a close-knit community where shops, schools, churches, arenas and factories were a few minutes stroll away.

Today, in the Burbs a similar level of comfort and security has been achieved. Yet the detachment of buildings from lands and developments from the rest of communities are for wanting. Opportunities to reconnect the Burbs and engage residents in climate change solutions abound. Viable, affordable technologies proven in community mentoring buildings now exist locally to serve as catalysts for moving this transformation toward a more livable, sustainable community.

The pioneering house next door will also inspire residents to reconnect their home experience with the environment and their suburban enclave with the community. And it is being done with investment in emerging technologies and services. New online tools such as tshgreenscreen will assist communities in assessing their level of sustainability and in developing action plans. Greenleaps (Green local environmental action partnerships) is also being developed for municipalities as an online network of local communities and their partners in other countries to take those action plans and enable communities to make quantum leaps forward by learning from the experiences and successes of their partners.

The Burbs represent a huge opportunity to demonstrate the successes to be reaped from Both/And thinking, balancing environmental stewardship with economic prosperity for over 40 million greener backyards.

BUILDING SUSTAINABILITY OR SUSTAINABLE BUILDINGS?

Drew Heard, Arup [1]
Russell Jessop, Arup[2]

[1] drew.heard@arup.com.au
[2] russell.jessop@arup.com.au

Keywords: green, building, rating, sustainability, social, LEED, BREEAM, Green Star

Summary

The take up rate of building rating systems such as BREEAM, LEED and Green Star has grown rapidly in recent years. These systems have provided the market place with simple ordinal scales for the relative performance of buildings. At the same time, they have become the de facto definition of sustainable buildings in the market place. This paper argues that we should not become complacent that highly performing buildings under these systems are the pinnacle of sustainable buildings. We need to acknowledge that whether a building is seen as sustainable depends on what issues are considered, how they are considered, and how trade-offs are managed. There are important issues that are not considered under these schemes, and actions that are arguably beneficial from a sustainability viewpoint that are not rewarded. The argument is supported by a comparison of the three systems mentioned, and against other recognised sustainability assessment tools.

1. Introduction

Today, green rating programs are becoming tools for current and future construction where major owners and developers of buildings are using them as a benchmark. There has been a presumption that a highly rated building is a building with lower energy consumption and lower environmental impacts then a non-rated building.

The following paper argues that we should not become complacent that highly performing buildings under these systems are the pinnacle of sustainable buildings. The paper compares LEED, Green Star and BREEAM and illustrates that the concept of a ‘green’ or sustainable building is socially constructed rather than absolute. Given that tools such as these are becoming the de facto green building standards in the industry (as evidenced by their inclusion in planning requirements, government building requirements and tenant requirements) there needs to be an understanding on how the definitions of a green building are developed, ‘what’ and ‘how’ issues are considered and how trade-offs are managed. Although the tools have an ability to differentiate between environmental impacts that affect different buildings, the paper discusses limitations surrounding their use.

The paper is a warning against complacency, rather than a critique of the green rating tools.

2. An overview of the rating tools and their use

2.1 Green Star

Green Star is an Australian benchmarking tool developed by the Green Building Council of Australia. Launched in 2003, Green Star drew from existing rating systems including BREEAM and LEED, but it is tailored to the Australian marketplace and environmental context. Green Star includes tools for office design, office as-built and office interiors. An office asset tool is in pilot study. Planned tools include retail, health, residential and education. The tool uses ten categories: energy, management, water, indoor environmental quality transport, ecology and land use, emissions, materials, innovation. Ratings (stars) have six levels, but only three are eligible for certification. Green Star uses category weighting factors that vary across states/territories to allow for differing environmental concerns and imperatives.

There are currently 70 Green Star certified projects in Australia. In Melbourne the council’s Environmentally Sustainable Office Buildings (ESOB) Policy (Melbourne Planning Scheme Clause 22.19) requires a 4 Star Green Star Certified Rating for office developments with a gross floor area of more than 5,000m^2.

Of the 72 points assessable for environmental impact 57% of them can be assessed as continuing environmental impacts over the life of the building, whilst the remaining 43% comes from one-time impacts from construction.

2.2 LEED

The LEED (Leadership in Energy and Environmental Design) was developed in 2000 by the US Green Building Council (USGBC). Currently, it is used to assess new commercial constructions, major renovations, existing building operations, commercial interiors and core and shell. LEED uses six categories to assess buildings: sustainable sites, water efficiency, energy and atmosphere, materials and resources, indoor environmental quality, innovation. Each category has specific design goals worth points - some of which are mandatory. The points awarded are totaled to earn projects one of four ratings: certified, silver, gold or platinum.

Currently, over 400 buildings have been LEED rated in the US and more than 3400 buildings are LEED registered (seeking certification). In the US, the tool has become a standard for 'green' design of buildings with many organisations beginning to use LEED as a minimum requirement. For example, the GSA (General Services Administration) responsible for the office space of all US government workers requires all new buildings to be LEED certified (and are 'encouraged' to aim for silver level certification) (Bowen, 2005).

To achieve certification the project team registers with the USGBC, who then requests detailed design documentation and results of energy modeling performed. Certification is then awarded by the USGBC, upon the awarding of at least 26 of the 69 points available. Of the 49 points assessable for environmental impact (excluding the 5 innovation credits which are unique to individual projects, and IEQ credits because their impacts are health related rather then environmental) 69% of them can be assessed as continuing environmental impacts over the life of the building, whilst the remaining 31% comes from one-time impacts from construction (Eijadi *et al.*, 2002).

There are several localised variants of LEED, including LEED Canada, LEED India and LEED Mexico. In addition to this several buildings outside the US have achieved the US LEED certification.

2.3 BREEAM

BREEAM (Building Research Establishment Environmental Assessment Method) was developed in 1990 in the United Kingdom. It is a building environmental assessment method that covers a range of building types including; offices, homes, industrial units, retail units, and schools. Other building types can also be assessed using 'Bespoke' (custom-made) BREEAM.

To assess a buildings performance, BREEAM uses nine categories: management, energy use, health and well-being, pollution, transport, land use, ecology, materials and water. The rating tools will award points for performance against criteria that are added together for an overall score then awarded a "Pass", "Good", "Very Good" or "Excellent" based on its overall building performance. It provides assessment opportunities for pre-design, design completion and occupied buildings.

In the United Kingdom, there are close to 100,000 buildings BREEAM certified and over half a million registered for assessment. The BREEAM assessment process and rating tools are updated and regularly in accordance with UK Building Regulations. Planning authorities are referring to BREEAM and EcoHomes Standards (the homes version) as a way of assessing planning applications. Many organisations, such as English Partnerships, have implemented sustainability standards for all new homes, retail, office, and industrial buildings built on its land (approx. 6,000 hectares), stating a BREEAM rating of 'Very Good' must be achieved (The Merton Rule, 2006)

2.4 SPeAR

SPeAR is an assessment tool developed in 2003 to assist in balancing the many factors that affect a sustainable project.

SPeAR has 4 "core" indicators: economic, environmental, natural resources and societal and is based on the DETR's publication in May 1999 of 'A *Better Quality of Life: A Strategy for sustainable Development for the United Kingdom'*. These core indicators are then broken down into a series of primary indicators.

A set of base sub-indicators, which can be custom made for individual projects, are then rated on a scale of -3 to +3. The tool then averages the score for all sub-indicators to produce an overall performance for that indicator. These results are then displayed on a rose diagram. Undertaking a graphical visualisation rather than a numerical rating clearly illustrates where the project is weak and strong, hence can be used to guide the team on where to focus.

3. What issues do the rating tools consider?

Generally, the rating systems consider a narrow range of categories to measure the green rating of the building, with the exception of the SPeAR tool, which considers a wider range of issues. Generally, the other tools can be broken down into a number of categories as shown in Table 1. This additionally shows a breakdown of the percentage weightings of each of the categories (where applicable, these are raw, unweighted scores). None of these three tools consider social or economic factors as part of their criteria.

Table 1: Percentage of credit points available. Based on Table 9, Fowler & Rauch (2006)

	Technical Content							
	Energy	Land-use and ecology	Water	Materials	Indoor Environment Quality	Operations & Maintenance	Other	Economic and social issues
BREAAM	25%	15%	5%	10%	15%	15%	15%	-
LEED	25%	20%	7%	19%	22%	-	7%	-
Green Star	21%	6%	9%	27%	18%	16%	4%	-

The similarities in the weightings do not necessarily imply that they consider the same range of items under these category headings. For example under Green Star 69% of the available energy credits are given for the buildings CO_2 emissions to be further reduced below a conditional requirement (as measured in kg CO_2/m^2/annum), whilst LEED offers 50% of the energy credits to 'optimise energy performance', which is based on the total energy cost, and make no direct reference to the actual CO2 emission level of the building. In addition LEED and BREEAM make a credit available for using Green Power, whilst in Green Star this is not specifically referenced; rather it would fall under the reduction in the buildings CO2 levels.

The amount of available credits for water usage is similar across the three standard rating tools. The actual awarding of points is different however. LEED, for example, does not award points for water metering while both BREEAM and Green Star do so. One category that LEED considers that neither BREEAM of Green Star considers is the heat island effect.

Much variation can be found in the use of environmentally friendly products, both in the amount of credit points available and in how the points are awarded. Whilst BREEAM will offer only 10% of its total credit points Green Star offers 27% of its points for using environmentally preferable products. This is slightly misleading however, as LEED has a conditional requirement for use of 'refrigerant management', whilst not offering any credits for it. Regardless LEED offers no recognition for the use of low GWP rated products, while both BREEAM and Green Star offer credits for this. LEED is, however, the only rating system of the three to consider the use of locally sourced materials as a sustainable measure. BREEAM is the only rating tool considered that awards credits for a reduction in NO_x emissions.

One measure that is considered by SPeAR, but disregarded by other building rating tools is the diversity and social responsibility aspect. This includes such things as responsible sourcing of skills, use of local personnel/skills, building accessibility, cleaning program, communal space and leisure facilities, distinctive cultural character, building adaptability and flexibility (including IT), sustainability economics and cultural heritage.

The inclusion of these indicates the difference between a sustainable rating tool, and a green-rating tool. LEED, Green Star and BREEAM are not sustainable rating tools. Rather, they are a tool that should be used as part of an overall sustainability strategy. However, due to the lack of a standard integrated approach they appear to have been adopted as a measure of sustainability.

The innovation credits available present further issues, depending on the rating tool used. Whilst Green Star's innovation credits require significant effort (an initiative or technology that is a 'first' in Australia or the world for example), the LEED innovation credit is much easier to achieve. In previous projects it as been awarded for such tasks measures as having an acoustic consultant, or performing a condensation analysis. When considering the effort to perform sophisticated energy modeling to achieve energy credits, it may be that LEED is too lenient in awarding innovation credits.

4. How are issues considered?

There is a large variation in the methods and models used by the different rating tools. Here we present the methodologies behind the energy credit. This shows that the variation is such that a building that is considered to have excellent energy performance as measured by one tool, may not necessarily be considered so excellent by the other two, due to the underlying methodologies used.

4.1 Energy

Energy credits in LEED are based on energy cost consumption based on the standard given in ASHRAE 90.1 – 2004. Initially the Energy Cost Budget (ECB) is calculated according to ASHRAE 90.1, and is the product of the baseline kilowatt-hour usage for the year and the energy cost ($/kWh) summed with the gas usage for the year, multiplied by the gas cost ($/MJ). The Design Energy Cost (DEC) is then calculated by multiplying the proposed energy and gas usage for the year, by the energy cost. The Energy savings percentage is then calculated via

$$\text{Energy Savings Percentage} = 100 \times \frac{ECB - DEC''}{ECB} \tag{1}$$

Where;

DEC'' = DEC – Renewable Energy Contribution.

This can misrepresent the actual environmental impact of buildings due to variations in energy cost. Scheuer and Keoleian (2002) presented an analysis of a real-life building, assumed to have a 75-year life span. Their results, reproduced in Table 2, show that, for an increase in the electricity cost, in order to achieve 1 LEED point the corresponding energy savings decreases significantly. Therefore planners are actually rewarded for having higher energy costs. The energy costs can be based on local utility rate schedules, ASHRAE adopted rate schedules or the LEED reference manual; this gives an incentive to use the highest cost out of these options.

Table 2: Energy usage for different electricity prices (Scheuer & Keoleian, 2002).

Electricity Price ($/kWh)	% elec. red. needed for 1 LEED point	Life span GJ energy saved
0.04	21%	215 669
0.07	18%	184 859
0.10	16%	164 319

This can also lead to inequities in the energy savings, as the cost multiplier is different for electricity and gas. For example an 18% reduction is electricity will produce 1 LEED credit, whilst it would take a 46% reduction in the amount of gas to achieve 1 credit. This large reduction in gas would likely produce substantially greater reductions in total primary energy consumption.

In Green Star the energy credit is calculated directly on the carbon dioxide emissions. The electricity consumption (kWh/annum) is multiplied by a greenhouse gas coefficient (kg-CO2/kWh) dependant on location and added to the gas consumption (MJ/annum) multiplied by a second, local, greenhouse coefficient. The greenhouse gas coefficients will depend on the location of the building. For example, the electricity greenhouse gas coefficient is 1.325 kg-CO2/kWh in Melbourne, compared with 0.936 kg-CO2/kWh in Perth, based on the production of electricity in Melbourne primarily occurring through the burning of brown coal. This emission of CO2 is then normalised by the nett lettable area of the office. Up to 20 points are awarded dependant on the percentage above standard the building is. This can directly impact the green rating of the building; the exact same building built in Melbourne and Sydney can actually have completely different rating.

BREEAM awards points for the building demonstrating a percentage improvement above the requirement for CO_2 emissions as set out in the 2006 Building Regulations. The calculations can be performed using a BREEAM approved tool such as the Simplified Building Energy Model (SBEM).

5. How are trade-offs managed?

Once again there is significant variability in how different issues are weighted between tools. In LEED issues are not weighted. This means that each category is simply awarded the number of points to reflect how important the USGBC thinks that credit is worth. This leads to certain inequities. One designer notes that they received 1 point for installing an advanced heat recovery system ($1.3 million), and 1 point for installing a bike rack ($395) (Schendler *et. al.* 2005). A life cycle analysis by Scheuer & Keoleian (2002) showed, however, that there is a large variation in the energy benefits per LEED point of each criteria – for example the energy criteria has a far greater environmental impact than material selection. In addition, this weighting is constant throughout the US – there is no consideration given to the location the tool is applied, despite the differing conditions through the US.

In Green Star a weighting is applied to the raw scores. The weighting factors vary with location – for example due to the scarcity of water in Melbourne it has a higher weighting then for a building in the Northern Territory. The raw score for each category is converted to a percentage. This is then multiplied by the number of weighted points available, to give a weighted score. For example a project may receive 4/13 points available for water usage (31%). In Victoria water is given 15 weighted points, and therefore the project receives 0.31x15 = 4.6 weighted points.

BREEAM operates similar to Green Star in that categories are weighted. They are 'pre-weighted' however, in the sense that the BREEAM manual simply refers to weighted scores to be added, rather then applying the weighting after the raw scores have been calculated.

SPeAR follows a different methodology. *All* sub-indicators are rated on a scale of -3 to 3. These scores are then averaged to produce an overall rating for that indicator. SPeAR, however, is not looking to produce a numerical rating at the end. Rather it simply wants to measure the performance of each indicator individually, to allow designers to focus on areas of the building with poor sustainability.

6 – Other Issues

6.1 Controversies

Proposals to award credit points are often subject to controversy. The pressure of industry lobbying groups, as well as the backing of companies with financially vested interests, has the potential to lead to a subjective assessment of these criteria.

6.1.1 Green Star timber controversy

The following is the current Green Star credit for timber:

"Two points are awarded where 95% (by cost) of all timber products used in the building and construction works have been sourced from any combination of the following:

- Reused Timber
- Post-consumer recycled timber
- Forest Stewardship Council (FSC) Certified Timber"

The FSC is an international organisation promoting the responsible, sustainable management of the world's forests. This credit is currently opposed by lobbyists from the logging industry. The main contention of the logging industry is that the current requirement is too restrictive, and that it should recognise other credible forest certification schemes, as well as changing the level of credits available (1 credit for 60% compliant timber, and 2 for 90%). This is due to the limited supply of FSC timber in Australia.

Due to this lobbying the GBCA has proposed to change the Green Star timber credit to recognise any recognised Forest Certification's Chain of Custody standard, as well as change to 1 credit for 60% compliant timber, and 2 credits for 95%. This has lead to criticism of the GBCA of reacting to the demands of industry lobby groups, and finically vested interests, instead of using independent, expert advice.

6.1.2 LEED PVC controversy

Currently the LEED system offers no credits for a reduction in the use of PVC materials. This differs from the Green Star system where 1, or 2 points are awarded for a 30% or 60% reduction (by cost) in the use of PVC by replacement with alternative materials. During the early course of LEED development a credit was proposed to award the minimisation of PVC. At the suggestion of this, industry groups came to the defence of PVC. The USGBC then referred the matter to their technical committee, which concluded that for environmental impact the evidence is that introducing a credit that rewards the avoidance of PVC could steer designers to use materials that are worse for the environment, except in the case of resilient flooring, where PVC materials were the worst of the materials studied (Altshuler *et al.* 2007).

6.2 "Point mongering"

"Point mongering" refers to when the sole focus of the design team is on gaining credit points regardless of whether it adds environmental value to the building. The driving force behind this is the prestige of obtaining a high level rating making the building or company 'green'. Design teams can become obsessively focused on getting credits regardless of whether they add environmental value.

One installation considered installing a reflective roof. LEED encourages this as a means to offset the "urban heat island" effect. The proposed system was in the Rockies, which, at 8000 feet, is not greatly affected by heat issues. The design team had two options - show it is not relevant, shrinking the pool of available points or take the credit knowing that the environmental savings are negligible. Related to this is the cost of some achieving some credits. In reference to LEED, Eijadi *et. al* (2005) showed that, of the 64 credits (excluding the innovation credits) 34 (53%) could be classified as either standard practice, or having a minor cost. With the focus on achieving a green-rating this could lead to designers focusing on 'easy' credits, rather then considering the actual environmental effect of the design.

Table 3 Breakdown of LEED credits (Eijadi *et al.*, 2005)

Category	LEED Points	Standard Practice	Design Effort: Minor Const. $	Significant const. $
Site	14	5	5	4
Energy	5	0	2	3
Water	17	0	2	15
Environment	15	1	10	4
Materials	13	0	9	4
Innovation	N/A	N/A	N/A	N/A
Totals		9%	44%	47%

There is qualitative data to support these observations. In a study of 35 LEED certified buildings 70% and 63% of the available credits for environment and site were awarded, whilst only 42% of the available energy credits were used, on average (Scheuer & Keolin, 2002).

A similar issue has been observed in Melbourne. There has been a significant rise in the number of buildings that are installing blackwater treatment plants. This is factored in Green Star's potable water calculator, which gives up to 5 points for reducing water below a best practice benchmark. This rise may be attributed in part to the current water shortages in Melbourne; however its efficacy at the city-wide scale is questionable (van Wyk, 2007).

6.3 Variation in energy-related environmental impacts of certified buildings

There has not been much research conducted on the relationship between certification and a building's environmental impact. Today green rating programs are becoming tools for current and future construction where major owners and developers of buildings are using them as a benchmark. For instance, there is a presumption that a certified building is a building with lower energy consumption and lower environmental impacts. However the rating tools were not designed to scientifically assess a buildings environmental impact, but functions as such by default, due to the lack of other standards and tools.

In fact, research indicates a significant overlap in the variability distributions for different LEED certification levels. This proves that being LEED certified may not always mean that energy-related environmental impacts have been significantly reduced. Research was performed using Monte Carlo based computer simulations (Crawford-Brown *et. al.* 2007). These simulations illustrate in many instances that individual buildings certified at different levels of LEED could have the same level of environmental impact. Figure 2 below illustrates this using simple probability distribution functions for the simulated mercury emissions for 1,000 LEED Silver buildings and 1,000 LEED Certified buildings (as an example). The grey area indicates the overlap area between the two certification levels.

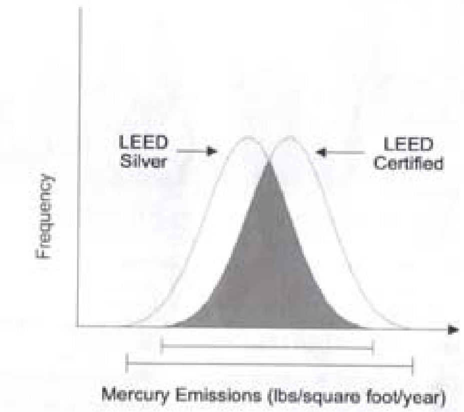

Figure 2 Simulated mercury emissions of Silver buildings compared to Certified buildings.

6.4 Eligible Buildings

The restrictions on what buildings are eligible to be rated are very restricting. For example the Green Star office tool requires that 80% of the GFA must be Class 5 Commercial Office space, and the whole building must be rated, not the part building. This had lead to the case where a multi-purpose retail/residential/office building such as Swinburne place cannot achieve a Green Star rating, when in fact the very nature of an all-encompassing multi-purpose building certainly promotes both environmental and social aspects of sustainability. A similar issue occurred with the Marine & Freshwater Research Institute. Its mixed nature meant that it was ultimately not awarded a Green Star rating. LEED and BREEAM seem to be much more forgiving in this sense; the LEED for New Construction rating can be applied to a much broader range of buildings, whilst BREEAM offers a custom (bespoke) rating tool for buildings that do not fall into one of the available categories. Once again a tool such as SPeAR is far more versatile here – it can be applied to any building or construction through its bespoke nature.

7. Discussion

There is no doubt that green building rating tools have helped to promote the concept of sustainable design. However the variation between the tools is such that the concept of a 'sustainable' building is blurred. As shown for the energy credit, different rating tools can use completely different measures for assessing the environmental impact – from energy cost, to CO_2 emissions, to kWh/year. In addition the software program used to perform the energy modeling can product varying results, as shown by a sample of BESTEST results (Judkoff, 1995; Sturn, 2007)

There seems to be a misunderstanding in the concept of a 'green' building and a 'sustainable' building. There is a fundamental difference between the two. A green building generally only considers environmental issues, whilst a sustainable development considers social and economic factors as well. A building may very well be classified as a green building; but how sustainable is it if the lifespan of the building is only 10 years, or if the materials have been sourced from overseas? Does a new building positively affect the local community, or the constituents of the building? These are all important questions to be considered. A building such as the Salk institute which has wide laboratories across two buildings fosters collaboration between researchers by having no walls between laboratories, and placing chalkboards in appropriate locations for researchers to write notes on. Figure 1 graphically illustrates the difference between a sustainable rating tool, and a green rating tool.

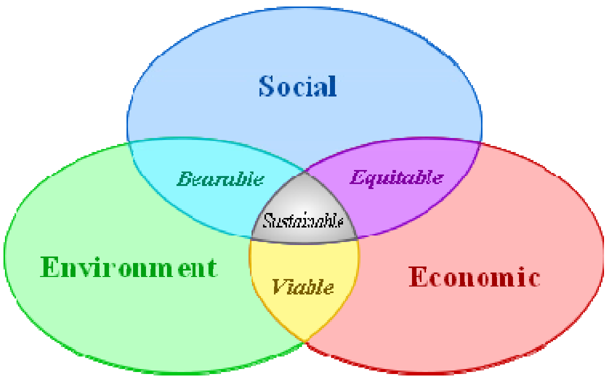

Figure 1 Relationship between green building and sustainable building

Related to this concept of sustainability within buildings is the architecture used. If a building is to be used for a period of over 50 years, it needs to have a certain level of usability, as well as a design that will be relevant over the time period. An example of this is the Melbourne Arup office located at 1 Nicholson St, which was constructed in 1959, and yet is still a functional and relevant building. Whilst it may not be the pinnacle of energy-efficient design, its simple glass cladding, along with appropriate orientation (no windows on the east and west faces) mean that the building is still able to be used as office space now. Another example is the UN building in New York. This was completed in 1950. Its east and west facing walls are covered in thermoplane glass designed to reduce heat absorption. On the otherhand, will newly rated buildings, still be used in 50 years?

The very nature of 'rating' a building promotes a form of 'elitism' with building. Essentially, a building needs a label to be ranked as 'green' when in fact there are many examples of sustainable buildings, which have no green rating at all. The rise of rating tools may lead to these building been received negatively in the public opinion, when in fact they may be highly performing buildings. An example of a highly performing unrated building is the DRW headquarters in Dusseldorf. In New York two buildings have recently been completed – the LEED gold accredited Hearst building, and the unrated New York Times building. Both buildings implement excellent green measures, yet the New York Times building is unrated. This doesn't make it less sustainable, however the popularity of green rating tools, may give that impression in the public eye. Furthermore, there are many examples of green buildings that were constructed many years ago such as the CIBSE/ASHRAE building in New York that have excellent sustainable performance, and yet pre-date rating tools by many years.

The rating tools mentioned all base their ranking of the environmental performance of the building on the basis of a set, fixed criteria. Whilst this is a tool that gives an easy way to rank, and compare building performance, a more accurate method would be to include additional assessment by means of Life Cycle Analysis (LCA). LCA investigates the environmental damages associated with a design across the life cycle of the product; from its harvesting and manufacturing to its destruction, or recycling. Doing this would greatly enhance the effectiveness of measuring the actual environmental performance of a design decision.

8 Conclusion

BREEAM, LEED and Green Star are three of the most widely used building rating tools available. Due to lack of a viable alternative they have become associated as a rating tool for sustainable buildings, when in fact they only consider the environmental impact of buildings, and not the societal and economic benefits. This is in contrast to a tool such as SPeAR. We have discussed the application of BREEAM, LEED and Green Star and showed that, whilst the issues they consider are similar, there is a wide variation, both in the methods used to asses these criteria, and in the weighting given to each criteria. It is argued that there is not a direct relationship between the certification level of the building and its actual environmental impact, and that in fact, the very nature, and popularity, of rating a building brings down other sustainable buildings that do not seek certification

Keywords: Sustainability framework, benchmark, indicators, microclimate, economic sustainability, environmental sustainability, social sustainability, ecological footprint.

Summary

The framework of sustainability for the built environment has been established internationally. Yet, there still exists gap between the high-level principles and its implementation to achieve the design of sustainable community. To close the loop, indicators that describe the degree of sustainability are required. This paper discusses how such indicators can be established for the unique context of Hong Kong under the principles of triple bottom line, and use a case of public housing development to demonstrate the concepts. Key elements of the framework include:

Social sustainability: Connectivity, Amenities, Neighbourhood and context, Culture and community heritage

Economic Sustainability: Character, Flexibility for Change, Re-use of Existing Foundation, Efficient Servicing Strategy

Environment Sustainability: Enhanced Health Environment, Natural Ventilation, Microclimate, Energy Conservation, Enhanced Comfort Environment, Water Saving

The case for study is the Hong Kong Housing Authority's Yau Tong Estate Phase 4 Shopping Centre and its neighbourhood (the Development). The project symbolizes the commitment of the Hong Kong Housing Authority to the environment and the society, and showcases an example of an integrated approach to green building. Numerous sustainable design features, from architectural to system design, are incorporated to support the principles of the Sustainability Framework developed.

1. Introduction

Sustainable development is of fundamental importance world-wide. In Hong Kong, the building industry is becoming the most important development and creates the greatest impact to the environment. A good building environmental design is to protect people and minimise its impact to the environment. From commercial to residential, low-rise to high-rise, public to private buildings, inclusion of environmental consideration into a building design would always bring us a sense of integration of intelligence and consciousness into our environment.

There are three key aspects of the sustainability framework, namely Economic Sustainability, Environmental Sustainability and Social Sustainability (Fig. 1)

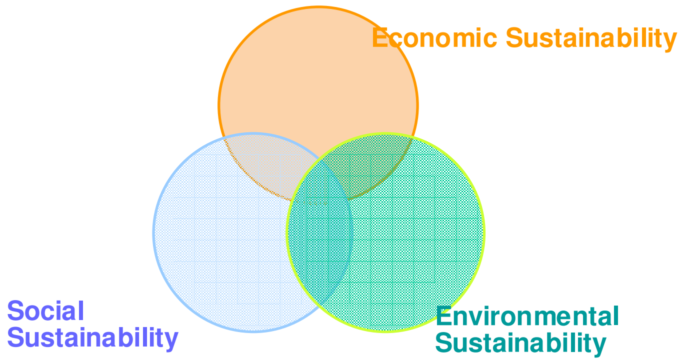

Figure 1 Sustainability Framework.

Economic Sustainability for a building development includes the identification of economic viability of the development, maximizing economic opportunities, and reducing operation and maintenance cost.

Environmental Sustainability focuses on the effective use of natural resources, optimizing energy efficiency of building systems, and reducing environmental impact to the surrounding environment.

Social Sustainability is related to the consideration of enhancing community coherence, social interaction and cultural enrichment of the development and the neighbouring environment.

To illustrate how the indicators can be established for the unique context of Hong Kong, the Redevelopment of Yau Tong Estate Phase 4 is selected as a case study to demonstrate the concepts.

2. Case Study at the Redevelopment of Yau Tong Estate Phase 4

Yau Tong Estate Phase 4 is the last phase of the comprehensive redevelopment of Yau Tong Estate. It is located at the junction of Cha Kwo Ling Road and Ko Chiu Road, directly abutting the southern end of the Mass Transit Railway (MTR) Yau Tong Station with the MTR underground tunnels traversing the site. It lies to the west of the existing Lei Yue Mun Plaza across the Yau Tong estate road.

The Development is a shopping centre with a total gross floor area of 54,300m² (Fig. 2). It is designed to serve the local district with a population of around 80,000 persons at its full occupation. There are also further opportunities to serve the potential future development at Yau Tong Bay, the existing industrial area, tourist attraction at Lei Yue Mun in the vicinity and a larger catchment from beyond through the MTR network. It comprises in essence –

a) A public transport interchange (PTI) on Level 1, including five bus bays, one cross border coach bay and two mini-bus bays;
b) Parking spaces for private vehicles and loading and unloading vehicles on Level 3;
c) A Community Hall on Level 2;
d) Retail space on Level 4 to Level 7;
e) Taxi stands and private car drop-off on Level 4; and
f) Common facilities for Yau Tong Estate on Roof Level, including basketball courts, community farm, children play areas, etc.;

Figure 2 The Redevelopment of Yau Tong Estate Phase 4.

3. Sustainability Design Approach

The design of the Development is to embrace and create synergy for a sustainable community focusing on vibrancy, health and social coherence. The design therefore has been approached with agendas covering economic, environmental and community aspects.

3.1 Economic Sustainability

To maintain competitiveness of the development throughout its life, the design elements introduced to bring retail success and major increase in value are –

3.1.1 Character of a regional type shopping mall

The sloping nature of the site and its proximity to the existing MTR structures results in a relatively high development cost. To improve the revenue generation and achieve economies of scale, the size of the development has been increased from 27,750m² to an optimum size of 54,300m² thereby generating additional gross annual revenue in the scale of US$5.7M and integrating with of the existing Lei Yue Mun Plaza as a regional type shopping centre with a total size of 60,000 m².

3.1.2 Flexibility of change

The layout design should have the capacity and flexibility to cater for changes to cope with ever-changing retail trends. A regular structural grid of 8 metres by 12 metres is applied to optimize flexibility and efficiency in retail planning; located the atrium close to the centre of the development to create shops of optimum depths on all frontages; and, aligned route of arcade primarily along the central atrium and connecting bridges thereby maximizing exposure and commercial attractiveness for all commercial tenants.

3.1.3 Re-use of existing foundation

Foundation works had been completed based on a previously approved layout design. Increase in size of the development of over 60% requires installation of additional foundation. By rationalizing the structural grid to align with the existing foundation as far as practicable and optimizing the use of the spare capacities of existing piles, only less than 20 percent of the building load is required to be supported by the additional foundation. In addition, an existing refuse collection point in the site shall be relocated being an enhancement of the open space design. Taking the opportunity, the remained foundation will be re-used for a new amenity building to serve local residents.

3.2 Environmental Sustainability

In response to the global agenda for environmentally sustainable development, the design embodies impetus towards maximizing environmental comfort, resources conservation and mitigating environmental loading on the neighbourhood. The areas for improvement that have been identified are -

3.2.1 Natural ventilation for PTI and carpark

The Development has been designed to utilize natural resources (e.g. wind) to provide a healthy environment for the users. For instance, natural ventilation will be utilized at the PTI and carpark with reduced length of PTI's enclosure through open foyer design and maximized opening on carpark walls. As a result, associated capital and running costs of the mechanical ventilation system can be reduced.

3.2.2 Enhancement of pedestrian wind microclimate

Furthermore, to receive the onshore wind from the waterfront of Yau Tong Bay in the hottest month, a portion of the existing vacant Shopping Spine structure over the MTR station that borders the public open space at Level 4 will be removed to enhance pedestrian wind microclimate.

3.2.3 Hybrid ventilation for shopping arcade

Energy conservation is another key theme for the design of the Development so as to minimize environmental impact. To reduce the energy consumption for air-conditioning, hybrid ventilation will be utilized at the shopping arcade. This combines the use of mechanical ventilation in extreme seasons (e.g. peak summer) and natural ventilation in mild seasons (i.e. spring and autumn). Motorized openings will be installed at lower level of the atrium for entrainment of cool ambient air. Similarly the same type of openings will be incorporated at the skylights for hot air to exhaust out (Fig. 3).

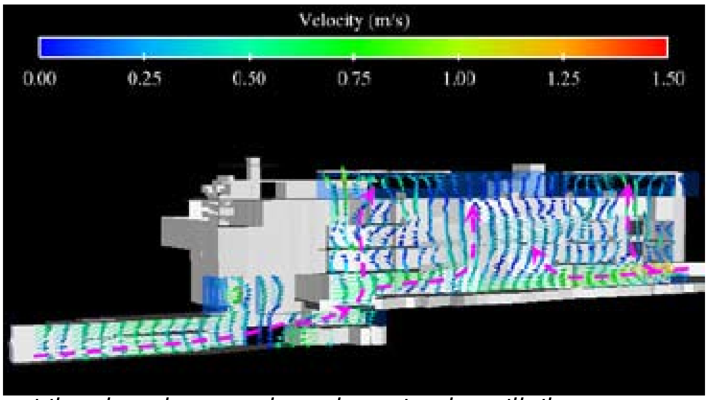

Figure 3 Airflow pattern at the shopping arcade under natural ventilation.

3.2.4 Use of water-cooled air-conditioning system

The design of Yau Tong Estate Phase 4 has also considered the use of more energy-efficient building services systems. Water-cooled air-conditioning system is better than air-cooled air-conditioning system in terms of energy efficiency. In addition, the Electrical and Mechanical Services Department, HKSAR Government (EMSD) is currently promoting the use of water-cooled air-conditioning system in Hong Kong and Yau Tong District is one of the pilot areas. In this connection, water-cooled air-conditioning system is proposed for the Development to enhance energy conservation.

3.2.5 Solar control

Two key features of the atrium of the Development are the large glass wall on the northwestern facade and the skylight over the atrium. Although they allow daylight infiltration to reduce energy consumption for artificial lighting, solar penetration at the same time would increase the cooling load of the building. To strike a balance between solar gain, acceptable daylight level, and offering an open view towards the harbour, several measures are examined to optimize energy efficiency. They include the consideration of high performance glass and vertical fins for the glass wall as well as provision of solar shading device for the skylight.

3.2.6 Green roof

In Hong Kong, the usability of the open space is largely influenced by climatic conditions, in particular the outdoor thermal environment. The outdoor thermal comfort is affected by the site microclimate, such as local wind speed, air temperature, solar radiation and relative humidity etc. To provide a better thermal environment to public, some phenomena, in particular the urban heat island (UHI) effect should be avoided. To reduce heat island effect and to enhance thermal comfort condition, the current design of the development has achieved 35% of the overall greening.

3.2.7 Water conservation – use of reclaimed water

The use of reclaimed water would reduce fresh water consumption and generation of wastewater. Condensate from air-conditioning system has been identified as the major source of reclaimed water which could be used for irrigation purpose. Such condensate will be treated with UV sterilization due to risk of human contact.

3.3 Social Sustainability

Upon completion, this development will emerge as the urban living room of Yau Tong area housing more than 80,000 people. Providing a physical environment, space and urban form that responds to the social and cultural need, enhancing people's access, amenity, comfort and memory map are inherent for a sustainable community.

3.3.1 Connectivity

The project has adopted Universal Design concept to achieve maximum connectivity to draw commuters of divergent sources into the heart of retail and leisure at Yau Tong. This includes a fully glazed elevated spine to connect to the MTR Station; express linkage to PTI through banks of escalators and elevators, footbridges connecting Levels 5 and 6 to the adjoining Lei Yue Mun Plaza for convenience, safety and comfort to residents of Ko Chiu, Lei Yue Mun and Yau Tong Estate in their day-to-day commuting; and a pedestrian precinct on Level 4 from the open plaza, through the main atrium onto Ko Chiu Road (Fig. 4).

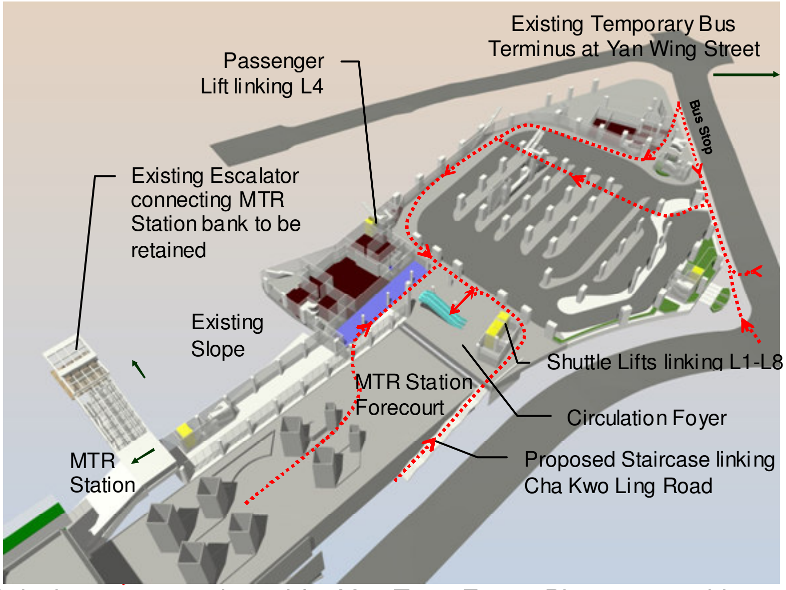

Figure 4 Universal design concept adopted for Yau Tong Estate Phase 4 to achieve maximum connectivity.

3.3.2 Neighbourhood and context

External space at the public domain of Yau Tong Estate is extremely limited. Through a removal of the existing Shopping Spine structure, decking over the existing escalators linking the MTR station and relocating the existing Refuse Collection Point, a sizable civic and community plaza of 3,600 m^2 outside the main entrance of the shopping centre is regenerated, with an amount of greening at approximate 35% of the gross area. To sensitively, interface the building entity with the adjacent built fabric and reduce the physical impact on the residential context, the building mass of the development is set back at the estate road level to create a receiving entrance to the plaza.

3.3.3 Community and cultural heritage

Sense of belonging is the driving force behind sustainable community. Community engagement is involved in the evolution of the plaza design. To unveil the heritage and uniqueness of Lei Yue Mun, imagery of rock cutting industry and artifact of historical importance are translated into dynamic architectural form; decks of al fresco dining were created to take advantage of the tourist attraction at Lei Yue Mun.

4. Indicators of Savings

A comprehensive environmental design study has been carried out for the Redevelopment of Yau Tong Estate Phase 4 by Ove Arup & Partners Hong Kong Limited. Performance assessment on the sustainability design for the development has been conducted. Several indicators on energy conservation and reduction in environmental impact have been identified.

4.1 Enhancing Health Environment

4.1.1 Natural ventilation at PTI

The dispersion behaviour of vehicle exhausts at the PTI has been analyzed under prevailing wind conditions (southeasterly and southwesterly). With mitigated open foyer design, it is illustrated that natural ventilation would be capable of maintaining acceptable air quality for at least 50% of the PTI area according to the requirement of Environmental Protection Department, HKSAR Government (EPD) under windy condition.

4.1.2 Natural ventilation at carpark

The natural ventilation performance of the Carpark has been assessed based on the criteria as required by Australian Standard AS 1668.2-2002. Based on the design calculation, it is found that natural ventilation alone could satisfy the ventilation requirement of 46% of the carpark area. Consequently, the energy consumption by the mechanical ventilation system and thus greenhouse gases emission can be reduced.

4.2 Energy Conservation

4.2.1 Hybrid ventilation

Natural ventilation with motorized openings to be installed at low level of the atrium and at the skylights will be utilized for the shopping arcade in mild seasons (i.e. spring and autumn), when the climatic condition including the ambient temperature and humidity satisfy the design conditions to meet indoor thermal comfort criteria as required by ASHRAE Standard 55-2004 (Fig. 5). The estimated cost saving is approximate US$24 thousand per year.

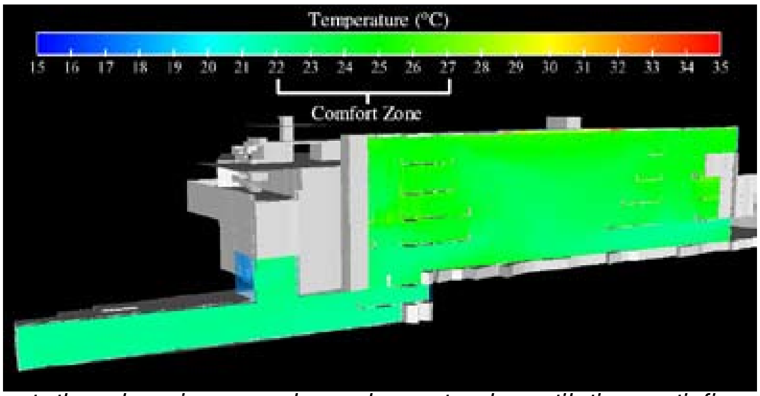

Figure 5 Temperature at the shopping arcade under natural ventilation satisfies the requirement by ASHRAE Standard 55-2004

4.2.2 Water-cooled air-conditioning system

Water-cooled air-conditioning system will be utilized for the Shopping Centre. Such system is better than air-cooled air-conditioning system in terms of energy efficiency. Taking into account the air-conditioning period with the utilization of hybrid ventilation, the estimated annual operation cost saving is about US$ 676,000.

4.2.3 Solar Control

Several solar control measures for the Arcade including vertical fins, high performance glazing for the northwestern curtain wall and solar shading devices for skylight were examined. Table 1 shows the matrix for comparison of solar performance for different fin and glazing options for the northwestern curtain wall. As much as 25% of annual solar heat gain can be reduced if combined measures are used.

External motorized blinds controlled by timer or weather sensors was also proposed to reduce solar load for the Arcade. The blinds, being made of fabric materials, can filter a significant amount (up to 60%) of solar radiation while at the same time allow diffuse daylight infiltration to the Arcade.

Table 1 Comparison of solar performance for different fin and glazing options for the curtain wall.

Annual Solar Heat Gain Reduction at the shopping arcade (compared to single glazed clear glass with no fins)		Fin Option		
		No fins	1m fins at 2.5m interval	1m fins at 1.25m interval
Glazing Option	Single glazed, clear glass	-	10%	21%
	Double glazed, clear glass	9%	12%	22%
	Low-e double glazed	19%	20%	25%

4.3 Enhancing Comfort Environment

Green roof has positive effect on building environment, especially in thermal aspect. Planted roof would reduce the roof surface temperature, thus enhancing both outdoor and indoor thermal comfort. Fig. 6 shows the surface temperatures of a hard roof of a public housing block and a planted slope. It can be observed that the temperature difference could be up to 30℃ (Fig. 6). Green roof would also increase thermal insulation such that thermal loading for the building could be reduced. In general, green roof can reduce the cooling load for the floor underneath by around 15% according to the findings by the National Parks Board (NParks) and Centre for Total Building Performance (CTBP), National University of Singapore (NUS) (2002).

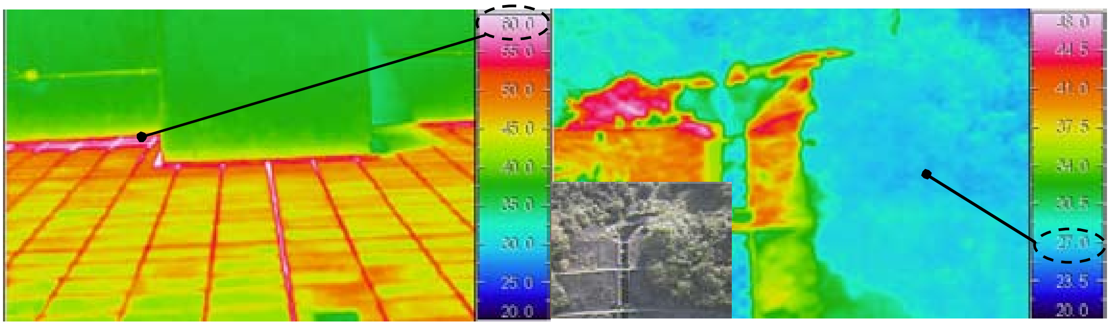

Figure 6 Comparison of temperatures of hard roof and surface covered with plantation

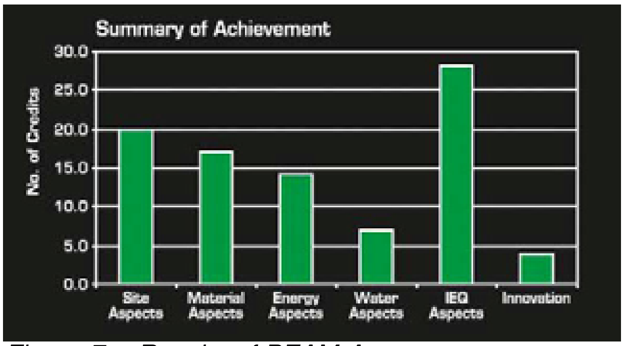
4.4 Water Conservation – Use of Reclaimed Water

Condensate from air-conditioning system will be reclaimed for irrigation purpose for water conservation. The amount of reclaimed A/C condensate would adequately cater for irrigation at Levels 1, 3 and 4, podium roof, as well as the soft landscape on L4 open plaza. Assuming the amount of water required for irrigation to be 2 L/ m² / day, the estimated annual cost saving for fresh water consumption is approximate US$2,400.

5. Performance Assessment – Building Environmental Assessment Method (BEAM)

A preliminary environmental evaluation for the Design and Construction of the Yau Tong Estate Phase 4 was conducted using Building Environmental Assessment Method (BEAM). It is the private sector initiative that gives recognition for enhanced environmental performance in the planning, design and construction of buildings in Hong Kong. The assessment was carried out based on BEAM New Building Developments (Version 4/04) to address the possible sustainability issues throughout the building life.

Results of the assessment show that the Development would achieve the highest Platinum rating under BEAM with anticipated score of 90.4 credits out of a possible 117.2 credits available, ie 77% of the available credits (Fig. 7). The design of the development is recognized by BEAM for best environmental practices in 6 key aspects: Site, Material, Energy, Water, Indoor Environmental Quality (IEQ) and Innovation. They encompass the important features of green roof, thermal comfort, recycling of reclaimed water and community engagement in this development.



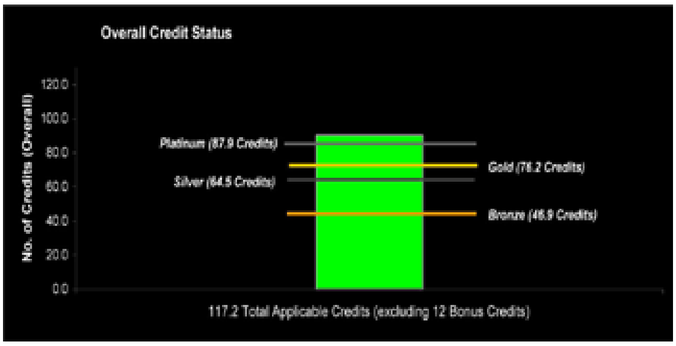


Figure 7 Results of BEAM Assessment

6. Ecological Footprint

6.1 Definition of Ecological Footprint

The ecological footprint is the predominant methodology used to highlight the impacts of consumption within the context of ecological limits. The methodology has been increasing in popularity since its initial publication by Wackernagel and Rees (1990). The footprint is a means of measuring a population's level of consumption by calculating the notional and direct land area needed to support them with the resources they consume and absorb the wastes they generate. The ecological footprint is measured in global hectares (gha) which means that the land can be located anywhere in the world and is representative of a standardized unit of average global productivity. In this manner the ecological footprint reallocates the environmental impact to the end user no matter where in the world the impact takes place. Ecological footprint calculation can take either a bottom up approach according to Chambers et al. (2001), or top down approach as suggested by Wiedmann et al. (2006), or use a combination of both.

Independent of the methodology used to conduct an ecological footprint study, one of the most important messages that it conveys is that we only have one planet with a finite land area therefore clearly demonstrating that we are constrained by ecological limits. Different from traditional environmental indicators, such as the Kyoto climate change targets, for which impacts are measured within a defined boundary such as a country, the ecological footprint takes into account all impacts on a population no matter where in the world the impacts are taking place. The ecological footprint is therefore taking a consumer rather than territorial approach in measuring environmental impacts.

6.2 Integrating the Ecological Footprint into the Design Philosophy

The average footprint in rural China currently stands at 1.6 global hectares per person (gha/capita) and that of an individual living in Shanghai is already around 7gha/capita. For a country that is urbanizing rapidly like China, it is important to make effort to reduce the impacts by all new cities. Lei and Wang (2003) stated that Hong Kong's Ecological Footprint in 2001 was 6.1 gha/capita, or 2.2 times the world average. If the situation remains unchanged, we would need at least 180 times the existing land and sea area we have to support our current lifestyles.

Olgyay and Herdt (2004) proposed two indicators on measuring ecological footprint for buildings, namely Index of Building Sustainability (IBS) and Index of Efficiency in Sustainability (IES). The IBS reflects the fraction of the annual carrying capacity of the project's land that is consumed by a building. On the other hand, IES is the quantity of land required to meet a sustainability goal. These two metrics can be applied to assess both construction and operation impacts. Smaller indices mean less impact to the environment. These indices could be used as indicators to architects and / or building designers to design high performance building with minimal impact.

Energy consumption by air-conditioning plays an important part in ecological footprint as it involves the use of fossil fuel. Based on the Hong Kong Energy End-use Data (2007), approximate 37% of total energy was consumed by commercial buildings, from which 28% (equivalent to 29,897TJ) was due to air-conditioning. And the study by Panizo (2000) stated that fossil fuel energy consumption accounts for approximate 20% (equivalent to 1.25gha/capita) of the total ecological footprint for Hong Kong. It may be concluded that the ecological footprint for fossil fuel consumed by air-conditioning in commercial buildings is 0.13gha/capita.

Through optimizing the design of Yau Tong Estate Phase 4, energy consumption by air-conditioning has been reduced through utilization of natural ventilation and water-cooled air-conditioning system. With a combined annual energy saving of 23TJ for air-conditioning, 0.0001gha/capita of land could be conserved. These measures not only reduce the demand on fossil fuel but also the generation of greenhouse gases.

7. Conclusion

Indicators for different aspects of the sustainability framework including Economic, Environmental and Social was established for the unique context of Hong Kong and demonstrated using the case study of the Redevelopment of Yau Tong Estate Phase 4 of Hong Kong Housing Authority.

The sustainability design approach for the case study was illustrated. Performance indicators for enhancing health and comfort environment as well as energy and water conservation were identified. This project symbolizes the commitment of the Hong Kong Housing Authority to the environment and the society through an integrated approach to green building design, from architecture to building systems.

Ecological footprint, which accounts the impacts of consumption by a development within the context of ecological limits, has also been incorporated into the design philosophy of Yau Tong Estate Phase 4. With the utilization of natural ventilation and water-cooled air-conditioning system, energy consumption by air-conditioning has been minimized. As a result, the generation of greenhouse gases is reduced with reduced demand on fossil fuel.

Keywords: regenerative design, ecotourism, Torres Strait, community design

Summary

Many critics are beginning to look towards a theory of development that moves beyond sustainability predicated on efficiency, towards sustainability based on active and positive contribution. One such exploration is termed 'Regenerative Design'. Regenerative design diverges from this perception of sustainability in three key ways. Firstly, it shifts the frame of reference from minimal to positive impact. Secondly, it questions human/environment relations based on the Cartesian separation of subject and object. Thirdly it attempts to reconnect environmentalism with a socio-political dimension, which has been lacking in much sustainability discourse.

What does this look like in practice? Can we develop regeneratively? These are the questions explored in this paper through the lens of a project carried out in the Torres Straight Islands in April 2007. The project team comprised architecture students from the University of Melbourne who visited Moa Island with the aim of designing an ecotourism facility. Extensive research was conducted prior to departure, which assisted the students during the one week intense charrette with community Elders and representatives. The local Kubin community was presented the opportunity to accept and comment on the preliminary designs, before the students returned to Melbourne to develop their ideas.

In Moa, the students learnt first hand about the complex issues surrounding community led design. The main challenge was to establish a clear understanding about what the facility needed to provide, in order for it to make a positive contribution to the entire community. It was initially difficult to gain this understanding as each community representative presented a unique set of problems which had either a social, economical, political or environmental agenda. This paper introduces the concept of regenerative tourism and reflects on the process of trying to develop architecture that becomes an active participant in its context.

1. Introduction

This paper introduces the ideas of 'Regenerative Design' and more specifically 'Regenerative Tourism' using a case study from the Torres Strait Islands in the concept stage of design.

1.1 Regenerative development

The development and exploration of regenerative development comes from a frustration with the inadequacy of the approach and pace of movement towards a more sustainable future. It is around 45 years since Rachel Carson's "Silent Spring" was published, warning us of the environmental impacts of our excessive use of chemicals. Kenneth Boulding's "Spaceship Earth" came out in 1966 reminding us that we only have one planet. This concern for over-consumption was echoed six years later in the 1972 Club of Rome Report "Limits to Growth" (Meadows et al. 1972). Yet our chemical use continues to grow while the average Australian has an ecological footprint that would require four earths to sustain. A more worrying demonstration of our failure to deal with these problems is that over 100 year ago Svante Arrhenius (1896) calculated that increasing carbon dioxide emissions from human activities will lead to global warming, and it is now sixty-eight years since Guy Callendar (1938) warned that global warming is already underway. It is 27 years since the first report from the Inter-governmental Panel on Climate Change (1990) yet our greenhouse gas emissions continue to rise. In fact, the recent Millennium Ecosystem Assessment report concluded that: "…the results of human activity are putting such a strain on the natural functions of Earth that the ability of the planet's ecosystems to sustain future generations can no longer be taken for granted". (Millennium Ecosystem Assessment, 2005:2) This report showed that nearly two-thirds of the essential services provided to us by nature are in such decline that collapse is likely.

The research to date that investigates this inertia in the movement towards sustainability has found that it is based on the Cartesian logic that places humans outside of, and in opposition to, nature. This approach maintains a reductionist approach to sustainability and attempts to solve problems within the same framework that has created them. There needs to be a different approach to the issue of sustainability and many environmentalists have called for this in the form of a paradigm shift in values; for example Schumacher, 1974; Naess, 1995; Sachs, 1995; Devereux, 1996; Capra, 1996 and 2002; Bossel, 1998; AtKisson, 1999; Kumar, 2002; du Plessis 2006 and 2007.

Apart from the failures outlined above, the problem might also stem from our understanding of what is meant by the term 'sustainable development'. Sustainability, depending on the point of view, is about sustaining, keeping things as they are – or not letting them get worse. The problem, and the cause of its contestability, and possibly the inertia, lies in what people are trying to sustain. The use, misuse and consequent renegotiation of the term 'sustainability' has resulted in a reduction of its potency. In particular, its connection with the conceptually divergent goals of economic growth and production under the popularised Brundtland definition of 'sustainable development' has led to skepticism of the value and meaning of this term. Furthermore, the framework of minimising impacts, or perhaps even more problematically offsetting impacts, is seen as both ineffective and presumptuous since it continues to grant indulgences on behalf of the planet.

It is for this reason that the authors began to investigate the concept of Regenerative Design. The idea of 'regenerative design' was first proposed by landscape architect John Tillman Lyle (Lyle 1994). Rather than the stability of sustainability, Lyle presents regenerative design as a dynamic process of participation, feedback and continual change over time. Lyle intends the concept to be applied not only to individual circumstances, but rather to the design of entire cities and landscapes. Thus, Lyle sees regenerative design as not only a change in process and product, but change in attitude towards our very relations with our environment (Lyle, 1994, pp. 7-8).

It is important to differentiate the position articulated in this paper from some others that are emerging within the discourse of regenerative design (for example Eisenberg and Reed 2003). The idea of regenerative design proposed here is more closely aligned with a position developed by Steven Moore. In 'Technology and Place: Sustainable Architecture and the Blueprint Farm', Moore provides a more critical analysis of regenerative design (Moore 2001). It is inspired by the apparently divergent figures of the social ecologist Murray Bookchin and the architectural critic Kenneth Frampton. For Moore, regenerative design offers the opportunity of reconnecting environmentalism with a socio-political dimension. This has been lacking in much sustainability discourse, particularly within the arena of sustainable architecture. Thus, notions such as transparency, local control, everyday practice and democratic negotiations are a core part of Moore's eight principles for regenerative design.

As an example, Moore distinguishes 'regenerative' from 'sustainable' technologies in two ways. Firstly, and most directly related to Lyle's conception of regenerative design, he argues that they must not only maintain a balance between production and consumption, but also result in a 'net increase in life-enhancing conditions' (Moore 2001, p. 131). Secondly, he argues that regenerative technologies must be 'socially visible and politically transparent' (Moore 2001, p. 130). By this, Moore intends to confront the idea of technology as a black box and reconnect people with the relations and means of production as well as making the technological intervention itself haptically and visually transparent. He also proposes that technologies grounded in place are inherently more democratic since the forces required for production (wind, sun etc) cannot be centrally controlled and dominated.

1.2 Regenerative development and ecotourism

The application of the idea of regenerative design to the tourism context is both pertinent and problematic. On the one hand tourism, as the world's largest industry, is seen as the answer to many social and environmental problems, particularly in developing countries (McMinn 1997). As well as the obvious environmental impacts of travel, there are also well-documented social impacts from tourism such as the loss of local traditions, the erosion of family structure, crime, and unequal distribution and consequent fighting over economic benefits (International Ecotourism Society, npd). On the other hand, the tourist experience is inevitably temporary and frequently superficial. The pace of the tourist schedule rarely allows for anything but a fleeting glimpse of life lived elsewhere. It is a tantalising experience with an 'other' underpinned by the notion of excess.

Ecotourism is burgeoning sector of the tourism industry, hailed as the fastest growing tourism sector at the end of the twentieth century and into the new millennium (Honey and Rome 2002). Ecotourism is generally associated with pristine, remote places that exhibit cultural and most particularly ecological difference. In fact, the International Ecotourism Standard explicitly includes a 'direct personal experience of nature' as a core principle of such tourism developments (Ecotourism Australia and the Cooperative Research Centre (CRC) for Sustainable

Tourism 2004). Other key features of the concept include low impact operation, education about environmental issues, and a positive contribution to conservation and to communities (Buckley 2003).

Green Globe 21 is a method used to assess the 'ecological' properties of a resort, operation or ecotourism offering. It does this through a series of requirements that, once met, lead to a label that can be used by the ecotourism operator. A review of the principles of Green Globe 21 demonstrates the synergies between ecotourism and sustainability with substantial effort focused on reducing impacts on the ecological, social and cultural context. However, there are other aspects of the principles that potentially move beyond the limitations of efficiencies, such as natural area focus, interpretation, education and ecotourism benefiting local communities.

Nevertheless, these potentially regenerative aspects of ecotourism are not well developed, particularly as they relate to the accreditation requirements of the international Green Globe certification program. For example, while great detail is provided on the requirements and benchmarks for ecologically sustainable practice, there is very little information to support what is intended by the notion of the 'presentation of natural values'. The inclusion of local communities and cultural differences within the ecotourism agenda also has potential to address some of Moore's concerns such as transparency, local control and democratic negotiations, but the requirements for ecotourism accreditation do not articulate the full potential of this regenerative agenda. Instead they restrict themselves to such issues as 'liaison with the local community' rather than full democratic participation.

While such issues are difficult, if not impossible, to integrate within the constraints of an certification system, there are moves within ecotourism to increase local control through, for example, the idea of community based ecotourism (CBE)where the community retains substantial control over the project and the benefits that arise from it (International Ecotourism Society npd). This is an important issue to address the negative and often unforeseen impacts that can arise in ecotourism projects and to facilitate the potential for net gains rather than losses, particularly within the localised social and economic context.

2. Regenerative concepts and the Moa Case study

There is no definitive answer or universally agreed definition for regenerative design. This paper engages and explores the concept by looking at an ecotourism project for the island of Moa in the Torres Straight Islands. As with 'sustainability', regenerative design is a contested concept with a common horizon of intent underpinned by a diversity of meanings and applications. However, regenerative design diverges from sustainability in three key ways. Firstly, it shifts the frame of reference from minimal to positive impact. Secondly, it questions human/environment relations based on the Cartesian separation of subject and object. Thirdly it attempts to reconnect environmentalism with a socio-political dimension, which has been lacking in much sustainability discourse. These concepts and their implication for architecture are further articulated in Owen 2007a, Owen 2007b, Owen and Hes 2007, Owen 2008.

2.1 Background on Moa

The Torres Strait Islands are located between the tip of Cape York and the southerly coastline of Papua New Guinea. Over 150 islands encompass approximately 48000km2 of shallow seas (Green 2006, p.3). Moa Island is located in the West Torres Strait and is one of 14 islands reserved for island communities (Finch 1977, p.1) Generally each island has one community; however Moa is unique with both Kubin and St Pauls communities.

Moa has a total population of 439 residents, with 201 people residing in Kubin and the remaining 238 living in St Pauls (ABS 2006). The population balance between the two communities is relatively equal, despite Kubin Community Council (KCC) having jurisdiction over 152km2 of land, while St Pauls controls only 17.7km2 (State of Queensland Government 2007). The two communities are connected by a 15km dirt road and each contains the essential services that allow it to operate independently. (Observation and Occasional paper 17, p.86)

Despite the presence of two communities on Moa, it is only the Mualgal people in Kubin who are considered to be the traditional owners of the land, with their ancestors coming from Muralug and living in "seven different villages scattered around the island" (Nawia 1991, p.1). This story of origin is markedly different to St Pauls village, which was set up as a reserve by the Queensland Government in 1904 following the forced repatriation of Pacific Island laborers. The issue of traditional land ownership is the cause of some animosity between local people in Kubin and St Pauls, particularly with regards to discussions about future development in Moa.

Education is valued in both the Kubin and St Pauls' communities, however facilities are limited. Individual primary schools teach children in Moa up to year seven. For years seven to twelve, local teenagers attend school on Thursday Island or boarding schools in Cairns and Townsville (Occasional Paper 17 2006, p.78-79). The process of sending teenagers away from Moa for educational purposes is both supported and opposed by the older generations. While education is considered to be "the pathway to improved opportunities for children", the forced distance between family members and exposure to western ideas is seen to "erode traditional culture" (Occasional Paper 17 2006, p.75).

Employment opportunities in Moa are limited, with the 2006 census identifying labouring, community and personal service workers and clerical and administrative workers as the three most common occupations. While the percentage of people working as clerical and administrative workers in Moa is on a par with the Australian national average, the percentage of people employed as labourers is three times higher, while community and personal service workers are twice as high. In contrast, the percentage of people working as professionals, managers and technicians or trades workers was over two times lower than the Australian national average (ABS 2006). These statistics support Noel Finch's claim that there are "not sufficient opportunities on the islands to cater for the higher education qualification gained by children who studied in the mainland" (Finch 1977, p.59).

The result is a problem identified as 'population mobility' and is of major concern to community elders, who claim that "young men go off to live on the southern mainland and with their going destroy the ability of the island to retain knowledge inherited from the past" (Lawrie 1970, p.xxii). This attitude exists even with emigration within the Torres Strait, as each island has a unique cultural heritage retained in traditional stories and legends passed by Elders (Finch 1977, p.22). Margaret Lawrie, who visited the Torres Strait in 1965-68 to record stories on behalf of traditional owners, explains that "ownership of stories is restricted to an island and to the groups and individuals within that island…[they] are limited in their telling to the island of origin" (Lawrie 1970 p.xxii). This means that youth who have chosen to relocate within the Torres Strait cannot technically adopt the culture of another island.

A research study conducted in 1999-2003, entitled 'Careers and Aspirations: Young Torres Strait Islanders', begins to identify the extent of population mobility based on a sample group of 105 Indigenous people aged 15-24. When the research group returned in 2003, only 59 of the original sample group interviewed in 1999 remained (Arthur, Hughes, McGrath and Wasaga 2004, p.1). Results from the 2006 census support the argument that there is a high rate of mobility amongst 15-24years olds, with only 15 percent of the population in Moa being within this age bracket, compared to 35 percent 5-14year olds and 24 percent 25-54year olds (ABS 2006).

The decision of young Indigenous people to relocate to mainland Australia for improved education or employment opportunities is one that contributes to the erosion of traditional culture. Other factors attributed include the widespread adoption of western culture and the diminishing role of the extended family in providing discipline and life skills in the older children (Occasional Paper 17 2006, p.78-83).

Background to the project

The field trip to the Torres Strait islands was organised by the Faculty of Architecture, Building and Planning at The University of Melbourne in association with the UNESCO Observatory. It was offered to students as an opportunity to gain experience working on a real architectural project in an environmentally and culturally sensitive context. The brief was for an ecotourism resort in Moa which carefully addressed the "cultural, sustainability, technical, socio-economic and environmental issues important to the people of Moa and the Torres Strait" (Joubert 2007). The field trip took place in April 2007, where eleven students and four academic staff were accommodated in Kubin for eight days and guided around the island by a group of local people introduced as community representatives (known here on as 'the working committee').

The first stage of the design process began in the weeks leading up to departure as the students researched the Torres Strait islands and existing ecotourism facilities. While the group successfully uncovered substantial quantities of information relating to the Torres Strait region, specific details on Moa were difficult to locate. This, combined with the working committee's decision to temporarily withhold details of the brief, made it difficult to assess which precedent studies were relevant. Consequently students arrived in Moa feeling unprepared.

The working committee claimed that their decision to withhold details about the project, until the students were in Moa, was made to avoid problems arising from preconceptions about what the community needed. The working committee wanted the students to be informed through experiences of the culture and environment.

The consultation period for the project was prolonged by the complex nature of the social/political setting in Kubin, generated by a lack of communication between the working committee and the (KCC). The sensitive nature of issues surrounding traditional land ownership and development in Moa resulted in the working committee proposing a top-down approach to developing the resort. Rather than actively involve the whole community from the beginning of the project, the working committee was concerned that the idea of developing an eco-tourism resort would not be widely accepted, because "it is difficult for the community to have an opinion of something that they have had no experience with" Their intent was to seek community involvement once a "picture" of what the resort could look like was generated "to give them something to get excited about" (Ben*).

When full details of the proposal were disclosed to KCC, they demanded transparency within the design process along with a longer consultation period that actively involved the whole community. This added to the constraints already impacting on the time available for the student's to conceptualise their designs. Consequently, this project only reached its concept development stage and thus the reflection on regenerative concepts is based on the opportunity presented to meet the needs of the Moa community.

1 – Adding value

The first point of differentiation between sustainability and the concept of regenerative design is the only one that is universally shared amongst all proponents of regenerative design. The premise is simple – that our actions should result in net benefits to our ecological and social environments. The application is more complicated, but it is based on what William Reed has described as 'building capacity rather than things'.

The net benefits of the ecotourism resort, relate to a number of long and short term goals set by the working committee in response to the local issues concerning employment, education, population mobility and loss of culture. At its most fundamental level, it is intended that the resort will increase the employment opportunities available on the island and discourage the current emigration patterns. A committee member described the current situation as a "loss loss situation", with youth who remain in Kubin encountering a "loss of opportunity" while those who leave have a "loss of culture". It is intended that by reducing the need young adults to leave, the community can start to work on strengthening the youth's connection to the local culture.

Detailed discussion with the working committee about their aspirations for the ecotourism resort revealed that the design brief was not large enough to support even their short term goal to prevent emigration from Moa by generating local employment. The absence of appropriate teaching facilities would prevent the necessary training from taking place in Moa. Following this realisation the group agreed that part of the design process was expanding the brief to include a cultural centre which would be a subsidiary facility to the ecotourism resort. Such a facility would enable long term goals to be set which would result in further net benefits for the island. These would include more general training courses to aid the skills shortage in Moa and the possibility of incorporating secondary school facilities to prevent emigration and improve literacy and numerously skills amongst adults.

In addition to the social and educational benefits of the resort, it is intended that the facility will add value through economic empowerment to the local population. It is proposed that this will be achieved through employing local people to operate the resort and utilising local labour and materials in the construction of the resort. It is intended that the resort will boost the local economy, providing opportunity for the creation of new businesses that compliment the resort and its visitor program. The working committee saw opportunities for expansion in supplies, entertainment, day trips to neighbouring islands, fishing and local arts and crafts.

2 – Working with nature

Many proponents of regenerative design invoke an ethic of care and a connection with the spirit of place as a necessary condition to challenge our current position. Not everyone is comfortable with embracing this perspective for fear of being labelled a new age hippy and dismissed as 'flaky eco-la-la', to use Murray Bookchin's condemning term. Nevertheless, the dominant mechanistic and reductionist attitude towards our world is something that regenerative design seeks to challenge. Working with nature is an important aspect of life in the Torres Strait. It is formally recognised as Ailan Kastom (Island culture) which is responsible for "govern[ing] how Islanders take responsibility for and manage particular areas of their land and sea country; how and by whom natural resources are harvested and allocation of seasonal and age-specific restrictions on catching particular species"(Green 2006, p.4).

The strong connection between Islanders and their land and sea country made it essential that the ecotourism resort be well integrated with the natural environment. During the consultation period, the working committee identified a number of key values which assisted in the design of the ecotourism resort. Twelve design principles were established from these key values, of which nine embodied the need for the ecotourism resort to work with and celebrate the natural environment. These principles can be best described through a narrative that outlines both the key features of the building form and the integrated visitor program. It is impossible to separate these two things as the resort was designed to support the visitor program, which was intended to deliver a connection with the spirit of place.

<u>The visitor:</u> A maximum of five visitors arrive in Moa in the late afternoon to commence a five day trip in Moa. The trip is marketed as part of a niche tourism package which operates for six months of the year. The working group specified the maximum number of visitors as part of their ethic of care, ensuring the quality of the visitor experience, while limiting the socio cultural impact of tourism in Moa. The program operates for only six (Ben).

<u>Connection/Ecological footprint:</u> The visitors are greeted by their local guide at the airport and are advised to collect their luggage and meet outside the terminal to begin their walk to the resort. To encourage greater responsibility on the part of each visitor with regard to the quantity of 'stuff' they bring to Moa, it is intended that the visitor travel to the resort on foot, carrying their own bags. As tourists we often take more than is necessary.

<u>Journey/Diversity:</u> With backpacks on, the visitors follow their guide out of the airport enclosure and across the road to an opening in the vegetation and the beginning of a raised boardwalk. The raised boardwalk to the resort is intended to immerse the visitor in the natural environment. While walking to the resort at a leisurely pace, the

group encounter a number of notably different ecosystems along the path of the boardwalk, from Melaleuca and Sedge to Pandanus and Acacia and Mangroves. The site for the ecotourism resort was chosen for the diversity of the ecosystems surrounding it.

Context/Technology/Local knowledge: Arriving at the resort, the symbolism and integration of nature in the design of the buildings is clear. The visitors acknowledge the role which the traditional housing typology has played in influencing the design of the accommodation huts. Each one is built using light weight materials to minimise heat gain and is oriented towards prevailing breezes to cool and ventilate its occupants. Natural light illuminates the interior space of the huts, which have been decorated to illustrate important totemic symbols of the Torres Strait region. The presence of traditional weaving and thatch over a recycled timber frame on concrete stumps, indicates that the construction is intended to be a contemporary interpretation, rather than a traditional reproduction. The inclusion of guttering and rainwater tanks, a solar hot water system over the amenities hut and photovoltanic panels expresses the self-sufficient aspirations of the resort. The seven huts are arranged around a performance area with open platform activity areas overlooking the ocean and the community beyond. The resort was design to integrate with nature. The accommodation huts are raised to prevent interference with natural tide patterns, flora and fauna. Local knowledge of materials and construction techniques will be combined with local technologies to ensure that the resort has no negative impacts on the surrounding environment.

Relationships: Once settled in, the local guide returns to the group and provides information about the available modes of transport on the island. Bicycle and walking are described as being the most accessible, especially around Kubin Village. The guide provides details of the daily program which is well structured and involves much integration with the local population, participating in activities that are formed through daily rituals. It is not intended that visitors remain in the resort during the day. The rigid visitor program, as designed by the working group, combines a variety of activities to encourage visitors to learn about the local culture and environment.

3 – Socio-political aspects

While the dominant mechanistic and reductionist attitude towards our world can be criticised, this same thinking has also provided environmentalists with a secure foundation of scientific 'proof' of planetary changes such as global warming. Nevertheless, there are so many things for which science cannot account. In particular, the socio-political dimension, which is the focus of the third point of difference, requires value judgements which can never be quantified. Sustainability does not exclude the socio-political dimension, but it defines it as a distinct realm; one of the four 'pillars' or three 'legs' depending on how the pie is sliced. Conversely, regenerative design is concerned with the complex web of relationships that form an integrated whole. This is an aspiration rather than a reality and unfortunately social relationships are too readily glossed over or presented as universal and homogenous. Throughout the design process, attempts were made to ensure that the socio-political aspect of the project was not overlooked. While in some respects this may sound contradictory when considering how the design process was initially dominated by a single group of people, the working committee aspired to represent needs and concerns of the community with each member pursing a social, economical, political or environmental agenda. There were various interesting and unexpected consequences as a result of this approach.

Firstly, prior to the arrival of the student group, it appeared that the members of working had not clearly established, as a team, their expectations of what a new facility should achieve. This may have been because of the high level of secrecy surrounding the proposal. Consequently upon commencement of the briefing and consultation period, various different perceptions of the resort started to emerge, creating confusion and contradiction as well as a platform for discussion and debate.

Secondly, while the various agendas were each theoretically represented by a member of the working committee, the issues were addressed on varying levels based on the strength of the individual personality. The committee members assuming responsibility for the economic and social aspects of the facility were strong, and sometimes officious, while in contrast, issues relating to environmental awareness were promoted by the student group.

Thirdly, it was often the case during the consultation period that the individual committee members could not easily incorporate their perceptions for the resort with that of another person. This is where the design process was valuable, as it brought out the varying dimensions of difference that existed amongst the various stakeholders and encouraged negotiation.

The vastly different ideas motivating Ben* and Penny* are an example of how regenerative design is concerned with the complex web of relationships. Ben's focus was on generating income and his ideas were closely aligned with the short term benefits associated with mass tourism. He sought to promote activities and experiences that could be marketed to high paying guests and some of his early suggestions included "tourist/antique shops alongside the beach…a gazebo, golf course, tennis courts, sauna…and a restaurant selling $17 steaks". Aside from being contextually inappropriate, his ideas gave no consideration as to how the infrastructure for achieving the experience could be designed or its possible environmental impact. He perceived the necessary 'ethic of care', that the design should invoke, as being transferable to someone else, preferably those being paid to maintain the facility during its six-month non-operational period, "when the land is left to heal".

In contrast, Penny* perceived the ecotourism resort as a tool that could be used to address the many social problems concerning employment, education, population mobility and loss of culture. To her, the facility was an opportunity to create an education and training centre supported by a small scale tourism venture. However, her ideas gave no attention to addressing the other related issues such as: possible adverse effects of tourism on the culture, management, governance, financing, ownership and maintenance.

By considering the socio-political dimension, the design process delivered a project that took aspects of both points of view.

Conclusion

Regenerative design is still evolving and maturing in its ideas and applications. Unlike sustainability it is not premised on an idealised end point but rather recognises the necessity of the process of development along variously divergent and convergent paths. This research aims to help in this evolution and maturation by adding concrete examples to the debate.

The student group in Moa set out to design an ecotourism resort that carefully addressed the "cultural, sustainability, technical, socio-economic and environmental issues important to the people of Moa and the Torres Strait". With limited resources and time constraints, the design process became more significant than the design outcome, in demonstrating what the issues were and how a new facility could address them. The Regenerative Design frame work assisted in this task by establishing realistic goals. The design process can be related to all three principles. In the case of the first principle, to be truly beneficial to the community, the ecotourism resort needed to add value to the lives and prospects of young people living in Moa, by getting them actively involved. This means adding capacity and capital to the current infrastructure and the first stage of this was achieved through the expansion of the project brief to include subsidiary facilities for education and training. Secondly, to be accepted by the community, the ecotourism resort needed to have a connection to place, which in this case meant reflecting the importance placed on Ailan Kastom (Island culture). Rather than promote the 'object' of the ecotourism facility, the design process engaged the community in a narrative that describes the articulation of the design through their environment. Finally, the socio-political aspect of the design process caused debate and enabled the varying dimensions of difference that existed amongst the various stakeholders to be challenged and negotiated, enriching the proposal.

A strong desire to find solutions to the many social problems concerning employment, education, population mobility and loss of culture in the Torres Strait, led to the perception that the any proposal must be surrounded by secrecy. The top-down design approach proposed by the working committee was not intended to place limits on what could be imagined, but instead assist in generating a picture that promotes exploring new possibilities. Wider application of the regenerative principles could encourage future ventures to start with a bottom-up approach that values working collectively to develop a vision.

Keywords: green community, construction, technology, building, sustainable, energy-saving, demonstration

Summary

China is one of the countries with the largest scale of community construction in the world. Great challenges are faced by China to improve the built environment of community in the viable, liveable and sustainable way. Based on the research achievements from the key state R&D program “Study and demonstration on construction techniques of eco-building in different areas in China” completed by our research group, this paper systematically introduces the latest technology development and a series of construction demonstration programs in the field of green community in different areas of China.

Firstly, the paper analyzes the great challenges faced by urban and rural community construction in China, including the Influence of community construction during the urbanization process and the development of towns and villages.

Secondly, the paper establishes the planning framework of green community construction in different areas, introduces the outcomes of technology integration system (including 16 key techniques in four fields) of green community construction in different areas. The four fields are: integration of construction and planning techniques for green community, integration of key techniques for green community construction, integration of green construction techniques for eco-building in community, and integration of evaluation indicators for environmental improvement in green community.

Thirdly, the paper introduces a series of technical application and construction demonstration programs of green community, e.g. ecological energy-saving community in Huazhuang town, eco-village and green volunteer community in Huairou district, energy-saving straw-bale housing in Baishan city in northeast areas, eco-planning and energy-saving techniques for community in forests district in Hailin city, and eco-community construction and habitation environment improvement in Jiangyin city.

Lastly, the paper proposes the strategies and suggestions for further development of green community in China.

1. Great Challenges Faced by Urban and Rural Community Construction in China

China is one of the countries with the largest scales of building construction in the world. There are more than 45 billion M^2 existing buildings in China (rural buildings accounting for three-fourths) and 1.6 billion M^2 new buildings constructed in 2006 alone. Currently, how to improve the built environment in the viable, liveable and sustainable ways are great challenges for China. Continuous growth on building construction in China improves the living conditions of residents but threatens the eco-environment in both urban and rural areas.

1.1 Influence of Community Construction during the Urbanization Process

(1) The amount of land resources declines rapidly with the expansion of building construction during the urbanization process. It is reported that the amount of farmland per capita was 933.38 M^2 in 2004 (Wang Xiaoming, et al. 2005), less than 40% of the world average level. For example, 40% of the farmland used for urbanization was taken as “Development Zones”, exclusive area designated for foreign and domestic investment for manufacturing.

(2) Urbanization in China is growing rapidly, resulting in the rapid growth of urban population (Wang Guangtao, 2006). In the past two decades, the urbanization rates have been growing by 1% annually and reached 43.9% in 2006. The development trend of urbanization rates in China is shown in Figure 1. Urban

population in China is predicted to increase from 577 million in 2007 to 828 million in 2020, while the rural population will decrease from 737 million to 622 million. The urbanization rate will reach 57% in 2020. Meanwhile, the number of metropolitan regions, composed of adjacent cities, will continue to increase and may exceed 12 by 2020.

(3) The energy consumption of building construction and maintenance has been increasing. The total area of existing buildings in China is up to 45 billion M^2, and another 30 billion M^2 new buildings will be added by 2020. The direct energy consumption for building construction accounts for about 27.6% of the total energy consumption in China whereas the percentage goes up to 46.7% if the energy consumed for producing construction materials is also accounted. During the construction process, steel consumption accounts for about 30% of national steel consumption; cement consumption about 25% of national cement consumption; water consumption about 47% of urban water consumption. The energy consumption level in China is much higher than that of developed countries. For example, heating energy consumption in unit building area is 2-3 times of that of developed countries given similar climate. The average life cycle of new buildings in China is less than 30 years, which is far shorter than the standard life cycle of 50 years. Only 5% out of the 2 billion M^2 buildings constructed in 2003 are designed with energy-saving efforts.

(4) The poor quality of waste water treatment and garbage disposal, which do not meet the national standards, results in worsening pollution of water resource and community environment. The recycle rate of disused building materials is low. In 2004, 6 billion tons of disused building materials were produced nationwide, including 2 billion tons of disused concrete, which were barely recycled.

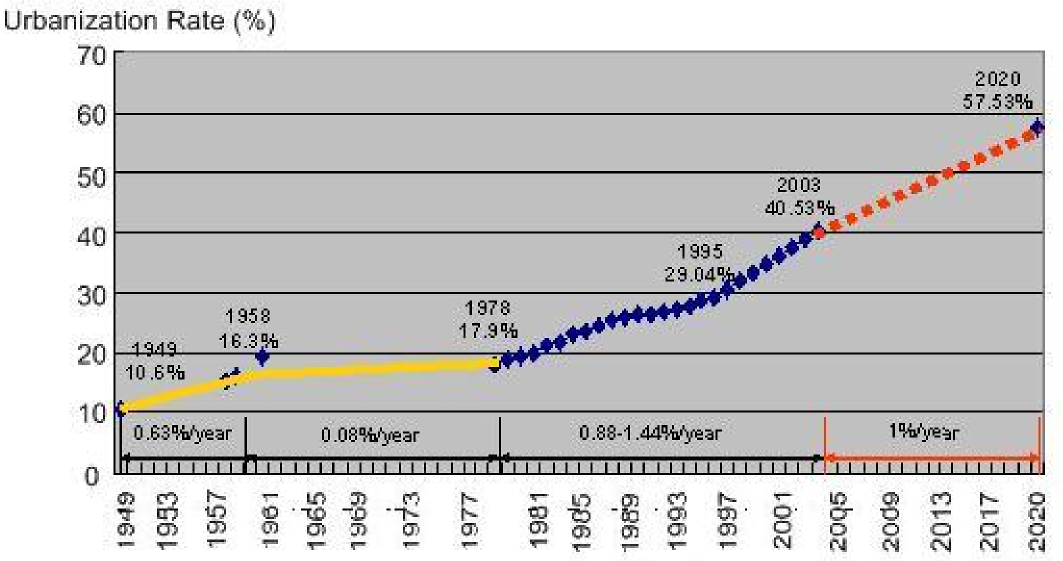

Figure 1 Development trend of urbanization rate in China

1.2 Influence of Community Construction during the Development of Towns and Villages

(1) The scale of community construction in towns and villages is huge: there are 3.207 million natural villages, 634,000 administrative villages, 22,000 market towns, and nearly 20,000 administrative towns, with 200 million farmers living in the countryside. The land for building in rural areas amounts to almost 170,000 km^2. The area of housing construction in towns and villages accounts for more than half of the national housing construction area. More than 600 million M^2 housing has been constructed in villages and towns every year. In 2005, the total area of existing building in towns and villages was 30.95 billion M^2, 83.2% of which was housing covering 25.76 billion M^2. The housing construction investment for villages was up to 256 billion RMB. In 2006~2020, 6 billion M^2 of new buildings will be built in villages and towns in China (Wang Xiaoming, 2008).

(2) The infrastructure construction of communities is underdeveloped in towns and villages. In 2003, infrastructure construction lagged behind significantly in 90% of Chinese villages and towns; 90% of rural families did not have flush toilets; only 53% of rural families had sanitary toilets; only 57% of body waste was treated properly; 90% of garbage was not classified and treated accordingly; 40% of rural households had no tap water supply and drainage facilities; 50% of rural area lacked basic roads; 60% of rural area had no facilities for public activities; and 60% of rural area had no emergency facilities for fire.

(3) The eco-environmental quality in rural areas is deteriorating. In rural areas, the green rate is less than 15%; biodiversity decreased rapidly and some species are even facing extinction; local traditional characteristics and historical cultural values are severely destroyed.

(4) Anti-disaster capability of rural infrastructure is far below that in urban areas. During the snowstorm disaster in early 2008, about 11 million M^2 of housing collapsed and 43 million M^2 housing was destroyed, most of which were rural buildings.

Chinese government has initiated a massive social project to build modern rural communities since 2006, offering great opportunities for improving the liveability of the rural environment.

Combining different characteristics in different areas, Chinese government is conducting the research and demonstration of green community construction. This has profound importance to the promotion of resource-saving and environmental friendly society, the realization of affordable society, and sustainable development of construction industry.

2. Technology Integration and Demonstration of Green Community Construction

2.1 General Introduction

China is a large and diverse nation with many regions different in economic and social development levels and natural resources. Different types of green community should be constructed according to the different economic situation with the principles of sustainable development.

From 2005 to 2006, the key state R&D program, "Study and demonstration on construction techniques of eco-buildings in different areas in China", was carried out by Huazhong University of Science and Technology (HUST) and China Academy of Social Science (CASS). This program aims to establish technological integrated system and demonstration platform for green community in five China National Sustainable Communities (CNSCs) with the technology support from five renowned universities in China. The five CNSCs are Huazhuang Town in Wuxi City Jiangsu Province, Jiangyin City Jiangsu Province, Huairou District Beijing City, Hailin City Heilongjiang Province and Baishan City Jilin Province, and the five universities are Huazhong University of Science and Technology, Tsinghua University, Jilin Architectural and Civil Engineering Institute, Harbin Institute of Technology and Nanjing University.

This program integrates four fields of green community construction technologies, including 16 key techniques; 9 green community construction projects with 12 demonstration sites have been completed in five cities. The program has achieved significant economic and social benefits in land and energy saving, environmental protection, etc.

We have established the planning framework of green community construction in different areas, as shown in Figure 2.

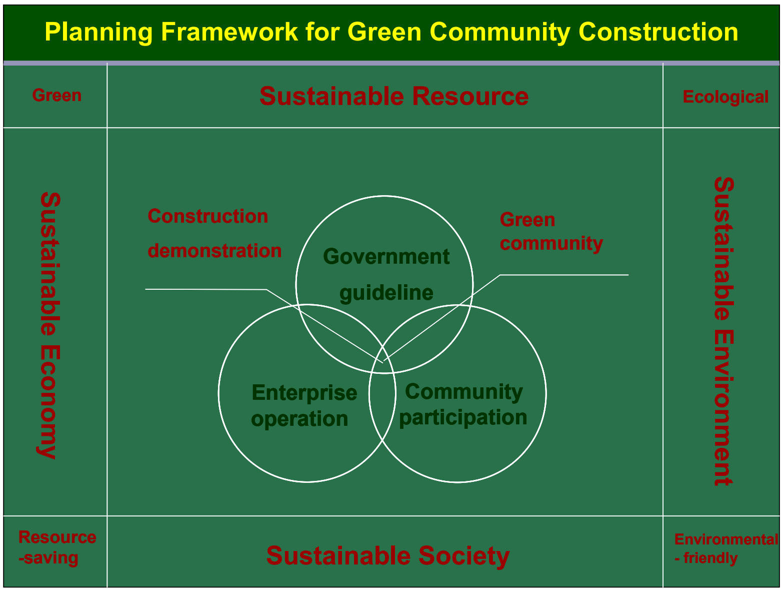

Figure 2 Planning framework for green community construction

2.2 Technology Integration of Green Community Construction in Different Areas

In this program, we have developed 16 key techniques in four fields according to the characteristics of different areas in China.

2.2.1 Field I: Integration of construction and planning techniques for green community

1) Construction guidelines for ecological and energy-saving community

The guidelines consist of five components: a) general principles; b) action plans for constructing ecological and energy-saving community; c) energy-saving actions for constructing ecological and energy-saving community; d) improvement of environment qualities in ecological and energy-saving community; e) process management for constructing ecological and energy-saving community.

2) Eco-planning guidelines for frost forested area construction

The guidelines consist of 4 components: a) optimal land planning; b) harmonious ecological landscaping; c) rational functioning of scenic areas; d) ecological facilities in scenic areas.

3) Planning for old village renewal and green volunteer homestead

The plan is composed of 6 parts: a) land planning for village renewal; b) road construction planning for village renewal; c) architectural style planning; d) greening system and environment planning; e) energy-saving planning; f) action planning for green volunteer homestead; g) eco-planning for green open space in communities.

2.2.2 Field II: Integration of key techniques for green community construction

4) Key techniques for green community construction

Three key techniques are integrated in the construction process: a) planning for green community; b) energy-saving for community buildings; c) ensuring ecological environment.

5) Integrated system of key techniques for green community construction in small towns

The integrated system includes 6 techniques: a) land planning for community construction; b) buildings insulating; c) energy-saving for windows and doors; d) clean energy sources such as solar energy; e) waste treatment and recycling; f) water quality assurance.

6) Eco-building construction technology for rural areas

Six practical technologies are applied in the following areas: a) low-cost construction; b) utilization of local materials; c) land saving; d) materials saving; e) water saving; f) energy saving.

7) Energy-saving and green construction techniques for scenic areas

The following main techniques are developed: a) heating system based on solar energy; b) hot water supply based on solar energy; c) heat preservation for buildings in low temperature areas; d) use of local building materials.

8) Straw-bale housing construction techniques for frost areas

A group of specialized techniques have been developed for straw-bale housing construction: a) wall materials of straw-bale; b) weight-bearing structures; c) peripheral structures, i.e. windows; d) maintenance and repairing.

2.2.3 Field III: Integration of green construction techniques for eco-building in community

9) Green construction guidelines for eco-building in community

The guidelines are composed of 7 modules: a) introduction; b) guidelines for selecting construction sites; c) guidelines for construction planning and design; d) guidelines for construction process; e) guidelines for buildings maintenance and operation; f) guidelines for buildings demolishing and reusing; g) guidelines for benefits evaluation of green construction.

10) Green construction control and evaluation for eco-building in community

The green construction management consists of three sections: a) goal management of green construction; b) process control of green construction at various stages; c) benefit evaluation index system of green construction (USGBC, 2002).

11) Construction regulations and standard for straw-bale housing

12) Construction techniques for eco-villages

A low-cost technology system has been established: a) local materials and environment; b) suitable energy sources; c) water treatment; d) gardening and afforestation; e) ecological transportation.

2.2.4 Field IV: Integration of evaluation indicators for environmental improvement in green community

13) Evaluation indicator system for residents in green community

The evaluation indicator system has been set up based on 4 sub-systems: a) evaluation of current ecological living conditions and energy saving; b) assessment of satisfaction level of local residents with regard to ecological environment; c) evaluation of energy-saving methods; d) suggestions of construction projects.

14) Evaluation indicator system for human settlement of community in rural areas

The evaluation indicator system consists of five different components: a) housing construction; b) landscaping and environment; c) application of technologies; d) infrastructure and community management; e) community cultural development.

15) Evaluation indicators for eco-building in rural areas in northern China

The evaluation indicators focus on five aspects: a) land-saving and outdoor environment; b) energy-saving and energy usage; c) water-saving and water resources usage; d) materials-saving and materials usage; e) indoor environment quality evaluation.

16) Evaluation indicator system for eco-efficiency in green community

The evaluation system consists of five sub-systems: a) eco-capabilities and pre-warning system assessment; b) energy saving efficiency evaluation; c) land saving efficiency evaluation; d) environment benefits evaluation; e) social benefits evaluation.

We have established the technology integration system of green community construction in different areas, which is shown in Figure 3.

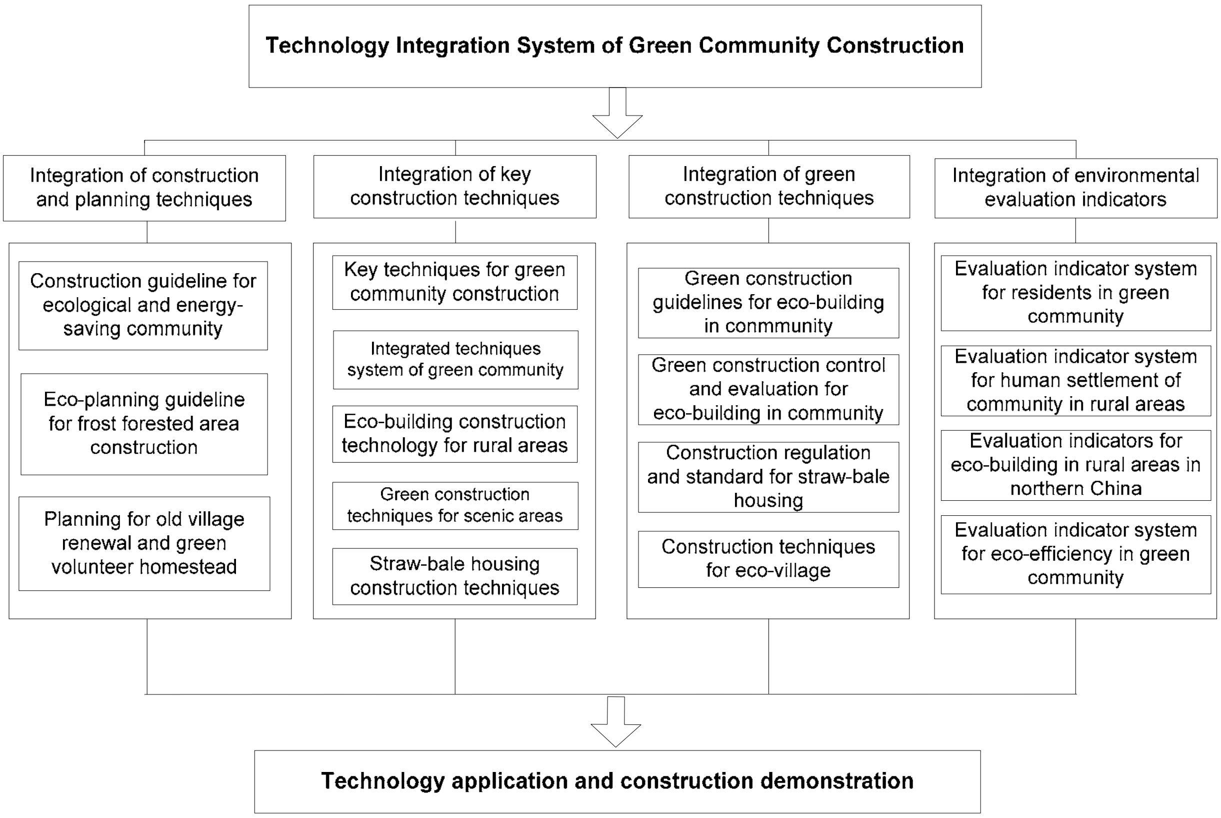

Figure 3 Technology integration system of green community construction in different areas

2.3 Technical Application and Construction Demonstration of Green Community in Different Areas

2.3.1 Objectives

Guidelines: sustainable development theory and modern construction techniques for green community.

Focus: establishing technology system of energy-saving and management method in different areas in China.

Purpose: setting up the demonstration of green community construction in different areas in China.

2.3.2 Content of green community construction and demonstration

Subject 1: Study and demonstration of ecological and energy-saving community construction techniques in Huazhuang town

Subject 2: Study and demonstration of Huairou eco-village construction and green volunteer homestead project

Subject 3: Study and demonstration of techniques for ecology and energy-saving straw-bale building in northeast countryside

Subject 4: Study and demonstration of eco-planning and green energy-saving techniques for eco-building in northeast forest and tourism area

Subject 5: Study and demonstration of improvement techniques for human settlement in rural areas of southern Jiangsu province

2.3.3 Outcomes of green community construction and demonstration

Demonstration 1: Eco-planning of green open space of communities such as Kaifa community in Huazhuang town (Figure 4)

Demonstration 2: Utilization of solar energy techniques in Shuiqingmuhua community in Huazhuang town

Demonstration 3: Digitalization construction and management for rural communities such as Luoxia community in Huazhuang town

Demonstration 4: Reduction, reuse and recycle for domestic refuse in Wuxi Yiduo Co. Ltd. of Environmental Heat-power Station

Demonstration 5: Utilization of green-energy techniques of light-electric curtain wall in Wuxi Wangxing Curtain Wall Decorative Engineering Co. Ltd.

Demonstration 6: Eco-village construction and green volunteer homestead in Huairou district (Figure 5)

Demonstration 7: Straw-bale housing construction in northeast areas in Baishan city (Figure 6)

Demonstration 8: Eco-planning and energy-saving techniques in northeast areas in Hailin city (Figure 7)

Demonstration 9: Eco-community construction and human settlement improvement in Jiangyin city (Figure 8)

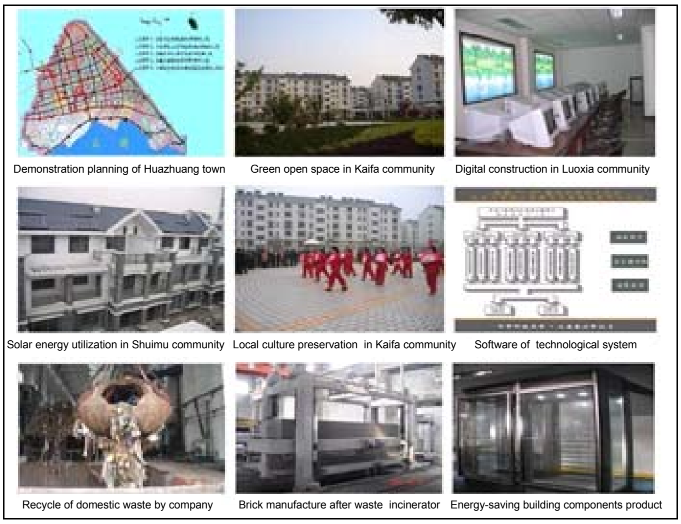

Figure 4 Ecological energy-saving community in Huazhuang town

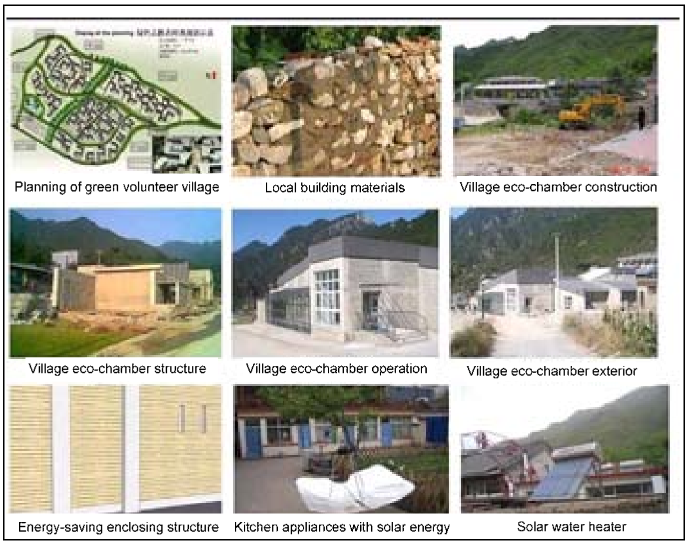

Figure 5 Eco-village and green volunteer community in Huairou district

Figure 6 Energy-saving straw-bale housing in Baishan city in northeast areas

Figure 7 Eco-planning and energy-saving techniques for community in forests district in Hailin city

Figure 8 Eco-community construction and habitation environment improvement in Jiangyin city

3. Strategies for Chinese Green Community Development

The development of Chinese green community is at its early stage and the technologies for green community construction require systematic research and improvement. Presenting green community in different areas as examples, this paper offers a group of demonstration models for promoting green community construction in China. Five strategies and suggestions for further development of green community are proposed as follows:

1) To meet the demand for construction techniques in different areas

Efforts should be made in 4 areas to meet the demand for construction techniques in different areas: a) to promote the R&D of construction techniques for green community in different area; b) to encourage public participation in green community construction; c) to research and develop green construction materials of community and indoor equipments; d) to set up the demonstration platform for green community construction in different areas.

2) To promote resource-saving and environmental-friendly green community construction

This strategy can be implemented by taking three measures: a) to save land for building construction; b) to save energy of building construction; c) to exploit resources in an ecological manner.

3) To promote the improvement of human settlement and functional qualities of buildings

This goal can be accomplished by focusing on 6 areas: a) to develop and promote guidelines for green community planning and construction; b) to improve residential area quality through green community construction and vice versa; c) to enhance the functional qualities of old residential buildings; d) to take into account local residents' preferred lifestyle and financial circumstances; e) to promote ecologically-friendly construction modes for green community.

4) To set up long-term operation mechanism by community participation

Participation of different parties should be encouraged to set up a long-term operation mechanism for green community: a) experts in relevant fields should be consulted on a regular basis; b) support from local businesses should be encouraged; c) members of local communities should be involved; d) favorable governmental policies should be set

5) To advance construction technology for green community and to promote international cooperation and exchange for liveable research projects

Keywords: eBusiness adoption, web-based design tools, internet portals, innovation diffusion

Summary

Web portals, online databases and E-business tools will play an increasingly important role in the building and construction industry for implementing and formalising sustainable design practices. This paper first offers a framework to identify and address a gap in the research literature on the incentives and impediments to the uptake of new E-business practices. We then focus on an E-business application for green building design using a case study involving the Melbourne City Council. Interviews with key stakeholders were designed and implemented to assess the usefulness of web sites and portals during three building stages: (1) design, (2) construction and (3) occupation. Results focus on the new Council House 2 Building (also known as CH2), one of 250 buildings for which the Melbourne City Council (MCC) has planning and operations responsibility. Finally, we extract lessons learned from this 'World Leader Status' Green Building to offer best practices that will support uptake and innovation of E-business in the design and early construction phases as well as the use of web portals and other online tools for decision-making in construction management procedures, commissioning purposes and ongoing facilities management.

1. Preface

This research project arose on the premise that little attention had been paid to understanding in great depth the social, cultural and economic reasons for the relatively slow adoption of e-business (defined in Table 1.1 below) in the vast majority of design, construction and facilities management (FM) industry. In Australia, much of the research investment has been devoted to the adoption of "high end" e-business tools and practices and, in particular, the development of computer software. This project sponsored by the Cooperative Research Centre for Construction Innovation (CRC-CI) aims to redress such balance.

Table 1 Construction E-business Definition

E-business in construction definition
E-business in construction involves any electronic exchanges of information in relation to the various stages of the design, construction and operation asset life cycle which includes: 1. internal organisational driven activity for firm core and support business including industry specific and generic business software applications, websites, email and electronic banking 2. externally linked online web based portals involving: design collaboration and document management; online tendering; procurement; purchasing and invoicing; and information 3. on-line or internal organisational facility management systems

In order to develop a greater awareness in the construction industry as to the value of e-business to organisations, a number of case studies were commissioned by the Cooperative Research Centre for Construction Innovation (CRC-CI) Project Titled "eBusiness Adoption in Construction" (London 2006). Six industry case studies were undertaken between two research teams from the University of Newcastle (UoN) and RMIT University to identify emerging web based tools and technologies and their adoption process in real life scenarios; including case studies with four Government organizations and two private sector organisations.

At an initial stage, the objectives of the project were to confirm and investigate the nature of the constraints to e-business adoption through theory and practice; then to identify strategies and techniques to raise awareness and increase adoption and diffusion in the industry based upon literature review and case study review of varying levels of e-business adoption environments; and then finally, to propose a technology adoption profile based upon the results of the case studies. A summary of the initial literature review is described below.

Table 2 Literature Review – Summary of Inhibitors and Drivers

Inhibitors to eBusiness adoption	
1.	The lack of awareness of what e-business is and what it involves and further to this a lack of awareness or reluctance to see potential business benefits (Ingirige 2002; NOEI, 2001; Parish, et al, 2002).
2.	Informed resistance to innovation based on values and attitudes (Frank, Zhao and Borman, 2004)
3.	The lack of security and the perception of an insecure environment; the need for a regulatory and legal framework; lack of systems (Bennet, et al, 2003)
4.	Market incentive, pressures and rewards and uncertainly regarding the financial returns from investments in various resources versus economic benefits (Tetteh, 2001; Veeramani, 2002)

Drivers to eBusiness adoption	
1.	Rewards, incentives and initiatives by governments including seeding programs, investment incentives and tax rebates (NOIE, 2001)
2.	Managerial characteristics or philosophy of the firms (Storey, 2004)
3.	SME's characteristics related to flexible specialisation; it is the flexibility of SMEs that can make adoption of ICT easier compared to larger more bureaucratic and inflexible organisations (Sotery et al, 1995)
4.	Production related factors assisting e-business adoption; for example e-business technologies have the potential to transfer complex design information accurately, thereby eliminating data transfer error as well as minimising delays as information is conveyed (NOIE, 2001)
5.	Reduction in transaction costs; small vendors and suppliers can bid on jobs using standardised forms on the site making bidding on jobs relatively inexpensive; costs in transferring information during the tender process is reduced. The website is also beneficial to large manufacturers as it creates an electronic auction market enabling organisations to receive a wide range of competitive quotations from vendors

One of the major research achievements derived from the case study review was the development of the concept of eBusiness adoption pathways for the building and construction industry. Although not described to great length in this paper, the theoretical framework became the basis for case study review and the development of the technology adoption profile which is fully described in London (2006).

2. Theoretical Framework

The theory underpinning the research investigation and case study review process was based upon Rogers' theory of Innovation Diffusion (1962; 1995). Whilst not referring specifically to the diffusion of e-business as innovation, Rogers' work does provide an initial framework through which examination of the diffusion of e-business through building design, construction and operations can be examined. Rogers' defines the diffusion of innovations as the process by which knowledge of an innovation is transmitted through communication channels, over time, among the members of a social system. The four key elements comprising Rogers' diffusion theory are defined as the: (1) *Innovation:* an idea, practice or object that is perceived as new; (2) *Communication channel*: can be mass media and/or interpersonal networks and is the means by which messages about the innovation gets from one individual to another; (3) *Time:* comprising both the innovation-decision process and the relative time which an innovation is adopted by an individual or group – an innovation's rate of adoption; and (4) *The social system*: a set of interrelated units that are engaged in joint problem solving to accomplish a goal.

Within this framework, diffusion is largely measured through the degree of adoption within a social system. Adopters are categorised by Rogers' as innovators, early adopters, early majority or laggards. These adopter categorisations are differentiated primarily in relation to diffusion as a temporal process - diffusion happens in time, whilst the other key elements of innovation, communication channels and social systems exert variable influence upon the temporal diffusion process depending on their specific qualities (London 2006). According to Rogers for example, communication channels vary in importance according to the type of adopter; mass media and expert knowledge has more influence on innovators, whereas personal networks are more important for late adopters (Rogers, 1995). The key processes in Rogers' diffusion theory are thus the adoption-decision process and the rate of adoption - comprising multiple phases and influenced by various factors. As noted earlier in relation to a discussion of the inhibitors and drivers for e-business, the adoption-decision process is a key phase through which an individual (or group) passes from: (1) First knowledge of the innovation; (2) Forming an attitude towards the innovation; (3) Making the decision to adopt or reject the innovation; and (4) Implementing the innovation and confirming the decision taken.

This transition from first knowledge of the innovation to its implementation, measured as a temporal process, encompasses the innovations rate of adoption. This may be affected by various factors relating to the key elements of Rogers' theory including; the specific attributes of the innovation in question – its relative advantage, compatibility, complexity, trial ability and observability (Rogers, 1995). Also influential is the type of innovation decision being made including whether the decision is optional/individual, collective/organisational and authoritarian/hierarchical. This factor parallels the recognition of organisational culture and managerial philosophy as a driver to e-business adoption. The following case study investigates E-business adoption pathways looking at scenarios at the design, construction and facility management stages.

3. Case Study: Melbourne City Council

The Melbourne City Council (MCC) presently has been involved in the planning and operation of over 250 buildings. This study uses the new Council House 2 Building (known as CH2) as the main case study to gain further understanding of how the uptake and innovation of E-business can be used in encouraging sustainable development in Design, Construction, Commissioning and Facilities Management. In comparing the original Council House Building to the new Council House 2 Building, design strategies aimed to achieve up to 80% reduction in energy use and up to 70% reduction in water use. MCC has established an Intranet browser to describe innovation strategies to its employees while also using their public website to make ongoing research reports more easily accessible - including CH2 AusIndustry's research findings with white papers and industry reports (Morrison, et al., 2005).

Results of this case study show that since the Council House 2 (CH2) building project began, the Internet, web portals, online databases, and tools have become influential and will continue to play an important role in achieving implementation of sustainable design in Australia. Although at the time when the Case Study took place the CH2 project had completed its design and construction phases, the project's underpinning environmental values are expected to continue over the life cycle of the building. In addition to addressing the uptake of E-Business through the design and early construction phases, this study also looks at how (1) web portals and other (2) online collaborative tools can be used and developed for construction management procedures, commissioning purposes and facilities maintenance operations in the rapidly increasing area environmental responsibility at social and corporate levels.

CH2 is a ten storey building designed by a multi-disciplinary team lead by the City of Melbourne's principal design team and a local architectural firm. Construction of CH2 commenced in 2005, with key contributions from the City of Melbourne including: Design, Project and Facilities Management. External consultants included: Architectural, Services Engineering, Environmental, Structural and Civil Engineering, Acoustics, Quantity Surveying, Builders and subcontractors.

4. Results Analysis

A premise is that online design and planning tools are already available but its use is not yet widely spread. Initial discussion with respondents took place to identify online tools that are preferred by industry in Australia. The study was then set to identify particular impediments and incentives for the uptake of E-business. Interviews were carried out with project stakeholders. For further detail on the full interview agenda and content analysis, refer to Aranda-Mena (2006) for full case study report. Refer to London (2006) for multiple case study analysis.

Interview results indicated that web portals with comprehensive and appropriate sustainability information related to the building and construction industry are not yet in full use across the industry. The broad scope of this project considers the world-wide potential for developing new sustainable products, tools, technologies and joint ventures to show what is possible. More specifically, the MCC Case Study aims to show how online tools, portals, resource databases for decision-making, payments, communication, presentation, reporting, and analysis are becoming increasingly available to industry. CH2 has proven to be a driver for innovation and collaboration, as a test bed for use, application, and piloting of new online business tools with contribution to the wider design, construction and facility management industries.

4.1 CH2 Goals

The overall CH2 goals have been achieved, including: (1) increasing the understanding and awareness of green building benefits; (2) increasing confidence in the selection of *green* and *eco-preferred* products; (3) increasing trust in the long term benefits; (4) facilitating information to justify the higher initial costs against life cycle costs, thus strengthening a business case; (5) alleviating the current situation of poor local availability of green building supply; (6) increasing understanding/communication across disciplines and with the client, and (7) indicating incentives for sustainability and general impediments to innovation. However, room for improvement still exists.

4.2 Areas for Improvement

The following issues need to be addressed: (1) lack of consistency in rating tools, regulations, and planning requirements; (2) behavioral issues related to industry/consumers *not acting on long-term value;* (3) lack of advice/tools not about products but about *management of investment;* and (4) lack of advice as to existing *building stock being poor* and its applications for re-use.

According to the AusIndustry's CH2 Materials Report (Morison, et al., 2005), no internationally successful program for labeling construction material has been achieved yet, despite several attempts. The main problem with labeling construction materials is that it is subject to context and location, especially in terms of life cycle and performance expectations. Greater success has been achieved using specification or material choice support tools such as EcoSpecifier and the US Environmental Building News, and guidelines such as the Aurora Material Selection Guideline and the US Federal Government's environmentally preferable purchasing (EPP) database. Labeling of materials is almost always completed by a third party independent from the manufacturer or its professional organisations, and usually includes some kind of certification.

4.3 Observations

To assist in improving construction, commissioning, and facilities maintenance, good policies and programs, real-time data, standards, benchmarks and online tools for decision-making are needed. For FM, most of the current online systems and tools can predict potential performance, but do not assess actual performance during construction and operation including affordability and costs.

As to the business case, the CH2 Total building costs $51.045 million, including $11.3 m on Sustainability Features (i.e. 22.1% of costs). The payback period claim is estimated that in 10 years time the sustainability features will have paid for themselves. Further benefits that could reduce this payback period include: (1) healthier staff – less time lost to colds, flu and other illnesses; (2) increased workplace effectiveness; (3) less costs for public domain and infrastructure; and (4) the value of this building as a guiding light in sustainable building.

In general, it is clear that the Melbourne City Council is making a considerable effort that will lead Australia towards cutting Greenhouse Gas emissions and reducing the use of Non-renewable Energy.

A follow-up study would suggest revisiting Melbourne City Council to ask pertinent questions such as: (1) Which online tools have been useful in facilitating the CH2 green building agenda?; (2) Ecospecifier was developed and tested during the design and building of – has it changed because of CH2?; (3) To what extent has this type of project contributed to laying the foundations for the use of the Internet to support the Green Building Agenda?; and (4) For the Architect, Engineer, Construction Manager, Commissioning Manager, and Facilities Maintenance Manager: how do you see your contribution in general terms in achieving the Green Building Agenda? (5) What is the role of planners in incorporating transport and land use considerations to further facilitate the green building agenda within the larger regional and urban context?

5. Discussion: Value Propositions

What current online tools such as Internet portals to facilitate designer's decision-making are preferred in industry? In aiming for a six Green Star pilot project, and becoming the first office building project in Australia to achieve such a rating, as stated previously, the CH2 building has become a technology test-bed and provides opportunity for innovation and research. For example, DesignInc, The Centre for Design at RMIT University, EcoRecycle Victoria and the Society for Responsible Design - in combination with the developments of the Australian Environmental Labelling Association Inc. in setting up the Good Environmental Choice Label - have helped standardise and identify environmental products and environmentally-preferred materials for design and construction through internet portals such as EcoSpecifier. The Melbourne City Council and other project players have taken up the enormous research task of sourcing and providing a decision-making tool for hundreds of products that have had to meet increasingly stringent standards in order to possibly be 'given the go-ahead' for the high-profile CH2 project.

The following table represents the set of tools used throughout the project. Web portal development took place during the course of CH2. These online business tools are organized into the following categories:

- Design: EcoSpecifier
- Construction: ACONEX
- Facilities Management: LOGOMETRIX

This section discusses the use of Internet portals as a decision mechanism for the selection of products, materials, construction suppliers and service providers. In the case of CH2, a great deal of the process was completed through research involving internet web searches. A six star rating was achieved when the design team only aimed for a five star certification, and it is believed this was partially due to the principal consultants attending an initial two-week workshop, followed by weekly design meetings that ran for eight months, to ensure a truly collaborative effort and integrated design approach.

5.1 Scenario 1: Design

Material selection and other decisions that have an impact for the life of the building are taken at the design stage. Even as recently as 1999, very few *Internet portals and search engine* tools were available to aid design teams in their research into green materials. Portals with ecologically sustainable products are now on the rise. In the case of CH2, one of those portals had only about 80 products listed at the beginning of the project, and there were no other local resources available. At the beginning of the CH2 design process, it was claimed that no internationally successful program for labeling sustainable construction material had yet been achieved, despite several attempts. This led to intensive research and academic partnerships for the development of an Internet portal which has increased its database from 80 environmentally certified products to over 1000. Involved research parties undertook the enormous task of vetting all potential products and materials that might be used on the project. The site then became a joint initiative of the Centre for Design at RMIT University, EcoRecycle Victoria and the Society for Responsible Design.

A rolling research and development program was designed, commencing in 2000. The key elements of this program were to: (1) establish a methodology for side-by-side comparison of products through the environmental performance questionnaire (EPQ);(2) establish a peer-review process to ensure transparency and accountability, and limit liability, through the involvement of the Commonwealth Scientific and Industrial Research Organisation (CSIRO); and (3) shortlist potential products and issue a questionnaire as a condition of consideration to suppliers for completion. There would be ongoing issues of the EPQ to other suppliers throughout the project as relevant; (4) establish in-house systems that would enable effective storage, referencing and use of data through easy access and inter-personal communication; and (5) integrate data into effective decision-making in the project in a timely manner through coordination and project reviews.

By 2004, the EcoSpecifier website had received over 100,000 visits and feedback from industry has shown that the site is the industry's leading resource on environmentally preferable materials. Currently, a commercial database of over 1000 building products exists that has been independently vetted against sustainability criteria, and provides guidance on the environmental impact of commonly available building products. As a brief summary, the tool is: (1) An online guide; (2) Used to source and increase use of environmentally preferred materials in the construction sector; (3) Helps architects, designers, builders, specifiers and consumers shortcut the materials sourcing process to find products that reduce environmental impacts and create healthier and more productive living and working environments; (4) The most comprehensive list of environmentally preferred commercially available in Australia; (5) Used to select materials with least environmental cost; and is (6) Used to gain an understanding of the principles of selection in order to identify, research, and develop alternative materials.

The site's ongoing development has seen major upgrades including powerful new functionality in the site's search engine, access to full product data, manufacturing details, and case study links for types of facilities. This includes education, commercial, health and aged care, industrial, laboratory, residential, and retail facilities.

5.2 Scenario 2: Construction

This phase of the project involved the selection of subcontractors and service providers. Issues that usually arise during this phase involve collaboration with suppliers and subcontractors and a good document management practice is paramount. Project members decided to use a web-based platform for collaboration throughout the design and construction process. Based on principles of trust and innovation, a commercial document management provider was selected. The chosen application was designed for use across various project phases. The key reasons the project team engaged in use of the tool was that the online collaborative information management service was secure and easy to use, it also promoted collaboration by allowing the reception, transmitting and management of construction correspondence, drawings, and other data, with limited printing and paper flow. Results indicated that the project extranet simplified document control, resources and project management; it also provided an easy way to save time and money on the project, technical support and training; and finally, it added confidence to the project. The firm, Aconex, is currently working with the Facility Management Association (FMA) to research current and future information management practices in the industry. For CH2, Construction Management was able to handle information more efficiently and improving project collaboration; as the Aconex tool could be used and designed for every phase of the project life cycle, minimising construction waste, and ensuring improved transparency, so that sustainable construction processed, techniques and materials would be timely implemented.

5.3 Scenario 3: Operations

An important phase of a project that often does not receive the attention it deserves is the commissioning phase (ASHRAE Guideline 0-2005). Personnel from CH2 and building users were involved in this phase for about six months and continue to be involved throughout the occupancy of the building. Understanding the initial operating of the building, post-occupancy evaluations, and monitoring of existing buildings is a meaningful world wide trend in the improvement of green buildings and facilities (Stumm 2000). In the case of CH2, a great deal of learning from the eventual occupiers took place and FM staff have been involved in the early stages of commissioning in order to better understand the maintenance requirements related to the number of innovations and sustainable technologies adopted. Issues here, include the selection of building fitouts, contracting and efficiency of mechanical/electrical/plumbing systems, understanding how reused water moves throughout the building in terms of use for the innovative shower towers that cool the air and water through evaporative cooling, use of renewable energy systems (i.e. photovoltaic cells and wind turbines) on the building, as well as natural ventilation strategies related to providing optimal comfort levels year-round.

In CH2, over 2000 sensors are now installed and are informing building operators building behaviours on regular basis. Other innovations that facilities managers are willing to implement in the green building industry include electronic energy audit tools, sustainability checklists to improve operations, and web-based tools that record and collect data for benchmarking and historical purposes.

Another e-business innovation that members of the FM community have discussed implementing includes a list (i.e. describing “Five things the individual occupant can do to make the building more sustainable”) that can be updated on the intranet site, depending on the base data and real-time data available, that could display various sustainability indicators: on energy, waste, transport, health, and others. Although not thoroughly investigated in this case study, interviews also noted that Facilities Management may undertake a study comparing post occupancy surveys and operations surveys which had been collected by CSIRO for CH1, in order to better understand the performance of CH2 in relation to occupant use.

The web based system, Logometrix, developed by Hansen Yuncken was chosen as a sustainability tool for measuring key performance indicators (KPIs) of CH2 facilities and services. The system can be accessed by registered Local Government Authorities (LGAs) or city councils over the internet and allows for strategic decision-making based on monitoring of real-time data and measurements of facility performance (i.e. through key indicators including energy use, water consumption, waste collection, and other aspects of end-users and building occupiers’ behavior). The facilities manager can then set the building as a benchmark in facilities management against other participating councils, through use of a browser interface, that can ensure that a comprehensive survey is conducted within a consistent ‘best practice’ framework – using the tool to ensure data is collected on specified parameters related to service delivery, physical, community and environmental performance. For the development and principles underpinning the Logometrix tool (http://www.logometrix.net), see Brackertz and Kenley Special Issue: Sustainable Communities (2002a, b). As noted by interviews, the Melbourne City Council Facilities Management team has been using this tool for two years allowing users to assess performance of buildings (i.e. CH2), and how they meet the environmental requirements and agreed upon goals of the users and designers.

6. Conclusion

This study has discussed the role of web portals to facilitate decision making during three building stages (1) the design process – especially on the selection of sustainable materials, (2) the construction process – especially on the collaboration between client, contractor, subcontractor and suppliers and (3) facility management – especially on building commissioning and occupation.

As a cause of the recently introduced green building and environmental legislation, new possibilities for energy savings, improved employee green practices are amongst the incentives and the areas adding market value of e-business within the industry. Although it is hard to ascertain whether CH2 will remain within its $51 million budget (including $11 million on sustainability features) due to delays in the completion of the project, the Melbourne City Council has claimed that up to $11 million could be recovered within 10 years due to energy cost savings and productivity gains. In this case study, e-business practices enabled informed and building performance decisions. Web-based tools were here reviewed and summarised.

Identified practices which are likely to accelerate e-business adoption include: (1) using case studies to demonstrate use of specific online tools; (2) facilitating training; (3) allowing time and space for error when introducing new practices; (4) increasing organisations awareness of research publications on e-business uptake; (5) offering follow up expert consultation; (6) establishing quantitative correlations on the use of specific e-business practices and improvements on green building performance; (7) highlighting collaborative decision-making; and (8) using e-business as a communication tool to ensure improved service to the client.

It’s been proposed that building projects like CH2 are the test-beds for innovation and in this particular case it certainly has been the catalysts for the development and uptake of the e-business tools and technology adoption model here investigated.

Keywords: Sustainability, office buildings, market value, perception. New Zealand.

Summary
Over recent years the global market for sustainable commercial property has substantially increased in importance and profile, with rapid growth occurring overseas which in turn has led to substantial changes in the property market. The New Zealand property industry has recently been introduced to the concept of sustainability, and although at an early stage there are signs of an accelerated uptake of sustainability in the industry. Even though targeted measures have been taken by the New Zealand Green Building Council and government, there is perhaps considerable hesitation and scepticism existing in the property market from both an investor's and a building owner's perspective. The research presented in this paper discusses the results of an investigation into market perception of sustainable buildings from the investment community in New Zealand. Property investors from New Zealand were surveyed about their perception of sustainable buildings in New Zealand and their actions with regard to their own commercial portfolios, as well as the relationship between sustainability and property investment decisions. The paper provides an insight into the rapidly evolving area of sustainability and office buildings, with the emphasis placed on the valuation process that seeks to assess a hypothetical purchaser's perspective of the relationship between sustainability and property.

1.0 Introduction
The market for sustainable commercial buildings is gaining momentum in the design and construction arena, however development and investment in sustainable buildings by the private sector remains limited (Reed & Wilkinson, 2005), particularly away from government pre-commitment. It seems there is limited information available detailing the financial viability of operating new or refurbished sustainable buildings, commonly referred to as 'the business case for sustainability' and relatively little research has been conducted into the relationship between sustainability and the market value of commercial buildings. To-date much of the emphasis has been placed on owner-occupied sustainable commercial buildings or the value perspective of sustainability from a tenant's perspective. However in order for sustainability to gain industry-wide acceptance it is critical that the majority of building owners and investors are assured of depth in the market, as well as the financial certainty and viability of sustainable buildings. Clearly if the continued supply and uptake of sustainable buildings is to continue in the property market, then it is essential that the links in the relationship between market value and sustainability are identified and understood. This process, in turn, will promote investment in sustainable office buildings.

Currently the market for sustainable buildings in New Zealand is being encouraged through government legislation and policy; however investment by the private sector in sustainable buildings generally has been slow to develop. This is partly due to the lack of proof confirming the economic viability of sustainable buildings, for example where the absence of detailed market evidence, sales data and lease transactions of sustainable buildings have restricted support for the argument that sustainable buildings are feasible (Lutzkendorf and Lorenz, 2005). The lack of concrete evidence about the correlation between value and sustainability leaves the investment industry uncertain about the financial benefits of sustainability (Madew, 2006). To-date much of the emphasis has been placed on normative research on owner-occupied sustainable commercial buildings, even though the majority of buildings in the market are owned by investors. This study investigates the financial business case for sustainable buildings from an investment perspective, where emphasis is placed upon the importance of using existing valuation methodology to accurately assess the financial viability of sustainable buildings in the current marketplace. This paper discusses the first stage of an on-going research project that was undertaken in New Zealand in 2007.

2.0 Investment Drivers for Sustainable Buildings

There has been substantial research into the design and construction of new sustainable buildings and the benefits from these buildings, particularly from a social and environmental perspective. However it has been argued there is an apparent "lack of mechanisms to align environmental and social issues with economic return" (Lutzkendorf and Lorenz, 2005, p.215). The lack of connection between sustainability and economic return affects the main stakeholders who invest in the property market, namely large financial, banking and superannuation vehicles. These are the key drivers in the property market. In many ways it may be argued that the case for sustainable buildings is being pushed by the demand side of the market, such as by occupiers. Existing research tends to be based on the 'circle of blame' reasoning shown in figure 1, where it may be argued that the occupiers and their demand for more sustainable space will break this circle and increase the take-up of sustainable buildings in the market.

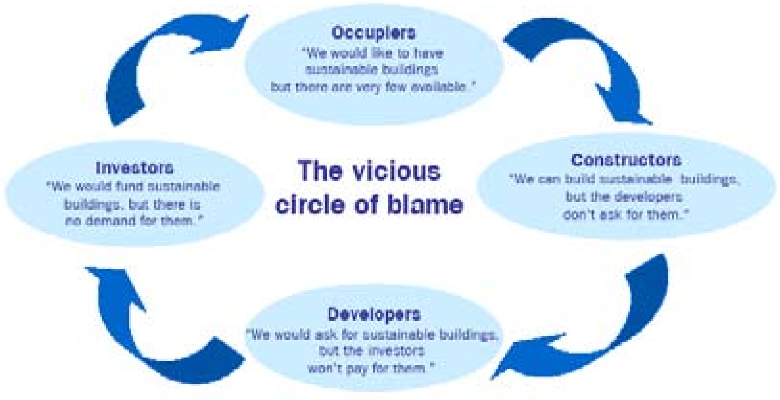

Figure 1. Circle of Blame (Source: Cadman,D.,2000).

However, some sectors of the investment community, given the correct drivers for sustainable buildings, may take it upon themselves to develop and invest in sustainable buildings. In order for this to happen, a solid business case should be developed where the financial benefits of sustainable buildings are fully understood by the investment sector in the market. Hence the 'circle of blame' in figure 1 is modified in the diagram in figure 2 where the determination of the investment value of sustainable buildings by valuers enables the investors to break the circle of blame. Note there is now a resulting flow-on effect through the stakeholder chain from development to occupation, identifying the market value of sustainable buildings by valuers helps to facilitate communication and an understanding of the value of sustainable buildings through the stakeholder chain. By empowering the investors with the knowledge and ability to actively invest in sustainable buildings, the market development for a more sustainable environment and hence the identification of the value of sustainability can be achieved.

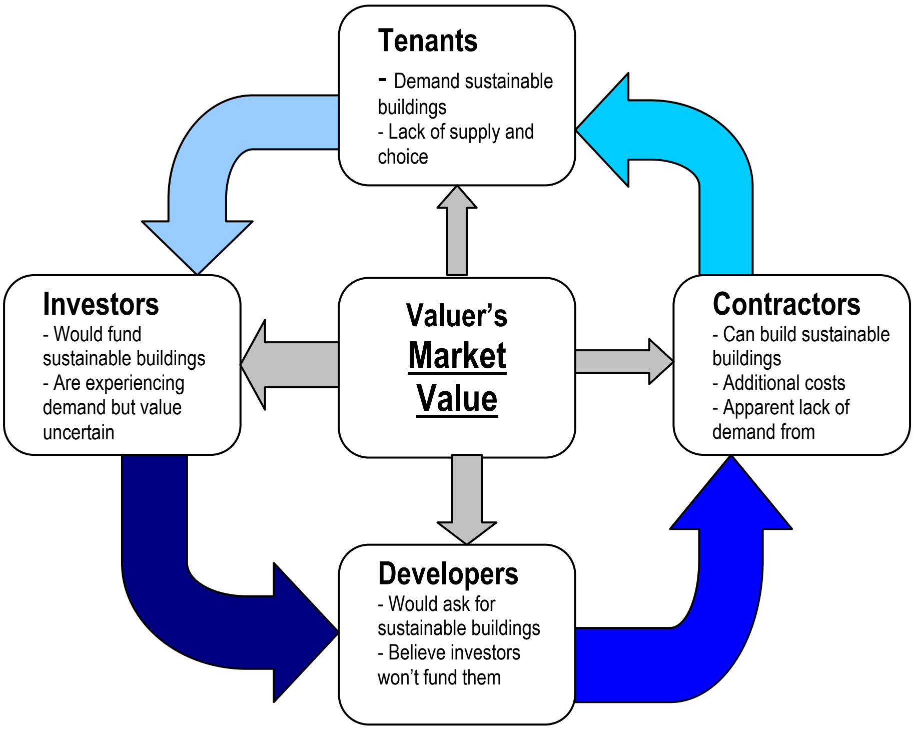

Figure 2. Communication between valuers and stakeholders
(Source: Cadman, D. (2000) Circle of Blame Modified by Myers et al. (2006))

New Zealand is lagging behind the major markets of Australia, United Kingdom, Canada and the USA, with sustainability for the built environment only being introduced in the mainstream property market in the last two years. However, the more advanced experience of other countries has yet to shed light on the financial viability of sustainable buildings and identify the links with market value. To assess why this may be the case the following model has been adopted from McColl-Kennedy et al, Marketing: Concepts and Strategies (1992), which assesses the product life cycle of sustainable buildings and identifies the current stages in the life-cycle of the Australian and New Zealand property markets.

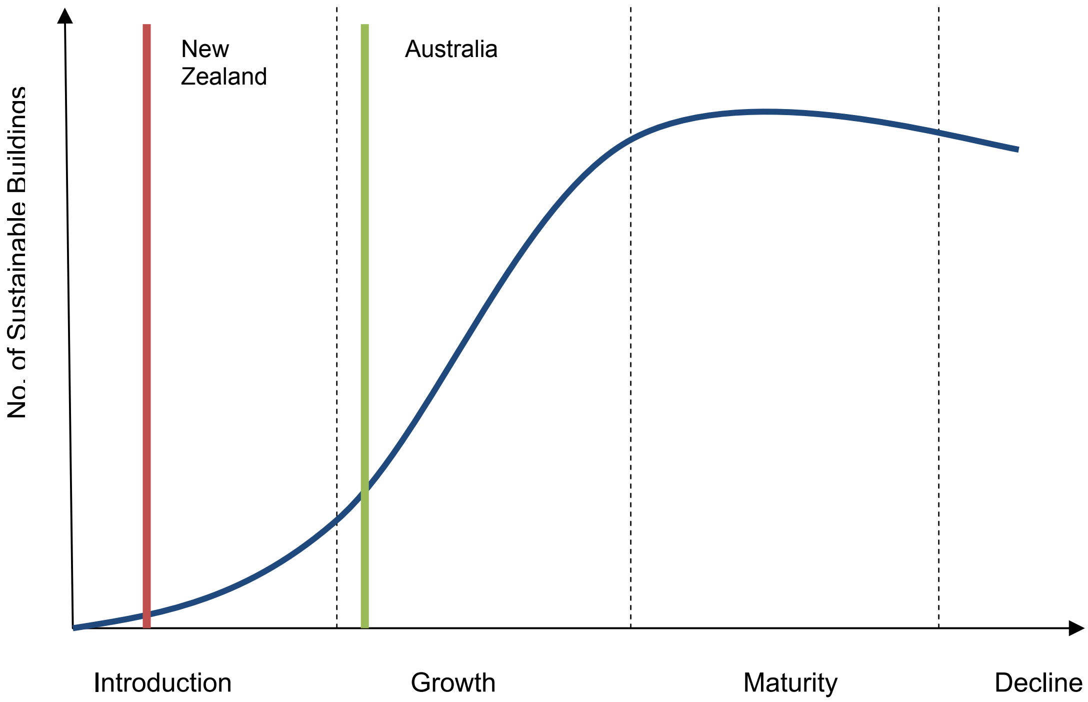

Figure 3: New Zealand and Australia's status in the 'Sustainable Building Market Life Cycle'

The figure above identifies the different stages of market development of Australia and New Zealand, Australia being somewhat more advanced than New Zealand, as the concept of sustainability in the built environment became more prevalent in the property industry early in this century. Thus it is provisionally identified that Australia is now entering a Growth phase, whereby there is increased acceptance of sustainable buildings by the industry spurring more development. New Zealand is still at the elementary stages of the Introduction phase, however with close ties to Australia through the majority of investment funds and institutions, New Zealand will most likely see an accelerated advancement through the Introduction phase.

Australia maybe entering the growth phase, as may the other major world markets, however there is still no conclusive evidence of the financial relationship between sustainability and value. This maybe because of where the markets are currently located along the product life cycle, the impact of financial benefits are not often perceived to their full extent until the Maturity phase is reached. The Growth phase indicates that many perceive a potential profit or value in developing sustainability in their portfolios. Once the Maturity phase is reached, it is commonly attributed that there is a certain financial value linked with this phase. However for the Maturity phase to be reached the property market needs to be convinced of the financial value of sustainable buildings. The purpose of study is to identify which elements in the relationship between sustainability and market value and thus have the greatest ability to impact the value. By identifying the market perception of two markets at different stages in the life cycle gives further insight into relationship elements that may influence the market value of sustainable office buildings.

3.0 Market Forces

Investors and developers need to know the extent to which sustainability is impacting property worth if they are to respond effectively to sustainability issues (Sayce and Ellison, 2003). This will require an analysis of how market value is determined for commercial office buildings. ‘Market value’ is defined by the International Valuation Standards Committee (IVSC) as “the estimated amount for which a property should exchange on the date of valuation between a willing buyer and a willing seller in an arm’s length transaction after proper marketing wherein the parties had each acted knowledgeably, prudently and without compulsion” (IVSC, 2008). Industry valuers undertake current valuation practice by the calculation of the present value of future income streams, which in turn determines the market value of the property. Investors, owners, developers and lending institutions rely on the valuation reports produced by valuers that state the market value of the asset. The crucial nature of decisions made in the finance industry requires a standardised methodology for the determination of a property’s market value.

Assessing the market value of income producing assets is commonly undertaken through two methodologies, namely (a) the capitalisation of income approach and/or (b) the discounted cash flow (DCF) approach. In Australia and New Zealand the discounted cash flow technique has commonly been used for determining the market value of office buildings through the analysis of cash flows of the property over a period of time (API, 2007).The determination of market value, whether using the capitalisation of income or DCF approaches, relies heavily on the current market rents and yields of comparable properties. A valuer undertakes a range of comparative analyses of other properties when identifying market rents and yields for the subject property. Thus key determinants of market value depend greatly upon the property market climate. The valuation community relies heavily upon comparable transacted evidence to determine the market rents and consequently identify market value. This heavy reliance on comparable evidence has been criticised widely (Aldridge, 1989; Burton, 1992; Crosby, 1997) and the increasing shortcomings of this reliance upon comparable rents is a key issue when identifying market rents for sustainable buildings. In addition there is a lack of evidence documenting rent transactions in the New Zealand market due to the limited number of sustainable buildings. In turn this makes it inherently difficult for valuers to assess an appropriate market value for sustainable buildings. There are also a variety of potential shortcomings evident when assessing conventional buildings for a market rent which was highlighted by Whipple (1991), Crosby (1992) and Teale (1995). A valuer needs to ascertain other market variables to assess whether the market evidence being used is appropriate for comparison, where some of these variables include: the level and availability of stock, vacancy levels, quality, landlord or tenant market, economic determinants, market pessimism and willingness of tenants’ to pay rental levels dependent upon tenant requirements.

Changing occupier requirements suggest that a focus upon sustainable space is an increasing prerequisite. A report published by Jones Lang LaSalle highlighted a substantial change in market perception amongst the occupiers, whereby the majority of occupiers across Asia Pacific were willing to pay more for sustainable space (Jones Lang LaSalle, 2007). On the other hand, Lorenz (2007) concluded that the financial benefits for sustainable buildings needed to be included within the property valuation process; these suggested benefits could be identified through gauging the gradual changes in market participants’ perceptions for favouring sustainable buildings. The investigation of the financial case for sustainable buildings focusing on market rents is only one element of the valuation equation. Thus the investor and developer's perception of sustainable buildings is equally important as they influence the market for sales and investment decisions. Therefore the initial investigation was to identify market perceptions from the viewpoint of owners and investors.

4.0 Research Methodology - Investor Market Perception in New Zealand

The objective of the survey was to identify the mindset of the investment industry in New Zealand, to determine or construe how sustainability will affect the property market in New Zealand. Once the interviews were undertaken the author broke down the responses into a literature analysis first and then applied some statistical methods to interpret the responses and understand the reality of investment in sustainable building in New Zealand. The survey was constructed in an attempt to understand the real investment intentions of major investors in New Zealand. The initial questions aim to gain an understanding of overall and general opinion of sustainability and then work towards the company's investment priorities. The surveys were undertaken between June and November 2007 and involved interviewing key property investors in the New Zealand market. Participants were asked nine unstructured questions relating to their organisation or company's key investment priorities and perception of sustainable buildings. The top 30 investment companies were identified and contact and interview times were made with CEO's and other high ranking employees through email, phone and in person. The response rate initially was 70% however, on further review it was determined that a number of interviewees were inappropriate and created bias in the survey, thus they were consequently removed, leaving a final response rate of 61%. The literature and statistical analysis of the results identified a group of outliers, and when further scrutinized it was found they made up a separate group to the majority of investors. Members of this group were not considered to be true investors in the property market, in that their interest in the building was short term rather than long term. A number of respondents interviewed were primarily developers with minimal long term investment priority; whereas the aim was to interview major investors who had a primary focus on owning and operating buildings in the longer term.

5.0 Data Collection and Analysis

Investor responses as to their perception and understanding of sustainability were delineated into three core respondent groups as detailed in table 1. Although all respondents had some knowledge of sustainability and its meaning their views of how it would affect their business were varied. Table 1. highlights the divergence in responses, with a majority of companies having a very positive outlook about sustainability (43%), a middle group who saw the long term positive nature of sustainability (36%) and a neutral or negative group (21%) who believe that sustainability does not affect choice when assessed financially.

The positive group see sustainability as a revenue generator, particularly the financial opportunities that can be gained from a branding, marketing and reputation for being more sustainable. Key opportunities identified by respondents were the ability to be market leaders and to gain significant market share through having differentiated assets (more sustainable) and creating that competitive advantage over the existing building stock. The majority of investor respondents could see this advantage being driven by both global and local drivers that would affect occupancy requirements of tenants, thereby creating an enhanced demand for sustainable space. It was acknowledged that the international investment community are starting to grade their portfolios and are interested in assets that provide more than the standard level of office quality.

The median positive group assessed sustainability as being something that would be nice to have but not at an expense. The belief was that sustainable buildings in the current market were additionally expensive to develop, without proven results of the financial return and ability to assess the risk involved to take on the challenge of sustainable development. Although realising the need to have more sustainable building stock, however not having excess capital to develop or extensively refurbish buildings, this group chooses to make more long term solutions by assessing their buildings and embrace sustainability where financial paybacks are proven. This group saw the potential for more long term gains rather than taking on the risk by being in a market leadership role. The risks and costs involved in being a market leader did not demonstrate significant advantage, and until the financial paybacks had been proven by undertaking sustainable practices only small steps would be taken towards incorporating sustainability into their property portfolios.

The last group held either a neutral or a negative view of sustainability for the property industry. Investors tended to believe that sustainability was not very important at present and only required consideration if the property had government tenants and was located in Wellington. They believed the demand was limited and not high or broad enough in the industry to change the occupancy requirements overall, particularly when price came into effect. They believed that tenants would continue to make decisions about premises solely on price (rental), and not on whether it had sustainable attributes. The only benefits they perceived that sustainability would offer them were reducing operating costs and recycling, although this did not equate to significant added value for the asset.

The vast majority of investors surveyed saw sustainability in a positive light, as long as it proved to provide financial benefits to the company. Little was mentioned about achieving corporate social responsibility (CSR) goals, helping the environment or reducing carbon emissions. Essentially investors are still interested primarily in the financial bottom line and how sustainability can be used to improve that bottom line.

Table 1: Company Perception of Sustainability and Buildings

Respondent group	**(a) Awareness & Importance**	**(b) Effects**	**(c) Why**
Very Positive Companies: 43% of total respondents	• Very High • Immediate Action	• Market leadership opportunity • Response to market demand • Global drivers	• Market competitiveness • Optimisation of property management • Market driven returns • Sustainability = premium
Positive Companies: 36% of total respondents	• Understand concept to be increase building efficiency • Medium to long term applicability • Sustainability desirable but not at a cost	• Upgrading of portfolio over time • Paybacks and financial requirements	• Medium to long term gains • Keep up with market
Neutral and Negative Companies: 21% of total respondents	• Not very important at moment • Only an issue for Wellington • If you want government tenants	• Limited to efficiency in operational expenditure • Recycling	• Sustainability is not affecting choice when financial aspects come into play • Wait for significant tenant demand

After identifying the investor's perception and understanding of sustainability, as well as potential benefits and drawbacks, the survey then asked if they were undertaking sustainable actions in their own portfolios. Table 2 shows a different response in comparison to the results in table 1, being approximately divided into thirds; 36% of investors actively undertaking sustainable initiatives in their portfolio, 29% of investors assessing the benefits and planning for sustainability and 36% currently not undertaking any action. Investors actively pursuing sustainability and implementing strategies throughout their portfolio have a strong corporate stance on sustainability, often linked to international parent companies where reporting and operating directions come from more advanced countries. In addition, the need to maintain their presence in the market as a leader who provides premium property has resulted in the accelerated uptake of sustainability by these companies. The majority of action being taken has a current focus on new development; however existing buildings in their portfolios are being upgraded and retrofitted.

The middle group of respondents are companies starting to assess the viability of sustainability and are looking at medium to long-term focus and upgrade plans. There are restricting factors for them, mainly financial, that are hindering their progress of adapting sustainability. At this stage they are looking at strategic planning, assessing appropriate buildings and the building's drivers for sustainability. This incorporated not only the physical attributes of the building, but asset drivers, focused on the retention or attraction of tenants and maximising future income streams. The corporate goals of the investor are not currently playing a large role in encouraging sustainable buildings and accelerating the uptake. The scepticism in the inactive companies is apparent with many viewing sustainability as a passing fad that will not have a significant grasp on the market. Lack of investor action is linked to market immaturity, lack of financial evidence supporting financial benefits of sustainability and the possible market depth and longevity. Overall investors are certainly watching the market and the overall progress, although there is a risk then there are still a number of major accepting investors who are embracing this risk and aiming to achieve market leadership and high market returns. It was evident that organisations that have strong corporate social responsibility reporting and objectives are aligning these with their business and property operations. Perceived gains were not necessarily as a result of tenant demand, but were from the organisation's position in the market and opportunity of providing and owning premium property.

Table 2: Company incorporation of sustainability into portfolio

Respondent group	(a) Activeness	(b) Action Taken	(c) Why
Active Companies: 36% of total respondents	• Currently implementing sustainability in portfolio • Strong stance on sustainability	• New Buildings • Upgrading and retrofitting of existing buildings	• Market leadership • Premium property • Market driven returns
Beginning to Act Companies: 29% of total respondents	• Assessing financial viability of sustainability for company • Medium to long term applicability planning	• Strategic planning for assets • Initial audits and assessments on selected buildings (appropriately profiled) • Paybacks and financial assessments	• Medium to long term gains • Sustainability desirable but not at a cost • Keep up with market
Inactive Companies: 36% of total respondents	• Low level of activity • Some strategic planning • Watching market	• Strategic planning • Analysis of cost-benefit ratio • Market research	• Lack of financial evidence • Uncertainty of market depth • Sustainability a fad

Tables 1 and 2 demonstrated the differences between the perception of sustainability and the actions of the organisations, from a ratio of 4:3:2 in perception to approximately thirds in actively undertaking sustainability, highlighted in figure 4.

Figure 4.Comparison of Industry Perception of Sustainability and Industry Implementation of Sustainability

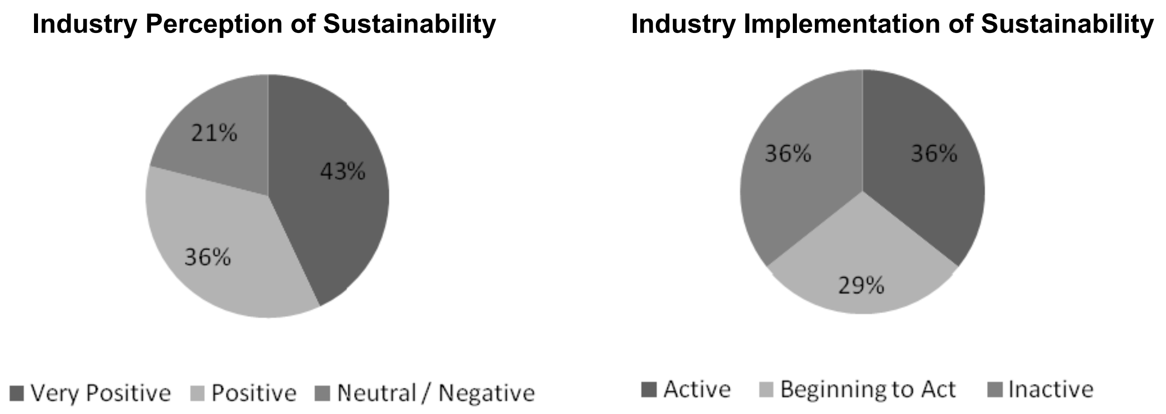

Table 3 and figure 5 highlight the importance in the property portfolio and whether investing in sustainable buildings is a priority. Initially looking at whether sustainable buildings are an important part of the organisation's portfolio, there was an overwhelming majority of 57% that declared sustainable buildings were not a consideration in the portfolio. 21.5% responded that sustainable buildings were not currently important and 21.5% declared that sustainability was an important part of their portfolio. This related to current investor priorities, where the second part of the survey identified intentions to invest in sustainable buildings. This resulted in a change in the ratio, with 57% of respondents claiming to want to invest in sustainable buildings, 21.5% who would consider investing but focused on their existing assets and finally 21.5% who would not consider investing in sustainable buildings at all. The results provided an insight into where investors believe the future direction of sustainable property. The majority (78.5%) of investors believed that sustainable buildings will be an investment requirement for their portfolios, either through new or existing buildings.

Table 3: Importance of Sustainability in your portfolio

(a) Are sustainable office buildings an important part of your portfolio?
(b) Is investing in sustainable buildings a consideration for your portfolio?

Respondent group to question 3 (a)	Respondent group to question 3 (b)	Why
Sustainable buildings are an important part of portfolio: 21.5% of total respondents (Call Group A)	Currently investing in sustainable buildings: 57% of total respondents Change +21.5% from Group B investors +14% from Group C investors	• Fundamental to remain in as a market leader • Premium property portfolio • Market driven returns • Response to tenant demand • Corporate Social Responsibility – company goals
Sustainable buildings not currently important: 21.5% of total respondents (Call Group B)	Consider investing but focused on existing assets: 21.5% of total respondents Change +21.5% from Group C investors -21.5% to Group A	• Analyse current assets and align with tenant requirements where required • Sustainability desirable but not at a cost • Keep up with market • Similar to other technological advancements
Sustainable buildings are not a consideration: (Call Group C) 57% of total respondents	Not considering investing in sustainable buildings: 21.5% Change -21.5% of total respondents -14% to Group A -21.5% to Group B	• Lack of financial evidence • Costs • Lack of demand • Market might be ready in 5-10 years time

Figure 5. Comparison of Industry Importance of Sustainability in Portfolios

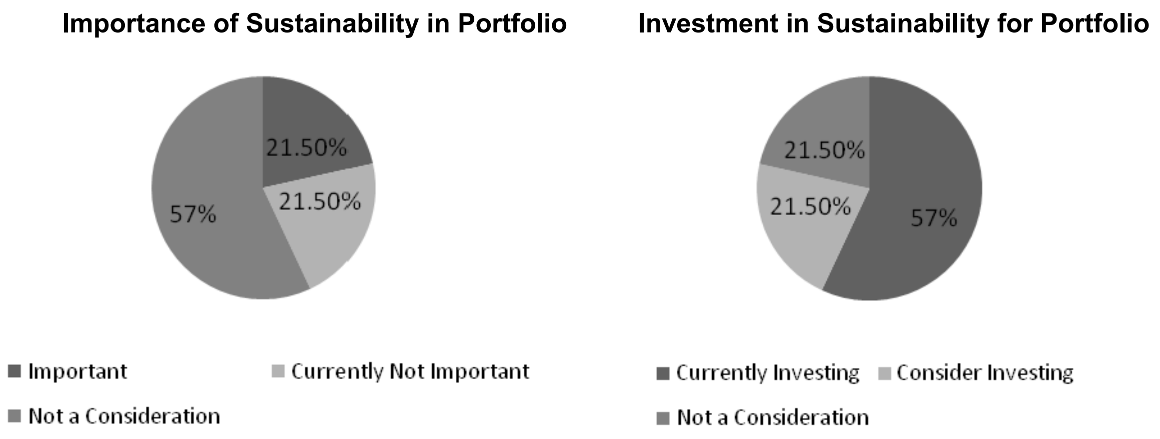

Table 4 presents the responses about whether a changing investment strategy will equate to different values for sustainable buildings, and whether investors are willing to pay a higher price for a more sustainable building. The investors want to have a sustainable building and what they are willing to pay to become a part of that sector is outlined in table 4. Overall 71% of respondents indicated they would pay a higher price to purchase a sustainable building, whilst only 29% stated they would not. The respondents, who affirmed they would not invest in sustainable buildings at a higher price, reasoned that the market was not mature enough to determine how much more should be paid for a sustainable building. In addition it was stated that the market for sustainable space is still very immature and there is a severe lack of evidence. From these companies' perspective, the financial evaluation of the operation of a sustainable building without having significant market evidence to pay a higher price subjects the company to a higher level of risk.

Table 4: Commitment of Investor to pay a higher price for Sustainable Buildings

Respondents	Respondents' Comments
Respondents who **wouldn't** pay a higher price currently 29% of respondents	• Market maturity • Caution about paying premium prices simply because some of the building characteristics are 'sustainable' • Rental quantum needs to be documented and researched further • Sustainable buildings subject to higher levels of depreciation due to the acceleration of technologies
Respondent who **would** pay a higher price currently 71% of respondents	• Only if market demonstrates growth in this area • Definitely if building had a rating ensuring that blue chip tenants would want the space and thus gaining better rents, if not now definitely in the future • Based on the potential reduced vacancy and reliable income stream • If lower operating costs are sustainable then by virtue of the resulting higher net building income a higher purchase price would result • The purchase of a conventional building would mean that in the future a significant upgrade would be required to remain competitive • Building will achieve better rents thus pay a higher price • Operating expenditure will be lower, thus creating more value and accepting a higher purchase price for the same cap rate • The effect will be more obvious as the market matures, however will there be high levels of obsolescence and deprecation in the existing stock • Otherwise in the future you will have to look at spending money to bring up ordinary assets to spec in the market and the opportunity of significant gain might be lost

Although the majority of respondents replied they would pay a higher price for sustainable buildings there were a number of associated conditions, which further supports a level of uncertainty that investors feel in New Zealand about sustainable buildings. The expectation was that a sustainable building would result in higher rents, reduced vacancy, premium or government tenants, reduced operating expenditure and a reduction in future capital expenditure all affect the return on investment ratio and the value of the property. Hence the argument that investors would pay a higher price is based on the perceived financial return they would receive from the property, which essentially is like any other investment. Some investors believed they would pay more just to have a sustainable building in their portfolio based on the understanding it is not necessarily physical financial return but certainly an intangible element of value for both the property and the organisation. How much physical financial value versus the intangible value of a sustainable asset is still yet to be thoroughly researched and the values identified.

6.0 The Future of Sustainability in New Zealand Property Stock

Overall the perception in the New Zealand investor market was that sustainable buildings will play an important role in property portfolios in the future. Although there is uncertainty about the value and market for sustainable buildings at present, investor optimism was clearly identified. However the level of uptake and investment in sustainable buildings would be accelerated if evidence for the financial case for sustainable buildings was proven. New Zealand investors seem to be embracing sustainable buildings in a different way to other global property industries. The inherent traits of New Zealanders as entrepreneurs, in addition to having the benefit of observing the development of sustainable buildings elsewhere in the world over the last decade and identifying the benefits accruing to market leaders worldwide, has resulted in an optimistic mindset and increasing adoption of sustainable buildings in the local market. The response in New Zealand has been accelerated by the release of the benchmarking tool (e.g. *Green Star NZ*), being the first and only sustainable rating tool for commercial buildings in New Zealand.

The future for sustainable buildings in New Zealand is positive and with the envisaged increased government requirements, both nationally and internationally, the development of sustainable buildings should continue. Nevertheless how these buildings are treated in a market sense is still yet to be fully understood, although the potential of a two-tier market is highly likely. Perhaps there will be a tier that encapsulates the sustainable buildings and then the second tier that is the rest of the building stock which is not thus far deemed sustainable. It appears likely that preference will be given by larger tenants for the upper tier of sustainable stock, which will in turn create new rental benchmarks, reduced vacancy and other perceived premiums. At the same time the remaining building stock may see a 'non-sustainability discount', possibly created from increased levels of vacancy, lack of tenant demand, lower rents and increased depreciation. This may be particularly evident in Wellington where government may decide only to occupy sustainable space, although that impact might be detrimental to the office stock in the Wellington area (note that the government occupies approximately 41% of office stock in Wellington). Potentially there may not be evidence that sustainable buildings will have premiums, but instead have a slower rate of obsolescence in comparison to non-sustainable buildings which will become obsolete at a faster rate. With preference being given to more sustainable stock, the potential for increased vacancies and lower rents will lead to a requirement for non-sustainable buildings to undergo extensive upgrades to keep up with the majority of the market. Although market rental and sales evidence might or might not prove that sustainable buildings achieve higher rents and prices, preference, vacancy and letting up times in addition to the impact of obsolescence and depreciation creates other avenues of investigation and research that is vitally important to the determination of market value of sustainable office buildings.

7.0 Value Case – Further Research

As with many other industry sectors the property sector is yet to fully embrace sustainability, although in New Zealand there seems to be a quite positive outlook at present towards sustainable buildings. However the majority of investors still appear hesitant to invest in sustainable buildings as they lack the appropriate tools to identify the investment benefits. It has been argued there are no 'real' proven incentives to invest in sustainable buildings as most of the benefits accrue to the occupier rather than the investor (Lawther et al., 2005), where the findings of this research appear to support this argument. To further discourage the investment community there are currently only "inappropriate financing models which focus predominantly upon immediate financial return, or lack of access to capital" (Lawther et al, 2005, p.58), which is in addition to other unsuitable cost and payback related tools.

In conclusion the valuation industry is yet to accurately identify and quantify the added value related to sustainable buildings, where the level of sustainability in a building is not yet fully reflected in the valuation process. At times this may restrict investors from identifying the financial benefits of sustainable buildings and consequently inhibit the investment and development of necessary infrastructure. A common thread throughout the interviews undertaken in New Zealand for this study was the resounding need for more information about the financial impact of sustainable buildings from an investor's point of view. The investment communities need evidence, analysis tools and methodologies that identify and prove the impact of sustainability on market value, which in turn will assist in advising investment decisions about sustainable buildings. In reference to the more developed markets of Europe, Lorenz (2007) emphasised the needs and key roles of valuation professionals and the valuation process itself to achieve a broader market penetration of sustainable buildings. Once value is identified in sustainable buildings, it should result in the demonstration to all within the property industry and those also in the investment and banking industries about the value of sustainability.

Keywords: green building, China, drivers, barriers.

Summary

There has been significant progress in the green building practice in China during the past decade, especially encouraged by China's Ministry of Construction by organizing several large-scale government-supported programs. The current establishment of the national renewable energy law and various energy efficiency regulations on the local level are also taking important roles to push the improvement of energy performance in buildings. However, compared to all the opportunities both on the technological level and policy level, the adoption of green building practice into the building sector in China is rather slow and limited to demonstration projects.

This paper investigated the finance, design and management processes of several green buildings in China in order to analyze the barriers that prevent the acceptance and wide adoption of green building practice in China. The selected cases included national demonstration projects, local government-supported experimental projects and voluntary projects. The focus of this paper is not to present details of successful green building cases in China, but rather, through how these projects were initiated and made possible both financially and technically, to identify the factors in the current building finance, design and management processes in China that are obstacles to major market adoption of green building practice. Identification of these barriers will lead to an intriguing discussion of what can be done to get over the barriers for effective improvement in green building development and sustainability in China.

1. Drivers of green building practice in China

Along with the huge volume of construction in China, there has been progress in the green building practice during the past decade, especially encouraged by the Chinese government. The major drivers that are pushing for green building practice are similar to the ones that are driving improvement of the overall energy effectiveness and efficiency in various sectors in China.

1.1 Deterioration of environment

Huge amount of fossil fuel consumption for electricity generation, industry, building operations and transportation, accompanying the country's rapid economic development and urbanization, has caused serious air pollution problems in most Chinese cities. Water scarcity and water contamination are also common problems that are impacting the everyday life of a large proportion of the population. China is facing the conjuncture of choking on its own development. The severe deterioration of environment in China has already made it impossible to continue ignoring the pollution problems associated with energy consumption. Buildings, as consumers of huge amount of electricity, natural gas and water, are under the pressure of improving their performance to alleviate environmental impact. Media exposure of pollution problems country-wide and the everyday experience of deteriorating environmental quality also led to growing public awareness that is needed for building the capacity for change.

1.2 Energy security

China is facing energy shortage to meet the ever increasing demand from industrialization, urbanization and the concentration of global manufacturing. It is now the second largest oil importer after the US. The energy security issue is now pushing China to seek for more and more energy sources globally; it led to an illusion, just like that in the US, that China can get oil from all around the world to feed its increasing energy needs. However, the soaring oil price and the concern of energy security did force China to improve its energy efficiency. Chinese government is investing in the development of green power "not only as a solution but also to improve its profile as a responsible international player" (Bezlova, 2006). In order to improve energy security, the government is also raising energy price to slow down the soaring energy consumption increase and to encourage energy efficiency improvements. The prospects for green building practice in China, which focuses on reducing energy demand in buildings, improving performance of building systems and exploring alternative energy supply strategies, have never been better.

1.3 External pressure

Pressure from outside China on its greenhouse gas emissions reduction and environmental pollution alleviation also forced the Chinese government to take on actions to adopt a more sustainable development path, though there is no obligation from the Kyoto Protocol for China. In the building sector, the global green building practice also started to have an influence on China, through knowledge and technology transfer, although the level of awareness of the public in China is still low.

2. New regulations, evaluation tools and organizations

In respond to the aforesaid three drivers, it is obvious that Chinese central government is playing an important role in promoting green building practice. Among the various efforts, establishing new regulations was among the most effective. An example is the China Medium- and Long-Term Energy Conservation Plan (ECP), issued by the National Development and Reform Commission (NDRC) of the State Council in November 2004, which has chapters directly targeting at building energy consumption reduction. It is the strongest push for green building practice in China so far.

The ECP notes that "during the Eleventh Five-year Plan period (2006-2010), new buildings should be strictly subject to the design standard of 50% energy conservation. Several major cities such as Beijing and Tianjin shall take a lead in implementing the 65% energy-saving standard." More specifically, the construction industry and building-related sections of the ECP call for:

1)Accelerating the reform of building heat supply systems and the promotion of energy-saving construction technologies and products. In China's large and medium cities, a charge system based on thermal metering will be widespread in district heating of residential and public buildings; small cities will be pilot of such practices.

2)Carrying out energy conservation retrofits on existing residential and public buildings in the northern regions where space heating is required shall be conducted in combination with urban reconstruction. Large cities are expected to improve 25% of building, medium cities 15% and small cities 10%. Buildings should use such materials as energy-saving doors and windows and new wall materials. In addition, the application of renewable energy such as solar and geothermal energies in buildings should be speeded up.

3)Conducting comprehensive energy conservation renovations of existing hotels and restaurants.

4)Expanding the use of high-efficient and energy-saving lighting systems, tri-phosphorus fluorescent lamps, high intensity gas discharge lamp and electronic ballast. Decreasing the usage of incandescent lamps, and gradually eliminating high pressure mercury vapor lamps. Implementing lighting product energy efficiency standards in public facilities, hotels, commercial buildings, office buildings, stadiums and gymnasiums and residential buildings.

5)Promoting high-efficiency energy-saving household and office electric appliances such as refrigerators, air conditioners, televisions, and washing machines; reduce appliance/technology energy consumption while in stand-by mode; implementing energy efficiency standards and labeling; and standardizing the market of energy-saving products.

Besides efforts on the central level to establish new regulations and tighten the existing codes for both national-wide and specific regions (e.g. the new residential building energy codes for "Hot-Summer Warm-Winter" (HSWW) climate zone in 2003), on the province- and city-level there have also been similar efforts to push the energy conservation and energy efficiency in buildings to a higher level. In addition to regulations, voluntary green building evaluation systems are being developed in China, though still at research and experimentation stage and the impact is still minimal, considering the low public awareness and the overwhelming pursuing for profit and rapid development. Also, the huge difference in climate and economic development conditions among regions in China pose significant challenge for the implication of evaluation systems to be able to reflect local requirements and priorities. It is actually a challenge for many green building evaluation tools in the world.

An example of voluntary evaluation tools in China, which is comparatively influential, is the Evaluation Standard for Green Building, issued by the Chinese Ministry of Construction, together with General Administration of Quality Supervision, Chinese Inspection and Quarantine, established in March 2006. China Academy of Building Research and Shanghai Academy of Building Research were the two major contributors in editing the standards. The standard concerns all new buildings, building extensions and renovations, including residential and public buildings. It consists of building performance monitoring and economic evaluation, for the entire building life-cycle. The main categories of criteria are: land conservation and environment protection, energy conservation and use, water conservation and use, materials conservation and resource use, indoor environmental quality and management (residential building) and life cycle performance (public building). The US voluntary evaluation system, the Leadership in Energy and Environmental Design (LEED), had significant influence on the framework and contents of this standard. According to the performance of the building, the developer will get a rating, on a scale of 1 to 3 (star system).

Before this standard was published, some developers use “green building” only to attract consumers. With current evaluation criteria, it is much more transparent and easier for the public to understand the actual performance of buildings. One year after this standard was in use, developers can only use the phrase “green building” to promote their development if it fulfilled the 6 categories of criteria in the standard.

Among the various forces to promote green building practice, several organizations also played a positive role, e.g. the China Sustainable Energy Program (CSEP) – Towards a Sustainable Energy Future for the People’s Republic of China and the China-U.S. Center for Sustainable Development. Though their focuses vary, their common goal is to coordinate the cooperation among the business community, governments, universities, research institutions and non-governmental organizations, and the cooperation between China and developed countries (mainly the US), to assist in China’s transition to a more sustainable future. They engaged with senior government officials and leading industry representatives who are charting the future development path for China, and initiated demonstration projects and developing new solutions by providing initiatives and grant-making. Another constructive role these organizations are playing is in supporting capacity building and technology transfer through linking Chinese experts with "best practices" expertise from around the world, to help Chinese agencies, experts, and entrepreneurs solving challenges for themselves.

3. Case studies of green building practice

In the effort of transforming the building sector in China towards more sustainable, there were several projects that were built with high performance standards, including national demonstration projects, local government-supported experimental projects and projects by private developers.

3.1 Energy Efficiency Demonstration Building, Ministry of Science and Technology of China, Beijing

This 10-storey, 12,960-square-meter building was developed by the Ministry of Science and Technology of China. It was completed in February 2004 at only US$770/square-meter.

This was a Sino-US collaboration project demonstrating the integration of multiple energy efficiency strategies. The high-performance envelope system integrated strategies included light-color composite block exterior wall, polyurethane waterproof roof insulation foam and super-light inorganic roof vegetation soil, thermal break aluminum frame with high-performance low-e glass, outdoor horizontal fixed shading device to control solar radiation for all south-facing windows, and reflectors for deep daylight penetration. The conditioning of the building adopted natural ventilation, multi-stage absorption chiller, ice-storage system, variable flow air conditioners and heat recycler on roof. The lighting system was featured with daylight sensors, occupancy sensors, and energy efficient lighting fixtures with 0-100% digital dimming ballasts. Other green strategies included variable-flow water supply system, storm water reclaimed at roof garden (70% roof area) and underground storage, waterless urinals and water-efficient toilets, automated building control for lighting, ventilation, thermal and security systems, and low VOC paint.

The actually measured annual energy consumption is 72.3% less than that required level by China Building Energy Efficiency Standard. According to the Chinese Ministry of Science and Technology (Yang, 2005), this building registers annual power consumption of 38.4 kWh/square-meter, 30% of the power needed by conventional office buildings in Beijing. A 15-kW roof PV system generates over 5% of the building’s power consumption in cost. 75% construction waste was reused, and over 90% building materials were harvested and/or manufactured locally. The annual electricity savings is 900,000 kWh. Annual savings on power and water expenses are over 700,000RMB (US$89,000). Building cost increased by 4 million RMB (US$510,000) on energy efficiency and green strategies (8%), but the payback period of the first-cost increase is only 7 years, based on the 2004 energy price.

3.2 SIEEB – Sino-Italian Ecological and Energy efficient Building, Tsinghua University, Beijing

This 10-storey, 20,000-square-meter building was developed by China's Ministry of Science, Technology and the Italian Environment Ministry and Tsinghua University. It was completed in July 2006 at US$1,700/square-meter, and will host a Sino-Italy education, training and research centre for environment protection and energy conservation.

Overall this building used some hundred energy efficient technologies and products developed by research institutes or manufacturers both in China and abroad. Nearly fifty US, German, Japanese, Denmark and Chinese manufacturers contributed their latest energy efficient technology and products to the building. Dozens of products or technologies were used for the first time in China. The envelope components, as well as the control systems and many technologies were the most updated Italian production, within the framework of a design philosophy in which proven components were integrated in innovative systems.

The building shape was derived from an analysis of the site and of the specific climatic conditions of Beijing. Located in a dense urban context, surrounded by some high-rise buildings, the building optimized the need for solar energy in winter and for solar protection in summer. The integration of a green roof and a solar PV roof on the recessed floors not only reduced energy consumption but also produced energy. The green roof helped to retain storm water. There are also grey water reuse systems in this building. Other building envelope and system strategies adopted included reflecting and semi-reflecting lamellas and louvers, gas engines coupled to electric generators for electricity generation with rejected heat for heating and cooling purposes, displacement ventilation and radiant ceiling systems, and a high efficiency lighting system.

The SIEEB project was the result of cooperation between the Italian Ministry for Environment and Territory and the Chinese Ministry of Science and Technology, and was also part of the "Clean Mechanism" project by Italian Environment Ministry. It was regarded as a platform to develop the bilateral long-term cooperation in the environment and energy fields and a model for showing CO2 emission reduction potential in the building sector in China. It was also the result of an international collaboration among consultants, researchers and architects. This integrated design process was a most distinctive part of the project and a key issue for the success. (Cucinella, 2006)

3.3 Green Demonstration Building of Shanghai Research Institute of Building Science

This 3-storey, 1,900-square-meter building was developed by Shanghai Research Institute of Building Science. It was completed in September 2004 at US$570/square-meter.

The Green Demonstration Building of Shanghai Research Institute of Building Science was a key project of the "Green Building Technique and Systems Integration" research by Shanghai Science and Technology Committee. As a demonstration project, the green building contained multiple green energy technologies, including solar thermal technology, photovoltaics, natural ventilation, and daylight. Four types of exterior wall materials and three types of roof materials with different U-value were used for different orientations. Horizontal adjustable exterior shading on the south façade and vertical adjustable exterior shading on the west were installed to reduce energy consumption by 47.8%. Solar thermal collector and photovoltaic systems were placed on the pitched roof, harvesting 0.2 kWh/square-meter solar thermal and generating 5 kWh/square-meter electricity annually. Integration with solar collectors, low-temperature floor heating and hot-water-driven desiccant dehumidification systems were adopted for winter heating and summer cooling. Desiccant dehumidification system reduced the air-conditioning energy consumption by 20%. 80% of the building construction materials are 3R material, such as concrete hollow blocks produced by recycled aggregates. The building also adopted an ICAST rain recovery system. The annual site energy consumption of this building, based on software simulation, is 56 kWh/square-meter, with the annual primary energy consumption level at 153 kWh/square-meter. (Zhen, 2005)

3.4 Tianpu Solar Building - Beijing Olympics scientific and technological demonstration project of new energy comprehensive utilization in buildings, Beijing

This 6-storey, 8,000-square-meter building was developed by Beijing Tianpu Solar Energy Industrial Company Ltd., completed in 2003.

This is a mix-use commercial building, with functions including office, apartment, exhibition, restaurants and recreation. It featured a 1,200-square-meter evacuate tube solar thermal air collectors integrated with the roof and a 50-kW photovoltaic system integrated with the south-facing facade. In the winter, the solar-heated hot water is stored in the underground reservoir and used for heating when needed; and in the summer, it is used to drive an absorption chiller to produce chilled water for cooling. Heating and cooling are provided through radiant panels to ensure thermal comfort of end users.

This building was the first demonstration project in China for the comprehensive utilization of solar energy. Because of good insulation and high-performance envelop, its heating demand is 40% less than that of a typical commercial building in Beijing; cooling demand is 28% lower. 80% of the building's energy consumption is supplied by solar income. The PV system generates 40,000 kWh of electricity per year. The lighting system and sometimes even computers and TVs in this building are powered by electricity from PV. Annual electricity consumption is 2 Million kWh less than an average commercial building with similar size and the same type. The solar thermal system generates 9 tons of domestic hot water per day on average, which results in savings of 13,000 cubic-meter natural gas annually (Gen, 2006).

4. Barriers for green building practice in China

Despite the strength of the push from Chinese government through policy and legislation, the adoption of green buildings into the main-stream practice in the building sector in China is still rather slow, so far largely limited to demonstration projects. The process through which the aforesaid green building projects were initiated and made possible, both financially and technically, reflected obstacles in the current building finance, design and management processes in China to large scale market up-take of green building practice.

4.1 The image of "green building"

In recent efforts in promoting green building practice in China, the image of green building was simplified as energy-efficient building, the understanding of which was often associated with application of high-tech building systems. It was also among the reasons that result in the perceived high cost of "green building" or "energy-efficient building". However, another important aspect of green building design and a critical element to achieve the "zero energy building" goal, the passive strategies, have not got enough attention. Climatic design, use of thermal mass, siting for passive heating and cooling, natural ventilation, daylighting and use of landscaping and trees for shading were all used extensively and smartly in traditional Chinese architecture, while in current green building practice, the value of these passive strategies didn't get recognized at a level that they deserved. Such passive strategies are generally the most inexpensive way to provide a comfortable and healthy building environment with minimal energy load, and will effectively contribute to demand reduction and energy conservation. The reason partially relies in the fact that high-tech active strategies are considered with higher “business value” that will help manufacturers and developers to promote their products and properties. The introduction of most green building demonstration projects in the media is not doing a good job promoting passive strategies.

4.2 First-cost-oriented business mind set

Decision making process in real estate and business is dominantly first-cost oriented in China. It is actually the case for a majority of countries and regions in the world. In China, this may be further exaggerated because of the speed of economic development. Business decisions tended to be immediate profit-driven. The primary impediment to a large-scale adoption of sustainable strategies in the building sector is “the perception that green buildings cost more, without any kind of comprehensive understanding of the real value that will be generated” (McDonough, 2007). Though research have demonstrated payback from green building and green building strategies through life-cycle cost including operation energy savings, as well as occupant-related benefits including improved health and workplace productivity, attraction and retention, it is still a challenge to communicate to the developers and building owners about the promising benefits from investing in green buildings. In addition, China is still a labor-intensive economy, in which the occupant-related benefits are difficult to be communicated to and accepted by developers and business owners. This is also the reason why the green building practice in China currently didn’t get much beyond the demonstration level. For demonstration projects, cost is often less a concern in the decision making process.

4.3 Fragmented delivery process

Due to the fragmented nature of the construction industry, project delivery is complex. Sustainability has added to this complexity, which in many respects are linked to the far wider issues of educating the public and promoting investment. In some projects, stakeholders participation came at the later stage of construction. However, implementing sustainability issues should start at the strategic and concept planning and project programming stage, when the technical and economic feasibility of alternatives will be compared in order to select the best possible approaches. There is a need to make clear the importance of stakeholder involvement in the early design of projects. Sustainability decisions made at the beginning of a project life cycle tend to have a far greater influence than those made at later stages, since design and construction decisions will influence the continuing operating costs and, in many cases, revenues over the building’s life cycle. Also, the use of holistic building concept and integrated design process need to be encouraged. Basic understanding of this concept will lead to appreciation of integrated design team, which encourages involvement of stakeholders from the beginning.

4.4 Finance and incentives

One strategy to promote market acceptance of green building practice, that has been proved effective, is by providing incentives or low-interest loans for the adoption of green building strategies. This kind of multi-instrument finance and incentive systems has not been established in China. At present, financial and taxation policies have not given enough support to energy conservation renovation, research and development of energy saving equipment and their application, nor to rewards for energy conservation. In some cases, incentives or financial support were provided to certain demonstration project, but only on a case-by-case basis.

The strong central control on real estate development is not only through the direct regulation of policies and codes, but also through the influence on loans from bank systems. Most of china’s financial institutions are still state-owned. Their decisions on loans are largely constrained by policies. At the central level, China's Ministry of Construction and Ministry of Finance are the major influencers of green building finance. For example, the National Project of Building Energy Conservation, as one of the 10 national energy conservation projects, will invest heavily by year 2010. In China, the centralized political system sets the priority of development. Some important projects can be encouraged and financially supported if they are considered important to achieve the national development goal.

Similar to the situation of finance and incentive systems, the insurance industry in China did not recognize or understand the value of green buildings, such as fewer health claims because of fewer employee illnesses. Insurance companies kept their traditional way of business and formulas of risk estimation, and did not provide discounted rates for green building features like energy-efficient lighting, heating and cooling systems, because they are less risky under the current and future conditions of energy shortage and insecurity.

4.5 Policy and policy implementation

The central power of the government could help enforce energy efficient practices, but that is not as simple as it sounds. First of all, in China, economic development still is the top priority over other things, including efficiency improvement and environmental protection. Many local governments and local industries are focusing on quick return-on-investment. They are reluctant to invest in improvement in energy and environmental performance, which is more about long-term competitive strength and sustainability. Secondly, China is a large country with regions at dramatically different development stages. There are increasing gaps between the more developed and developing areas in China, literally between the coastal areas and the inland. Centralized policies might not fit situation in different regions, and face local resistance. When the centralized government enforces strict energy efficiency policies, these policies often face obstacles and resistance from local authorities in the less developed regions. Some local governments reject energy efficiency policies with the excuse that they must focus on economic development or that energy efficiency policies will limit economic development. Compared to inland China, businesses in cities in the coastal area are more market-driven, though the policy influence is still strong. The coastal area has advantages in promoting green products and businesses.

The implementation of policies and regulations is another challenging issue. The new codes and standards, which fall well behind those developed countries, were purposely designed to encourage compliance. This is understandable, but does little to promote the use of the best available materials and technologies on the international market. Energy conservation laws and regulations are not complete. The “China Energy Conservation Law” was promulgated and put into effect in 1998. However, the lack of compliance and slack enforcement of the law is rampant; the supporting regulations are incomplete, and the exercisability of the law also remains to be improved. Although the building design codes for various climatic zones, targeting 50% energy saving, have been formulated and promulgated successively, only less than 5% of newly-constructed urban buildings as a whole in the country comply with the design codes of building energy conservation.

4.6 Knowledge and technology gap

In China, the knowledge about the importance of energy conservation is insufficient; guideline policy to give priority to energy conservation has not been fully implemented. The development and dissemination of energy conservation technology is inadequate. Also, the capacity building in energy conservation regulatory and service institutions lags behind. These factors all contributes to the difficulties for the implementation of policies and regulations. Similarly, the capacity in China to analyze energy savings and renewable energy opportunities in buildings and to develop policies to capture those opportunities is yet to be built. Improvement in knowledge and technology transfer will help to reduce the reluctance of businesses to try green building strategies that they are not familiar with, and even go further to undertaken in-house study and explore innovative measures that will both make business sense and benefit the environments and employees.

Mutually profitable cooperation and exchanges between China and several developed countries, e.g. US, Germany, Australia, etc., in the fields of ecological technology and green building design and development will be helpful to reduce the knowledge and technology gap. However, the international cooperation at present is mostly focusing on make prototype buildings, while not on the training of local professionals and exerting impact on local building components and materials industries. Since there is not yet a ready supply of 'green architects, builders, materials providers', in many cases, the 'green materials and services' still relies on import, which makes the upfront cost of green building even higher and more difficult to popularize.

4.7 Social awareness

Though there is global pressure on China’s GHG emissions reduction, small portion of the public in China are really conscious of global climate change. For the construction industry in China, sustainability is still a relatively new concept, though there is generally an increase in awareness. However, this awareness is not across the whole spectrum of the building sector. Low level of public awareness has resulted in a lack of understanding of the need for sustainable design, therefore natural resistance to change. The economic barriers are also inextricably tied to the low awareness situation.

In China, though corporate social responsibility (CSR) topics are discussed, environment-related CSR is very little in practice. Many global corporate tend to make less efforts in their operations in China or other developing nations. Corporate executives are usually not personally concerned about global warming. Most developers in China make decisions according to market needs. Very few of them think about social responsibility of creating better built environment for the public. Many landmark buildings designed by some star architects often do not care about promoting the green building concept, while caring more about the branding and image. It is a challenge for the central and municipal governments as well as business owners to choose the “right” architects. On the other hand, employees do not have the awareness about condition of their work environment, energy consumption and global warming.

5. Conclusion and suggestions

In China, there have been already a number of demonstration green buildings in several cities. The Ministry of Construction (MOC) has recently announced 25 demonstration projects for using renewable energy in buildings, as well as awarded 40 building projects and building technologies the title of “National Green Building Innovation Award”. Owners of some large-scale building complexes and high-rise buildings are among the first to consider building life-cycle cost, including operation expenses, and are willing to adopt energy conservation strategies. The Chinese government announced in March of 2006 a new five-year plan to rigorously implement eco-friendly construction standards, refurbish old buildings to improve energy efficiency, and enhance studies on eco-friendly technology, equipment and materials, which will become preferred options in construction projects and improve the legal system to facilitate building energy conservation. The MOC also signed a memorandum of understanding with the US Green Building Council "to address the impact of the built environment on China, the U.S., and the world".

However, green building is not yet common practice in China, even for the newly built office buildings. For example, for all the new buildings built in 2003, only 5% fulfilled energy efficiency standards. When it comes to energy efficiency, newly built buildings are not necessarily doing better than old buildings, though China has set the goal to reduce building energy consumption by half. Most of the green building demonstration projects in China were government-financed projects. The financial support from the government was the critical element to make these projects possible. The government will keep on playing an important role in promoting and financing green building project, before the market start to take over.

The identification of barriers that exist in the building finance, design and management processes, including the image of "green building", first-cost-oriented business mind set, fragmented delivery process, lack of systematic financial support and incentives, problems of policy implementation, knowledge and technology gas and the low public awareness, is the first step in initiating an intriguing discussion of what can be done to get over these barriers for effective improvement in the building energy performance and sustainability in China. Important strategies include:

1)Initiate an awareness campaign targeting the design professionals, stakeholders in the building sector, higher education and the general public, to build the capacity of a main-stream market acceptance. For China's building sector, the most critical thing is to convey the understanding to various stakeholders that clean environment and economic development can be achieved at the same time, and actually one helps the other.

2)Keep developing green building policies and regulations and emphasize on effective implementation, including providing support for the interpretation of codes and laws.

3)Build a business case of green building practice, collect credible evidence of the advantages and necessity of green building practice, specific to China's building market, and emphasizing life cycle cost savings and benefits of green buildings.

4)Develop a systematic series of financial leverages to promote green building practice, including incentives, tax breaks, low-interest loans, as well as insurance programs, that will accelerate the major transform in the building market toward green practice.

Keywords: Sustainable Building, Real Estate Marketing, Factor analysis

Summary

The majority of the housing performance measurement focuses on primary function encompasses aspects of its use, access, space, connectivity, community, private, security and price etc. However, Environmental crises such as ozone layer depletion, global warming, and ecosystem destruction and resource depletion have increasing importance in our daily life (Langston & Ding, 2001). In Taiwan, Much construction strategy of government recently centers on the concept of ecologically sustainable development, such that establishment of Taiwan Green Building Evaluation System, Green Building Material Labeling systems, Performance Certification Labels etc. This paper adopts a non-monetary approach of the value-evaluating analysis to explore sustainability influence to the real estate marketing. The intention is to provide appropriate information of the environmental values, users' health and well-being to be considered when building owners, design teams, tenants or developers on the decision-making process of a housing development and as a principle for consumers making a purchase decision.

1. Introduction

In recent years as the transitions of the values and living type attitude in Taiwan, the house is developed and already marched toward maturing stage gradually, and the option of a house product becomes a variety of choices. At the same time, as the international sustainable building development and the sustainable and energy-saving policies advocated in Taiwan, modern consumers do not focus only on the residence to live, but also consider added values of the residence such as environmental factors including lighting, ventilation, noise…and so on. Thus if can apply the concept of sustainability, energy-conservation and healthy to use in the planning and design stages of the building that can improve living environment quality and implement the development of the sustainable house effectively (Hill, & Bowen, 1997). It is namely this main idea of research.

House can be defined as a residence product from a real estate investment view. Several marketing studies have explored the effects of patronage decision on consumers that when consumers have the higher perceived value of goods; it will promote their purchase intentions (Sirohi, Mclaughlin, & Wittink, 1998; Grewal, Krishnan, Baker, & Borin, 1998.) Moreover, it also showed that when consumers experience higher psychological cost, will reduce their purchase wills (Baker, Grewal & Levy, 1992; Wakefield & Baker, 1998; Wakefield & Blodgett, 1999). Remarkably, however, in the consumer's opinion, have a positive relationship between the perceived cost and the high performance of sustainable building. Therefore, this study utilizes the consumer's evaluation to examine the effects of the cost-benefit analysis upon the sustainable building performance, and whether to influence consumers' willingness or not.

2. Method

2.1 Applying the concept of Cost-Benefit Analysis for Measurement of Sustainable Performance

Cost-Benefit Analysis (CBA) estimates and totals up the equivalent money value of the benefits and costs to the community of projects to establish whether they are worthwhile. The principle is to calculate various kinds of cost and value of benefit. It is a formal discipline used to help appraise, or assess the case for a project or proposal, which itself is a process known as project appraisal; and an informal approach to making decisions of any kind.

Vogtländer (2002) proposed an assessment indicator with regarding environmental cost-benefit to clarify the environmental eco-efficiency on the performance of products or serve. So, it is to put emphasis on reducing the consumption of resources and the impact of the environment to offer the additional value and interests of the products.

Ding (2005) firstly start to apply the cost–benefit analysis (CBA) approach to develop a multi-criteria approach for a sustainability index focuses on identifying, quantifying and incorporating environmental issues into the decision-making process. The sustainability index combined objective factors, e.g. costs (financial return) and energy usage, together with subjective issues such as external benefits and environmental impact. Both financial return and energy consumption are relevant to the resource input in project development. The other two criteria (external benefits and environmental impact) focus on the effects building development has on the natural and man-made environments. Aimed to optimize financial return, maximize resource consumption and minimize detrimental effects to the natural and man-made world.

2.2 Conceptual model

The paper applies marketing researches, such aspects as the consumer's patronage decision is effected by perceived merchandise value (Sirohi, McLaughlin & Wittink, 1998), and the relationship between perceived cost and patronage intentions (Baker, Grewal, and Levy, 1992). The research adopts the previous evidence that the role of value or perceived cost as an intervening factor between product and choice to frame this approach model that the sustainable building product directly affects the house-purchase choice, or consider an intervening factor of the residential benefit. A proposed conceptual model showed in figure 1.

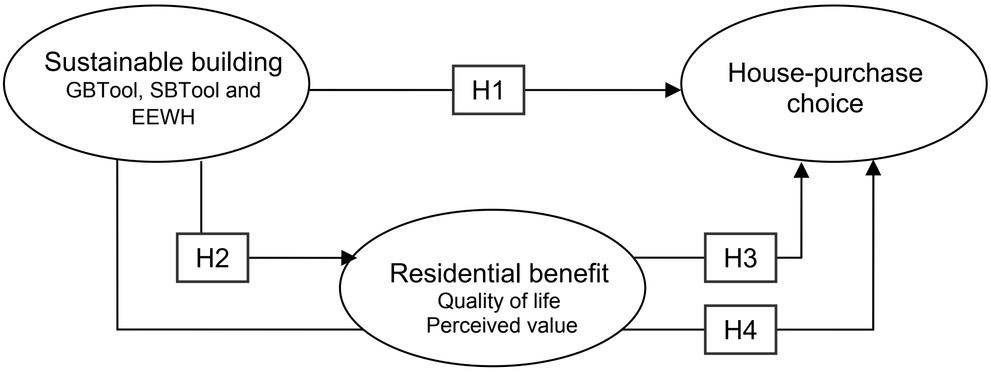

Figure 1 A proposed conceptual model

2.3 Questionnaire

This questionnaire contents four parts. The first part is 'sustainable building' that sorted out assessment issues of Taiwan Green Building nine indicators (we also called the 'EEWH' system), GBTool and SBTool to frame twenty-five items. The second part is 'intervening factor of the residential benefit', which base on the proposed sustainability index model of Ding that include two aspects of 'quality of life' and 'perceived value'. Quality of life refers to the positive contribution and benefits of a project in terms of improving living standards arising over the operational life of a project under the global environmental changes. There are eleven items adopting the front question sentence way. The third part is 'house-purchase choice', the mainly intention to understand consumers on acceptance of sustainable building and their purchase wills, it has eight items. The fourth part is the basic data of consumers which items include sex, marital status, age, education degree, job, income, house type and location etc... This research uses Likert Scale as the questionnaire rating scale (Babakus & Mangold, 1992) to investigate. Question presented using a scale of 1-5 to express the level of all issues in evaluation process. The respondent is asked to indicate his or her degree of agreement with the statement or any kind of subjective or objective evaluation of the statement, so mark high form important and satisfied.

2.4 Hypothesis

There are less researches can extract the respective dimensions from 'sustainable building', 'residential benefit' and 'house-purchase choice' parts, and the 'sustainable building' part consists of many assessment items. So, this paper will adopt factor analysis to analyze the investigated data of the questionnaire. For the above-mentioned conceptual model, the following is to set up the four hypotheses (Baker et al., 1992; Sirohi et al., 1998)

A living environment will directly affect consumer's purchasing decision derived form the literature (Lin, 2004). About 91% of the consumers agree to use the construction company of green marketing. In Taiwan, a study found that up to 91% of consumers believe that the developers adopting green marketing will pay much more concern on the environment. The consumers' perspective toward the image of these developers and their concern about the green marketing factors of residences are linear and proportional. On the consumers' attitude toward "green residences", there are up to 62.8% of consumers willing to pay 1-5% of extra price to buy a residence that is more natural and healthier; and further, 23.7% of the consumers would even like to pay 6-10% of the prices more (Fang, 2005), it is obvious the partiality attitude to "ecological housing", "green building" of most consumers is front. Thus, it is proposed that:

H1: There will be a position relationship between 'Sustainable building performance' and 'House-purchase choice.'

Sustainable development concerns attitudes and judgment to help ensure long-term ecological, social and economic growth in society. Applied to project development, it involves the efficient allocation of resources, minimum energy consumption, low embodied energy intensity in building materials, reuse and recycling, and other mechanisms to achieve effective and efficient short- and long-term use of natural resources (Ding, 2005). Figgea (2004) proposes a new approach to measure corporate contributions to sustainability called Sustainable Value Added, and it takes into account both, corporate eco- and social efficiency as well as the absolute level of environmental and social resource consumption (eco- and social effectiveness). The overall result can be expressed in any of the three dimensions: economic, environmental and social aspects of sustainability. Thus, it is proposed that:

H2: There will be a position relationship between 'Sustainable building performance' and 'Residential Benefit.'

Baker (1992) found when consumers experience higher psychological cost, will reduce the will of patronizing. However, there is a analysis between housing quality (including a location and a building quality component) and losses in property price that the prices for high-quality houses have remained more stable than the prices for average or low-quality houses within an overall market downturn(Lützkendorf, 2007). So the residential benefit will obviously influence consumers' house-purchase choice. Thus, it is proposed that:

H3: There will be a position relationship between 'Residential Benefit' and 'House-purchase choice.'

There a real breakthrough in green marketing that sustainability can be made the distinguishing factor of choice and a precondition is that sustainability must be communicated in terms of a reliable indicator, preferably in terms of money (Vogtlander et al., 2002). The hypothesis with intent to understand whether will influence the will of buying sustainable building because the cost-effective is considered in the house decision at the current Taiwan. Thus, it is proposed that:

H4: The sustainable building performance will consider the intervening factor of Residential Benefit and has a positive effect on 'House-purchase choice.'

From the result, 'Sustainable Building' can consist of six factors, such as Integrated Environmental Performance, Operating Performance, Waste Reduction, Environmental Loading, Energy Saving and Maintenance; 'Residential Benefit' can include both Quality of Life and Cost Recovery factors. And, tests of 'House-purchase choice' are affected by Sustainable Building is supported by the data and 'Sustainable Building will be through the Residential benefit variable to affect House-purchase intention,' especially the Quality of Life factor as an indirect variable. Therefore, this research shows that the homebuyer will not only satisfy a living demand but also consider the additional Residential Benefit from Sustainable Building on making the House-purchase choice.

3. Analysis

3.1 Sample

This research samples and fills in the questionnaire with the people of 20 to 61 years old. This questionnaire time is from September of 2006 to January of 2007, grants 400 shares altogether, through filtering further, reject and leak and answer, cancel and fill out and select repeatedly, fill out and have illogical invalid questionnaires to answer apparently, it amounts to 280 to count the effective questionnaire; the effective rate of recovery is 70%.

3.2 Factor Analysis

Applying Principal components analysis (PCA) of Factor Analysis, twenty-five items of 'Sustainable building performance' dimension can be extracted to six main factors. The highest factor's explained variance is 25.133%, others are 7.365%, 6.609%, 5.734%, 5.419% and 4.611% in order, and showed there are six factors which Eigenvalues are greater than 1. So it is suitable to keep six factors to explain

'Sustainable building performance' dimension and named 'environmental performance', 'operating performance' , 'waste reduction' , 'environmental loadings', 'energy-saving' and 'maintenance', and the total explained variance is 54.871%, shown in Figure 2.

	Factor	Eigenvalue	Explained variance (%)	Cumulation(%)
1	environmental performance	5.781	25.133	25.133
2	operating performance	1.694	7.365	32.498
3	waste reduction	1.520	6.609	39.108
4	environmental loadings	1.319	5.734	44.842
5	energy-saving	1.246	5.419	50.261
6	maintenance	1.060	4.611	54.871

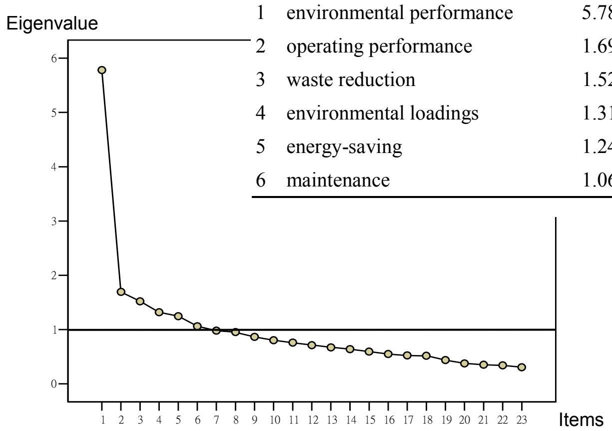

Figure 2 Scree and Eigenvalue of 'Sustainable building performance' dimension

As the same procedure, eleven items of Residential benefit dimension that can be extracted to two factors of 'quality of life' and 'perceived cost return' which explained variance are 46.047% and 11.553% respectively, and the total explained variance is 57.601%.

About the House-purchase choice dimension, only one factor can be extracted, and named 'house-purchase choice.' The total explained variance is 51.653%.

3.3 Satisfaction Analysis

From the satisfaction analysis of measures shown in Figure 3, the means of three factors, of 'environmental performance', 'operating performance' and 'waste reduction', are higher than other factors and their score all are above 4. But, the means of energy-saving and 'perceived cost return' which present the lower level of agreement.

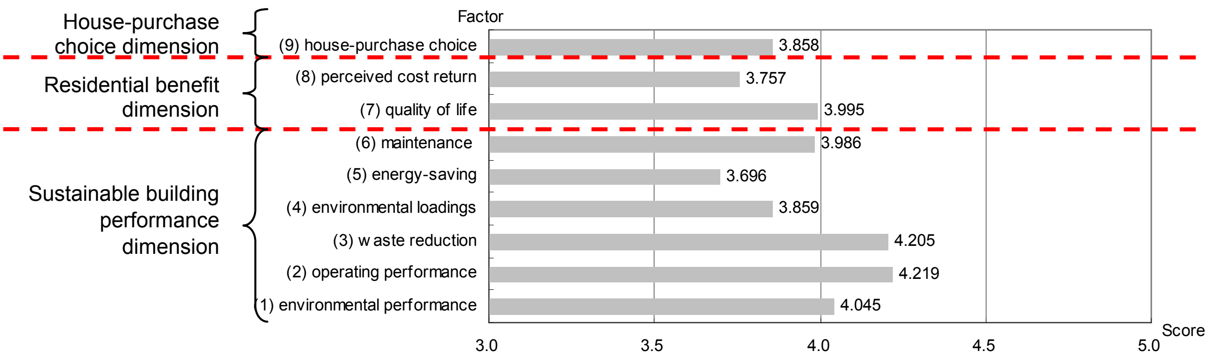

Figure 3 Means of the Factors

4. Validation hypotheses

The hypotheses were tested using correlation analysis, path analysis, AVOVA and linear regression analysis.

4.1 Correlation analysis

In table1, factors inter-correlation indicated there is a statistically significant between the majority factors of 'Sustainable building performance' dimension (environmental performance, operating performance, waste reduction, environmental loadings, energy-saving and maintenance) and 'House-purchase choice' dimension. Thus, this provides most support for hypothesis 1: There is a position relationship between 'Sustainable building performance' and 'House-purchase choice.'

There is also a statistically significant between all factors of 'Sustainable building performance' dimension (environmental performance, operating performance, waste reduction, environmental loadings, energy-saving and maintenance) and two factors of 'Residential benefit' dimension (quality of life and perceived cost return). Thus, this provides total support for the hypothesis 2: There is a position relationship between 'Sustainable building performance' and 'Residential Benefit.'

Quality of life and perceived cost return of 'Residential benefit' dimension have a significant effect on House-purchase choice, and the correlation coefficients are greater than 0.6. This is due, of course, to verify the hypothesis 3: There is a position relationship between 'Residential Benefit' and 'House-purchase choice.'

Table1 Factors inter-correlation

Dimension	Factors	Sustainable building performance						Residential benefit		Purchase
		(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)
Sustainable building performance	(1) environmental performance	1.000								
	(2) operating performance	0.554(**)	1.000							
	(3) waste reduction	0.391(**)	0.371(**)	1.000						
	(4) environmental loadings	0.387(**)	0.429(**)	0.266(**)	1.000					
	(5) energy-saving	0.346(**)	0.348(**)	0.185(**)	0.274(**)	1.000				
	(6) maintenance	0.235(**)	0.137(*)	0.223(**)	0.163(**)	0.096	1.000			
Residential benefit	(7) quality of life	0.554(**)	0.452(**)	0.408(**)	0.372(**)	0.403(**)	0.177(**)	1.000		
	(8) perceived cost return	0.349(**)	0.254(**)	0.242(**)	0.306(**)	0.257(**)	0.131(*)	0.562(**)	1.000	
Purchase choice	(9) house-purchase choice	0.412(**)	0.328(*)	0.334(**)	0.398(**)	0.326(**)	0.097	0.649(**)	0.578(**)	1.000

** p<0.01 for a two-tailed test
* p<0.05 for a two-tailed test

4.2 Path analysis

Via above-mentioned correlation analysis, has accepted hypothesis 1, 2 and 3, is still unable to verify directly the hypothesis 4: The Sustainable building performance will considered the intervening factor of 'Residential benefit' and has a positive effect on the House-purchase choice and acceptance. Also, House-purchase choice has two factors of quality of life and cost return. Therefore, the next discuss adopt the path method and through three measures to test the effect of the intermediary role for House-purchase choice in the model.

4.2.1 Residential benefit Dimension

The four factors of environmental performance, waste reduction, environmental loadings and energy-saving of 'Sustainable building performance' to have the positive influences on 'Residential benefit' which effects are of 0.324(**), 0.172(**), 0.152(**) and 0.193(**), and on 'House-purchase choice' which effects are of 0.202(**), 0.164(**), 0.233(**) and 0.163(**). Moreover, 'Residential benefit' has a high effect of 0.528(**) on 'House-purchase choice'. Apparently these provided the partial support (environmental performance, waste reduction, environmental loadings, energy-saving and maintenance) for the hypothesis 4: The sustainable building performance considered the intervening factor of Residential Benefit and has a positive effect on 'House-purchase choice', as showed in Table2.

However, the two factors of operating performance and maintenance of 'Sustainable building performance' have a low effect on 'Residential benefit' and 'House-purchase choice'. It meant that the two factors (operating performance and maintenance) reject hypothesis 4.

Table 2 Total influence of Sustainable building performance on House-purchase choice

Factor	Sustainable building performance affect House-purchase choice	Sustainable building performance via Residential benefit	Total effect of Sustainable building performance on House-purchase choice
Sustainable building performance (independence variable)	direct effect	indirect effect	Sum of both direct and indirect effect
environmental performance	0.202(**)	0. 171	0.373
operating performance	-0.002	--	--
waste reduction	0.164(**)	0.091	0.255
environmental loadings	0.233(**)	0.080	0.313
energy-saving	0.163(**)	0.102	0.265
maintenance	-0.009	--	--

** p<0.01 for a two-tailed test
* p<0.05 for a two-tailed test

4.2.2 Quality of life Factor

The four factors of environmental performance, waste reduction, environmental loadings, energy-saving and maintenance of 'Sustainable building performance' to have the positive influences on quality of life factor which effects are of 0.321(**), 0.184(**), 0.105(**) and 0.196(**), and on 'House-purchase choice' which effects are of 0.202(**), 0.164(**), 0.233(**) and 0.163(**). Moreover, 'quality of life' factor has a high effect of 0.473(**) on 'House-purchase choice' dimension. Apparently these provided partial support (environmental performance, waste reduction, environmental loadings, energy-saving and maintenance) for the hypothesis 4.

4.2.3 Perceived cost return Factor

The three factors of environmental performance, waste reduction, environmental loadings and energy-saving of 'Sustainable building performance' to have the positive influences on 'perceived cost return factor' which effects are of 0.253(**), 0.184(**) and 0.134(**), and on 'House-purchase choice' which effects are of 0.202(**), 0.233(**) and 0.163(**). Besides, 'perceived cost return' factor has just a medial effect of 0.312(**) on 'House-purchase choice' dimension.

However, the three factors of waste reduction, operating performance and maintenance of 'Sustainable building performance' have not a significant effect on 'perceived cost return' factor and 'House-purchase choice' dimension. It meant that hypothesis 4 is not supported by half factors of 'Sustainable building performance'.

4.3 Structural model

The results and parameter estimates (total effects) are show in table 3. We show in figure 4 are significant total effects between 'Sustainable building performance' and 'House-purchase choice' that is considered the direct effect and indirect effect of the intervening factor of Residential Benefit.

Table 3 Final model results of total effects

Factor	support factors	Path coefficient	Discriminant
H1: There is a position relationship between 'Sustainable building performance' and 'House-purchase choice.'	environmental performance	0.202(**)	Partial support
	waste reduction	0.164(**)	
	environmental loadings	0.233(**)	
	energy-saving	0.163(**)	
H2: There is a position relationship between 'Sustainable building performance' and 'Residential Benefit.'	environmental performance	0.324(**)	Partial support
	waste reduction	0.172(**)	
	environmental loadings	0.152(**)	
	energy-saving	0.193(**)	
H2-1: 'Sustainable building performance' has a position relationship on 'quality of life' factor.	environmental performance	0.321(**)	Partial support
	waste reduction	0.184(**)	
	environmental loadings	0.105(**)	
	energy-saving	0.196(**)	
H2-2: 'Sustainable building performance' has a position relationship on 'perceived cost return' factor.	environmental performance	0.253(**)	Partial support
	environmental loadings	0.184(**)	
	energy-saving	0.134(**)	
H3: There is a position relationship between 'Residential Benefit' and 'House-purchase choice.'	residential benefit	0.528(**)	Support
H3-1: 'Quality of life' has a position relationship on 'House-purchase choice.'	quality of life	0.473(**)	Support
H3-2: 'Perceived cost return' has a position relationship on 'House-purchase choice.'	perceived cost return	0.312(**)	Support
H4: The sustainable building performance considers the intervening factor of Residential Benefit and has a positive effect on 'House-purchase choice.'	environmental performance	0.373(**)	Partial support
	waste reduction	0.255(**)	
	environmental loadings	0.313(**)	
	energy-saving	0.265(**)	
H4-1: Sustainable building performance via 'quality of life' factor to affect House-purchase choice.	environmental performance	0.354(**)	Partial support
	waste reduction	0.251(**)	
	environmental loadings	0.283(**)	
	energy-saving	0.256 (**)	
H4-2: Sustainable building performance via 'perceived cost return' to affect House-purchase choice.	environmental performance	0.275(**)	Partial support
	environmental loadings	0.290(**)	
	energy-saving	0.205(**)	

** p<0.01 for a two-tailed test

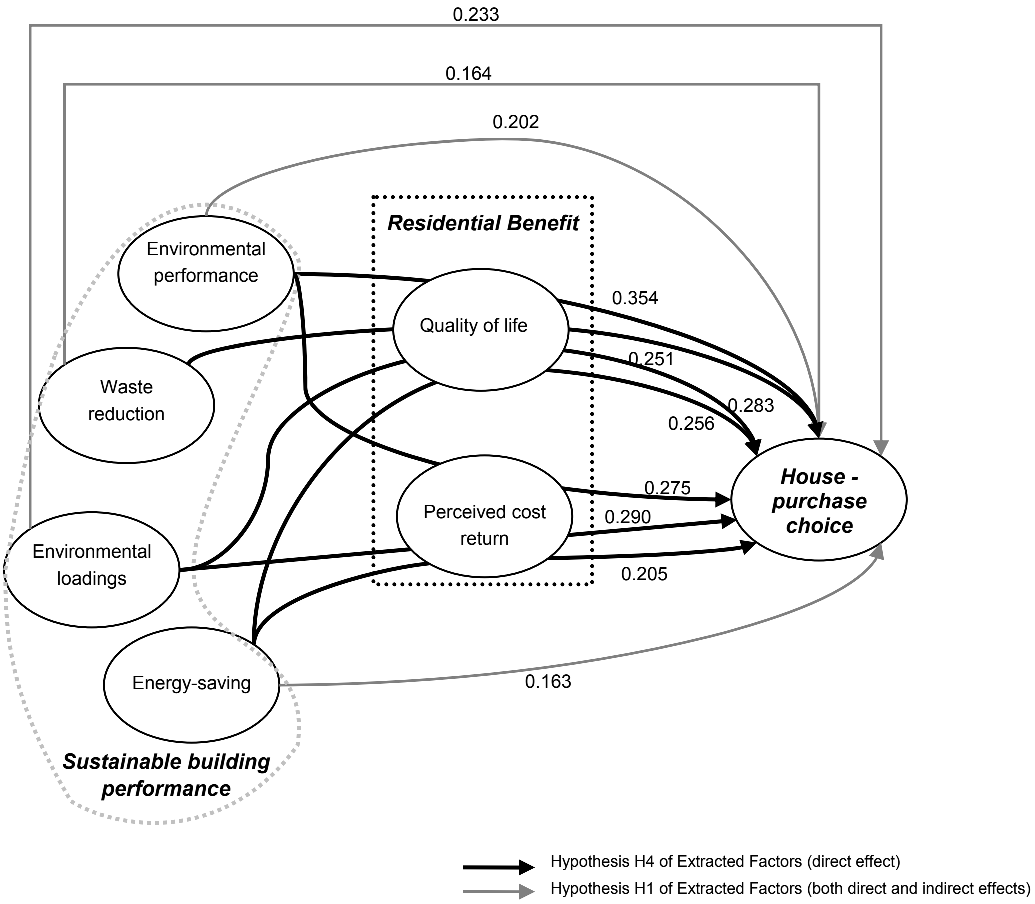

Figure 4 A structural model of effects between Sustainable building performance with House-purchase choice.

5. Conclusion

In this paper we applied the marketing studies to measure the effects of the purchase intentions and willingness of the consumer and the cost–benefit analysis approach (Grace, 2005) on the real estate marketing to structure our conceptual model and hypothesis: the sustainable building product directly affected the house-purchase choice, or considered an intervening factor of the residential benefit.

From the result of factor analysis: 'Sustainable building performance' could be simplified with six factors of environmental performance, operating performance, waste reduction , environmental loadings, energy-saving and maintenance, and 'Residential benefit' also was extracted two factors of quality of life and perceived cost return.

The results verified hypotheses that 'a position relationship between the Sustainable building performances with House- purchase choice.' Meanwhile, it also testified the effects of which sustainable building performance via an intervening factor of Residential Benefit affecting House-purchase choice is specifically higher than the direct effect of which Sustainable building performance affecting Residential Benefit. Besides, the path coefficient for quality of life on affecting Residential Benefit is larger than perceived cost return. Therefore, it is helpful for House-purchase with the highlight of indoor environment quality, surroundings quality, community amenity, sanitation, security, and reducing energy consumption etc.

The results of satisfaction analysis indicated the two factors of operating performance and maintenance obtained the high scores, but the perceived cost return show a low score. It meant the house-purchase consumers have an affirmative attitude on the operating performance and maintenance of 'Sustainable building performance', but they regarded with increasing building cost or expense. Therefore, perceived added cost is a key determinant is meeting house-purchase customers' desires.

Overall, the government, building owners, design teams or developers must highlight and clarify the residential benefit concept of cost return and quality of life when promote the sustainable building policy and implement green building system in Taiwan future real estate marketing.

ECONOMIC INCENTIVES AND BUILDING RATING SYSTEMS IN ITALY

Andrea MORO Arch.[1]

[1] iiSBE, Torino, andrea.moro@iisbeitalia.org

Keywords: building rating systems, economy and finance

Summary

The field of performance rating and labelling is proving to be a very cost-effective way to improve the performance of new and retrofit buildings, since it can induce the industry to raise performance standards. Concerning government agencies and public bodies, the availability of a building environmental assessment tool would improve the policies aimed to promote sustainable building. An innovative system based on financial and economic incentives to promote green building has been launched in Italy, involving public institutions, banks and assurance companies. The core of the incentives system is Protocollo ITACA, a rating tool based on SBTool.

1. Introduction

A modern approach to reducing the environmental impact of buildings tends to involve a broad multi-issue approach, and is usually referred to as a sustainable building model that is the focus of much theoretical and practical activity in both design and performance assessment. The field of performance rating and labelling is proving to be a very cost-effective way to improve the performance of new and retrofit buildings, since it can induce the industry to raise performance standards. Researchers and government agencies consider performance rating and labelling systems as one of the best methods of moving the marketplace towards a higher level of performance. By means of these systems it is not only possible to assess the energy performance and the use of renewable sources but also the performance with regard to other environmental issues like the water and material consumptions, the solid waste and the effluents, the indoor environmental quality, the quality of service. Systems that assess the environmental performance of buildings and provide a certification offer an approach that can induce the private sector to raise performance standards and that allows in the same time the public administration to develop effective policies in the field of sustainable building. Consequently, several are the potential users of a building environmental assessment tool: public bodies, investors, customers, designers, construction companies.

Concerning government agencies and public bodies, the availability of a building environmental assessment tool would improve the policies aimed to promote sustainable building. It means that a clear definition of the green building requirements and the possibility to measure the performance would force the construction industry toward a higher level of sustainability. Regulations could be enforced including this tool and financial incentives could be fixed using the assessment tool to grant the green designs. In the market a financial inducement is likely to be effective in an environment where financial return is a primary objective. Using the core elements of an building environmental assessment tool, the government agencies and the public bodies would have a method to control in a objective and complete way the performance of new constructions and refurbishments. The core elements of the assessment tool could be used as part of building codes, regulations, urban plans or as a basis to grant high performance buildings with financial incentives or tax reductions.

The availability of a building environmental assessment tool in the market could allow the investors, real estates purchasers and tenants to choose the higher performance buildings. A building that has undergone a design process that results in a high level of energy efficiency is likely to be of higher quality, and will have lower operating and maintenance costs. Capital cost and design time increases are modest, and such buildings have been shown to attract desirable tenants. All these factors are very likely to combine to result in a higher long-term asset value. A significant number of other actors should become users of the assessment tools. These include real estate brokers, major development companies with an interest in high performance; banks, architectural and engineering associations. There is also a growing realization that a major jump in performance levels, at least in market economies, will depend on changes in market demand, and that such change cannot occur until building investors and tenants have access to a relatively simple method that allows them to identify buildings that perform to a higher standard. Engineers and architects can also use the system to predict the environmental performance of their designs, before contract documentation is finalized.

2. SB Method and SBTool

iiSBE (international initiative for a Sustainable Built Environment) manages an international activity to develop and test a new method (SB Method) of rating the sustainable performance of buildings, continuation of the Green Building Challenge process. SBTool is the software implementation of the method. The GBC process was begun with *Natural Resources Canada*, but in 2002 responsibility was handed over to the *International Initiative for a Sustainable Built Environment* (iiSBE), an international non-profit organization. In the GBC process, the basic method and software has been developed in consultation with participating national teams, which then modify the generic system to suit their local conditions, and test it on case study buildings. Currently several countries are involved in the process.

The SBTool is a second-generation assessment system; one that is designed from the outset to allow adaptation to the very different priorities, technologies, building traditions and even cultural values that exist in various regions and countries. In order to use the system, national teams must adjust the values and weightings embedded in the system, thereby assuring results that are relevant to local conditions, and then test the assessment system on case study buildings in each country.

SBTool provides approximate assessments of a broad range of potential environmental performance parameters, all related to performance benchmarks that are relevant to the region and building occupancy. SBTool is primarily designed to act as a framework for scoring and weighting, using data that is generated in external models that perform detailed studies or from other similar sources. The final result of the assessment is a score that express the potential environmental performance of the building compared to the minimum acceptable performance for that use and geographic area (benchmark).

One of the most important characteristics of the SBTool is that it is the result of a wide international process, and is designed to be adaptable to specific regional conditions. This means that it is a methodology that could be validly applied in different countries, while maintaining an overall consistency in structure and method. The advantages of having a global standard for building performance assessment are very strong. If meaningful information about performance is to be exchanged between countries, then a uniform definition of performance parameters must be developed, even if the calculation tools providing data on, for example, energy consumption and emissions, vary between countries. Further, the rapid growth of global corporations, and their desire to work to a recognized international standard, give to SBTool a significant commercial importance in the medium term that could help to move the market toward a better sustainability.

3. Protocollo ITACA

In 2001, a working group on green building was established by ITACA, Federal Association of the Italian Regions. One of the main objective of the association is to promote and disseminate the good practices for the environmental sustainability and to develop common policies. The aim of the working group on green building was to establish an objective set of requirements to define “what is” a green building and to study an evaluation method to measure “how green” a building is. The need was expressed by the Public Administration: to improve the green building practice, through different incentives, it is necessary to fix requirements and a rating system. The ITACA working group was composed by the representatives of the Italian Regions, by Environment Park and iiSBE Italia, the local chapter of iiSBE.

The working group decided to base the ITACA new rating system on SBTool, a unique rating tool in that it has followed an approach that places gives local authorities the ability to adapt the tool to their own conditions and priorities. In this respect the needs of Italian Regions is similar to the international pressures that led to an adaptable SBTool framework; a necessity to have a tool that could be adapted to regional characteristics. For this purpose, the weight and benchmark approach has proven to be useful. The result has been the “Protocollo ITACA” that has been officially approved by the Conference of the Presidents of the Italian Regions on January 2004. Actually the “Protocollo ITACA” is the reference rating system of the regional authorities in Italy.

As a consequence of these factors, the “Protocollo Itaca” is strongly based on SBTool. It is hierarchically structured in the same way, with Performance Issues, Performance Categories, Performance Criteria, Performance Subcriteria. The weighting system is the same of the SBTool as the scoring system. All performance criteria and sub-criteria are set within performance scales ranging from –1 to +5, where 0 is the minimum accetable performance in the industry practice. Performance scores refer always to an explicitly declared benchmark. The final result of the application of the protocol is a score ranging from –1 to +5 for the whole building.

4. Economic incentives for SB and Protocollo ITACA

An innovative system based on financial and economic incentives to promote green building has been launched in Italy, involving public institutions, banks and assurance companies. The core of the incentives system is Protocollo ITACA.

Economic incentives are an important mean to encourage stakeholders in the building sector to adopt more sustainable approaches in design, construction and operation

The Protocollo ITACA has an institutional and public value, considering that it is the reference building environmental assessment tool for the Italian regions. Since 2004 the Italian public administrations have at disposal a tool to implement new policies to promote sustainable building, having the possibility to “measure” in an objective way the environmental quality of buildings. By means of an agreement with ITACA, iiSBE Italia has taken the responsibility to update and maintain the Protocollo ITACA, acting as scientific support to the association of the Italian regions. In this way it is assured the connection between the national level (Prototcollo ITACA) and the international one (Green Building Challenge), fact that gives scientific accreditation to the Italian rating system. Many Italian Regions have already adopted the Protocollo Itaca (Piemonte, Lombardia, Friuli Venezia Giulia, Marche, Toscana, Basilicata, Calabria, Liguria) for different scopes. The most recent development concern the use of Protocollo ITACA in both public and private funding programs for sustainable building. A compact and simple version has been developed (12 criteria) for the institutional applications, to facilitate the application of the rating system and its diffusion.

The most important application of Protocollo ITACA is in the framework of the “Social Housing Plan 2006-2012” of the Regione Piemonte. For the first time in a public funding program, it is mandatory for all the building to reach al least a score of 2 (new contruction) or 1 (renovated building). Considering the extra construction costs connected to a better environmental performance, the Region will give an economic incentive of 5.000 euro per apartment. The incentive could be higher in the case of scores superiors to 2 (new constructions) or 1 (renovated building). The “Social Housing Plan 2006-2012” of the Piemonte Region foresee the construction of 10.000 apartments. The total amount of funds for sustainable buildings is 54.000.000 euro. The total public funds available in the social housing plan is 750.000.000 euro. A similar approach has been followed by the Marche and Liguria Regions in their Social Housing Plans. Also in this case it is requested a minimum performance to be included in the plan. The funds for sustainable buildings are 20.000.000 euro per region.

On the private side the Intesa San Paolo Group bank (the major bank group in Italy) has launched in January 2007 a new bank product concerning green building, “Aedifica Bioedilizia”. The purpose is to promote sustainable building by means of funds available for construction companies. Intesa Sanpaolo Group offers preferential rates and conditions reserved to high performance buildings:

- for the company, during the construction stage, euribor 6 months spread range between 0.80% and 1.75% on installment rates depending on the rating expressed by the company
- for private purchasers at loan contracting stage: depending on the specific type of loan
- credit check fees amounting to 0.20% of funding with a minimum 300,00 Euros
- exemption from penalty on installment plan refunds

To obtain the reduction of the interest rate, it is necessary to have the building (that has to be funded) reaching a rating score of at least 2 (for new buildings) or 1 (for renovated buildings) as a result of the application of Protocollo ITACA. If the score is lower, the building is considered not “green” enough to obtain the reduced interest rates from the bank. Should the original eco-sustainability criteria not be complied with, a one-off fee shall be due, amounting to 0.40% of the granted loan and all previously refunded installments.

To further improve this approach, the Piemonte Region has stipulated an agreement with the Intesa San Paolo Group and other 6 banks concerning the possibility for users to obtain reduced home loans. In this case the construction company asks for the interest rate reduction in the name of the future tenants. The Protocollo ITACA has to be applied to assess the environmental performance of the buildings that contains the apartments to be funded.

Also the assurance companies have been involved in the incentives system. Companies are now proposing reduced cost for different kind of policies:

- for builders: construction risk policy and post-built policy;

- for tenants: fire policy and public liability policy.

The discounted policies can be obtained only by buildings rated by Protocollo ITACA (minimum score of 2 for new constructions and of 1 for renovated buildings).

Considering the role of unique scientific support for ITACA on rating systems, iiSBE Italia will act as certification body in the framework of these funding programs. iiSBE Italia is requested to assess the consistency of the assessments carried out by the construction companies that apply for the interest rate reduction or for the economic incentives.

5. Issues

Designers and construction companies are not used to rating system and green building in general. In contexts where green building is new the rating system must be simple, intelligible and easy to apply. A complex and heavy system, also if more correct from a scientific point of view, could cause the failure of the policy. In the context of policies based on economic incentives, training programs for professionals should be foreseen as appropriate supporting tools (handbook, guides, software) and support desks.

The establishment of target performances is a major issue. Too high performance targets in comparison with available funds can produce a failure of the policy. In the same time too loose performance levels don't allow to reach the objective of raising the standard practice. Before launching a policy it is necessary to carry out several studies on green building (existing or simulated) to understand in the specific context what could be the extra cost correlated with the different levels of performance.

It is fundamental to use a rating system adapted or developed in the context of application. The performance scores must be correlated to the local practice and availability of technologies and materials. The use of an "imported tool" would cause major problems.

Keywords: existing building, energy, emissions reduction, trigeneration, cogeneration

Summary

In approaching the refurbishment of the landmark building, 101 Miller Street North Sydney, all aspects of the buildings services were reviewed, including the proposed installation of trigeneration technology, to achieve unprecedented levels of greenhouse gas efficiency from a refurbished commercial office tower. This paper describes how an approach of selective improvement and upgrade of the existing building's services, along with the use of trigeneration technology, improved the energy efficiency, electrical demand management and power supply reliability of the building. The application of trigeneration and its integration into an existing building infrastructure is described. The technical and regulatory complexities of the installation of natural gas powered generators into the existing building envelope and the implications this had for the final system design are highlighted. The paper concludes that the targeted adoption of trigeneration technology, labeled 'Green Transformers' by the City of Sydney Council, has an important role to play as a transitional technology in reducing the greenhouse gas emissions of Australia's existing building stock in the short to medium term.

1. Introduction

101 Miller Street, North Sydney is a landmark 37 700 m^2 office building in the North Sydney central business district. The building was occupied by a single tenant from the completion of original construction in 1992 for 15 years. The tenants' decision to vacate the premise from mid 2007 presented both a significant challenge and rare opportunity for Mirvac to undertake a holistic refurbishment of the building to maintain its premium landmark status and to achieve unprecedented levels of greenhouse gas efficiency from a 15+ year old building.

The design and development process was undertaken with the goal of achieving a 5 star Australian Building Greenhouse Rating (ABGR – now known as NABERS Energy). Accordingly, the building owners have entered into a precommitment agreement with the New South Wales (NSW) Department of Environment and Climate Change to achieve the 5 star rating within approximately 12 months of practical completion of the refurbishment.

2. 101 Miller Street Background

Original construction of 101 Miller Street was completed in 1992. Over the next 15 years the plant was serviced and maintained regularly so that at the time the building was vacated in mid 2007 the plant was generally in very good condition.

During the period 2002 – 2005 the building improved its NABERS Energy rating from 3 to 4 stars through careful tuning and management of the building air conditioning and control systems. This was considered by the building management to be virtually the optimal performance that could be gained from the existing plant and represented excellent performance on the NABERS Energy rating scale.

With the building empty by mid 2007, the owners embarked on a major refurbishment to maintain its landmark status for the next stage of its life.

Figure 1 101 Miller Street

The decision was taken to take the building offline for the refurbishment for a period of approximately 12 months. The following key sustainability goals were set for the refurbishment:

- 5 star NABERS Energy rating (Base Building), representing best building performance.
- Registered for Green Star (Office Design Version 2)
- Provide future tenants with services capable of achieving a 5 star NABERS Energy tenancy rating.

Electricity reliability in the North Sydney area, along with potential tenant concerns about infrastructure, grid demand and the availability of back-up power sources all played a key role in informing the design process.

3. Plant and Services Upgrade Plans

In planning the services upgrade the following issues were identified:

- The existing Variable Air Volume (VAV) air distribution system was in excellent condition, meaning major changes to the HVAC system were neither justifiable nor desirable.
- The lifts system control and motors had suffered accelerated wear due to previous single tenant usage pattern.
- A significant portion of the building upgrade costs were to be invested in the refurbishment of the ground floor lobby and commercial office floors.
- The energy and greenhouse gas efficiency measures needed to be carefully targeted to provide maximum cost and energy benefit whilst still achieving the ambitious targets set.
- Demand reduction is a significant issue for the utility provider in the North Sydney area and as 101 Miller Street is one of the area's major power users, efforts to reduce energy demand would be well received.

In order to maximise the efficiency of the existing plant and services the following energy reduction measures were targeted:

- All new electric motors to be high efficiency type.
- Upgrade primary and secondary condenser water system to variable volume type.
- Upgrade cooling towers fans to variable speed type.
- Upgrade of outside air system to provide increased volume of outside air for free cooling modes.
- Upgrade of power factor correction equipment to reduce maximum demand.
- Upgrade existing cooling water chillers to higher efficiency chillers.
- Upgrading of the existing Building Management System (BMS) to incorporate changes to the control systems necessitated by the plant upgrades and to provide enhanced energy sub-metering and overall control.
- Upgrading of the carpark ventilation systems with variable speed drives and carbon monoxide level based control.
- Installation of high efficiency T5 fittings, high frequency electronic ballasts and intelligent lighting control system with daylight sensing and future motion control.

Modeling of the base building NABERS Energy rating confirmed that the upgrade changes made would increase the rating from 4 to 4.5 stars, representing an increase in greenhouse gas (GHG) efficiency of about 16%. Whilst this was an impressive result for a 15 year old building with a traditional VAV type air conditioning system, it was clear that additional steps would be needed to achieve the targeted 5 stars.

The measures noted above optimised the energy efficiency of the plant and therefore maximised the considerable economic and embodied energy investment in the existing plant.

Mirvac had previous experience with trigeneration from Vision Estate in Glenfield, NSW, a residential housing estate developed in partnership with GridX Power, an Australian energy provider. The system at Vision Estate represented a world first for mass replicable housing, consisting of three onsite natural gas power generators supplying electricity, thermal cooling and heating to a residential estate.

Following on from the success of the Vision Estate project, Mirvac began investigating the potential to install a trigeneration system at 101 Miller Street, and found that this would provide the large increase in greenhouse gas efficiency targeted for the project.

Significant issues needed to be overcome, including the need to adhere to a tight project timeframe, physical space limitations, integrating the system with the grid power and the existing power distribution infrastructure.

4. Trigeneration Solution

Trigeneration refers to the simultaneous generation of electricity, heating and cooling from a single source, such as natural gas.

In the trigeneration system at 101 Miller Street, electricity is generated using a natural gas fired electricity generator. The waste heat from the generator is used to provide thermal cooling for the air conditioning services through the use of an absorption chiller. Absorption chillers use the waste heat to provide the energy to drive the cooling process rather than an electrically-powered compressor in conventional chiller systems. The absorption chiller system is used to supplement the standard electric chillers in the building and accounts for approximately 60% of total cooling capacity.

Gas fired electricity generation without trigeneration loses up to a third of input energy as waste heat whereas a trigeneration plant utilises that waste heat to provide cooling and heating. The combustion of natural gas as opposed to coal fired electricity generation is significantly more greenhouse gas efficient.

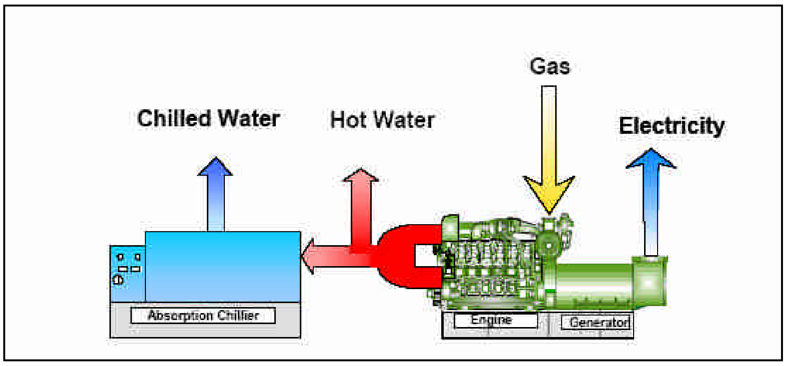

Figure 2 Trigeneration system schematic

Mirvac partnered with Cogent Energy Pty Limited to design, install and operate the trigeneration plant at 101 Miller Street. The installation at 101 Miller Street consists of 2 x 1.2MW natural gas generators and 2 x 750kW absorption chillers and associated control and switchgear, providing peak power of 2.4MW and 1500kW of cooling capacity.

Considerable time and consultation was undertaken with Energy Australia (EA), the grid operator, to agree and finalise the way in which the trigeneration system would interface with the grid. The option to export power to the grid was considered, however due to concerns expressed by EA with regard to potential upstream issues this was eventually discounted. The benefit of being able to export to the grid is that the gas engine can continue to run at maximum efficiency during low load periods by exporting surplus energy.

Consequently the size of the plant was limited by the need to ensure the natural gas generator maintained an efficient operating load. Notwithstanding this, the benefits to future tenants and the surrounding areas will include;

- Parallel import operation of the natural gas generator plant to ensure backup from the grid in case of natural gas generator failure.
- Targeted best practice 5 star NABERS Energy performance.
- Lower power costs for the building owner and tenants.
- Reduction in North Sydney peak demand by up to 3MVA @ 0.8 power factor, reducing stress on power supplies in the area.

Careful planning was required to physically fit the plant into the building as well as to ensure compliance with stringent standards regarding Nitrous Oxide (N_2O) emission, which are produced by the natural gas generator. A significant lead time of over 12 months was required to obtain an Environmental Protection

Agency (EPA) license for the site. N_2O emission modeling was undertaken to demonstrate that emissions were within required EPA limits.

A potential barrier to implementing trigeneration more broadly is the lack of regulatory certainty regarding treatment of exhaust gases, particularly for larger generators. Greater clarity in this area will provide necessary confidence to encourage investment in this low carbon emission technology.

The support of the NSW Department of Planning in the form of a $400,000 grant to assist in the cost of installation was obtained in recognition of the positive impact the installation would have in reducing grid peak demand in the area. The first new tenants at 101 Miller Street are expected to commence occupancy in June 2008 and the trigeneration plant will be providing demand reduction benefits by the 2008/09 summer period.

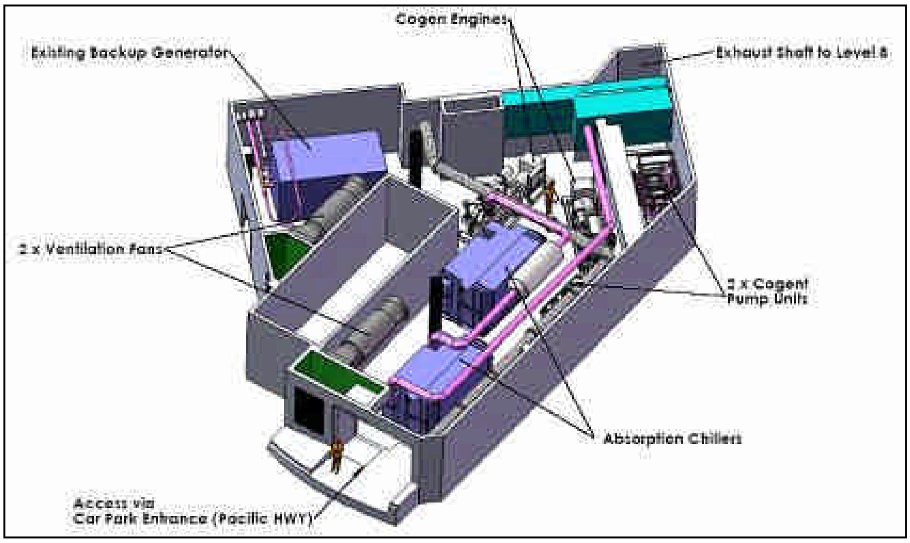

Figure 3 Trigeneration System Plantroom Layout

5. Conclusions

The evaluation and application of a wide range of good engineering practices and technologies within an existing building has resulted in a highly efficient building achieving best practice levels of GHG performance using low risk, proven technologies with a track record of success. Additional benefits include a reliable low cost energy supply for the base building and tenancies, along with power grid demand reduction.

The establishment of a carbon pollution reduction scheme, along with a raft of complementary policy measures is placing a new level of pressure on the built environment to improve GHG efficiency in short time frames. Improving the GHG efficiency of the existing building stock will play a central role in reducing sector-wide emissions.

High costs, and difficulties associated with major refurbishments of existing building services will continue to be a major barrier to progress on emissions reductions. With these barriers in mind, trigeneration and cogeneration technology is a realistic option in some cases to supplement energy efficiency measures in the existing building stock and beyond.

Trigeneration importantly provides replicable, immediate-start technology, to assist in driving the property and energy sectors towards a low carbon future. This highly efficient system provides industry with an important buffer, by significantly reducing GHG emissions in the immediate-term, while awaiting the development and commercialisation of future low emission technologies over the medium and longer-term. Australia's abundance of natural gas means that the technology is applicable broadly and well into the immediate future. The additional demand reduction and reliability benefits of decentralised power generation provide additional incentives for utility providers and planners to encourage the targeted adoption of these technologies.

To encourage the use of cogeneration and trigeneration technology, a number of regulatory and integration issues, including grid export, and exhaust emission levels need to be clarified and certainty provided. The ability to export trigeneration energy to the grid should be encouraged to provide flexibility and maximise the efficiency in the running of the plant, whilst ensuring the integrity of the grid.

The "Sustainable Sydney 2030 – City of Sydney Strategic Plan" recently released by the City of Sydney Council identified cogeneration and trigeneration, termed Green Transformers, as being key component to their vision of cutting emissions by 70% on 2006 levels by 2030. The trigeneration system at 101 Miller Street provides an example of how this vision can be realised.

THERMAL STORAGE-AN EVALUATION OF THE THERMAL PERFORMANCE OF THE BRIGHTON EARTHSHIP

Andrew MILLER BSc. PhD. CEng. MCIBSE[1]
Kenneth IP MSc. PhD. CEng. MCIBSE[1]

[1] Centre for Sustainability of the Built Environment, University of Brighton, UK. a.miller@brighton.ac.uk

Keywords: thermal storage, autonomous, sustainable building, rammed earth, earthship

Summary

The Brighton Earthship is an autonomous building, built on the outskirts of the city on the south coast of the UK. Based on the design philosophy of Mike Reynolds it incorporates 'glass and mass' to permit solar gain and develop long term thermal storage. The thermal store is constructed of rammed chalk utilising end of life car tyres as formers to build the wall. The Earthship was built as a demonstration project and visitor centre for the Low Carbon Network and is the first of its type to be built in the UK.

This paper describes the design principles of an earthship and in particular the use of thermal mass to achieve seasonal energy storage. It reports on long term thermal measurements within the thermal store and demonstrates the heat transfer pattern between the store and the internal space.

1. Introduction

The resources of planet earth, energy, water and materials are finite and must therefore be treasured and used wisely. The term earthship was coined by the architect Michael Reynolds whose design philosophy is to produce buildings that produce no stress or depletion of these resources. Earthships are designed to be autonomous through rainwater harvesting, grey water recycling and on site treatment of black water before disposal and to optimise the use of waste stream and re-used materials for construction. The philosophy is captured by the statement 'The EARTHSHIP is a participant in the prevailing systems of the planet Earth. It causes no conflict, no stress, no depletion, no trauma' (Reynolds 1990). The vision of the earthship inventor included the provision of affordable houses that could be constructed by 'self-builders' from easily available materials, preferably waste from other activities. It uses old car tyres as the basic building block, rammed with the earth removed from the construction site.

The Brighton Earthship has taken these design principles for the construction of a visitor centre within Stanmer Park Brighton. It has been constructed, primarily with volunteer labour, by the Low Carbon Network. It is the first of its kind in the UK and the Centre for Sustainability of the Built Environment (CSBE) at the University of Brighton has monitored its progress and installed instrumentation to evaluate its thermal performance.

The thermal performance of the building is based around the principles of glass and mass. It incorporates large areas of south facing glass backed by a thermally heavyweight structure. The thermal mass is provided primarily by the tyre wall to the rear of the building. This wall is constructed from used tyres rammed with chalk, thus adopting a waste product as a construction material.

The thermal store is at the rear of the building (to the north in the northern hemisphere) with the front elevation constructed primarily of glass to admit maximum solar radiation. The angle of glass in the front elevation is optimised to maximise the transmittance of winter solar radiation as illustrated in Fig. 1.

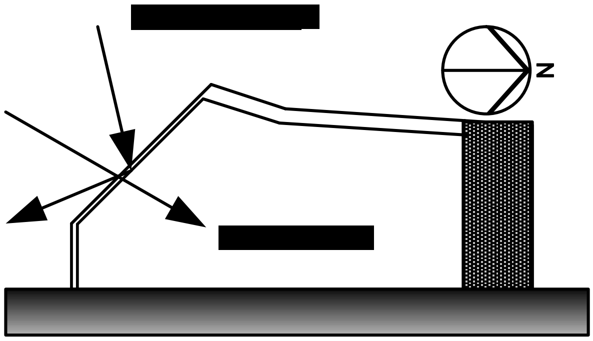

Fig.1 Solar transmittance to earthship

2. The Brighton Earthship

The original earthship design was developed and constructed in Taos, New Mexico, however since then there have been several demonstration projects in other countries. The Brighton Low Carbon Network, responsible for the construction of the Brighton Earthship, was formed after a talk given by Mike Reynolds, in April 2000 in Brighton. Funding and planning permission allowed work to begin in Stanmer Park, on land owned by Brighton and Hove City Council in July 2002. Initial training for the construction was provided by the American construction team.

The Brighton Earthship (Fig.2) is essentially made up of three main rooms, the conservatory and the main living area including kitchen and bathroom internal partitions, usually referred to as the 'nest', and the hut which provides additional living accommodation.

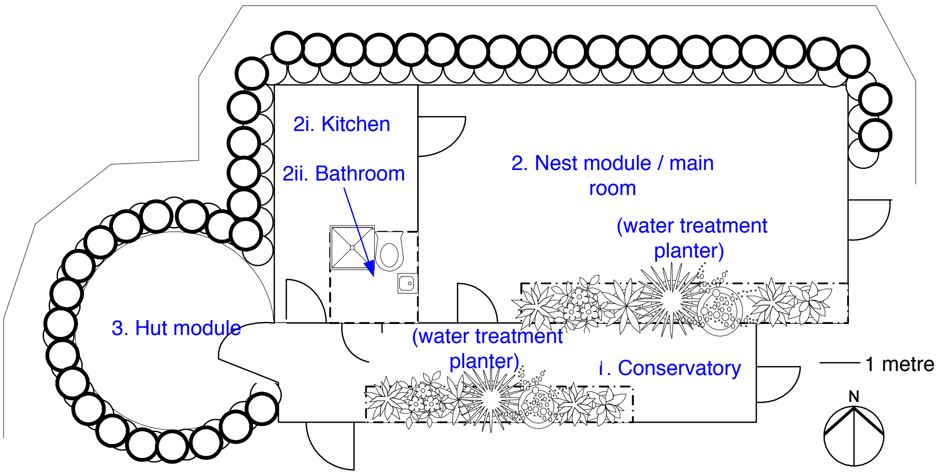

Figure 2 Plan of the Brighton Earthship

The internal area of the main part of the building is 80m^2, with the hut adding a further 12m^2. The thermal store which wraps around the back of the main area is approximately 135m^3 of rammed chalk.

2.1 Temperatures measurements in the tyre wall

The construction of the thermal storage to the rear of the building consists of the tyre wall plus a further thickness of approximately one metre of rammed chalk before a layer of insulation and waterproof membrane separates the structure from the surrounding earth.

Temperature sensors were installed in the tyre wall to the rear of the main living space. They were positioned at heights of 0.63m, 1.26m and 1.89m above floor level inside the building and at depths of 250mm, 500mm and 750mm into the thermal store, as illustrated in Fig. 3. There is therefore a matrix of nine sensors installed to establish temperatures in the thermal store in the living area. A second matrix of sensors have been installed in the kitchen wall.

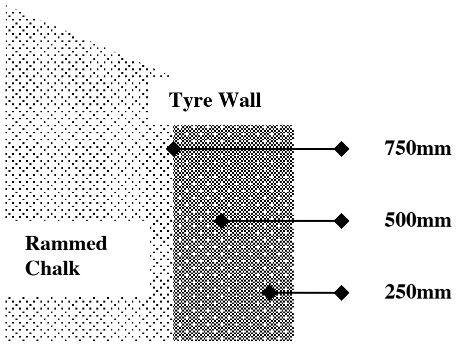

Fig.3. Temperature sensors in the thermal store

3. Thermal Storage

The thermal capacity of building materials is often utilized to maintain thermal comfort in buildings. Thermally heavyweight construction dampens swings in internal temperature taking longer to preheat and longer to cool down than lightweight buildings. It is often used to advantage for domestic buildings storing daytime heat gains to be utilized later in the day when space heating is required. It has a further advantage in the summer of absorbing peak gains and reducing the likelihood of overheating in highly insulated buildings. Thermal capacity therefore is commonly used for diurnal heat storage and can be beneficial in reducing space heating energy consumption.

Earthship design utilizes the thermal capacity of the construction materials that have been selected to develop seasonal rather than diurnal heat storage. The thermal store is charged throughout the summer absorbing solar radiation and incidental gains from the inside of the building. Heat from the store is gradually released during the winter months maintaining comfort temperatures inside of the building.

Anecdotes from occupants of the original earthships in Taos New Mexico have suggested that it has taken over two years to achieve thermally comfortable conditions in winter. The thermal store has taken two years to become fully charged. In practice however it is possible to charge the store using portable heaters prior to occupation.

The flow of heat into and out of the store will be dependent upon many factors including the exposed area, the temperatures maintained and the activity within the building. One of the aims of this research is to understand more of the interaction of the thermal store to enable better consideration of the required size of the store for use within the UK climate.

4. Results

The Brighton Earthship has been constructed as a visitor centre and as such experiences different internal gains from those of an occupied house. It also has different requirements with respect to thermal comfort conditions and ventilation compared with a family dwelling. Monitoring at this stage however is simply to identify the natural thermal performance of the building and the thermal store.

4.1 Average temperatures in the tyre wall

In Fig. 4 the average of all nine sensors in the tyre wall is presented, indicating the overall performance of the thermal store. During the period between November and early spring the store temperature dropped by over 5^{o}C and rose to a peak of over 9^{o}C above this by late summer. At the end of the first 12 months monitoring the store remained 2^{o}C higher than at the beginning. In addition the minimum temperature of the store during the second March was higher than the first, indicating that the store is charging.

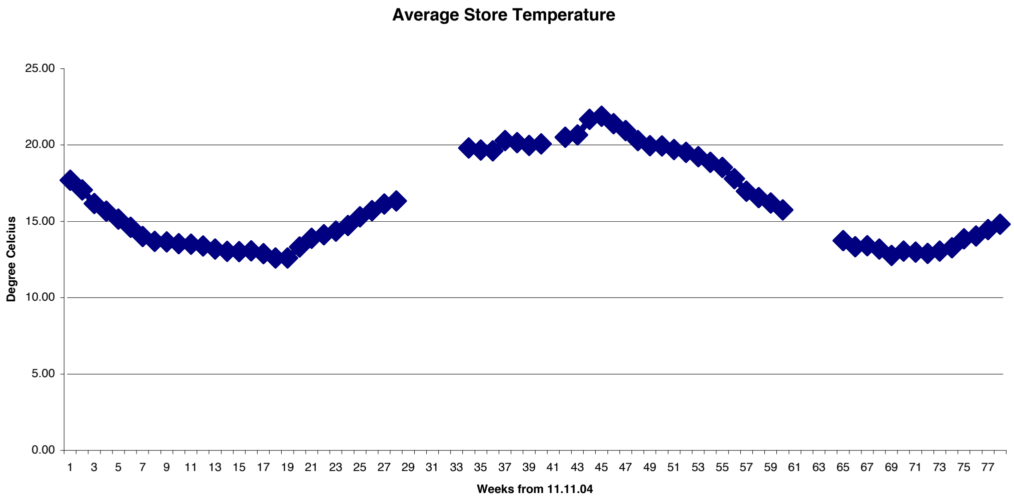

Fig. 4. Average temperatures in the thermal store

4.2 Vertical temperature gradient in the store (floor upwards)

The average temperatures within the store provide an overall view of when the store is receiving and when it is supplying heat. Further analysis of the individual temperature sensors within the wall demonstrate the pattern of heat storage.

The vertical temperature gradient within the store, measured at 0.63m, 1.26m and 1.89m above the floor, demonstrates the means by which the store is being charged as seen in fig. 5.

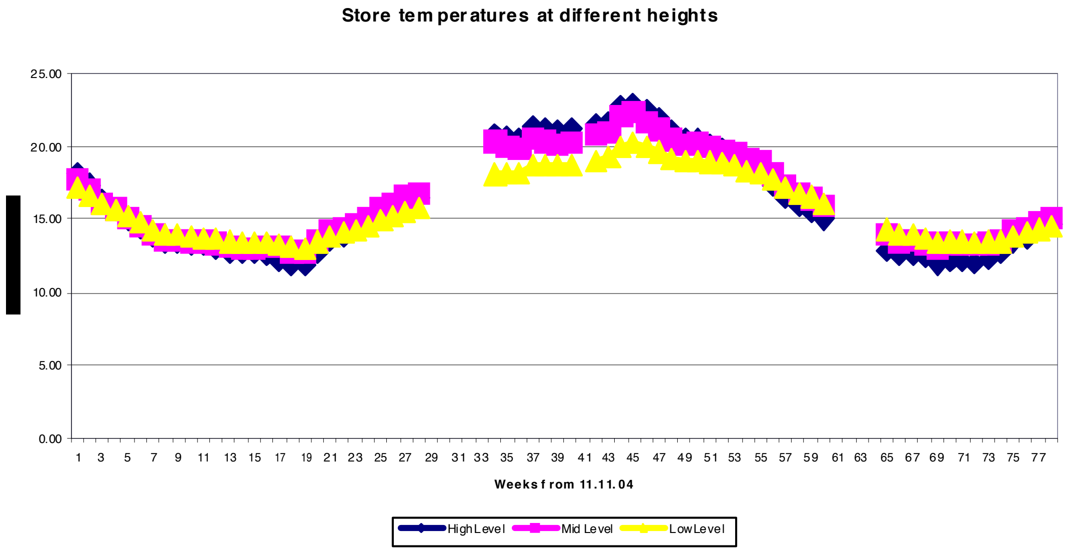

Fig. 5. Vertical distribution of temperature in the thermal store

Initial temperatures of all sensors are very similar demonstrating the uniformity of conditions. However as monitoring progresses during the winter it is the higher points in the store that show lower temperatures. Further, during the summer months the higher points in the store prove to be higher than the others.

Temperature swings at the top of the store are greater than in other parts, reaching a maximum of over 23^{o}C in September and a minimum of just below 12^{o}C in March.

These conditions may be explained by the configuration of the store and the internal space, because the earthship is built on a sloping site with the top of the store being ground level at the back of the building and consequently exposed to the external climate (Fig. 6). However the top level of the thermal store is highly insulated and should therefore be largely unaffected by the external climate. The resulting conditions are therefore in need of further investigation.

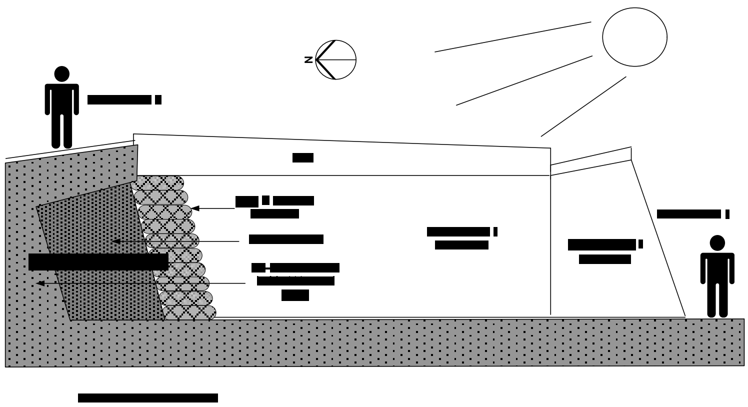

Fig. 6. Exposure of thermal store at ground level

4.3 Horizontal temperature gradient within the tyre wall

The temperature gradient measured by the sensors at different depths away from the wall surface is an indication of whether heat is flowing into the store from the room or back from the store into the room. (Fig. 7)

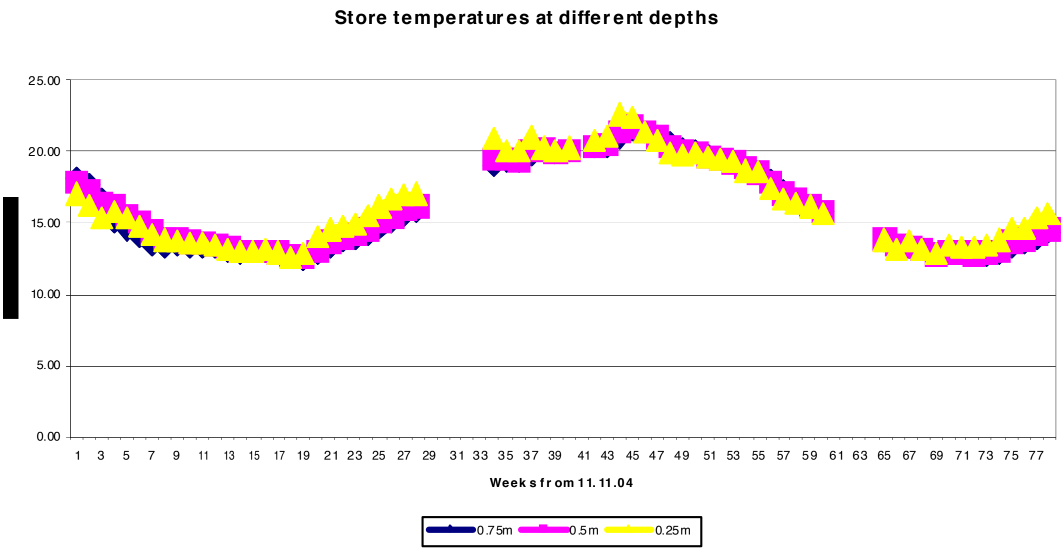

Fig. 7 Horizontal temperature gradient in the thermal store

The initial pattern of temperatures gives little indication as both shallow (250mm) and deep (750mm) sensors are lower than the one at 500mm and the relative conditions change until early February when temperatures at all depths are very similar until early spring. At this point there is a clear gradient from shallow to deeper sensors with the temperature nearest the surface being highest and changing more rapidly. The thermal store is therefore charging, with heat being conducted from the higher surface conditions to the lower temperatures within the wall. The current analysis has been based upon weekly average temperatures within the store but further analysis of diurnal fluctuations will give a more detailed understanding of how the thermal store is charging and discharging.

At the beginning of October, the direction of the gradient appears to change, with the shallow temperatures being lower than the deeper ones. Heat is being conducted from the store towards the room in order to maintain stable conditions within the space.

4.4 Energy stored in the tyre wall

It has not been possible to evaluate the full extent of the thermal storage as it has only been practical to install sensors up to a depth of 750mm into the wall and in a limited number of positions. Further, the analysis to date has been based primarily on the sensors buried in the wall to the rear main room. However, it is reasonable to assume that the results are indicative of conditions within the entire thermal store which wraps around the kitchen, as well as the back and side of the main room. This represents a total volume of 135m^3.

Estimation of the thermal capacity of the wall at this stage is based simply upon published figures for the thermal capacity (1.1 kJ/kg ^{o}C) and density (2500 kg/m^3) of chalk (ArupGeotechnics 2002). It is appreciated that there are dangers with using these simple assumptions because of the composite nature of the wall including tyres and chalk, and of the lack of data with respect to the density of compaction or moisture content of the finished wall. However they enable the order of magnitude of energy storage to be considered.

Based on the above assumptions, the thermal capacity of a 135m^3 chalk store is 370MJ/^{o}C. The Brighton earthship store, which showed an average 2^{o}C rise over the first year of measurement, has therefore captured 740 MJ more than it has released over that time period.

The continuing monitoring and analysis will include both internal air temperatures and incident solar radiation, but given the unpredictable occupation pattern and level of activity it has not been considered appropriate to attempt this analysis to date.

4.5 Energy flows into the tyre wall

During the weeks from November through to the end of March the average temperature of the thermal store dropped steadily by a total of 5^{o}C. This represents a reduction of 1850 MJ. At its peak by mid September the store temperature had risen 9^{o}C and had therefore taken in 3330 MJ, but by the end of October had dropped 2^{o}C and emitted 740MJ.

Examination of the temperatures at a horizontal depth of 250mm into the wall shows them to be above the temperatures at 500mm and 750mm throughout the period when the average temperatures are rising. This demonstrates that the heat energy is flowing into the wall at this stage storing the incident solar radiation and internal gains.

5. Conclusion

The Brighton earthship has provided the Centre for Sustainability of the Built Environment at the University of Brighton the opportunity to gain real time measurements within the thermal store of a building designed on the principles of ‘glass and mass’. The unfinished nature of the building has meant that the results are not representative of an occupied building, however the results clearly indicate the nature of energy flows to and from the store.

The next stage in the analysis is to evaluate energy flows accounting for the external climate conditions including incident solar radiation and the temperatures within the occupied space. Monitoring will continue at least until steady cyclic conditions are achieved within the store and an assessment of whether additional winter heating will be required for an occupied building.

Development is also in progress to produce a computerised thermal model of an earth sheltered building in order to enable further analysis and optimisation of the thermal capacity and heat transfer properties of the store.

Keywords: thermal insulation, thermal bridge, energy, floor radiant heating, IIS (Internal Insulation System), EIFS (External Insulation and Finish System

Summary

In apartment buildings, which are the most common type of residential buildings in Korea, hot water pipes used for heating are installed on the slab. The IIS (Internal Insulation System) is typically applied in most Korean apartment buildings. Consequently, there are many cases in which the layer of insulation is disconnected by the structural components at the joints of the wall-slab and wall-wall in the envelope. These joints become thermal bridges where the risk of inside surface condensation and heat loss increases. In particular, the amount of heat loss is significant at joints that are adjacent to hot water pipes used for heating. It is expected that the EIFS (External Insulation and Finish System) is the solution to this problem. In this study, a survey is carried out on the condition of EIFS in the current market. The front wall-slab joint and the side wall-slab joint of an apartment building that has been recently completed were selected as typical thermal bridges. The annual heat loss through each joint in both cases of applying IIS and EIFS was evaluated by a heat transfer simulation. From the results, it was found that the application of EIFS to the front wall-slab joint could reduce the amount of insulation by 47.2% and reduce the annual heat loss by 4.2%. In the case of the side wall-slab joint with EIFS, a 29.7% decrease of annual heat loss was obtained by increasing the amount of insulation by no more than 4.9%.

1. Introduction

Due to greenhouse gases and global warming problems, endeavours have been made in many countries around the world to construct more energy efficient buildings. In the past, the emphasis was placed on energy conservation within buildings for economical reasons alone. However, environmental reasons have recently become an important global issue. In Korea, the degree of self-sufficiency in energy is no more than 3.2%, yet it is ranked as the 10th largest annual consumer of energy in the world. The energy consumption in Korea has been increasing by 5.1% every year since 1990. In 2005, energy consumption in buildings constituted approximately 25% of the total domestic energy consumption, while the energy consumption in apartment buildings, which are the most common type of residential buildings in Korea, constitutes about 36% of the total energy consumption in buildings.

Compared to commercial buildings, apartment buildings have lower internal heat gains from occupancies, lighting and equipment and are dominated by the envelope load. Therefore, the heating load is significantly larger than the cooling load in the Korean climate, while thermal insulation is a very important factor to consider. In addition, the conductive heat transfer should be reduced through the envelope because hot water pipes that are used for radiant heating are typically installed on the slab in Korean apartment buildings. The internal insulation system (hereafter IIS) has been typically applied to most Korean apartment buildings since the first modern apartment building was built in the early 1960s. Thus, there are many cases in which the layer of insulation is disconnected by structural components at the joints of the wall-slab and wall-wall in the envelope. These joints become thermal bridges where the risk of inside surface condensation and heat loss increases. In particular, the amount of heat loss is considerable at joints adjacent to hot water pipes for heating. Conversely, the external insulation and finish system (hereafter EIFS) can prevent the occurrence of the thermal bridge, by fully continuing the insulation at the joints of the wall-slab and wall-wall in the envelope. In addition, this is expected to increase the heating efficiency because thermal mass such as a concrete wall is placed inside the insulation (see Figure 1).

Because apartment buildings are the most common type of residential buildings in Korea, whereby the same or similar details are repeated, it is expected that there is significant potential to save the heating energy consumption by applying the EIFS. However, there are very few apartment buildings where EIFS has been applied. It is a consequence of the reluctance of the construction industry to take risks involved in a new system and the lack of concern for energy conservation. Thus, in this study, the aim was to verify the feasibility of EIFS in terms of energy conservation. The condition of EIFS in the current market was surveyed. The front wall-slab joint and the side wall-slab joint of the recently completed "E" apartment building were selected as the most common type of thermal bridge. The annual heat loss through each joint in both cases of applying IIS and EIFS was evaluated by a heat transfer simulation.

2. Present condition of EIFS on the market

EIFS is installed on the structure in the order of insulation board → base coat with reinforcing mesh → finish from inside to outside. On the basis of the fixing method, EIFS can be divided into two types, that of an adhesively fixed system and a mechanically fixed system. In the adhesively fixed system, the insulation board is fixed with adhesive. In a mechanically fixed system, tracks are inserted into the insulation board which is fixed with tracks and a small amount of adhesive. A ventilated EIFS is also available, which eliminates moisture through an air cavity and is an integrated system combining the insulation board with the finish material. In Korea, the adhesively fixed system is most often applied, and polystyrene foam is used for insulation material (see Table 1 and Table 2).

3. Annual heat loss evaluation in both cases of applying IIS and EIFS

3.1 Evaluation overview

The front wall-slab joint and the side wall-slab joint at the typical floor of the "E" apartment building were selected for the evaluation. IIS was applied to the "E" apartment building, which was recently completed in Seoul, Korea. The annual heat loss through each joint in both cases of applying IIS and EIFS was calculated by a three-dimensional annual transient heat transfer simulation. The Physibel Voltra 6.0W was used as a simulation tool. The Physibel Voltra 6.0W is a multi-purpose commercial code based on the finite difference method.

3.1.1 Modeling

The front wall-slab joint and the side wall-slab joint are shown in Figure 2. Both of these are typical thermal bridges that appear repeatedly in apartment building envelopes. For the front wall-slab joint, it was assumed that the expanded balcony type floor plan was applied. A PVC framed double glazing window system was applied to this joint. Vertical section drawings for both cases of applying existing IIS and EIFS are shown in Figure 3. In the case of the existing IIS, it can be seen that mineral fibre insulation of thickness 60mm and depth 1,515mm is additionally installed under the slab to reduce heat loss due to the thermal bridge. Figure 4 shows the simulation model. As Physibel Voltra is for a three-dimensional transient heat transfer calculation only, simulation model was built by extending two-dimensional section as shown in Figure 3 to the direction of z axis by 1,000mm. The guardrail, which supposedly has almost no influence on heat loss, was ignored and the section of window frame was simplified for the convenience of calculation. Vertical section drawings of the side wall-slab joint in both cases of applying existing IIS and EIFS are shown in Figure 5. In the case of the existing IIS, it can be seen that expanded polystyrene extruded insulation of thickness 15mm and depth 480mm is additionally installed under the slab to prevent inside surface condensation caused by the thermal bridge. Figure 6 shows the simulation model. It was assumed that mineral fibre insulation was applied to the wall of both joints, considering that the requirements for fire-resisting qualities have been increasing. In addition, it was assumed that the adhesively fixed system was applied in the case of EIFS.

3.1.2 Simulation conditions

After modelling the area to be evaluated with CAD data, the annual heat loss at the inside surface of the simulation model was calculated under the condition that hot water was supplied according to the heating schedule. Here, heat loss implies the sum of the heating load and the lost heat through the envelope among the heat supplied by hot water for heating. The annual hourly standard weather of Seoul was used for setting the outside temperature. Boundary conditions are shown in Table 3. Air cavities were set as BC_FREE, which is the boundary condition type for enclosed cavities of unknown air temperature. In this condition, convective and radiative heat transfer is calculated using equations below.

$$q_c = h_c \times (\theta_a - \theta_s) \quad (1)$$

q_c : Convective heat flow density(W/m^2) h_c : Convective heat transfer coefficient (W/m^2°C)

θ_a : Air temperature(°C) θ_s : Surface temperature(°C)

$$q_r = F_{ij} \times h_{rb} \times (\theta_i - \theta_j) \quad (2)$$

q_r : Radiation density(W/m^2)

F_{ij} : Geometric view factor from surface i to surface j $(0 \le F_{ij} \le 1)$

h_{rb} : Black radiation heat transfer coefficient(W/m^2°C)

θ_i, θ_j : Surface temperature(Surface i and j)(°C)

A hot water supply schedule for radiant heating is shown in Table 4. It is difficult to create a schedule for the generalization of hot water supply because there is an individually controllable heating system for each residential unit and the thermal requirements of the residents are considerably varied. The hot water supply schedule was therefore generalized, based on the previous study regarding a hot water supply pattern for the apartment building with the lowest outside temperature in Korea. Water temperature while heated was set to 65°C. Hot water cools gradually while not heated and its temperature should be calculated. However, water temperature of every time step must be specified to make its temperature function in Physibel Voltra. Due to this limitation of Physibel Voltra, water temperature while not heated was compelled to set to the inside air temperature for adding no heating or cooling loads. Considering that the objective is to compare the IIS with the EIFS under the same condition, modelling in this manner is supposed to be allowed. Calculation parameters and material properties are shown in Table 5 and Table 6, respectively. In order to increase the accuracy of the calculation result, all the properties of materials for EIFS only were measured at the Korea Testing and Research Institute for Chemical Industry.

Table 3 Boundary conditions

Month	Inside		Outside	
	Temperature (°C)	Surface heat transfer coefficient (W/ m^2°C)	Temperature (°C)	Surface heat transfer coefficient (W/ m^2°C)
Dec. to Feb.	20.0	5.8	Dry bulb temperature in standard weather data of Seoul	34.0

	Finish	0.196	1,521	965

3.2 Annual heat loss evaluation results

3.2.1 Front wall-slab joint

The volumes of insulation installed in the simulation models are 0.159 m^3 for IIS and 0.084 m^3 for EIFS, indicating that EIFS has 47.2% less insulation. Thus, it is expected that the heat loss of EIFS might be more than that of IIS, even though the heat loss could be reduced with EIFS due to the thermal bridge. However, the annual heat losses of IIS and EIFS are 1,586,945.3 MJ and 1,520,282.4 MJ, respectively, which indicates that EIFS has 4.2% less annual heat loss (see Table 7). Consequently, the heat loss through the thermal bridge adjacent to hot water pipes used for heating is significantly large in the existing IIS. Thus, it is concluded that the application of EIFS to the front wall-slab joint is very efficient in terms of both the amount of insulation and energy conservation. Figure 7 shows the temperature distribution of the front wall-slab joint at the time (05a.m. 6th Jan.) of the lowest outside temperature (-12.3°C) in the year.

Table 7 Monthly and annual heat loss (MJ) and the volume of insulation (m^3)

Month	Front wall-slab joint		Side wall-slab joint	
	IIS	EIFS	IIS	EIFS

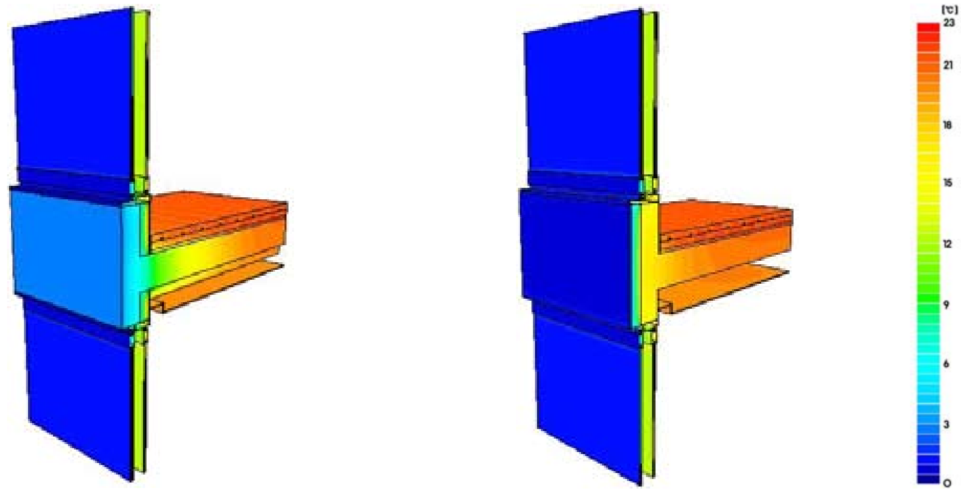
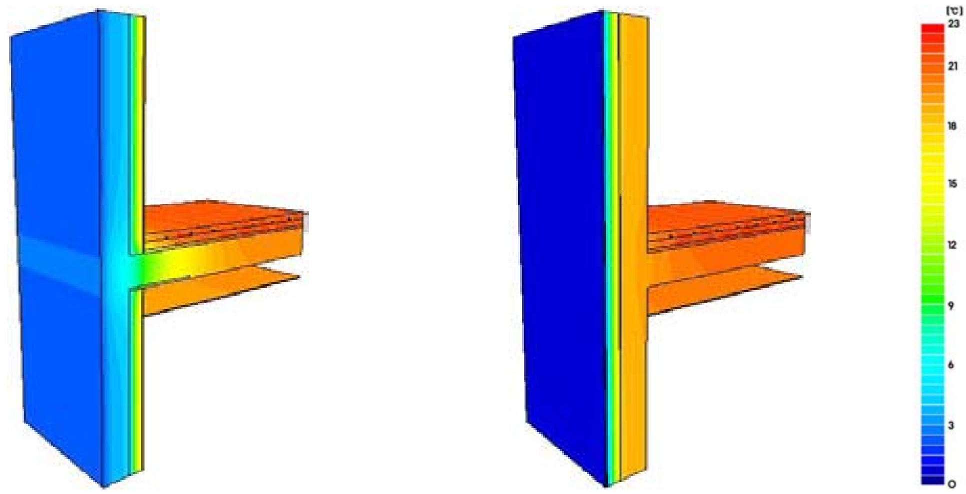
Nov.	186,382.9	178,907.9	54,092.1	37,861.2
Dec.	253,073.2	242,964.1	74,279.5	52,055.8
Sum	1,586,945.3 (0.0%)	1,520,282.4 (-4.2%)	463,864.6 (0.0%)	325,886.6 (-29.7%)
Volume of the insulation	0.159 (0.0%)	0.084 (- 47.2%)	0.286 (0.0%)	0.300 (+ 4.9%)



(a) IIS (b) EIFS

Figure 7 Temperature distribution of the front wall-slab joint at the time of the lowest outside temperature



(a) IIS (b) EIFS

Figure 8 Temperature distribution of the side wall-slab joint at the time of the lowest outside temperature

3.2.2 Side wall-slab joint

The volumes of insulation installed in the simulation models are 0.286 m^3 for IIS and 0.300 m^3 for EIFS, indicating that EIFS has 4.9% more insulation. The annual heat losses of IIS and EIFS are 463,864.6 MJ and 325,886.6 MJ, respectively, indicating that EIFS has 29.7% less annual heat loss (see Table 7). Thus, it is concluded that the application of EIFS to the side wall-slab joint is very efficient, because a 29.7% decrease of annual heat loss is obtained, with an increase in the volume of insulation by no more than 4.9%. Figure 8 shows the temperature distribution of the side wall-slab joint at the time (05a.m. 6th Jan.) of the lowest outside temperature (-12.3°C) in the year.

4. Conclusions

In apartment buildings, which are the most common type of residential buildings in Korea, hot water pipes used for heating are installed on the slab. IIS is typically applied to most Korean apartment buildings. Consequently, there are many cases where the layer of insulation is disconnected by the structural components at the joints of the wall-slab and wall-wall in the envelope. These joints become thermal bridges where the risk of inside surface condensation and heat loss increases. It is expected that EIFS is the solution to this problem. Based on the market survey, the general types of EIFS were investigated. The front wall-slab joint and the side wall-slab joint of a recently completed apartment building were selected as typical thermal bridges. The annual heat loss through each joint in both cases of applying IIS and EIFS was evaluated by a heat transfer simulation. From the results, it was found that the annual heat loss through the thermal bridge adjacent to hot water pipes used for heating was significantly large in the existing IIS, even though additional insulation was installed under the slab in order to reduce heat loss. It was found that, compared with the existing IIS, for the front wall-slab joint with EIFS, not only was the amount of insulation reduced by 47.2% but the annual heat loss was also reduced by 4.2%. The side wall-slab joint with EIFS, compared with the existing IIS, was found to reduce the annual heat loss by 29.7% with no more than a 4.9% increase of the amount of insulation.

The aim of this study was to verify the feasibility of EIFS in terms of energy conservation. In order for EIFS to be widely used in apartment buildings which tend to be high-rise, it is considered that the durability and the construction methods required to facilitate the installation should be confirmed.

STUDIES ON SOLAR ENERGY FOR RESIDENTIAL USE IN AUSTRALIA WITH CONSIDERATION OF CLIMATE CHANGE SCENARIOS

Xiaoming WANG[1], Zhengen REN, George GROZEV, Chi-Hsiang WANG

Urban Systems Program, CSIRO Sustainable Ecosystems, Commonwealth Scientific and Industrial Research Organisation, Highett, Melbourne, VIC 3195, Australia

Keywords: solar energy, solar irradiance, demand and supply, climate change, residential buildings, AccuRate.

Summary

The potential for solar power to meet residential energy demand under climate change scenarios is investigated in this paper. While the residential energy demand is determined by the various factors directly associated with buildings and their environment, the extent to which this demand can be met by solar energy will clearly depend on the level of solar irradiance and the orientation at which the solar panel is mounted. Observations of direct normal solar irradiation and diffuse irradiation by Australian Bureau of Meteorology are utilized to map total solar irradiation on horizontal or tilted panels in Australia, offering a straightforward, though specific approach to estimate the supply capacity. The mapping shows that the supply capacity is both temporally and spatially dependent, with the difference in yearly total solar irradiation of up to 30% at different locations in Australia. To maximise the supply, the solar panel orientation should also be properly selected. Meanwhile, the software platform, AccuRate, is applied to simulate the demand, having given a typical building design with five star energy rating subject to a typical climate environment in Australia. More consideration about the effect of global warming in A1FI climate change scenarios on the demand is also taken into account. Observations of the demand and supply over time show that, in addition to the trend and seasonal changes, there exists significant noise that is stochastic in nature. The reliability of solar energy supply to satisfy the demand is then considered. Design options in regard to the panel size requirement to balance the supply and demand are investigated by considering cases in Melbourne and Alice Springs in Australia. The result may provide an effective approach to understand the practicality of solar energy use and minimum requirement for solar panel design, in terms of the size and orientation at a specific location to balance residential demand with a high degree of confidence.

1. Introduction

Effective design and utilization of solar energy for residential buildings depend on the understanding of the extent of supply capacity by solar power, which is spatially and temporally sensitive. It is also related to the understanding of residential energy demand. While the demand is determined by building design, occupants and their environment, the supply capacity is essentially associated with the solar irradiance received on designed solar panels in addition to its efficiency.

1.1 Energy Demand of Residential Houses

It has been estimated that Australian households are ultimately responsible for over half of the total energy use in Australia, either directly or indirectly through the consumption of products and services (ABS 2001). The direct household energy consumption accounted for 27% of the total in 1997-98. Fig. 1 shows the percentage of each component of energy use in Australian residential buildings during 2005-06. It was found that space heating and cooling accounted for 42%, hot water 24%, and appliances 34%.

The energy demand required for electrical appliances, cooking and water heating is largely unaffected by the design and thermal performance of building envelop. Climate may have secondary impacts on the energy

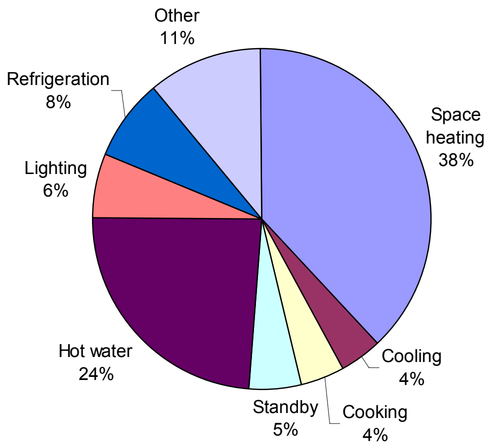

Figure 1 Residential energy consumption by end use 2005-06 (CIE (2007) and Pears (2007))

[1] To whom all correspondence should be addressed. Email: Xiaoming.Wang@CSIRO.AU

demand of refrigerators, freezers and hot water systems. There are other behavioral factors, such as the temperature level selected for laundry and the usage frequency of dryers, which may also have an influence on the energy demand. Demand for space heating and cooling has been considered as the largest energy end use in residential buildings. Heating and cooling loads of a specific residential building can be predicted by building energy performance models, such as EnergyPlus[2] and AccuRate[3]. Climate change may also have a significant impact on the demand for heating and cooling as a result of the increase in temperature. It may consequently affect the energy rating of buildings, depending on where they are located.

1.2 Solar Irradiation

Solar irradiation, which attenuates when travelling through the atmosphere, may be related to mixed gases, ozone, and water-vapour according to the models such as the so-called Meteorological Radiation Model (Muneer et al, 2000; 2006), and it is also often estimated on the basis of cloud cover. The Australian Bureau of Meteorology (BoM) provides cloud observation in oktas, which represent the cloud coverage by scores ranging from one to eight, with one indicating no cloud and eight indicating the sky fully covered with cloud. More detailed information may include the first low cloud, second low cloud, middle cloud, high cloud, and total cloud amount. Cloud coverage may also be described by average daily or monthly sunshine period or duration.

Models to estimate solar irradiation by using recorded weather data are generally divided into two categories, i.e., sunshine-based and cloud-based (Iziomon et al, 2002). Traditional *Page model* [Singh et al, 1996] is sunshine-based. There are variant models that modify the *Page model* to consider the nonlinearity of the ratio S/S_0, the effects of latitude, solar altitude (Lin et al, 1999) and atmospheric water vapour content (Iziomon et al, 2002).

Sunshine-based models provide a simple approach for estimating solar irradiance on a horizontal surface over daily and monthly periods, but may be inaccurate when a tilted surface is considered. The total daily solar irradiation on a tilted surface is a function of the normal direct irradiation as well as the corresponding solar altitude that varies over day time. Therefore, knowing the daily or monthly average value correlated to sunshine duration does not give a direct answer to the total daily solar irradiation on a tilted surface. In this case, the more proper approach is to assess solar irradiation based on cloud cover information by using a smaller time scale, such as hourly intervals. The *Kasten model* (Iziomon et al, 2002) provides a relation between total solar irradiation and cloud amount. More empirical models were developed by Gul et al, (1998) and Ehnberg et al (2005).

However, a more straightforward approach is the direct use of solar irradiance data acquired by the observation stations operated in each State and Territory. When the normal direct irradiation and diffuse irradiation are included in observation, the total solar irradiation on a tilted surface may simply be estimated by Eq.(2). Though the results from the approach are specific to those observation locations, spatial interpolation may be applied to obtain the total solar irradiation at other locations.

2. Assessment of Supply Capacity of Solar Power

2.1 Irradiance Distribution in Australia

BoM data available to us consists of hourly climatic data, which includes direct solar irradiance on a plane normal to the beam (G_{ND}) and diffuse solar irradiance on a horizontal plane (G_d). The data covers 77 locations including 64 in Australia, as shown in Fig.2. Some major cities have dual observation stations.

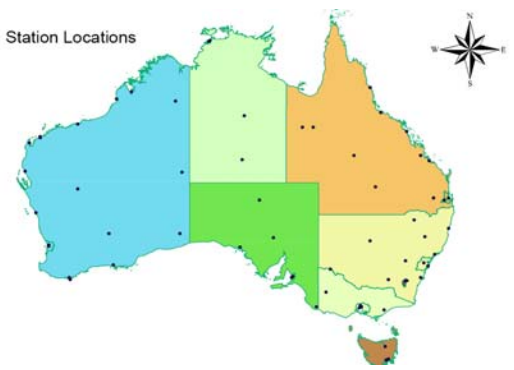

Figure 2. Locations of observation sites for the data

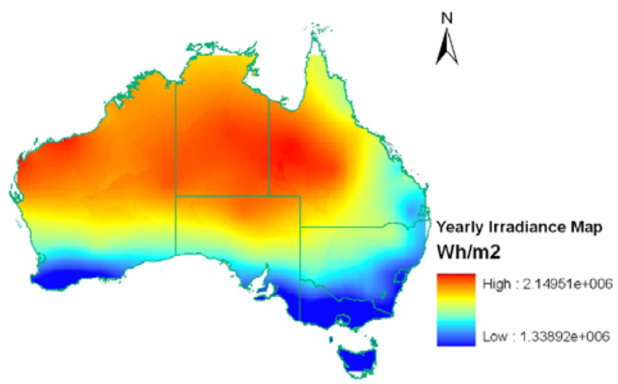

Figure 3. Maps of yearly solar irradiance on a horizontal surface

[2] See information in www.eere.energy.gov/buildings/energyplus/.
[3] See information in www.hearne.com.au/products/accurate/.

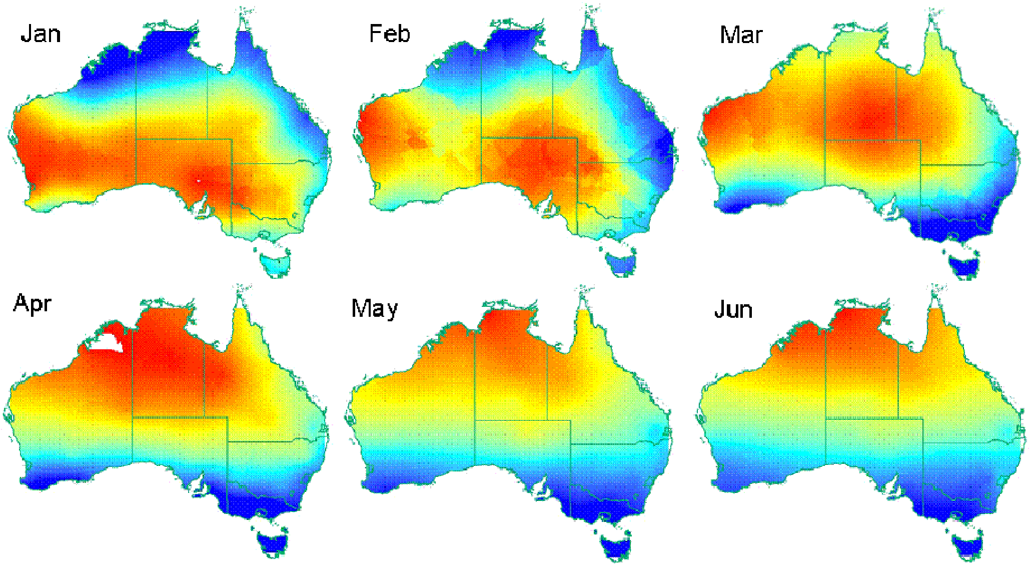

Figure 4. Maps of monthly solar irradiance on a horizontal surface from January to June[4]

Most data were recorded for a period of 10 years between 1978 and 1987 with some as early as 1961. The total solar irradiation can be simply given by:

$$G_{D\theta} = G_{ND}\cos\theta + G_d \frac{(1+\cos\alpha)}{2} \qquad (1)$$

The total solar irradiation is relevant to solar altitude, which depends on the locations and varies over a yearly period. Fig.3 maps the yearly solar irradiance on a horizontal surface in Australia, and Fig. 4 describes its seasonal changes. The difference of the total solar irradiation at different location or during different seasons can be fairly significant. Fig. 5 presents the average monthly solar irradiance in cities located within 7 climate zones, defined in Building Code of Australia (BCA). Although the pattern generally follows the common sense that there is higher irradiation in summer and lower in winter, it is not always true in tropical areas, such as Darwin.

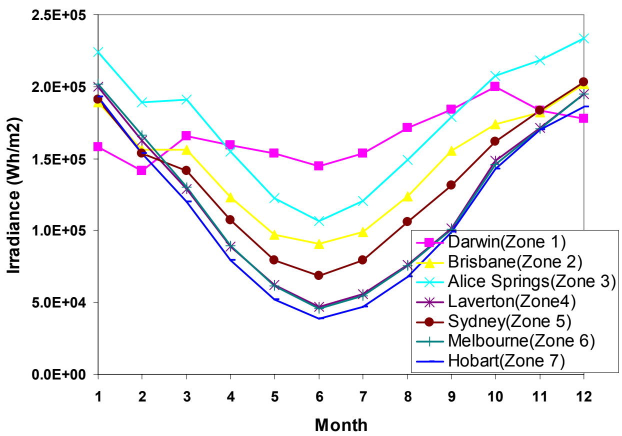

Figure 5. Monthly average solar irradiance in citieslocated in 7 climate zones defined by BC

2.2 Solar Irradiation and Supply Capacity

Fig.6 shows the average total daily solar irradiance on a horizontal surface in Melbourne, Alice Springs and Darwin, and Fig.7 presents the average cumulative electricity amount that could be generated on a 1m^2 horizontal panel over a year by assuming that the efficiency of the solar panel is 13%. The cumulative supply capacity in Melbourne is about 30% lower than in Alice Springs and Darwin.

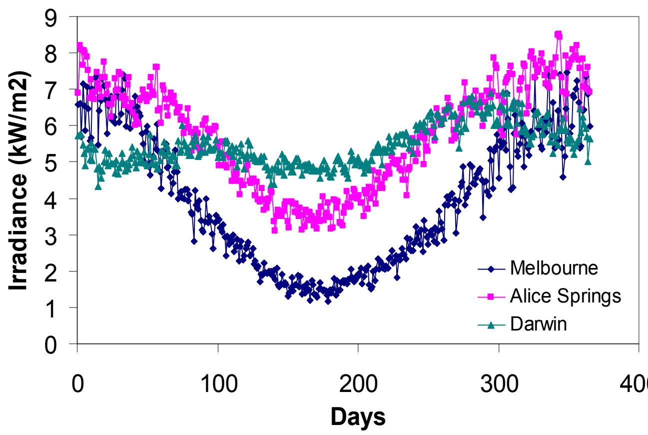

Figure 6. Average daily solar irradiation on a horizontal surface

It should be emphasized that the azimuth and tilt angle of a panel have a considerable influence on the total solar irradiation on its surface. While it is generally understood that

[4] The colour describes different scales in each diagram to highlight the spatial difference, rather than the difference amid months.

the solar panel would receive more irradiation when facing north (or azimuth angle =0), the selection of tilt angle becomes quite important for solar panels to achieve maximum exposure to solar irradiation. In fact, the pattern of average total daily irradiance on a solar panel may be completely changed as a result of the variation of tilt angle, as shown in Fig.8. It is generally understood that the total solar irradiation obtains a considerable increase when the panel surface is allowed to maintain normal to the solar beam.

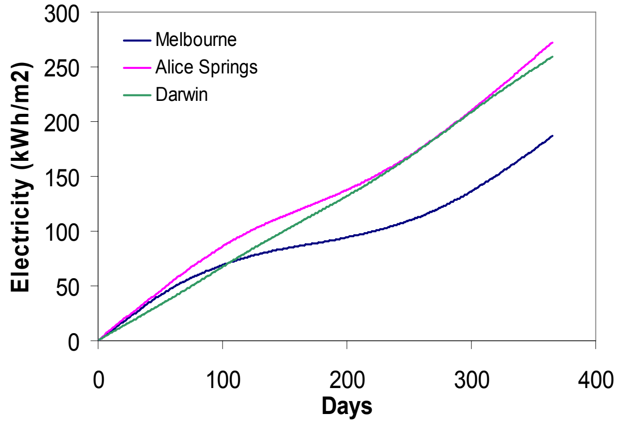

Figure 7. Cumulative supply capacity of a 1m^2 horizontal solar panels

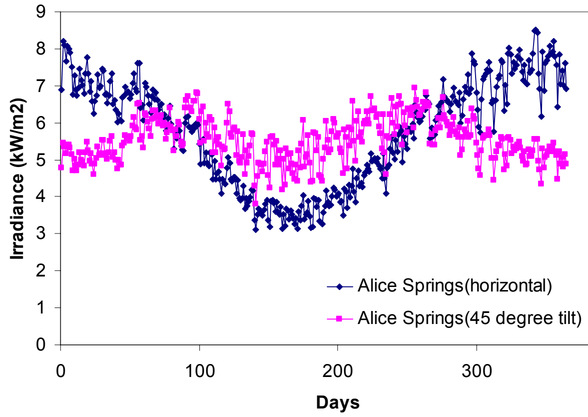

Figure 8. Average total daily solar irradiance in Alice Springs.

Assuming the efficiency of solar panels is 13%, the cumulative supply capacity of north-facing solar panels with different tilt angles in Melbourne and Alice Springs is shown in Fig.9. The results illustrate that a proper change of tilt angle may increase the supply, but the increase of tilt angle would not always be able to achieve more capacity.

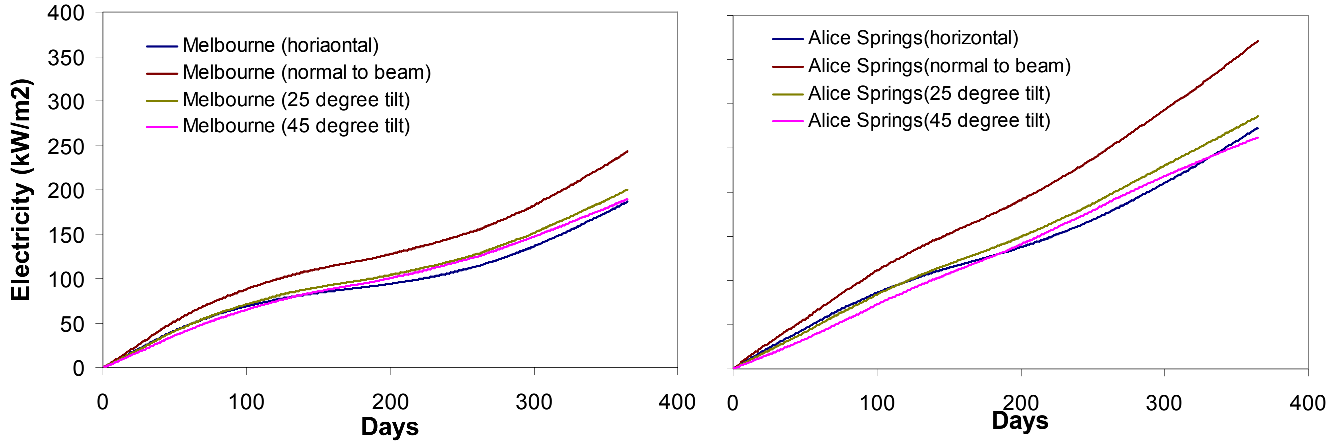

Figure 9. Cumulative supply capacity of north-facing solar panels with different tilt angles in Melbourne and Alice Springs

3. Energy Demand Simulation of Residential Houses with Effects of Climate Change

AccuRate, software developed by CSIRO to simulate residential energy use, is to be applied to simulate the energy demand. The current version of AccuRate only deals with heating and cooling energy. The other components of the house's energy demand were estimated from data available from the Australian Greenhouse office's Your Home technical manual (AGO 2008).

To illustrate the process involved in accessing energy demand of residential houses, a conventional single-storey house with a floor area of 224 m^2 (and a conditioned floor area of 173 m^2) was modeled by AccuRate. The house has four bedrooms (master bedroom with ensuite and WIR), a kitchen/family area, a living room, a laundry, a separate bathroom and toilet, a rumpus room and a double garage. The house satisfies the 5-star energy rating requirement in Melbourne and Alice Springs. The hot water system is solar hot water system boosted by electricity (40%). Given the location of houses in addition to above details, AccuRate may output hourly heating and cooling space energy requirements. These were first converted to the energy consumption by multiplying the requirements by the assumed efficiencies of a reverse-cycle heat pump in heating or cooling mode. A daily profile of hourly energy consumption for appliances and hot water (i.e. excluding heating and cooling) was simulated. The profile was then added to each day of heating and cooling energy consumption to create a file of total hourly energy demand, which may also be aggregated to the total daily demand for Melbourne and Alice Springs, described as BAU, i.e. business as usual, in Figs.10. Typically, there is relatively more demand in Melbourne for heating in winter, while more demand in summer for cooling in Alice Springs. Occasionally, there is also high demand for cooling in hot days in Melbourne.

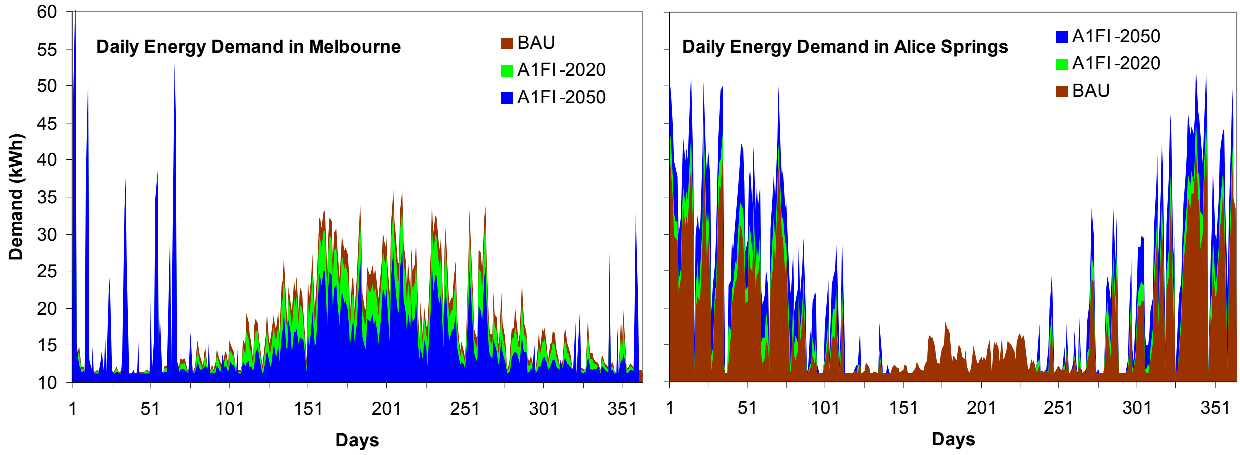

Figure 10. Residential energy demand for a typical four bedroom house in Melbourne and Alice Springs: 1) BAU, 2) A1FI climate change scenario in 2020, 3) A1FI climate change scenario in 2050

Considering the emission scenario A1FI defined by IPPC Special Report on Emission Scenarios (SRES) (IPCC 2000; CSIRO, 2007), OZClim[5], developed by CSIRO, is used to project climate change in Australia for 90th percentile temperature variation in 2020 and 2050, respectively, as shown in Fig.11. The temperature increase is 0.6°C and 2.0°C for Melbourne, 0.9°C and 2.9°C for Alice Springs (North Territory).

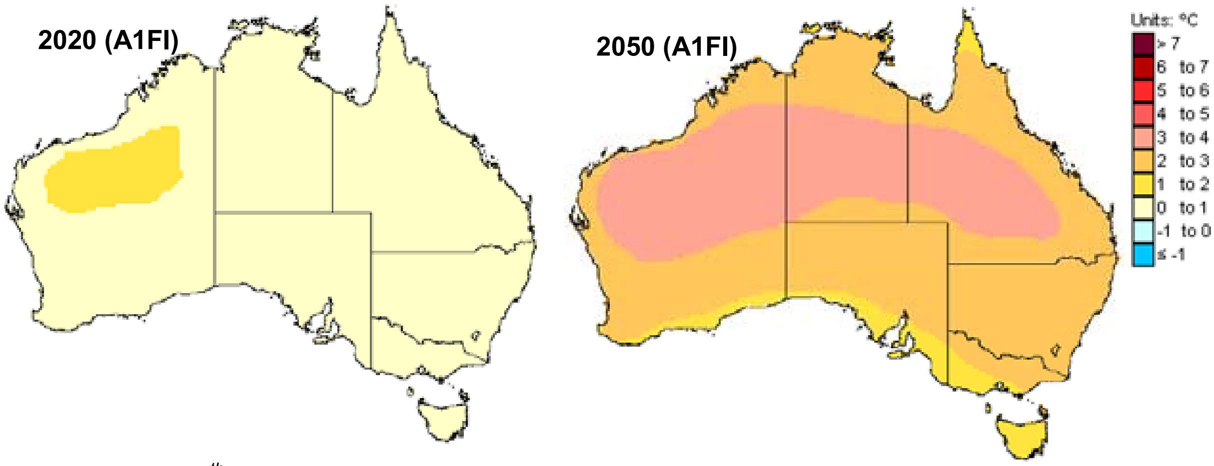

Figure 11. 90th percentile temperature variation projection in 2020 and 2050 by OZClim

Table 1 describes the effect of climate change on the yearly energy demand. In Melbourne, the energy demand decreases with the global warming scenario, 5.5% and 13.5%, respectively. However, in Alice Springs, it increases 6.3% and 23.3%. The increase in Alice Springs is quite significant. As shown in Fig.10, the decrease in Melbourne is caused by the reduction of energy use for heating in winter as a result of increasing temperature, while the increase in Alice Springs results from more demand of energy consumption for cooling in summer. Based on the current practice in the energy rating for residential houses, the 5 star rating for the typical house is also affected by the climate change, as shown in Table 2. While the energy rating in Melbourne increases, it may drop significantly in Alice Springs.

Table 1. Yearly energy demand in three climate scenarios

Location	BAU (kWh)	2020 - A1FI (kWh)	2050 - A1FI (kWh)
Melbourne	6759	6384	5844
Alice Springs	6569	6985	8102

[5] See information in www.csiro.au/ozclim.

Table 2. Energy rating in three climate scenarios

Location	BAU	2020 - A1FI	2050 - A1FI
Melbourne	5.1	5.7	6.6
Alice Springs	4.9	4.4	3.3

4. Reliability of Solar Power Supply

The fundamental questions in solar power design are what size of a solar panel would be required enough to balance the residential energy consumption demand, and how reliable the supply is. Assuming that a solar panel has 13% efficiency, the minimum size requirement of the solar panels to balance total yearly demand can then be estimated by the comparison of the demand with the supply capacity discussed in section 3. Table 3 gives the minimum panel size, which is not only related to the location of the panel, but also the orientation of the panel. The panel with tilt angle of 45° will reduce the panel size requirement in Melbourne, but it increases in Alice Springs. By maintaining the panel normal to the solar beam may reduce the size by 23% in Melbourne and 26% in Alice Springs when comparing with the size required for the horizontally placed panel. Meanwhile, as a result of climate change, the size requirement of a horizontal panel reduces by 5.5% and 13.5%, respectively, in Melbourne. However, it increases by 4.4% and 23.3% in Alice Springs.

Table 3. Panel size required to balance total yearly demand

Orientation	Melbourne (m^2)			Alice Springs (m^2)		
	BAU	2020-A1FI	2050-A1FI	BAU	2020-A1FI	2050-A1FI
Horizontal	36.18	34.18	31.29	24.11	25.64	29.74
45° tilt, facing north	35.67	33.70	30.85	25.07	26.65	30.92
Normal to solar beam	27.82	26.28	24.06	17.73	18.85	21.86

It should be emphasized that the balance of total yearly demand and supply does not mean that the solar power may maintain the daily supply to meet the demand. Both demand and supply over a year are affected significantly by stochastic fluctuation. Ideally, the panel size has to be large enough to meet the maximum daily demand in a year. However, considering the uncertainties involved in the demand and supply, it seems more logic to determine the size requirement on the basis of the concept of reliability, which is defined as the probability to balance the daily demand given a panel size. The reliability is fitted with lognormal probability distribution. Its density functions are given by Fig.12, where three climate scenarios are considered. For Melbourne, the density function shifts to the side in smaller size values, while it moves to another side for Alice Springs.

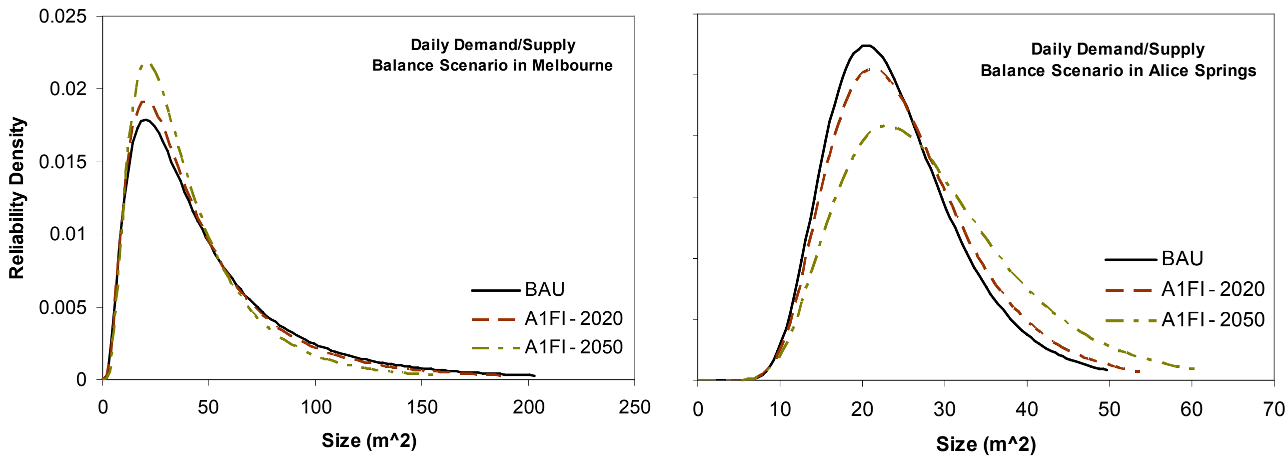

Figure 12. Reliability density in Melbourne and Alice Springs, given a solar panel size, in three climate scenarios

Considering three climate scenarios, Table 4 displays the estimation of horizontal solar panel size required to balance the daily demand with 90% reliability in Melbourne and Alice springs. The lower and upper bound of the estimation with 95% confidence are also described. The low radiation in winter has significantly increases the requirement of solar panel size in Melbourne. It is quite substantial for a four bedroom house and not much feasible for implementation in practice.

Table 4. Horizontal solar panel size required to balance daily demand

Climate	Melbourne (m^2)			Alice Springs (m^2)		
	90th percentile	Lower bound	Upper bound	90th percentile	Lower bound	Upper bound
BAU	106.87	91.82	125.75	35.23	33.06	37.72
2020-A1FI	97.48	84.24	113.99	37.33	34.95	40.07
2050-A1FI	81.46	71.42	93.80	43.75	40.66	47.33

Table 5 considers the effects of solar panel orientation on the size requirement. Once again, it indicates that the panel with tilt angle of 45° will reduce the panel size requirement in Melbourne, but it increases in Alice Springs.

Table 5. Panel size required to balance daily demand with consideration of orientation

Orientation	Melbourne (m^2)			Alice Springs (m^2)		
	90th percentile	Lower bound	Upper bound	90th percentile	Lower bound	Upper bound
Horizontal	106.87	91.82	125.75	35.23	33.06	37.72
45° tilt, facing north	77.82	69.16	88.32	40.24	37.07	43.93
Normal to solar beam	71.66	62.50	82.97	25.88	24.22	27.78

The high size requirement to balance daily demand in Melbourne is problematic for practical applications. Considering that the unconsumed energy can be used to charge batteries, it is not necessary to have the supply meeting the daily demand. Provided that the size of panels is large enough to ensure the balance between cumulative supply and demand, the size requirement may be reduced without compromising reliability.

Similar to the approach applied to the assessment of the panel size requirement to balance daily demand, the size to meet cumulative demand with 90% reliability over a year is described in Table 6. As seen, the size is considerably reduced, especially, in Melbourne.

Table 6. Panel size required to balance cumulative demand with consideration of orientation

Orientation	Melbourne (m^2)			Alice Springs (m^2)		
	90th percentile	Lower bound	Upper bound	90th percentile	Lower bound	Upper bound
Horizontal	47.34	44.50	50.59	29.29	28.79	29.84
45° tilt, facing north	42.99	41.01	45.21	37.99	36.38	39.79
Normal to solar beam	34.89	32.98	37.07	23.04	22.47	23.66

5. Conclusions

Observations of direct normal solar irradiation and diffuse irradiation by Australian Bureau of Meteorology were utilized to map total solar irradiation on horizontal or tilted panels in Australia, which is then converted to solar energy supply capacity to meet the demand. The study demonstrated that the supply capacity is both temporally and spatially dependent, with a difference in yearly total solar irradiation of up to 30% at different locations.

Energy demand of residential house is determined by the various factors directly associated with residential houses and their environment. AccuRate, developed by CSIRO, was used to simulate the demand for a typical 4 bedroom residential house with five star energy rating. The demand is affected by climate change. To understand the extent of the influence, the temperature increase in A1FI climate change scenario for 2020 and 2050 are taken into an account for the demand assessment. While the energy demand in Alice Springs climbs with the increase of temperature as a result of climate change, demand declines in Melbourne. This is due to the considerable reduction of energy consumption for heating in Melbourne, while the temperature increase may push up the demand in Alice Spring for cooling in summer. It is also interesting to mention that the energy rating for the house in Melbourne increases, while it drops quite significantly in Alice Springs as a result of climate change.

The size of solar panels may be estimated by the balance of total yearly demand and supply, but it ignores the stochastic nature in both residential demand and solar radiation. Demand and supply are fundamentally stochastic processes in addition to seasonal fluctuation patterns. The failure of solar energy supply to satisfy the demand describes the exceedance probability over a certain period, while the reliability represents the probability of supply to meet demand, given the size of a solar panel. Lognormal distribution function is applied to fit the reliability of daily supply. 90% reliability or 10% exceedance probability is considered to estimate the size requirement of solar panels. However, meeting daily demand is a very strict requirement, which is actually not necessary when batteries can be utilized to store the unconsumed supply. In this case, the size of solar panels is determined by the maintenance of the balance of cumulative supply and demand. As given in the example in Melbourne and Alice Springs, the size requirement is significantly reduced.

However, according to the estimation, the size requirement of solar panels is still quite significant, especially in Melbourne. With current technology, it is not practical to purely rely on solar energy to meet residential energy demand. Other renewable energy may also be applied to offset the demand, Nevertheless, continued efficiency improvements in solar power technology will increase the feasibility of solar power to meet the major proportion of residential energy consumption.

Keywords: statistics, long-term prediction, commercial building, energy conservation

Summary

In Japan, despite slowing in the population and maturation of domestic economy activities, energy consumption of commercial sector increases remarkably. Therefore, the countermeasure for commercial sector holds important clues to the energy conservation and CO_2 emission reduction. In this paper, the potential of energy conservation in Osaka(one of the typical mature cities in Japan) are discussed.

Firstly total floor space and specific energy consumption of commercial buildings in Osaka for the previous years were estimated. As a result, the factor that have increased energy consumption was the specific energy consumption.

Secondly we predicted total floor space of buildings in Osaka towards 2030.

Next we analyzed the specific energy consumption using a database. Specific energy consumption of actual buildings varies widely. We predicted energy consumption of commercial buildings in Osaka assuming that the dispersion of actual data of specific energy consumption was the difference between an inefficient building and an efficient building for energy consumption. And we studied the practical countermeasure equivalent to the minimum energy consumption by energy simulation.

Based on the above study, it was possible that energy consumption as of 2030 will be 0.5-0.7 times of current status if energy efficiency of all buildings as of 2030 is as high as the highest level of existing buildings.

1. Introduction

Each consumption-intensive country should promote the reduction of energy consumption and CO_2 emission to fight climate change. In Japan, despite slowing in the population and maturation of domestic economy activities, energy consumption of commercial sector increases remarkably. It is caused by particularly commercial sector along with household sector. Therefore, the countermeasure for commercial sector holds extremely important clues to the energy conservation and CO_2 emission reduction. In this paper, the potential of energy conservation in Osaka ; one of the typical mature cities in Japan, towards year 2030, are discussed.

2. Methods Description

2.1 Status of floor space and energy consumption

We estimated total floor space of buildings -office, shop, hotel and hospital-of previous periods(1991-2003) in Osaka using census and statistics. We calculated the office floor space by multiplying the number of office workers and working space per worker, the shop floor space by multiplying selling space of notification basis and the scaling factor, the hotel floor space by multiplying the number of guest rooms of notification basis and floor area per room, and the hospital floor space by multiplying the number of hospital beds of notification basis and floor area per room.

Secondly, we estimated energy consumption of commercial sector by sales data of utility company and statistics, and allocated in proportion as floor space of each building category.

Next, we analyzed specific energy consumption of each building category from the database "ELPAC" which is made up by academic society and economic organization in Japan.

2.2 Prediction of energy consumption

We predicted floor space of office, shop, hotel and hospital in Osaka by developing the regression model of working space per office worker, selling space, the number of guest rooms and the number of hospital beds, using estimated figures of time series . And we applied the figures predicted by a think tank or assumed to the number of office workers and explaining variable of the regression model.

2.3 Potential of energy conservation

We studied some actual countermeasure to verify potential of energy conservation obtained from the prediction, using the model Yamazaki developed(2002).

3. Results

3.1 Status of floor space and energy consumption

3.1.1 Transition of floor space and energy consumption

We estimated energy consumption and floor space of buildings -office, shop, hotel and hospital-of 1991-2003 in Osaka. Figure 1-4 show the results of office, shop, hotel, hospital.

Both of the floor space and energy consumption of hotel has been increasing. However, regarding office, shop and hospital, despite of leveling-off of the floor space in this 12 years, energy consumption has been steadily increasing. The cause of leveling -off of floor space is economic and population growth. (One thing which I would like to mention here is that health facilities for recuperation of hospital has been converted to welfare facility.) Therefore it means that specific energy consumption has been increasing.

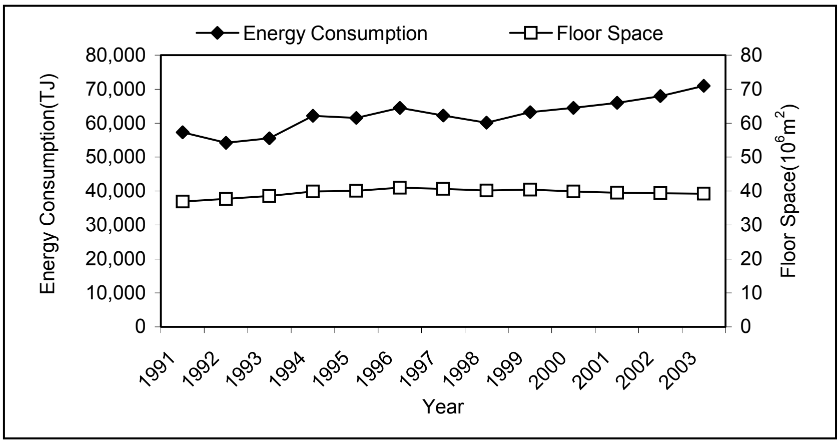

Figure 1   Energy consumption and floor space of office in Osaka.

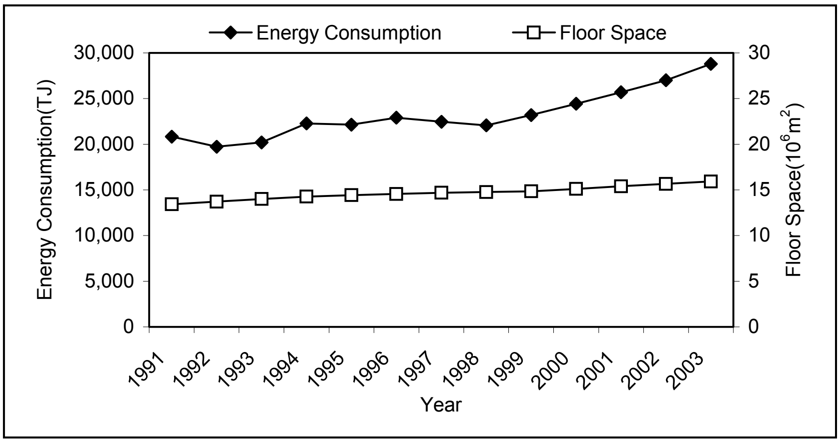

Figure 2   Energy consumption and floor space of shop in Osaka.

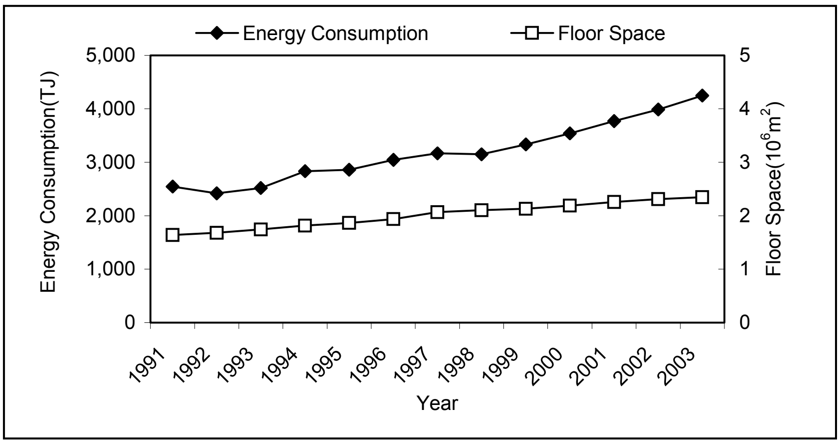

Figure 3 Energy consumption and floor space of hotel in Osaka.

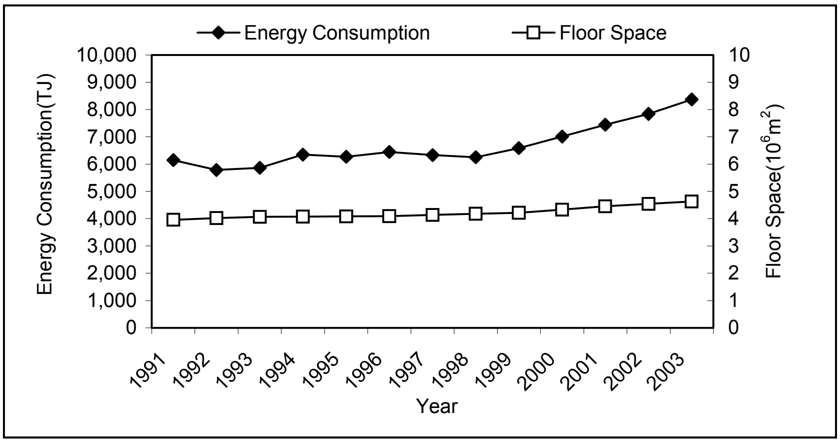

Figure 4 Energy consumption and floor space of hospital in Osaka.

3.1.2 Status of specific energy consumption

We analyzed specific energy consumption using a building and energy database(ELPAC). Figure 5-8 show the results of office, shop, hotel, hospital. As shown in the figures, the maximum value is three or four times of minimum value. The energy performance in addition to the condition and so on have an effect on the specific energy consumption of buildings. It can be considered that the dispersion of actual data of specific energy consumption was the difference between an inefficient building and an efficient building for energy consumption.

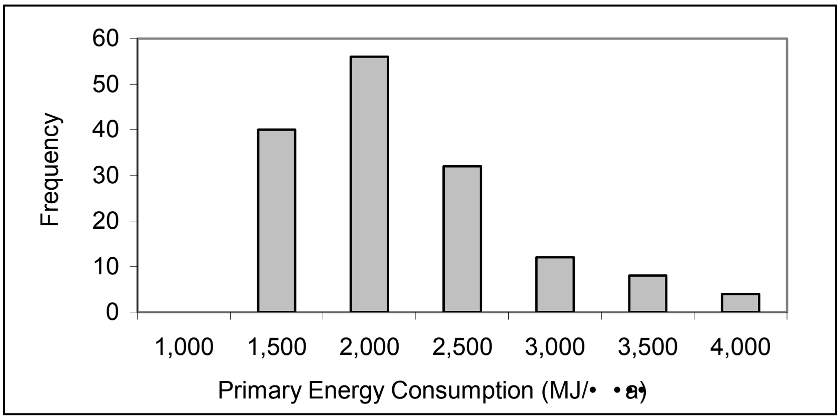

Figure 5 Primary energy consumption of office in Osaka.

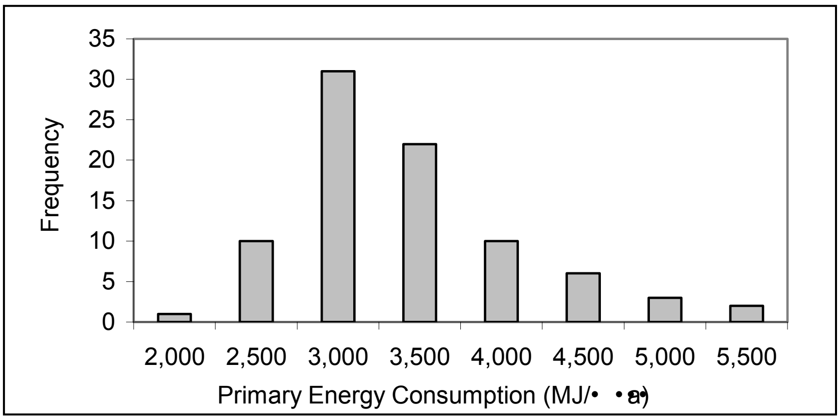

Figure 6 Primary energy consumption of shop in Osaka.

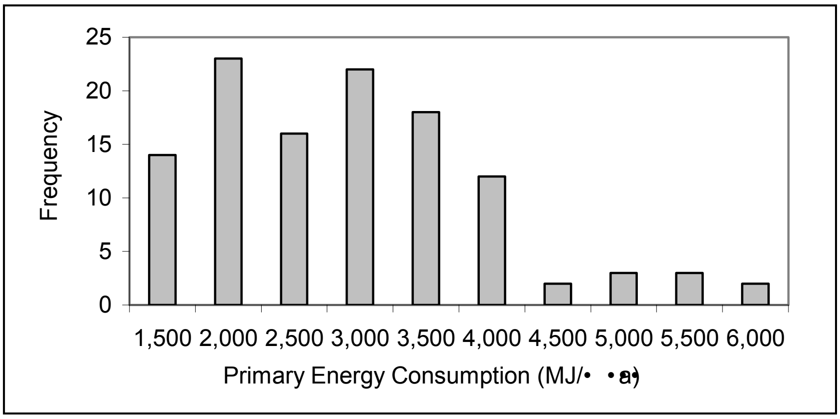

Figure 7 Primary energy consumption of hotel in Osaka.

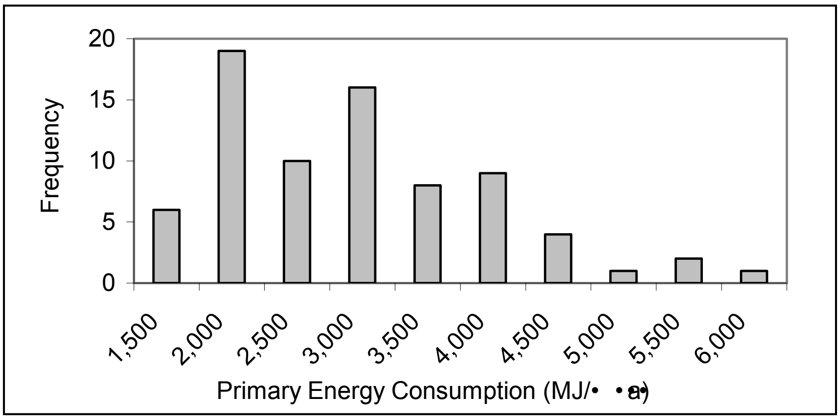

Figure 8 Primary energy consumption of hospital in Osaka.

Next, Figure 9 shows the statistic score obtained from figure 5-8.

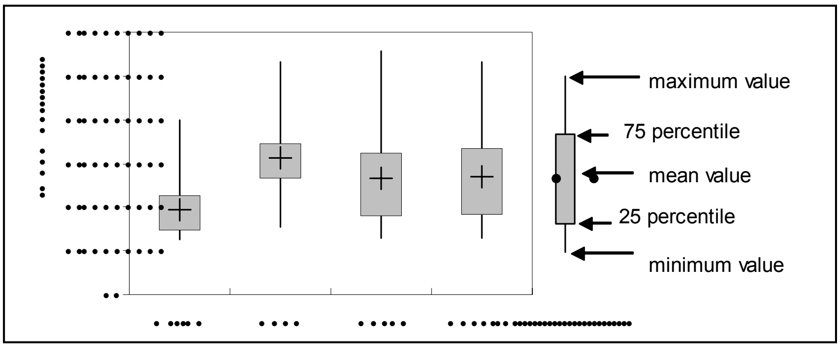

Figure 9 Statistic of Primary energy consumption of each building category.

3.2 Prediction of floor space and energy consumption

3.2.1 Prediction of floor space

We predicted the total floor space of each building category. The regression models relative to office, shop, hotel and hospital are as follows.

$$Sp/Wrk = 1.79 \times \ln(Yr - 1990) + 21.8 \qquad R^2=0.89 \qquad (1)$$

Sp: Floor space (m^2)
Yr: year

$$Ss = 0.377 \times Income + 163521 \qquad R^2=0.34 \qquad (2)$$

Ss: Selling space (m^2)
Income: Annual income of households(billion yen/a)

$$Rm = 35149 \times \ln(GRP) - 579845 \qquad R^2=0.55 \qquad (3)$$

Rm: The number of guest rooms
GRP: Gross regional production

$$Bd = -3082 \times \ln(Year - 1987) + 124833 \qquad R^2=0.50 \qquad (4)$$

Bd: The number of hospital beds
Yr: year

The predicted floor space using the models given above are shown in Figure 10-13. It is indicated that floor space of office and hospital will be level-off and floor space of shop and hotel will be increase slightly. However, as above mentioned, health facilities for recuperation of hospital are not categorized as hospital but as welfare facility which is not subject in this study.

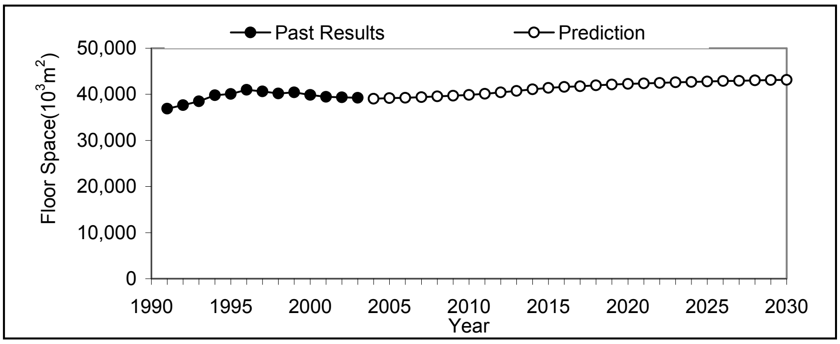

Figure 10 Past results and prediction of floor space of office in Osaka.

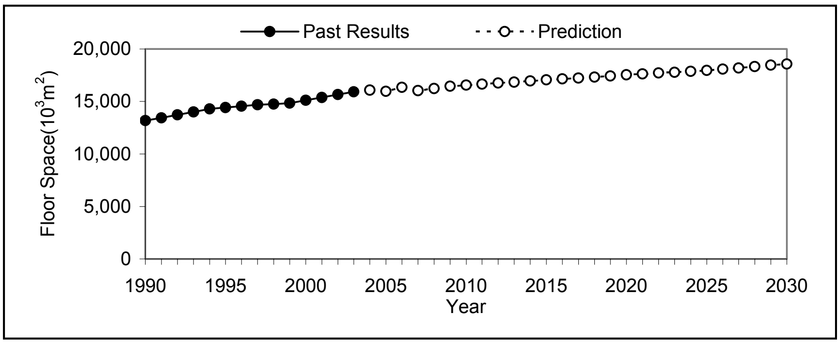

Figure 11 Past results and prediction of floor space of shop in Osaka.

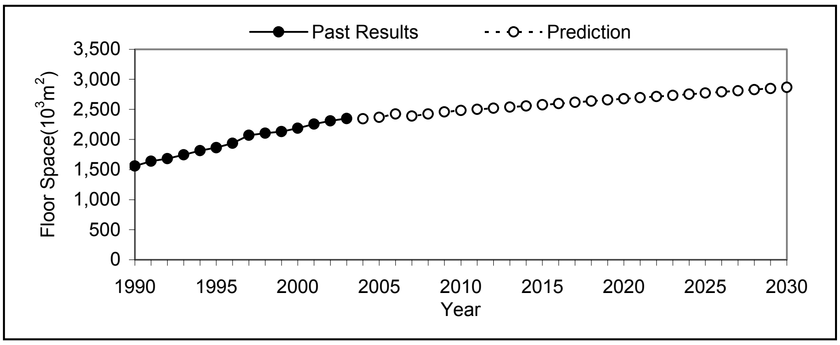

Figure 12 Past results and prediction of floor space of hotel in Osaka.

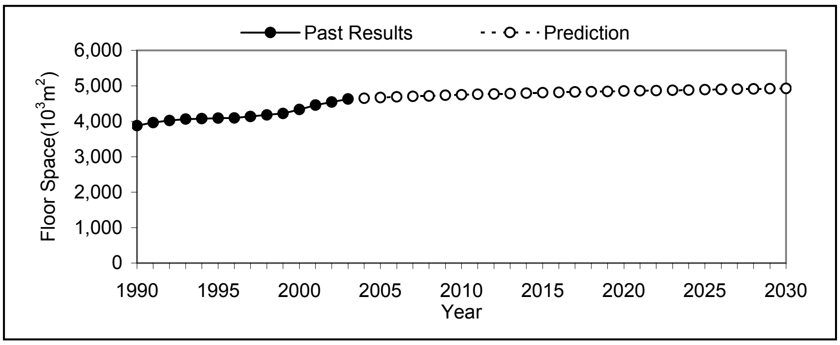

Figure 13 Past results and prediction of floor space of hospital in Osaka.

3.2.2 Prediction of energy consumption

We predicted energy consumption by multiplying the specific energy consumption and the floor space predicted of each building category. We assumed here 3 cases of energy efficiency. Case B is on condition that the average specific energy consumption as of 2030 will be at the same level as the average as of 2004. Case A is the case of the minimum value as of 2004, and Case C is the case of the maximum value as of 2004. Table 1 shows the condition of each case.

Table 1 Specific energy consumption (MJ/m^2a) for prediction

Building type	2004	2030 (2030/2004)		
		Case A(Min.)	Case B(Ave.)	Case C(Max.)
Office	1,950	1,259 (0.65)	1,950 (1.00)	3,998 (2.05)
Shop	3,132	1,538 (0.49)	3,132 (1.00)	5,300 (1.69)
Hotel	2,649	1,282 (0.48)	2,649 (1.00)	5,557 (2.10)
Hospital	2,680	1,286 (0.48)	2,680 (1.00)	5,312 (1.98)

Figure 14-17 show the prediction. The figures in each graph indicate the ratio of energy consumption (2030/2004). Case B is the result caused by only floor space increase. In Case A(Minimum Case), energy consumption can be kept in from 0.51 to 0.71 of current level. However, in Case C(Maximum Case), energy consumption will extend approximately twice.

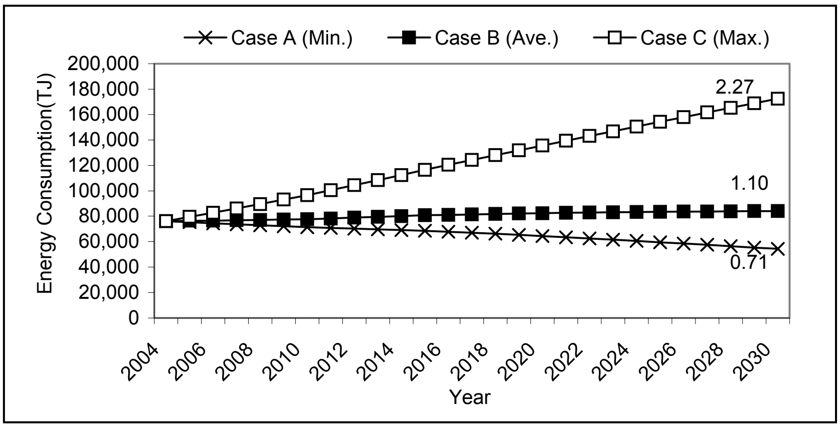

Figure 14 Prediction of energy consumption of office in Osaka.

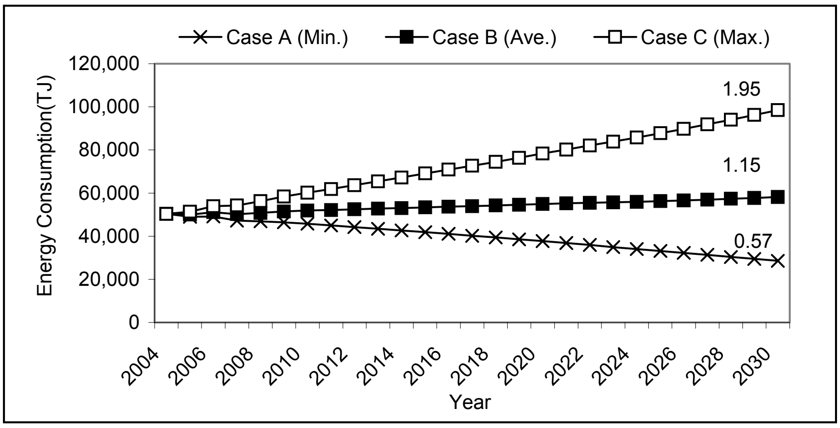

Figure 15 Prediction of energy consumption of shop in Osaka.

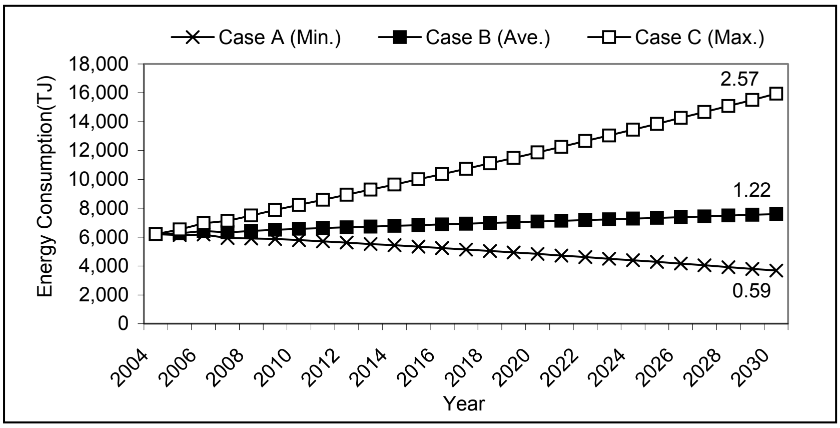

Figure 16 Prediction of energy consumption of hotel in Osaka.

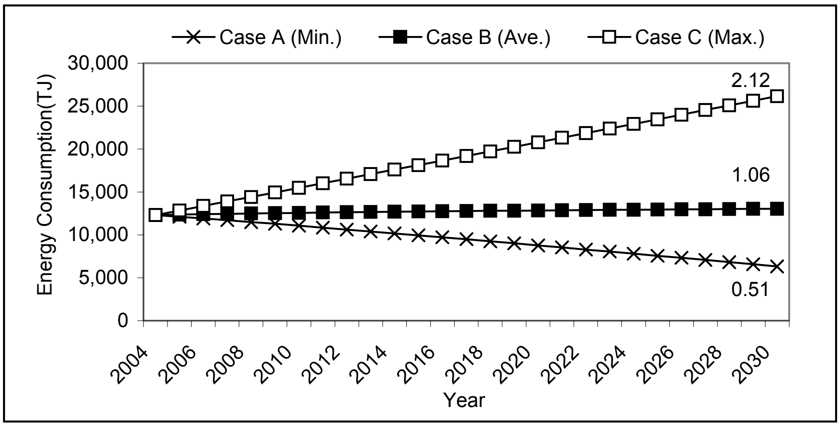

Figure 17 Prediction of energy consumption of hospital in Osaka.

3.3 Potential of energy conservation

We studied some actual countermeasures to verify the potential of energy conservation obtained from the prediction using the simulation model Yamazaki developed(2002). Table 2 shows the countermeasure and each performance as an example of office. As shown, it is possible that energy consumption can be kept in 0.72 times of current level. Additionally if other countermeasures are adopted, the efficiency can be more increased.

Table 2 Actual countermeasure for energy consumption

	Model of Case B	Model of Case A
Coefficient of heat transmission of external wall(W/m^{2}K)	2.14	0.66
Windows area ratio(-)	0.35	0.66
Coefficient of heat exchange for outdoor-air inlet(-)	0.35	0.70
indoor calorific value(W/m^2)	40	20
Coefficient of Performance (Cooling)(-)	2.58	2.87(10%UP)
Coefficient of Performance (Heating)(-)	3.13	3.48(10%UP)
Primary energy consumption(MJ/m^{2}a)	1,887	1,363
Ratio	1.0	0.72

4. Conclusion

In this paper, we estimated the total floor space and energy consumption from 1991 to 2003, and analyzed the specific energy consumption using a building and energy database. Next, we verified the possibility of the achievement by the prediction and simulation. This work has demonstrated as follows.

1) According to the prediction of floor space, when energy efficiency of all buildings as of 2030 is as high as the highest level of existing buildings, energy consumption as of 2030 will be 0.5-0.7 times of current level.

2) However, when energy efficiency of all buildings is no more than the lowest level of existing buildings, energy consumption as of 2030 will be twice of current status.

3) It is possible as a practical matter to achieve the energy efficiency of 0.7 times of current level. We verified that that the actual countermeasure are, for example, the improvement of coefficient of heat transmission of external wall, windows area ratio, and so on.

TITLE: THE WARREN CENTRE'S 'LOW ENERGY HIGH RISE' PROJECT

Sue SALMON[1]
Robert MITCHELL[2]

[2] Sue Salmon, Project Director of The Warren Centre's Low Energy High Rise Project, former program manager for the Australian Building Greenhouse Rating (ABGR) scheme
[3] BE (Chem, 1979 UNSW, Australia), MBA (1986, IMEDE, Switzerland), Chief Operating Officer, The Warren Centre for Advanced Engineering, University of Sydney, Australia

Keywords: existing office buildings, energy efficiency, non technical barriers, evidence based initiatives

Summary

The Warren Centre for Advanced Engineering's Low Energy High Rise project is engaging the commercial building sector and facilitating their development of an evidence-based suite of initiatives to avoid the non technical barriers and advance the uptake of cost-effective energy efficiency.

Key Low Energy High Rise project outputs to date are: a detailed literature review; an industry developed list of non technical barriers to energy efficiency upgrades; a comprehensive research survey of building performance and management practices; and industry's preliminary ideas for the suite of initiatives that will be further developed as the major project output.

A distinguishing feature of the Low Energy High Rise Project is the comprehensive survey being conducted as a core element of the project. The work of industry stakeholders involved in developing the suite of initiatives will be underpinned by current evidence on both building energy performance and management practices gathered from the wider industry in response to the project's survey.

The Low Energy High Rise project is currently conducting the most comprehensive survey of building energy performance and management practices in a minimum of 160 Australian office buildings over 5000m2. While analysis of data from the survey has not yet been undertaken this paper provides background on the project; outlines the development of the non technical barriers; the content of the survey; the initial ideas industry has advanced for the suite of initiatives; and the approach that will be taken to further develop and refine the contents of the suite of initiatives. It will canvas areas that the research can be expected to point to and that will be available to be presented in detail to SB08, along with the refined suite of initiatives.

1. Introduction

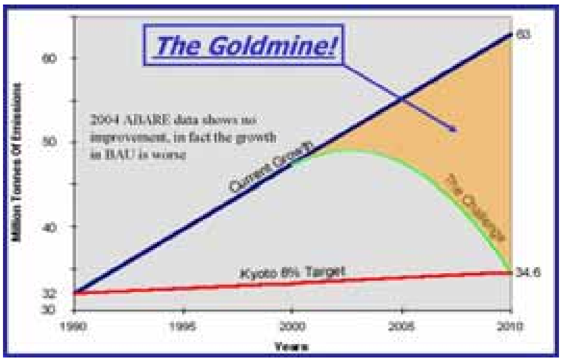
1.1 Background

1.1.1 Intent

The Warren Centre for Advanced Engineering's Low Energy High Rise project is engaging commercial building owners, investors, tenants, contractors and suppliers to develop a suite of evidence based initiatives to avoid the non technical barriers and advance the uptake of cost-effective energy efficiency in existing commercial office buildings.

1.1.2 Context, Issues and Opportunities

The 1999 Australian Greenhouse Office Report, Australian Commercial Building Sector Greenhouse Gas Emissions 1990 – 2010, provides the most recent data on energy use and greenhouse production from the commercial building sector. There have been no annual updates to demonstrate improved commercial building energy efficiency rather, the AGO Report projections to 2010 indicate that "the commercial buildings sector is expected to increase it greenhouse gas emissions to nearly twofold from 32 Mt of CO_2 per annum to 63 Mt between the years 1990 and 2010 under the Business as Usual scenario", see Figure 1 at right.[1]



The AGO Report noted "existing and announced greenhouse abatement and energy management initiatives may be

[1] Australian Commercial Building Sector Greenhouse Gas Emissions 1990 – 2010 Executive Summary Report 1999

expected to produce an impact of 1.4Mt of CO_2 per annum only due to their current low level of penetration or application". The study noted that voluntary measures could deliver higher levels of abatement than policy and measures in place in 1999.

Case studies exist to demonstrate that commercial building upgrades can deliver energy efficiency improvements of 20% and greater, cost effectively. Investa Property Group, achieved a 9.9% reduction in electricity consumption and a 13% reduction in gas consumption in 2005 through its energy management program which applies to 36 buildings across their office portfolio. Total financial savings from Investa's energy management program in 2005 were $600,000.

We are at the current point in the property cycle when the emphasis is on building upgrades. Many buildings are at the end of their 20 – 25 year cycle and are due for refurbishment. NSW Department of Water and Energy inform us that refurbishing a building from 2.5 stars to 3.5 stars would deliver 20% savings, which, across the whole national commercial office building stock (tenancies and base buildings) represents about 1.1 million tonnes of CO_2 equivalent per annum. An improvement from 2.5 stars to 5 stars would deliver 50% savings or 2.75 million tonnes of CO_2 equivalent per annum. These improvements equate to roughly $100 million and $250 million per year in energy savings.

1.1.3 The Low Energy High Rise project management structure

The project has a large Steering Committee drawn from industry stakeholders to oversee the project's progress and a smaller Planning Group that meets regularly to manage the project on behalf of the Steering Committee. The Planning Group comprises: Sue Salmon (Project Director), Mary Casey (McLachlan Lister), Jamie Wan (Bassett Consulting Engineers), Dr Paul Bannister (Exergy), Robert Quinn (National Project Consultants), Keith Bashford (The Warren Centre), David Hood (David Hood & Associates), Dr Martin Poole (Epuron), Robert Mitchell (The Warren Centre).

The work of the project is performed by teams of volunteer stakeholders organised according to the current needs of the project. Initially three working groups were formed representing 1) building owners, 2) tenants and 3) intermediaries. These groups provided input the Literature Review and the survey content as well as 'barrier identification'. As the project moves into 'initiative identification and analysis' the volunteer-working group members will form into smaller groups including representatives of each of the three initial groups, to focus on developing one or more initiatives.

Some 95 people (representing 73 organisations) are engaged with the project either through its Steering Committee or one of its working groups).

1.1.4 The Low Energy High Rise sponsors and participants

The following organisations are making a tangible contribution to the project's resources either through intellectual or financial contributions, or both: A. G. Coombs Group, Aeris Technologies Ltd, AGL, AMP Capital, ARUP, Australia Post, Australian Constructors Association, Australian Property Institute, Bassett Consulting Engineers, Bendigo Bank, Bligh Voller Nield, Bovis Lend Lease, Brisbane City Council, City of Sydney, Colliers, Colonial First State Global Asset Management, Commonwealth Bank, CSR Bradford Insulation, David A Hood & Associates, Davis Langdon, DEGW Asia-Pacific, Demand Management & Planning Project, Australian Department of Environment & Water Resources, NSW Department of Environment and Climate Change, DLA Phillips Fox, Ebsworth and Ebsworth Lawyers, Edge Environment, Energetics, Energy Conservation Systems, Envirolite, EPURON, Eureka Funds Management, Exergy Australia, FiveD, General Property Trust, Glenside Group, Haden Engineering, Hastie Group, Investa Property Group, J.P.Y.N Enterprises, Jones Lang LaSalle, Key Services, KODO, Low Energy Supplies & Services, McLachlan Lister, Mirvac Group, National Projects Consultants, NSW Fire Brigades, Optus, Qld Environmental Protection Agency, Resource Connections, Schneider Electric, Shelston IP, Spotless Group, Steensen Varming (Australia), Stockland, Sustainability Victoria, Sustainable Built Environments, Syneca Consulting, Szencorp, Team Catalyst, The Cox Group, The Warren Centre, Thunderbolt Design, Total Energy Solutions, United Group, University of Sydney, UTS, Vericap Finance, Westpac.

Implementing the Low Energy High Rise project survey has significantly expanded the project's engagement with the property sector. Each building nominated by the building owners to participate in the survey identified a portfolio manager, asset manager and building manager as well as one tenant to complete the surveys for each building. As a result a further 400 plus people in the industry have been introduced to the project, are contributing the factual basis for the development of the suite of initiatives and will have an opportunity to contribute to the development of the initiatives.

1.1.5 The Warren Centre's methodology

The LEHR project is being conducted by the Warren Centre for Advance Engineering, which is in the Engineering Faculty of Sydney University. It is an independent, industry linked institute fostering excellence and innovation in advanced engineering throughout Australia. It is a self funding, not for profit think tank controlled by industry representatives.

The Warren Centre's objective is to help create wealth in the nation by stimulating development of new engineering technology and encouraging integration of innovation and engineering technology into development of public policy and wealth creation. The Centre provides independent comment and advice to Government and industry.

The Warren Centre's unique approach is to bring together leading people in a selected field of engineering technology to work as a major project team to:

- Focus on removing barriers to commercial success in that field
- Develop new insights and knowledge in the technology; and
- Accelerate the technology's application in Australian industry.

Over 25 years Warren Centre projects have been observed to deliver beneficial change to the community. The Centre achieves change by facilitating the stakeholders (representing particularly academic, industry and government interests) in the issue at hand through a process wherein the stakeholders accept their common interests, agree the current situation and construct a vision of where they would like to take those common interests. Together the stakeholders then define a pathway from the 'now' to the vision, the barriers to moving along that pathway, and strategies to overcome those barriers. In practice it is the stakeholders that do the thinking, not The Warren Centre itself. The very significant impact of that is the high degree of implementation of recommendations from the Centre's work.

It is an objective of all Warren Centre projects to engage as many of the stakeholders in the project as possible, within the limitations of effective project management. While this will typically add to project cost and time it is generally paid back in full by the implementation achieved.

By involving the key decision makers in understanding the barriers and developing the solutions, these major projects result in important breakthroughs in technology and impact on Australian engineering practice and business enterprise.

2. The non technical barriers to energy efficiency upgrades

2.1 Identification of the non technical barriers

The starting point for developing industry agreement on the non technical barriers to energy efficiency was the Literature Review that was conducted at the start of the Low Energy High Rise Project. It was critical that the project build on work already undertaken so the project's Supply and Demand Working Groups added to, rejected, refined and prioritized the wide range of barriers identified in the Literature Review. The Literature Review itself set out the barriers that had been identified in the National Framework for Energy Efficiency (2004) and the Productivity Commission (2005). It categorized barriers as either Market or Organisational Failures. Market Failures were further categorized as Transaction costs; Lack of information; and Principal Agent Barrier and Externalities. The Organisational Barriers were in turn broken down into Behavioural, Institutional, and Cultural barriers.

Each Working Group adopted a different approach to their evaluation of the barriers identified by the Literature Review. The Supply Working Group had a higher level of shared understanding of the industry and experience of the barriers and was more readily able to respond to and evaluate each barrier. The Demand Working Group, which comprised tenants and those who provided services to tenants in office buildings, understandably did not have a high level of shared industry knowledge and confined their discussion to barriers the Literature Review identified that applied to tenants.

2.2 Barriers Identified by the Working Groups

The following table sets out the Working Group's list of agreed non technical barriers. In refining the suite of initiatives, the industry will assess the proposed initiatives against the identified barriers. To enhance the impact of the initiatives, initiatives will be evaluated on their capacity to affect a number of barriers simultaneously.

Low Energy High Rise Barrier Description
Low Energy High Rise Project - DEMAND WORKING GROUP BARRIERS
Lack of information (SKM 2006)
Expected payback time for commercial tenants is around 3 years (SKM 2006)
Building occupants do not fully recognise the health and productivity benefits from having better indoor environment quality (SBLP, 2006).
Lack of visibility of both energy efficiency measures and their benefits (Pears 2007).
Lack of information on the positive effects of green designs on the productivity of organisations working in office buildings (Kosholeva 2007)
The split money flows between payers and users (AEC 2005)
High investment hurdles (AEC, 2005)
Perceived risk with reliability, operation, maintainability, suitability of new technologies (SKM 2006)

Low Energy High Rise Barrier Description
The budgeting issues (Jopson 2006) (Energy is a low order item of low value)
Low management priority (SKM 2006)
There is no specific function with the organisation of commercial tenants that focuses on energy use. Sometimes there is a specific energy manager, but often it is a sustainability, facility or communication manager (Sheehan 2007).
Tenants are left out in the design process (Kosholeva 2007)
Corporation culture that is not comitted to green issues, out of sync with staff issues.
Market does not have clear understanding of what each Australian rating tool measures (SBLP 2006).
Transaction costs for project management, securing capital budgets, and investigating alternatives (SKM 2006)
It often takes 18 months to 2 years of occupation before you have a reasonable set of energy bills to base your occupancy ratings on (Field 2007).
Lack of interest by staff in a tenant organisation in energy efficiency
The people that make decision on tenancy accommodation are affected by the function of their firm, their institutional context, opportunistic behaviour and personal preferences (Ross, 2003).
Lack of prestige for energy managers (AEC 2005)
Major refurbishments take a long period of time (> 1 year) and require tenants to operate the building at least for a year before the ABGR can be re-checked (Hennessy 2004)
The CBD office market is not rational neither perfectly competitive, because of a lack of a coherent centralised market place and incomplete and poorly disseminated information processes (Ross 2003).
Higher rent premium (APEC 2005)
SUPPLY WORKING GROUP BARRIERS
Competition for capital (LEHR SWG 2007)
Whole building refurbishment is v. difficult due to varying timing of tenant lease expiry for a given building (LEHR SWG 2007)
Unwillingness to upgrade existing equipment to higher EE before end of serviceable life (LEHR SWG 2007)
Lack of awareness of building energy use (where it goes - breakdown) (NEEF 2004)
Limited understanding of potential cost effective energy actions (NEEF 2004)
Poor commissioning and maintenance of service systems (NEEF 2004)
Lack of knowledge transfer/feedback between designers and operators (LEHR SWG 2007)
Split incentives and split responsibilities between developer, owner and tenant (NEEF 2004, LEHR SWG 2007)
Short-term costs versus life-cycle costing (LEHR SWG 2007)
Absence of reward for outstanding design (LEHR SWG 2007)
Existing low cost of energy (NEEF 2004)
Inertia to change (NEEF 2004)
Risk Aversion (PC 2005)
Energy Efficiency is not integrated into core business (LEHR SWG 2007)
Short time horizons (PC 2005)
Client design briefs to consultants and builders do not take energy efficiency into consideration (NEEF 2004) (LEHR SWG 2007)
Accounting practices favour revenue streams over cost reduction strategies (NEEF 2004)
Limitations with network providers contraining opportunities for building energy efficiency e.g. wind,solar feed-in (LEHR SWG 2007)
The use of 'rules of thumbs' and routines affecting the ideal choice (PC 2005)
Insufficient time in design and retrofit planning stages to explore alternative design options (LEHR SWG 2007)
No mandatory disclosure of energy performance (LEHR SWG 2007)
Lack of information on past total energy consumption limiting assessments (NEEF 2004)
Jurisdiction specifc standards increasing complexity of design and construction (NEEF 2004)
Implementation cost of EE technologies & processes which entail additional costs.(PC 2005)
Lack of education and vocation programs (NEEF 2004)
Lack of specialised knowledge such as building controls (LEHR SWG 2007)
Lack of knowledge of benchmarking data (such as past energy data) and rating tools. (LEHR SWG 2007)
Reduced incentives for private providers to supply information (PC 2005) (LEHR SWG 2007 added control of IP)
Lack of effective incentive schemes (LEHR SWG 2007)
No repeat purchasing of building services equipment (PC 2005)
Risk and uncertainty reducing the level of investment or restricting access to finance (PC 2005)
Uncertainty within an organisation on outcome of energy efficiency projects (NEEF 2004)

Low Energy High Rise Barrier Description
Loose fit (flexible) design in base building overtaken by value management (LEHR SWG 2007)
Services designers often ignored (NEEF 2004)
Adverse selection, whereby supplier can promote products as energy efficient, even if they are not (PC 2005)
Lack of understanding of the consequences of rapidly changing expectations re environmental impact of buildings (LEHR SWG 2007)
Lack of standard cost-benefit analysis (NEEF 2004)
Services can encourage energy waste as part of the service / Perception that high energy use . Energy waste is a prerequisite for quality - combine - *"Perception that high quality includes high energy service and high level of waste"* (LEHR SWG 2007)
Decision makers not resourced to implement energy efficiency projects despite short paybacks (6 - 12 months)(LEHR SWG 2007)
Historical budget allocations (EEF 2004)
Procurement policies do not encourages innovative technologies (LEHR SWG 2007)
Industry cynicism about potential performance of new energy efficiency technologies(LEHR SWG 2007)
Management not responsive to significant energy efficiency opportunities identified in due diligence reports (LEHR SWG 2007)
Cost of obtaining information on energy efficiency (PC2005)
No means of capturing the benefits of being the first mover (PC 2005)
Moral hazards for energy eficiency auditors after contracts are signed (PC 2005)
BCA strategies seen as a monetary waste hence endeavour to avoid BCA upgrades (LEHR SWG 2007)
Satisfying rather than exceeding the brief (LEHR SWG 2007)
Decision making that satisfies minimum requirements rather than aiming for best practice (LEHR SWG 2007)
No legislation driving compliance with “energy efficient” parameters (LEHR SWG 2007)
Middle management inertia irrespective of senior management commitment to energy efficiency (LEHR SWG 2007)
Conservative approach during design phase (high inbuilt safety factors i.e.over-engineering) leading to energy inefficiencies (LEHR SWG 2007)

3. Low Energy High Rise project research survey

The Low Energy High Rise Project Steering Committee and Planning Group recognised from the outset that the project needed to be evidence based to effectively drive market transformation. The empirical data allows the project to understand what is happening in the market and what actually works and to make this the basis for the development of the suite of initiatives.

3.1 Development of the research survey

As soon as the project concept was resolved in consultation with industry, the project Planning Group commenced work immediately on early drafts of the survey. The initial draft survey was then presented to the Supply and Demand Working Groups for comment as well as the Steering Committee and a wider industry group that had expressed interest in the project. Once the survey content was resolved three companies were asked to respond to a tender to create and manage the survey online. National Project Consultants and Exergy Pty Ltd won the tender for this work.

3.2 Contents of research survey

The Low Energy High Rise project survey is designed to develop an assessment of the performance of the current market with a specific emphasis on the ability of given physical building types and management structures to deliver energy efficiency. The intention of the survey is to identify the empirical performance range and theoretical performance limits associated with:

- Building type, servicing, and age
- Management, ownership and maintenance structure
- Tenant / landlord relationship

To this end the project has designed three different surveys to be completed by people in four different roles who are involved and have influence over energy management in an existing office building – the tenant, the building manager, the asset manager and the portfolio manager. The three surveys are: a tenant survey; base building survey and manager survey.

The intent of the base building survey is to understand the relationship between building technology and performance. The management survey seeks to understand the relationship between building management and building energy performance. The tenant survey seeks to understand the extent to which tenants are managing energy in their tenancy and influencing landlord approaches to energy management. The manager and tenant surveys are confidential to the respondents however the base building survey is accessible to the building manager, asset manager and portfolio manager involved in the management of each building.

The online survey generates a building identifier number for each building as the basis for managing the large number of responses being provided by a “representative tenant”, a building manager and potentially an asset and a portfolio manager depending on whether the building is individually owned or owned by a portfolio where all three management roles are likely to be involved in managing the building.

Topic areas in the base building survey include: building details; building performance data; refurbishment history and plans; building architecture; building services; dominant air conditioning type; lighting; building management system and monitoring; car park; water use; building operation; leasing details; energy and water management; maintenance.

Topic areas in the management survey include: level of authority; authority over energy matters; responsibility limits; incentives; attitude; response activities such as what level operational changes have you made in the past year to maintain or improve energy efficiency in relation to the buildings you are involved with; knowledge and qualifications; barriers and incentives.

Topic areas in the tenant survey include: tenancy details covering lease commencement year, expiry, extension options; plans to relocate; program for improving energy efficiency and choices of lease type to influence landlord energy services.

3.3 Implementation of the research survey

The domain for the study is office buildings of 5000 m2 NLA and above capturing 75-80% of capital city CBD buildings graded D or higher with 160 buildings determined as the statistically valid number to participate based on this domain. Building nominations were sought for 180 building nominations to allow for some attrition.

Predominantly buildings nominations were sought from building owners to ensure that the various management layers were aware of and were given authority to participate in the survey. Contact details for a “representative tenant” were also sought from owners to simplify the process. To ensure that buildings nominated for the survey were widely representatives, nominations were sought from the private sector and public sector covering large and small portfolios with buildings in capital cities and regional centres.

Government portfolios participating include: Queensland Public Works, NSW State Property Authority, ACT Department of Territory & Municipal Services, Department of Defence, SA Department Transport, Energy & Infrastructure, Victorian Department Treasury & Finance, WA Dept Housing & Works, and the NT Government Property Management Unit. Private sector nominations came from a wide range of organizations. Building nominations were made via a nomination form that identified the portfolio manager, asset manager, building manager and tenant for each building. Important steps in implementing the surveys included:

- Ensuring that all named on the BNF have been made aware they are participating in the survey
- Provide all with user names & passwords to access the surveys
- Providing incentives to engage the respondents
- Setting deadlines for survey completion and providing feedback to building owners on who had / had not completed the surveys.

The most recent assessment of survey completion on 2nd April, 2008 showed that 70.21% of base building surveys, 52.49% of manager surveys and 44.79% of tenant surveys had been completed. Further work is in train to ensure high levels of completion for each survey type.

3.4 Analysis of the survey data

Once high levels of survey completion have been achieved the data will be analyzed including by:

- Testing the quality of the data by questioning its completeness and assessing its credibility
- Looking at cross correlations of everything against everything
- Identifying correlations that align statistically by drawing together things that produce results, things that happen together, whether or not they produce a result e.g. gross lease/good building energy performance/ this management approach/ this type of building and
- Identifying responses that point to good / poor energy performance

The results of the survey will be presented in a research report to the industry sponsors and then to all project participants and the wider industry.

Once the survey results have been determined the information will be provided to the groups developing the suite of initiatives to ensure a strong relationship between the proposed tools in the suite of initiatives and the survey outcomes.

4. Development of the Suite of Initiatives

4.1 Initial process to develop suite of initiatives

Work has commenced on developing the suite of initiatives including at a meeting of the Low Energy High Rise project's Steering Committee and Planning Group, a Brisbane meeting of project participants and at a joint meeting of the Supply and Demand Working Groups. The table below shows the draft list of initiatives that have been suggested by the three meetings. The initiatives have been further categorized for easier reference.

Broad Area of Impact	Examples of Individual initiatives
Change BUSINESS DECISION MAKING PROCESSES.	Tax Breaks Govt. Funding Incentives Depreciation – accelerate Valuation Protocols Energy Efficiency in Due Diligence Carbon Credits will change accounting rules.
Change the MARKET DYNAMICS	Green Leases National Standards for lease agreements Mandatory Green Power Purchases Mandatory ABGR ratings Mandate the landlord pays for energy use Regulate to prohibit low efficiency products Legislate emissions limits Re-commissioning Programs Plan for Green Business Landlord Guarantee re Max Energy use Focus of lower graded buildings Whole Precinct projects (extend the boundaries)
SIMPLIFY and reduce FRAGMENTATION.	Resolve conflicting regulations (National) Standards for:- Energy Efficiency Maintenance Measurement Up-grade triggers Capped Energy Consumption
INFORM and ENCOURAGE –	Green Guides, Information Packs Case Studies Lead by Example Energy Benchmarking Visualization Techniques Visual rating and metering Mandatory Disclosure
BUILD CAPACITY	Education Training Skills Development Replicate Programs Empower Tenants Accredit Building Operators

4.2 Refined process to direct further development of the suite of initiatives

The Low Energy High Rise Project's Planning Group has recognised that the draft initiatives were directed at what Government and others could do, rather than what industry can control. The aim now is to refine and direct the process for developing the suite of initiatives by:

- Working on four scenarios aimed at taking an average building and improving its energy efficiency to ABGR 4 – 4.5 stars

- Ensuring the initiatives reflect what really happens in the industry
- Working below the Government policy level & focussing on what the industry can effect and implement

The four scenarios that will be developed reflect industry experience and will be:

- An existing building with a minor capital expenditure budget
- A floor by floor upgrade in an existing building
- Complete building refurbishment
- A new Sustainability Manager in a portfolio required to introduce sustainability and to improve building performance

The issues the working groups will consider in developing each scenario will cover:

- Obtaining the budget
- Managing required resources and time
- Securing internal competence
- Securing external competence
- Managing relationship with tenants before, during and after the necessary activities in each scenario
- Getting the scope of works right
- Executing the scope of works successfully
- Commissioning the scope of works correctly
- Maintaining the ongoing level of building energy performance

The expected output from the scenario development exercise will potentially be:

A few new key enabling tools produced by industry that will:

- Be evidence based
- Relate to each other and have exponentially increased results because they are synergistic

These new enabling tools for the suite of initiatives may include:

- A list of tenant rules to go into lease contracts
- An overarching, step by step process for initiating upgrades
- Guidance on using and interpreting ABGR ratings
- Overarching technical and financial guidance on improving building energy performance
- A different business model to collect energy efficiency opportunities in a group of buildings with different owners to the market as an investment opportunity
- A well constructed gross lease

5. Project's next steps and the new information that can be presented to the Sustainable Buildings 08 Conference

The Low Energy High Rise Project will implement the approach outlined above to develop the suite of initiatives that will be the key project output. These new enabling tools will be assessed against evidence from the survey and further refined. We recognise that it will be critically important to cross correlate the site of initiatives with the evidence from the survey to show empirically that the new tools will work.

The project aims to identify a group of buildings from the survey that are demonstrating aspects of the suite of initiatives and identifying how they are being executed in practice. The project will then use this knowledge to develop models of the processes, for example a particular management structure that is shown to be effective.

The Low Energy High Rise Project Planning Group expects that detailed results from the survey and a more refined suite of initiatives will be complete and able to be presented to the SB08 Conference.

ENERGY PERFORMANCE OF BUILDINGS IN THE AUTONOMOUS PROVINCE OF SOUTH TYROL, ITALY

Yan SCHMITT [1] **Marco CASTAGNA [1]**, Alexandra TROI [1], Wolfram SPARBER [1]
Luisa ZAMPIERI[2], Gianfranco MINOTTI[2], Bruno GOTTER[2]
Georg PICHLER[3]

[1] Institute for Renewable Energy, European Academy of Bolzano, Bolzano, Italy, renewable.energy@eurac.edu, www.eurac.edu
[2] Institute for Social Dwelling (Istituto per l'edilizia Sociale, IPES) Bolzano, Italy, www.ipes.it
[3] Department for Air and Noise (Ufficio Aria e Rumore), Province of Bolzano, Italy, www.provincia.bz.it

Keywords: Region of South Tyrol, energy performance of buildings, social housing

Summary

The province of South Tyrol shows promising tendencies in the field sustainable buildings and specifically in the field of energy performance of buildings.

A major driving force for this process is the regional energy certification system for buildings which was launched in 2002, long before the European directive on Energy performance of building had to be implemented by the European countries. The system has led to a significant increase of the share of low energy construction (space heat requirement up to 50 kWh/m²a), from approx. 2% in 2002 to nearly 60% in 2007 in the residential sector.

Another important column for low energy construction is the activities of the regional entity for social dwelling. In fact, already for the working program of 2001-2007 which included 2550 dwelling units, the IPES (Istituto per l'edilizia sociale della provincia autonoma di Bolzano) committed to erect buildings with a maximum calculated annual space heat requirement (SHR) of 50 kWh/m². Some 10 buildings, with around 130 apartments according to 1% of the stock of IPES have been refurbished to a SHR of between 50 and 70 kWh/m²a in the last years.

Outstanding the forward-looking general working program, IPES has realized several lighthouse projects for sustainable building. One of those projects, is IPES's first passive house. The building with 8 dwellings is since July 2006 under monitoring by EURAC.

1. RUE, RES and sustainable construction in the Province of South Tyrol

The Province of South Tyrol with its approximately 500.000 inhabitants has an outstanding position in Italy regarding environmental, RUE and RES issues. Many figures are comparable to those of the neighboring country of Austria which again can for several aspects be regarded as forerunner in Europe.

Over 700 hydro power plants are in operation in South Tyrol producing more electricity than the annual consumption. In 2005, 4.000 small biomass heating plants (20-100 kW) and over 30 biomass district heating plants (0,8-34 MW) were installed. Further, one third of all Italian solar thermal installations were in operation in South Tyrol, resulting in a collector surface of about 0.33 m² per capita (Autonome Provinz Bozen 2008).

In fact 45% of South Tyrols energy consumption (excluding from traffic) is covered by renewable energy sources. It is the declared goal of the regional government of the autonomous province to increase that figure to 75% by 2012 and 100% by 2020 (Laimer 2006, Autonome Provinz Bozen 2008).

One of the major approaches to reach that goal is the reduction of energy consumption for space heating. Since January 2005, the regional government requires a maximum SHR of 70 kWh/m²a for new buildings. This decision has its funding amongst other on the fast success of the certification scheme for energy performance of buildings described below. Currently strong attention is given to energetic refurbishment of buildings, comprising measures such as the publication of brochures, the establishment of an information line and the retention of the regional subsidy scheme after the introduction of then national tax relief scheme for energetic refurbishment.

2. The regional energy performance of buildings certification scheme, CasaClima

Even before the European “Energy performance of building directive” (EPBD) was released in December 2002, the Autonomous Province of South Tyrol had introduced an energy certification scheme for buildings. In the beginning, the certification was a voluntary measure.

But already by January 2005, the regional government required a maximum space heat requirement (SHR) of 70 kWh/m²a for new buildings, applying the CasaClima certification for documentation. The success of the first years of the voluntary scheme and the new availability of specialized planers and craftsmen paved the way for this initiative of introducing a minimum requirement. Since beginning of 2008 the CasaClima scheme represents the implementation of the EPBD for the Autonomous Province of South Tyrol.

2.1 Classification of energy performance

Through the scheme, buildings can be classified according to their space heat requirement. This allows constructors, potential buyers and tenants to estimate heating costs of a dwelling and enables the comparison with other constructions, also regarding the buildings envelope and thermal comfort. The “Department for air and noise”, which at first stage was in charge of the scheme, therefore developed a standardized calculation method. Buildings are classified in categories. For reasons of facilitated comprehension the categories as well as their graphical representation are similar to those typical for household appliances (see figure 1). The categories reach from CasaClima Gold (10 kWh/m²a) over CasaClima A and B (30 and 50 kWh/m²a) to thermal protection classes C (70) to F (160).

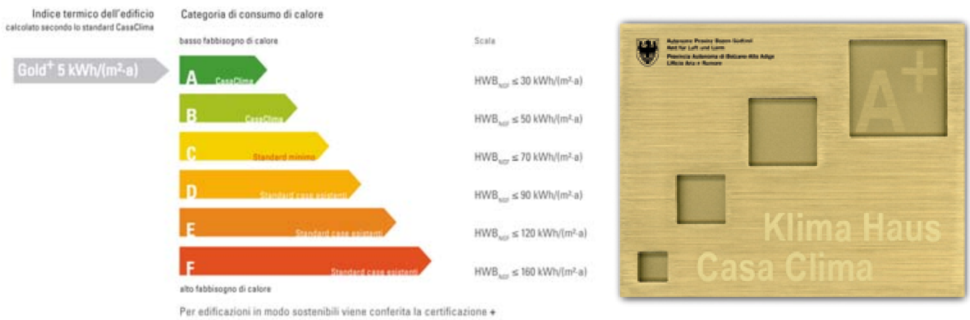


Figure 1: Energy Efficiency Categories and CasaClima insignia

2.2 Additional label for sustainable construction

To underline the fact that not only energy consumption for heating is crucial for sustainable development in the building sector, the option of having a building certified as “CasaClima plus” was established, whereas the plus stands for “sustainable construction”. To attain this classification buildings have to fulfill the following set of requirements. The space heat requirement must be below 50 kWh/m²a. The latter must be provided without the use of fossil fuels except in case of connection to district heating or an already existing system. Further, restriction regarding the use of materials are set. EPS, XPS and PU may not be used for walls and pitched roofs, no PVC may be used for flooring windows of doors and finally the use of tropical wood is prohibited. Additionally to those restrictions, the object has to have at least one of the following features. (i) a PV-system, (ii) a ST-system, (iii) rain water usage, (iv) a wood, clay or straw construction or (v) a green flat roof.

2.3 Development of low energy construction in Sputh Tyrol

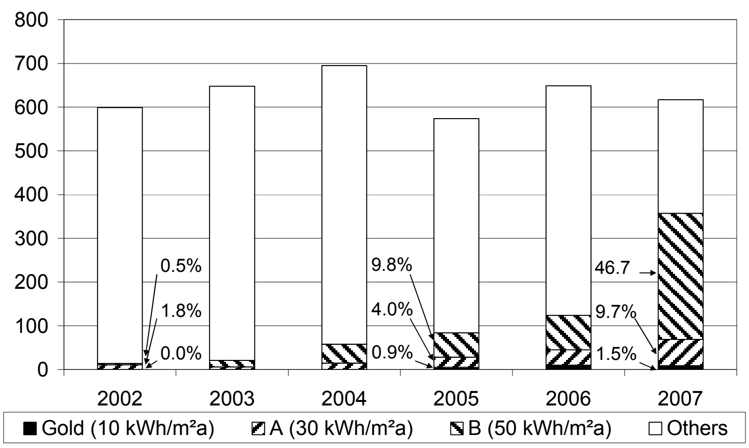

Figure 2: Repartition of CasaClima on new residential buildings in South Tyrol (Schmitt et al. 2007 ‘KlimaHaus …’)

The CasaClima project had the declared goal of increasing low energy architecture in South Tyrol which it did with outstanding success. The number of buildings certified as CasaClima B or better since the introduction of the scheme has grown from 14 in 2002 to 357 in 2007 (Schmitt et al. 2007 ‘KlimaHaus …’). Since the already ambitious class C was introduced was introduced as minimum requirement in 2005, the share of buildings underbidding this with at least CasaClima B has grown from 15% to 58%.

2.4 Accompanying measures to the CasaClima initiative

In order to increase the demand side in South Tyrol a set of measures is conducted: On the one hand the owners of buildings of category B, A and Gold obtain an insignia for the front door, which they are in general proud to show (see figure 1). In the beginning days the insignia further represented a good starting point to involve people who were not yet familiar with the topic. In special cases, such as outstanding buildings or energy performance, the insignia was submitted by the very popular official in charge for environmental affairs of South Tyrol.

On the other hand the CasaClima project launched an annual award for the “best CasaClima”. Five different categories are nominated i.e. dwellings, commercial buildings, tourism, energy plus and refurbishment. The award usually generates good media attention thus increasing the popularity of the project and probably is a further motivation for architects for best practice in sustainable architecture.

The supply side as well is considered intensely by the CasaClima project. One of the major tasks of the CasaClima Agency is the organization and the conduction of educational courses for planers and craftsmen. The Agency first was founded to conduct promotional measures and has meanwhile overtaken also other tasks of the “Department for air and noise” concerning CasaClima. By 2007, around 8000 planers and Craftsmen had visited basic courses (3200 in 2007), around 650 planers had achieved CasaClima Expert (110 in 2007) (Schmitt et al. 2007 ‘KlimaHaus …”).

The Agency further organizes a conference accompanying the “KlimaHouse fair”. Animated by the success of CasaClima, the trade fair of Bolzano decided in 2005 to host this annual fair which has become since, with 36000 visitors from all over Italy, an event of national importance for sustainable construction.

3. The activities of the regional entity for social housing IPES (Istituto per l’Edilizia Sociale) in the field of sustainable building

The IPES is a public body that, with its some 200 collaborators, on the one hand acquires, maintains and administrates around 12000 own apartments and on the other hand manages the provincial funds for housing subsidies.

Since long IPES is committed to low energy architecture and has built multiple lighthouse projects in South Tyrol, also for eco-buildings. In general the motivation for these projects was to investigate the feasibility of innovative standards for social housing, but also to explicitly be a pacemaker for energy savings in housing in South Tyrol (Minotti 2006). This commitment is not least due to the strong engagement of the former President Mrs. Franzelin, who is very sensitive to environmental issues, and in particular did highly favor lowered energy costs for the IPES clientele.

In the last working program of IPES, that was in set up under her presidency, a maximum space heat requirement of 50 kWh/m²a was decided for the 2550 new dwelling units to be built in the years 2001-2007. However, already in the beginning of the 90’s IPES had notable tendencies towards innovative low energy construction. For instance when in 1990 a house was planned that would later be certified as “category C” (70 kWh/m²a) by the CasaClima scheme.

Regarding low energy, one of nowadays most important objects is the passive house in Bronzolo that was accomplished in the first half of 2006 and since then is monitored by EURAC.

4. The IPES passive house Bronzolo

The IPES passive house Bronzolo (PHB) is one of the first multi-family buildings in passive house standard in Italy The planner of the building services calculated for the project a space heat consumption of 9 kWh/m²a according to the aforesaid certification scheme. Due to that and the fact, that is features all above mentioned sustainability requirements (see section 2.2), it was labeled “CasasClima Gold plus”. As the building is IPES’s first construction attaining passive house standard, the management decided to conduct a monitoring campaign. This should principally verify the design figures and provide technical support in case of deviations.

Figure 3: South façade of the IPES passive house in Bronzolo

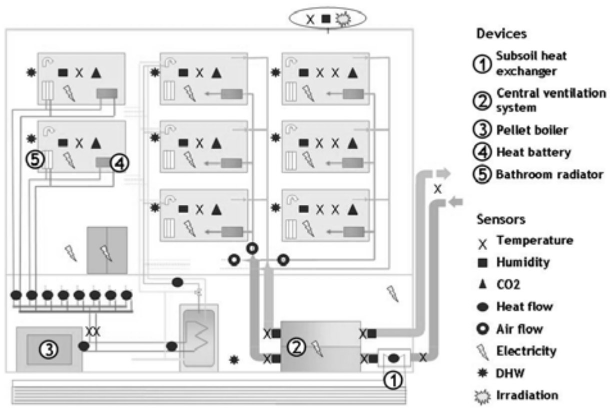

Figure 4: Scheme of monitoring devices and sensors

4.1 Description of the building

The object is a solid brickwork construction with 28 cm external mineral foam insulation. The compact structure contains 8 apartments on three floors with a total living area of 576 m². The basement comprises the building services room, the garage and storage rooms. The green flat roof has a beam structure and a wood construction to create inclination with an average thickness of around 60 cm filled with cellulose. Main features to avoid thermal bridges are e.g. the placement of the foundation walls on foamglass and the static and thermal separation of garage ceiling and basement ceiling. The balconies are suspended as they could not be field mounted for obligatory reasons. According to the producers of the windows, a particularity of the building is the construction which enabled the mounting of the windows after the finalization of external works, which could have damaged the frame.

4.2 The monitoring system

The building is equipped with a monitoring system showing a high level of detail (see figure 4): Each apartment has a multiple sensor measuring temperature, CO_2 and humidity to evaluate living comfort. Energy requirements of the single apartments are registered with heat flow counters and electricity meters. Furthermore, heat flow counters, temperature, humidity and air velocity sensors register the functioning of the building services. Finally, the common electricity consumption is measured as well as climatic conditions by means of a weather station.

A first two years monitoring of the building was assigned by IPES to EURAC before finalization of the building in May 2006. The monitoring period started in July 2006 and has since provided data for two summer and two winter periods.

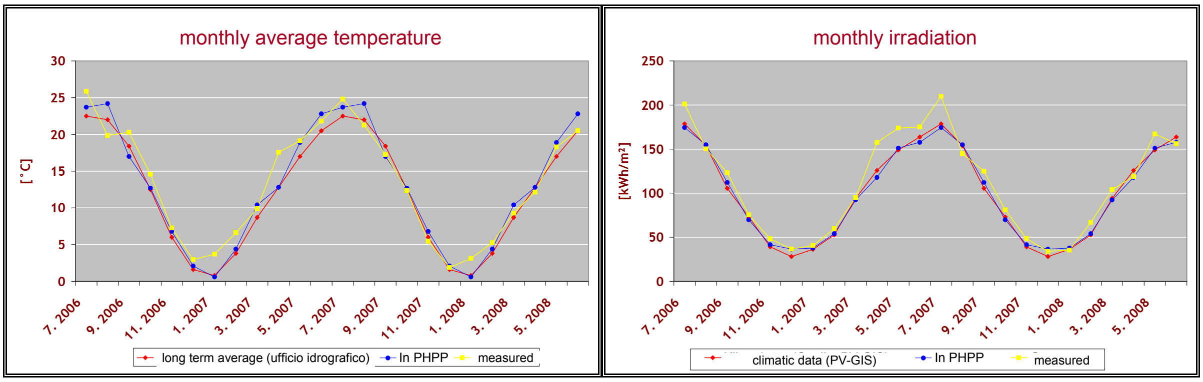

Figure 5: Climate conditions (temperature at the left and irradiation on the right side) during the monitoring period, compared to long time average and PHHP planning values.

4.3 Summer behavior

July 2006 appeared to be extremely hot in Bronzolo, with an average temperature of 25.9°C compared to the long term average of 22.5°C (see figure 5). Inside the building the average temperature in July was of 28.9°C with a maximum of 31.2°C, which demonstrates clearly that a very well insulated building envelope does not obligatorily prevent from overheating, and that in the case of the PHB overheating is an important issue (Schmitt et al. 2007).

There is no central cooling device installed, which is yet typical for dwellings in the region, though summer temperature peaks can easily compete with southern regions in Italy. However, for social housing cooling systems are hardly realizable. Therefore IPES and EURAC discussed other possible solutions to overcome the situation of overheating. In fact it was found out, that the distributed user instructions did not include the explicit recommendations for intensive airing at night and the use of the installed shading elements that need to be activated manually. This possible lack of information was made up by the distribution of new instructions. Further it was found out that supply air was actually heated up by nearly 2 K through the high temperature in the building services room and possible leakages in the ventilation system which was partly due to the poor functioning of the ventilation of the service room. This was removed through the installation of a new ventilation system for the latter. In 2006, the effectiveness of the measures could not be assessed because outdoor temperatures rapidly and persistently felled in August.

In the year 2007 indoor temperatures again rose considerably above comfort level with 3520 h/a (40%) of average indoor temperatures above 25°C. Though in a survey most of the tenants confirmed using the shading elements and practicing night ventilation in summer, it is not clear to what extend they actually do. A recent dynamic simulation of the building revealed, that if the air exchange rate of forced ventilation was increased only from 0.8h^{-1} to 1.2 h^{-1} when outdoor temperatures are lower then indoor temperatures, the number of hours in which indoor temperatures surpass 25°C could be lowered to 1139 h/a (13%) (Castagna et al. 2008). Such an increase of forced ventilation is actually not feasible in this case, since the system was simply not designed for that. But the outcome emphasizes that in this case an intense night airing and according cooling of thermal mass could significantly increase living comfort without the need for active cooling. Finally measurements have shown that there is potential for mitigation of overheating in summer through electricity saving measures. The consumption per square meter between the apartments highly differs and in general average temperatures in July (26.5 – 29 °C) are distributed in function of occupancy level (CO_2-level) but also in function of electricity consumption (1.2 - 3.5 kWh/m²) which do not necessarily go hand in hand (see figure 7).

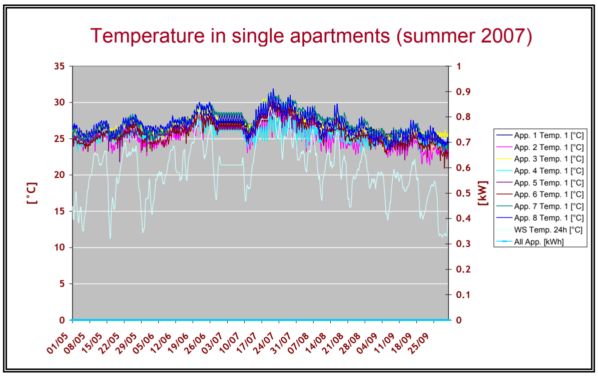

Figure 6: Indoor temperatures during summer 2007

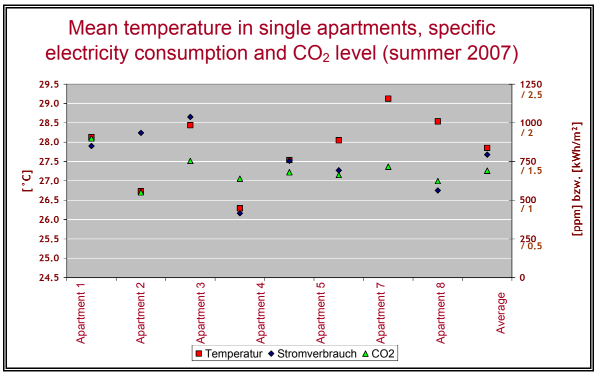

Figure 7: Mean indoor air temperature of single apartments, compared to specific electricity consumption (kWh/m²a) and CO_2 level (ppm)

4.4 Winter behavior

The winter performances have so far proven not to be entirely satisfactory. Though the winter 2006/2007 was comparatively mild in South Tyrol (2100 degree days instead of 2700 long term average), the space heat consumption (SHC) of the PHB was with about 25 kWh/m² higher than predicted. Figure 8 shows the SHC of the single apartments of the PHB for both the winters 06/07 and 07/08 in comparison to the SHC of passive houses measured in the European CEPHEUS project (Feist 2001).

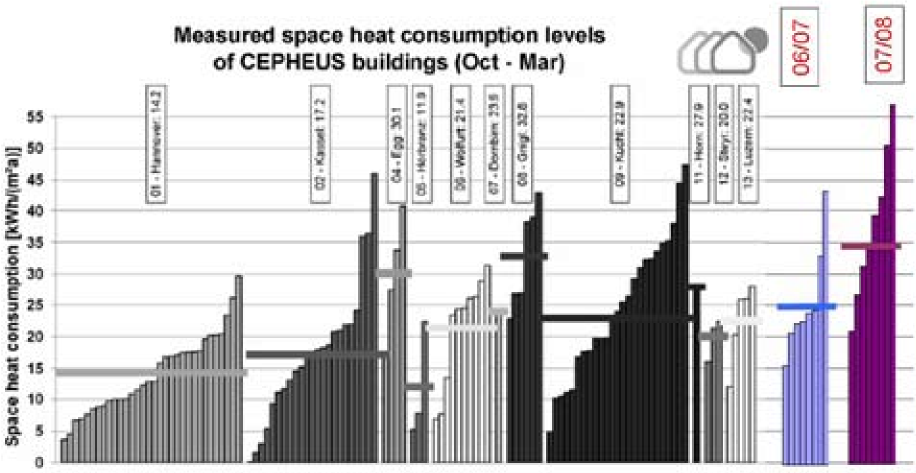

Figure 8: Space heat consumption for the PHB in 2 monitoring periods, compared with other passive houses in Germany as documented in the CEPHEUS study by Feist (2001)

The elevated SHC in 06/07 was attributed to losses through manual ventilation, the fact that indoor temperatures were in average 2 K higher than in design calculations and possibly to drying of the concrete in the first year of occupation.

The even more elevated SHC in 07/08 is partly due to the fact that the winter had more degree days (2500) and that average temperatures in the apartments were even slightly higher. But mostly it is due to malfunctioning of the ventilation system. On one hand a casual programming caused a periodic (night and weekend) switch off of the ventilation and on the other hand an unexpected clogging of the heat exchanger of the geothermal plant occurred. Both has led to a significant reduction of the supply air stream which on the one hand probably caused further manual ventilation and according losses and on the other hand remarkably reduced the efficiency of heat distribution (preheating batteries of supply air for each apartment) during the malfunctioning. A normal efficiency for the concerned period would have lead to a similar SHC for 06/07 and 07/08.

5. Conclusion

Concluding, it can be sustained that IPES has had an important share in the development towards sustainable and low energy construction in South Tyrol. The wide use of renewable energy sources and the political commitment for further enhancement of sustainable energy use in the region, are of course important background, but without the IPES's confident and highly visible practical realization of low energy buildings in the early phase, also the outstanding development of the CasaClima initiative might have been a little slower.

The CasaClima project had the declared goal of increasing low energy architecture in South Tyrol which it did with outstanding success. The success of the first years of CasaClima as voluntary scheme and the new availability of specialized planers and craftsmen paved the way for the initiative of introducing a minimum requirement, and still development goes on: Since the already ambitious class C was introduced as minimum requirement in 2005, the share of buildings underbidding this with at least CasaClima B has grown from 15% to 58%.

Energy performance of buildings certification schemes allow in a neutral way consumers to estimate the thermal comfort and running costs for heating. This is supposed to raise awareness and thus increase the market for low energy architecture from the demand side. In the case of CasaClima, this is probably not sufficient to explain the results. The strong political devotion and a package of accompanying measures created a regular hype around CasaClima. In fact "CasaClima" has been elected South Tyrols "Word of the Year 2007".

Looking at a most ambitious buildings, as the IPES' passive house in Bronzolo, which is one of the first multi-family passive houses south of the Alps, IPES has even tried to go one step further.

The monitoring of both the achieved comfort levels and energy consumption showed good results: Comfort levels, both regarding temperature and humidity as well as CO_2 levels, are within comfort levels for most of the year. Energy consumption is – if mathematically compensating the periods of malfunctioning – are also within the range of other "real" passive houses (see figure 8).

Summer behavior shows periods with high temperatures – but not in all apartments the same degree, what suggests that also user behavior has a not negligible influence on the results. As in other regions, where air conditioning systems are not commonly used in residential buildings, even if outdoor summer temperatures can reach high values, the behavior of tenants regarding shading, night ventilation and internal loads prevention is critical for summer comfort. Unfortunately there are not yet available data for comparison with other IPES' buildings' summer behavior.

Also tenants evaluate living in a passive house positively. Despite the above described small cases of malfunctioning and a few other inconveniences the tenants mostly rated the ventilation system as of very satisfactory and measurements have shown that it has in general been working well e.g. for what regards air humidity in winter, which was not lowered below comfort level.

Within IPES, there is however and will be an important discussion whether ventilation systems with heat recovery should or not become standard for new buildings, a indispensable feature for very low energy and passive architecture according e.g. to the CasaClima agency. This discussion will accompany, in the next years, other institutions and housing companies in South Tyrol, since similarly to Germany and contrary e.g. to France the installation of ventilation systems is not standard for housing constructions.

CHANGING THE CULTURE OF COMMERCIAL BUILDINGS IN AUSTRALIA: THE ROLE OF GREEN LEASES

Keywords: commercial, building, green lease, education, culture, tenancy

Summary

Innovative new 'green' commercial building developments are emerging across Australian cities. This is a positive change. However, to advance the overall sustainability of Australia's commercial buildings sector two key issues need to be addressed. The first is the importance of focusing on the sustainability of the whole building - the base building and the tenancies. The second is the importance of focusing on existing buildings, as new buildings are a small proportion of the total building stock.

In addressing these issues, tenants hold the key. Their decisions and actions have significant potential to enhance or undermine the sustainability performance of commercial buildings, both new and existing. The potential to create change through tenant decisions and actions is significant given the emergence of corporate sustainability as a key business driver. However, this will require a culture change in the way leases are negotiated. One way of facilitating this process is through the use of 'green' leases.

A green lease is different from a standard lease in that it incorporates ecologically sustainable development (ESD) principles to reduce the building's environmental impacts. This paper focuses on the way green leases for office tenants can be used to create culture change within tenant operations and offices, as well as influencing building managers and building owners. It looks in detail at the *Green Lease Guide* developed by Investa for use with tenants of commercial properties.

1. Introduction

1.1 The Importance of Commercial Buildings

Commercial buildings have a significant environmental impact. The Australian Greenhouse Office (AGO, 1999) estimated in 1990 that commercial buildings were responsible for about 32 million tonnes (Mt) of greenhouse gas emissions. Emissions are currently increasing at about 3 to 4% per annum, which means they are approximately ten percent of Australia's total greenhouse emissions. Commercial buildings also account for about ten percent of urban water consumption (NABERS, 2006).

There is much attention now being paid to new 'green' commercial buildings to reduce this impact. More and more new buildings are being constructed to meet five and even six star Green Star (and up to 5 star NABERS ratings). However, new buildings only make up a small percentage of the commercial building stock. Urgent action is needed to improve the environmental performance of the existing stock if we are going to achieve the necessary reductions in resource use and greenhouse gas emissions. In many cases, the benefits from the operational energy reductions achieved with new developments will not even compensate for the embodied energy involved in their construction, as illustrated below.

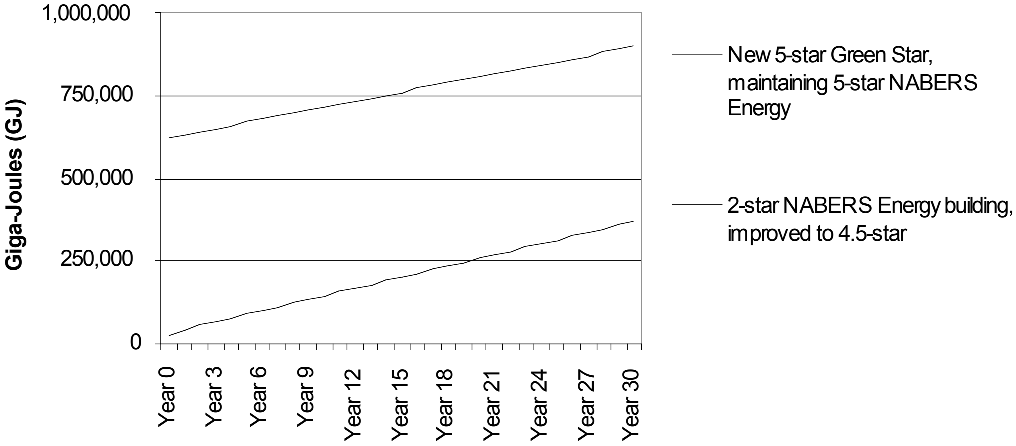

Figure 1 Lifetime energy comparison of new and upgraded buildings

Figure 1 illustrates this point with two alternative options for a hypothetical 25,000 m^2 building on a site in Sydney, Australia. In the first option, an existing building is upgraded from a 2 to 4.5 Star NABERS Energy rating, in a manner consistent with that which has been undertaken in a number of buildings in Investa's portfolio (Investa, 2007b). An alternative option would be to demolish then construct a new building that meets a 5 Star National Australian Built Environment Rating Scheme (NABERS) rating. Embodied energy is calculated at 25 GJ/m^2, a fairly typical figure. Over 30 years, the new 'green' building will have used more than twice as much energy as the upgraded existing building would have (Roussac, 2006).

A typical commercial office 'base building' is merely a skeleton which an interior designer uses to create an office. Occupants relate most closely to the light, colour and amenity of their fitouts, not the base building, and the tools they are given to perform work, such as their workstations, tables, meeting spaces, partitions and offices.

For a building to be 'green' it must have a green interior, not just a green base. An interior designer (who understands factors that affect indoor environmental quality) working in close collaboration with the occupants should be able to create a 'green' office tenancy in almost any building that meets relevant Australian Standards. This is even more clearly the case if the base building owner commits to vigilant maintenance of base building services such as heating, ventilation and air conditioning systems.

It's a common misconception that to be 'green' a building has to use contemporary design and state-of-the-art technology. In fact, some of the best performing buildings are older buildings where the building manager has taken measures to optimise performance and has supported tenants to do the same. Some green outcomes are better achieved through improved building management practice, while others might require capital expenditure on either the base building or tenant fitout.

Fitouts and refurbishments are responsible for the consumption of a large amount of resources. Investa estimates that the average life of a typical office fitout in its portfolio is just over ten years. Treloar et al. (1999) estimated that the total life cycle energy consumption of fixtures, fittings and furniture at a churn rate of 5.6 fitouts over 40 years (i.e. a life of just over seven years) was close to, if not more than the operational energy use for the case study building. Clearly, fitouts also need to be designed with the environment in mind.

1.2 The Role of Tenants

Tenants therefore have a vital role to play in improving the sustainability of the commercial building stock. However, they often do not have the same drivers to go green as do building owners who have a building life-cycle perspective. To achieve significant advances requires a cultural change and often an increase in expertise and resources. As with many issues, there is often a gap between espoused values and observed actions. This can be for a variety of reasons.

Many tenants may be interested in committing to a greener building. However, it is often unclear how to incorporate 'green' commitments and requirements into a lease. The perceived degree of uncertainty around the success and cost of green measures is also a deterrent. Other tenants may be unaware of the benefits of occupying a greener building. Consequently, tenants often fail to take up green measures even though it would in fact be in their business interest to do so. Unless tenants are aware of the benefits, what to specify and how to implement green commitments, they will usually opt to occupy a building with a conventional lease, especially if there are additional upfront costs associated with a green lease.

One example of the business benefits to tenants is that for each one star improvement in a tenancy NABERS Energy rating, tenants will save about $3.70 per square metre in annual energy costs.

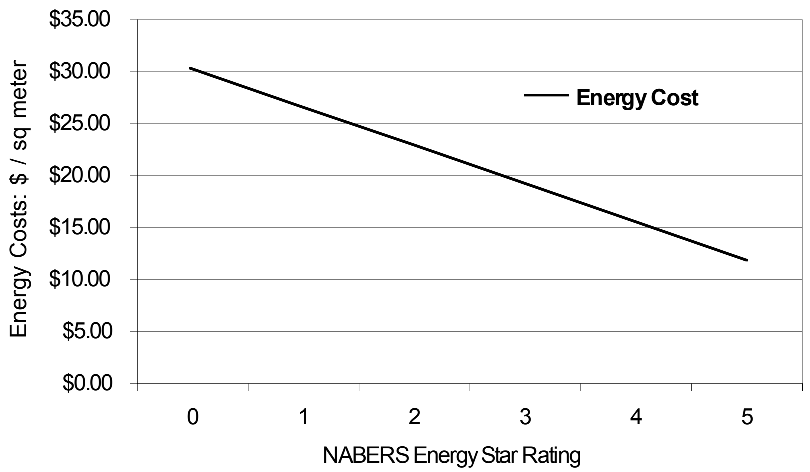

Figure 2 Relationship between ABGR rating and energy costs

As another example, about 60% of tenants' energy costs are for lighting. Tenants can have a very direct impact on this by asking for efficient lighting systems and making sure they are used efficiently.

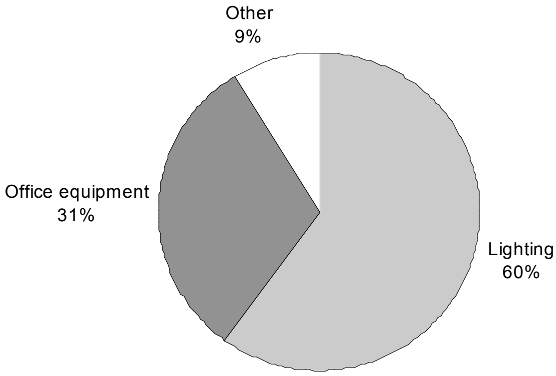

Figure 3 *Energy costs in a typical commercial tenancy*

The *Green Lease Guide* attempts to address these barriers by demonstrating the benefits of green commitments and providing practical information about implementation.

2. Green Leases

2.1 What is a Green Lease

A 'green lease' is different from a standard lease because it incorporates ecologically sustainable development (ESD) principles to reduce the building's environmental impacts. The green property market is still immature, resulting in uncertainty in the marketplace about what 'sustainability' or 'going green' means, what are the most appropriate 'green' measures that might be adopted in a building and the costs of implementation. People are familiar with what to expect from a standard building lease, but both parties may not know what to expect from a green lease.

Incorporating new requirements into a green lease requires knowledge and cooperation. A balance needs to be struck between cooperative and prescriptive approaches to negotiating environmental outcomes. Some Australian governments have implemented prescriptive type green lease requirements by specifying minimum NABERS ratings for properties they lease.

Leases can be issue specific, such as a minimum NABERS water rating, or a comprehensive package of measures as outlined in the *Green Lease Guide*.

The important considerations of a green lease for a tenant include:

- What do they want – what does 'green' mean and what are the targets
- What is the starting point – use measurement and rating tools to establish the baseline
- How to achieve the desired outcomes – obligations of tenant and landlord
- Who gets the benefits
- What has been achieved – auditing progress
- How to resolve disputes – who decides who is responsible for not achieving a target.

2.2 Green Rating and Evaluation Tools

A range of tools and aids exist to help in assessing and improving the environmental performance of existing buildings for tenants. In Australia these include:

- NABERS Energy rates a building's *actual* yearly greenhouse emissions. Almost a third of the national Australian office market (by net lettable area) has been rated using NABERS. Ratings can be obtained for the base building, an individual tenancy and the building as a whole.
- NABERS Water compares actual energy and water use to benchmarks. Indoor Environment and Waste rating tools have also recently been released.
- Green Star Office Design for office refurbishments, Office Interiors for new fitouts and a suite of associated tools for other development types.
- Ecospecifier also provides information of environmentally preferred products and materials.
- Good Environmental Choice Australia has an eco-labelling scheme for a range of products.

There are also a range of efficiency star rating labelling schemes for energy and water to assist in selecting efficient appliances, fixtures and fittings.

2.3 Benefits of a Green Lease

A Green Lease has a number of significant potential benefits for tenants:

- *Enhanced reputation*
  - Organisations are increasingly expected by shareholders and the community at large to demonstrate corporate social responsibility—'doing the right thing' in respect to the environment, employees and the community.
- *Attract and retain talented employees*
  - The importance of attracting and retaining talented employees is increasing in the face of a predicted decline in Australia's workforce (Colliers International, 2006)
- *Enhance employee well-being and productivity*
  - Research indicates a link between a good indoor environment in offices and improved employee well-being.
- *Enhance and protect organisational knowledge*
  - Workplace design influences the way staff share and develop knowledge.
- *Reduced liability*
  - It is an employer's duty of care to ensure a safe and risk free working environment.
- *Increased profitability*
  - All of these benefits can create significant cost savings for an organisation. In addition, there are direct cost savings such as lower electricity bills. Other building costs that tenants may not directly pay for (waste management, water use, air conditioning, etc.) are lower in a green building and a case can be made for passing these on.

3. The Green Lease Guide

3.1 Background

Tenants often see 'green' as synonymous with 'new'. This is not good for the environment, because it's crucial that we preserve and enhance as much of the built environment as possible, and it's not good for tenants – because in general, it's wrong.

Following the environmentally sensitive fitout of its Sydney head office, Investa sought to educate the market about the benefits of incorporating environmental considerations (many of which have well-being and productivity spin-offs) for tenants. It was found that tenants often lack the resources and expertise to deliver the environmental initiatives they would like to see integrated into their tenancies.

Investa has a variety of precedent leases (i.e. base leases that are developed to reflect the agreement specifics) for use in different markets and to reflect the terms agreed between landlord and tenant. All Investa precedent leases have a set of clauses that establish environmental objectives and an attached schedule which specifically sets out the commitments made by each party.

Despite the lease presenting commitments in a very cooperative form, in most cases tenants would not commit to specific actions in the schedule for a variety of reasons, including:

- environmental features being low on the negotiation priority list;
- an unwillingness to add non-traditional commitments to the deal;
- other landlords not negotiating Green Lease provisions; and
- failure to recognise benefits of high quality building management and fitout design.

The Guide was a response to these challenges. Among its objectives were the following, to:

- showcase best practice and help tenants avoid costly design mistakes (both for them and the landlord – if their fitout ultimately leads them to fall out of love with the building).
- help strategic decision makers articulate their design requirements, and hold project teams accountable.
- fuel demand for quality building management.
- take the focus beyond energy to address a broad range of environmental factors.

The Green Lease Guide is introduced as early as possible in a lease negotiation, ideally when the tenant is evaluating a series of accommodation options. Its target audience is strategic decision makers within companies – it's not a 'technical' document.

The Guide has been designed to:

- step tenants through all the environmental issues they'll face in undertaking a fitout;
- give tenants guidance on options, their costs and benefits;
- represent a quantum leap in Green Lease thinking and explain the role of the landlord;
- provide information and images that can be used for related educational initiatives; and
- contribute to a significant and measurable reduction in environmental impacts from commercial office tenants.

3.2 The Guide's Structure

The Guide comprises three main sections, each containing a number of topics. Each of the topics has an associated checklist to guide good practice and is given a rating from one to three stars for money savings, employee well-being, and reputation and corporate image.

Every one of the commitment options presented in the Guide is replicated in a succinct schedule that appends to the lease. The schedule serves as a summary of all the commitments made by each party and, because it does not contain any legal clauses, it is suitable for attachment to any standard commercial lease. In addition to making it accessible to any organisation that wants to use it, it provides the added benefit of allowing the lease clauses and green commitments to be negotiated independently of each other.

3.3 Green Lease Certificates

A recent improvement has been the development of a Green Lease Certificate to support the green leasing process. The Certificate expresses the level of commitment both the tenant and landlord have agreed to. It has been attractively designed so tenants will be inclined to display it. Its purpose is to give tenants recognition for their Green Lease commitments. It can also be used by Asset Managers and Facilities Managers as a marketing tool to promote their buildings and management attributes.

The Green Lease Certification process works as follows:

- Once the tenant has signed the Green Lease and it has been returned to the Asset Manager, a certificate template is marked up to reflect the commitments made under the lease.
- The certificate is then signed and presented to the tenant for display.
- The Certificate is reviewed and amended (as appropriate) on each anniversary of the lease.

4. Case Study: 50 Ann Street, Brisbane, Australia

Commercial lease negotiations between landlords and tenants in Australia typically focus on rent, the timing and mechanisms for rent reviews, lease term and incentives like rent free periods and fitout contributions. In short, the negotiations focus on financial aspects that impact both parties directly. Financial considerations that impact one party only are generally not addressed in the lease negotiations. This means that the negotiations will consider the cost of operating the base building (because this is passed either directly or indirectly to the tenant), but not the cost of operating the tenancy which is a matter for the tenant alone.

One of Investa's most significant recent negotiations was the renewal of 25,382m2 for 13 years with the Queensland State Government at the building known as "State Law" at 50 Ann St, Brisbane. The negotiation was unusual in that both parties took a 'total occupancy cost' approach to exploring opportunities to overcome split incentives. Split incentives arise when a party invests capital without a means of generating a return on its investment, because the revenues/ savings accrue directly to another party. For example, a landlord may invest in energy efficient lighting, but the tenant captures the resultant energy cost savings.

A broad ranging review of the building was undertaken to identify a variety of environmental efficiency initiatives, both within the base building and also the tenancy areas. The result was a series of recommendations including a comprehensive tenancy lighting upgrade. The majority of these were proposed as part of the lease offer, including a landlord 'incentive' specifically allowing for the upgrade of lighting and installation of occupancy based controls at the landlord's expense. The projected savings were then able to be factored into the lease analysis by the tenant.

One important factor that gave the tenant confidence to budget for the projected savings was the offer of a guarantee. The guarantee included an undertaking by the landlord to take the tenancy NABERS Energy rating from an unofficial rating of 2.5-stars to 4.0-stars, or perhaps even 4.5 depending on the participation of staff. In doing so, the tenant would save more than $150,000pa in energy costs, principally through the upgrading of light fittings and installation of a managed lighting control system (MLS).

To give confidence that the forecast savings would be achieved, Investa guaranteed that if the tenant's energy consumption exceeded the guaranteed maximum amount, they would be reimbursed for the additional energy expense and the amount of Green Power required to offset the additional greenhouse emissions would be procured on their behalf. This offer was subsequently made available to all tenants and is now referred to as the Investa Greenhouse Guarantee, incorporating the following features:

- If the tenancy performance is better than the guarantee, the tenant keeps the savings.
- If the bills are higher than guaranteed, the tenant is reimbursed for the difference.
- If the environmental impact is greater than guaranteed, it will be offset with Green Power™.

For most tenants, the guaranteed outcomes are delivered without any capital outlay or increase in operating expenditure, with the cost of energy-saving equipment and systems financed through ongoing energy savings. The Investa Greenhouse Guarantee has been designed to make the transition to energy efficient tenancies as painless, cost-effective and risk-free as possible.

The lighting upgrade project was complemented by various other energy and water saving initiatives that in the past three years have delivered year-on-year emission reductions and water savings of more than 30 percent for the building as a whole.

- Tenant energy & maintenance savings of $185,000pa.
- Tenant ABGR to increase from 2.5 Stars to 4.0 Stars.
- Tenant greenhouse emissions reduced by 1,206 tonnes pa (equivalent to taking 270 cars off the road).
- Various base-building ESD initiatives.
- Building valuation increased from $75m to $87m ($10m due to market cap rate compression, $2m due to the lease).

Investa's sustainability platform and willingness to commit to a series of base building environmental efficiency initiatives were major factors in the tenant’s decision to negotiate exclusively with Investa and directly contributed to the $2 million valuation uplift for the property.

5. Conclusions

There is clearly a place for new flagship new green commercial office buildings. However, they are not the sole answer to addressing the impact of buildings on the environment. New green commercial buildings can only truly lay claim to the “green” mantle if they are green on the inside, as well as the outside. A green base building must be supported by a green office fitout to deliver its full potential. Furthermore, much can be done to significantly reduce the impact of existing buildings, and in many cases this may be more effective than new construction.

What is needed is a way to transform the culture of building owners and tenants towards a greater appreciation of the value of green buildings. This will reduce the environmental impact of Australia’s building stock, help tenants achieve the optimal outcome from their workspace and, as a consequence, help landlords maximise the value of their commercial office assets. Green leases provide a way to facilitate that process.

Summary

In facing of the problems of global climate change and along with the promoting of the concept of sustainable development, developing ecological community has become an important policy goal in Taiwan. However, how the concept of ecological communities should be promoted to the potential homebuyers remains an unanswered research question. This paper explores a planning approach for promoting the concept of ecological communities. Through an examination of the pilot ecological community project in Tainan Salun High Speed Rail Station of Taiwan, this study identifies the target markets and the demand of services of ecological communities. By incorporating research methods involving interviews, field survey, and a questionnaire survey, this study finds that the demand of the facilities and services of ecological communities is related to the household income and the values of ecological communities perceived by homebuyers. Based on the results of the empirical studies, this study develops a set of marketing strategies for promoting the development of ecological communities.

Formatted: Font: 11 pt

1. INTRODUCTION

The concept of ecological community has received widespread attention in Taiwan in the past decade. This concept outlines a vision for building a living environment that integrates the considerations of ecological integrality, economic efficiency, and social equity. However, since the concept of ecological community has proposed a new type of community development and lifestyle that is different from the current housing market products, how this concept can be efficiently implemented in current community planning and real estate practices in Taiwan has become a critical issue. Employing research methods involves field investigation, in-depth interviews and questionnaire survey, this research attempts to explore two research questions: (1) How decision-makers in community design and land development should identify the key elements and facilities in building eco-communities in Taiwan? (2) How should we develop suitable marketing strategies to promote eco-communities in the existing real estate market? Through our empirical study, a set of workable strategies are suggested in order to promote the concept of ecological community in Taiwan.

2. LITERTURE REVIEW

2.1 Sustainable Development

The concept of sustainable development provides a theoretical foundation of the construction of ecological communities. With the promotion of the concept of sustainable development and ecological design, the notion of ecological communities has received much attention in Taiwan. Sustainable development is a broad concept. According to the Brundtland Commission (1987); sustainable development refers to "development that meets the needs of the present without compromising the ability of future generations to meet their own needs" (WCED, 1987). This popular definition introduces the concepts of long-term environmental sustainability and inter-generational equity, but it also suffer from attacks because it over emphasize an anthropocentric approach. The other widely cited definitions of sustainable development include those proposed by the International Union for the Conservation of Nature (IUCN) and the World Conservation Union (WCU). The International Union for the Conservation of Nature (IUCN, 1986) pointed out that "Sustainable development should seeks to respond to five broad requirements: (1) the integration of conservation and development, (2) the satisfaction of basic human needs, (3) the achievement of equity and social justice, (4) the provision of social self-determination and cultural diversity, and (5) the maintenance of ecological integrity." While the World Conservation Union in its 1991 report, Caring for the Earth, defined sustainable development as "improving the quality of human living within the carrying capacity of supporting ecosystems" (WCU, 1991). These popular definitions, together with related interpretations of sustainable development, provide a new framework for examining many critical housing and community development problems associated with current land development patterns and our behavior toward the use of natural resources.

2.2 The Concept and Key Elements of Ecological Communities

The concept of ecological community includes the meaning of ecology and of community. It was born out of a need to integrate the concepts of sustainable development and ecological design with the concept of community design and management. The notion of ecological community includes an important meaning of "succession," which applies not only in ecology aspect, but also in economic and social aspects. As noted by Roseland (2000), a sustainable (ecological) community is a community that uses its resources to meet current needs while ensuring that adequate resources are available for future generations. US environmental protection agency defined the meaning of community from an eco-community point of view, and pointes out that the key idea is that the people involved in any "community" have a common interest in protecting an identifiable, shared environment and their quality of life (USEPA, 1999). In summary, an ecological community resembles a living system and community governing institution where human, natural, and economic elements are interdependent and draw strength form each other. In addition, rather than being a fixed community development pattern, an ecological community will continually adjust itself to meet the social and economic needs of its residents while at the same striving to preserve the ecological integrity of its supporting ecological system. This new approach of community design and governance provides an alternative of community development that is suggested by many researchers to be able to avoid many of the current planning problems, such as the destruction of natural capital, unmanaged urban sprawl, declining quality of life, loss of species, and increasing in social inequality. Since "community" is the key element of spatial planning and regional governance as well as one of the most important action units to promote sustainable regional development, implementing the concept of ecological community may help build a sustainable future that aims at achieving the goals of maintaining environmental integrity, promoting economic efficiency, and promoting social equity and environmental justice.

Based on a review of related literature and our interviews, the basic planning principles of ecological communities can be summarized as follows: (1) managing development based on the limit of carrying capacity of regional ecosystem; (2) establishing the interdependent relationship between community development and ecological system; (3) minimizing ecological footprint by reducing the consumption of land and other resources; (4)encouraging compact development to reducing the conversion of natural and open lands to urban and developed uses; (5) using public space efficiently and fairly; (6) maintaining diversity and expanding the ideas of promoting diversity from bio-diversity to social diversity; (7)empowering communities to sustain prosperity and expand economic opportunity; (8) accumulating social capitals and building a stronger sense of community; (9) fostering a bottom-up community planning approach and mobile local citizens and their government (see e.g., Van der Ryn and Calthrope 1991; Calthorpe 1993; Beatley, 1998; Roseland, 2000; Lee 2003; ODPM 2004). Based on literature review and previous experiences, the key elements of construction an ecological community can be summarized in Table 1.

TABLE 1: The key elements of ecological communities

Local development planning and local environmental improvement:
land development plans that encourage compact development patterns; land use planning that encourages compatible mix-use; land use plans and measures that conserve environmentally sensitive areas; comprehensive community landscaping and community greening
Local transportation planning and management:
provision of public transit systems; manage the supply and demand of parking spaces; planning of pedestrian network and activities; supply of bicycle networks; livable street design
Community environmental management:
household waste recycling and waste reduction; supply of green infrastructure (e.g., a sewerage system; green ecological corridors); recycled product purchasing
Energy efficiency:
green building programs; renewable energy use programs; energy conservation programs; water conservation and gray water programs
Community socioeconomic Development:
housing development that attracts residents from diverse socio-economic backgrounds; economic development that encourages local employment; community self-help programs that improve safer environment
Organization/administration/governance:
community self-management and self-help programs; community citizen participation and education programs; the involvement of chief executive officers of local governmental agencies; involvement of the business communities; community partnership programs and various partnership networks.

3. RESEARCH METHODOLOGY

To achieve the purposes of this paper, this research employs a case-study approach. The ecological community project in the Salun Special District around Tainan High Speed Rail Station of Taiwan was selected as the case setting. This case is a pilot project currently actively supported by the Taiwanese government in order to build an eco-city and several ecological communities around the newly constructed HSR station in the Tainan County. It aims at creating a new generation of new town and community development model in Taiwan that incorporating the concepts of eco-cities and eco-communities. The research methods applied to the case study are as follows:

Field Investigation: field investigation was employed to analyze the environment of the research area, local and regional resources, local settlement patterns, demand of public facilities in communities, industries, and social-economic background of the research area. Apart from taking notes and mapping during on-spot observations, photography was also employed to record the environmental images and spatial characteristics of the research area.

In-depth Interviews: this research selected people with an interest in living in ecological communities for in-depth interviews. A modified snowball sampling method was used in which appropriate key subjects were selected and interviewed, and then further interviewees were suggested based on the recommendation of these initial research subjects. Initial research subjects were identified based potential homebuyer lists provided by local and regional real estate agencies and local governments. It is hoped that through in-depth interviews, researchers are able to investigate the demands and needs of the proposed ecological community. A total of 46 research subjects were interviewed.

Questionnaire Survey: questionnaire survey was used to investigate the basic need of the ecological facilities and services of the proposed ecological community as well as the individual's willing-to-pay for living in the proposed ecological community. The survey was the major information collation method for exploring the facility demand of the ecological community.

4. PLANNING FOR ECOLOGICAL COMMUNITY IN THE TAINAN SALUN SPECIAL DISTRICT

4.1. The SALUN Pilot Project and Planning for Ecological Community

This study uses the Salun ecological community project as research case. The Salun Special District, covers 299 acres and centers on the Tainan Salun High-Speed Rail Station, is selected as the research area. It is one of the four special districts designated to promote comprehensive land development around the newly constructed Tainan high speed rail station. It is also the first rail station area in Taiwan that attempts to build a new town, employing the concept of eco-city and eco-communities. Currently, the special district around the station area is mainly agriculture use. The proposed land use plan has classified this special district for several major land uses, including 27.7 % of the land for residential use, 15.8 % for industrial use, and 3.64% for commercial use.

FIGURE 1 The layout of Salun eco-communities (Sources: the Commission of Economic Development, National Taiwanese Government)

In terms of location characteristics, the Salun special district is close to Tainan High-Tech Science Park and Kaohsiung High-Tech Science Park. It is located within 40 minutes driving distance of the CBD (Central Business District) of Tainan City. In general, the site is a good candidate for building a new town that can serve both as an industrial incubator center and a dormitory city for high-tech professionals and/or other middle to high socio-economic-classes of professionals in the region who desiring for a better community living environment. Currently, the infrastructure system and the land subdivision have been completed, and most of the land is waiting for development. The residential land in the Salun special district is suitable for developing high quality eco-communities for the professionals mentioned above. To promote a planned land development patterns and to manage the growth of the new town, the Tainan County government has attempted to develop a prototype and related guidelines for ecological community development in the Salun HSR Station area. The proposed ecological community plan integrates the suggested planning principles of ecological communities mentioned above and also considers the feasibility of the real estate market. The layout of the proposed ecological community plan is shown in Figure1.

This study attempts to develop workable planning and marketing strategies for promoting the development of ecological communities in Taiwan. The empirical process includes: an environmental analysis, STP analysis, the willing -to-pay analysis for the proposed ecological community services, and the development of planning and marketing strategies. Based on literature reviews and interviews, the following community planning criteria are suggested for the proposed ecological community:

(1) Site: A community size of 10,000 or more square meters with pedestrian and Bike routes connected to the community center and transit stations is suggested.

(2) Types of housing stock: Middle to low density housing with diverse housing types, including multifamily housing, apartments, and 3.5-story townhouses; the average housing density is suggested as 100-125 housing units per block and 250-300 housing units in a community to be serviced by a community service center and shared facilities (this is a necessary scale to support the efficient provision of community services). The major housing size is suggested as 250-400 square meters per housing unit with shared community public gardens and space.

(3) Ecological Infrastructure and Technologies: Green open space networks; gray water circulation systems; shared community farmland and gardens; bike routes and pedestrian walkways connected to major activity sites; and community e-learning center are preferred.

4.2 Strategic Planning for the Salun Ecological Community

A strategic planning approach is used in this study. Compared to the traditional planning approach, the strategic planning approach is more flexible, adjustable, process-oriented, and more likely reach a good consensus. For a new product like an ecological community, this approach provides a useful tool to define the target market and develop useful strategies that may lead to useful community actions.

Based on the experience of related literature and our previous studies, the process of strategic planning for promoting the ecological communities in Salun of Taiwan is divided into four steps as shown in FIGURE 2.

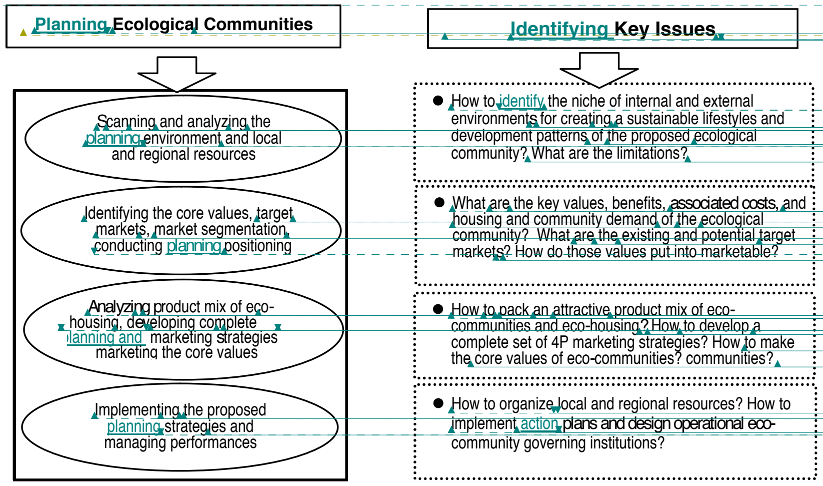

FIGURE 2: Steps and key questions to develop marketing strategies for promoting Ecological Communit

4.2. Identifying the demand of facilities and services of Ecological Communities

To explore the demand of facilities and services as well as to explore the willingness to pay of potential customers for the provision of ecological community facilities and services, this study conducted a questionnaire survey of 86 research subjects. The research subjects were identified and surveyed based on lists provided by local and regional real estate agencies. The result is shown in Table 2 (Wu 2007).

TABLE 2: Demand of Facilities and Services of the proposed Ecological Communities in Salon of Taiwan

	Facilities	Degree of demand	Facilities demanded (within 10 percent increase of total construction cost)	Facilities demanded (within 20 percent increase of total construction cost)
Energy system	Day lighting	4.21	√	√
	Photovoltaic's electricity	3.86		√
	Biomass fuels	3.21		
Water System	Rain water storage	4.11	√	√
	Gray water recycling	3.85		√
	Bio-climatic design	3.46

Ecological lifestyles	Sustainable building materials	3.79		√
	Healthful food and drink	4.26	√	√

Notes: 1. The number represents the average score of the item evaluated by the research subjects, the rage of score is from 0 to 5, the higher the value is close to 5, the strong the effect the item is.

2. √ indicates that the facility or service is desired by the surveyed home-buyers given the proposed increase in total construction costs.

5. DEVELOPING MARKETING STRATEGY FOR ECOLOGICAL COMMUNITY

Based on field observations, interviews, and questionnaire survey, this study proposes the following 4P marketing strategy for the ecological community:

Product Strategies

Our product strategies consider the ecological community as a product mix and try to sell the product mix to the target market. A product mix is a combination of products that can be offered to satisfy the need of desired customers. According to our survey results, three levels of the products are considered (see FIGURE 3). Each level adds certain customer values, and the three levels together form a customer value hierarchy. First, the most fundamental level is the "core product," which is the essence of the product that the customers really want to obtain. This research identified the core product of the proposed ecological community as: "healthy, ecological living, healthful editing, and the common interests for their children." Developers should keep in mind that they should be these core product providers. The second level is the "tangible product," which includes the community amenities and ecological infrastructure of the proposed ecological community such as ecological housing, green infrastructure, community open space, landscaping, community gardens, etc. The third level is where the developer and marketer could prepare as augmented products that can provide some extra satisfaction for the consumers. In the ecological community project in particular, the augmented products may include affective appeal, emotional support, environmental education, an image of a pure nature, the model of community development.

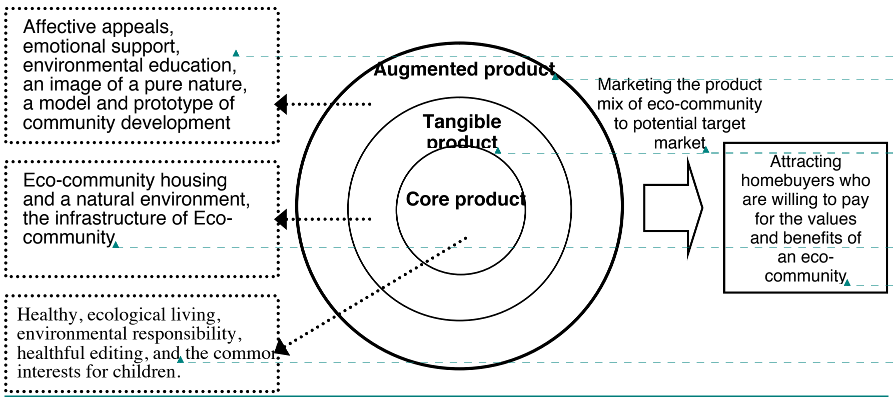

FIGURE 3: The three levels of the ecological community product

Price Strategies

Based on our questionnaire survey and interviews with potential eco-housing homebuyers, this study finds that the demand of ecological community is related to the increase in total construction cost and household income. The increase in total cost is depending on the ecological infrastructure and facilities provided. Figure 4 presents a conceptual diagram based on the results of our survey. In general, if a household's monthly family income is above 150,000 NT dollars, they may accept more than twenty percent increase in total construction cost for building an ecological community with more ecological infrastructure and ecological technologies. If a household's monthly income is between 800,000 NT and 150,000 NT dollars, they may accept about ten percent increase in total construction cost which can only afford to build some basic ecological community infrastructure and ecological community technologies. However, if a household's monthly family income is below 80,000 NT dollars, then the household may not prefer or may not be affordable to own an ecological housing product.

The survey result shows that the ecological community housing with related infrastructure, services, and green building facilities will primarily attract customers with a middle- to high-income who strongly appreciate the value of nature, health, and well managed community life. Price strategy thus depends on the attributes of potential customers and the context of the complete product package. Given the high competition of the real estate market and the increased demand for better living quality in Taiwan, current

homebuyers are not only considering the attributes of eco-housing, but also desire for a better community environment and community management, as well as a lifestyle in praise of health and slow.

Place and Promotion Strategies

Since there is no real housing product that meets the full concept of ecological community in the current housing market, the project proposed in this study is based on some assumptions and scenarios. Place strategies and promotion strategies are discussed here together and are thus focused on how to communicate the basic concept, the simulated environment, and the scenarios to the potential consumers and the general public. There are two key missions here that marketers must address: (1) the demand of the target market that is associated with the buyer's socio-economic characteristics and lifestyle; and (2) public and environmental education that helps consumers understand the values and benefits of the ecological community.

These promotion strategies, therefore, should package the require information and key concepts of the ecological community products together and make people aware, understand, appreciate, and purchase these concepts as a total product mix. Also, the goals of promotion should include building a well-known and positive image of the proposed ecological community. The tools of promotion mix should include five elements: (1) advertising, (2) sales promotion, (3) public relations and publicity, (4) personal selling, and (5) direct marketing. The following are our suggestions based on our survey.

1. Providing public education and citizen participation programs (such as eco-community workshops) that introduce to the general public the meaning and importance of developing ecological community.
2. Enhancing the introduction capacity and knowledge for marketing eco-communities, including the training of personnel and provision of training programs for sales.
3. Building a simulation and demonstration system for packaging the core concepts and values of ecological community and marketing them through advertisements and diverse communication channels to the target market.
4. Using media marketing frequently to attract the perception of the desired target market. For example, use such media tools as ecological newspapers, introduction brochures, and median interviews with well-known stars and scholars who favor eco-communities.
5. Creating websites of ecological community that are connected to websites of schools, NGO, foundations, and local government to distribute the updated information about the development ecological community worldwide.
6. Utilizing event planning as a tool for ecological community promotion, such as regional and local special EXPO or cultural and recreational events to attract homebuyers and investors.
7. Designing an attractive and positive image of the proposed ecological community and the locality, including meaningful logos, an attractive name of the ecological community, and identification systems that emphasize the core value and special characteristics of the ecological community.
8. Establishing long-term partnership relationships with business and different government agencies to build useful cooperation relationship that can help promote and maintain the ecological community

6. CONCLUSION

This study presents a planning and marketing approach for promoting ecological communities. Through empirical study of the pilot ecological community project in Tainan of Taiwan, the result shows that successful implementation of the ecological community concept will require an integrated and comprehensive marketing approach, including identifying the core values and the target market of the proposed ecological communities, packing an attractive the product mix of ecological communities, finding a suitable market positioning, preparing a financial study of the relationship between the project costs and the supply of green infrastructure and facilities, and developing a complete set of marketing strategies.

By incorporating research methods including interviews, field survey, and questionnaire survey, this study finds that the demand of the facilities and services of ecological communities is related to the household income and the values of ecological communities perceived by homebuyers. Therefore, marketing the benefits and the key values of ecological communities to the potential eco-housing homebuyers and the general public should be an important task. Based on the empirical study, this study identifies the product mix of ecological communities and suggested a complete set of marketing strategies for promoting them. Ecological community cannot be developed overnight; promoting the values and concepts of ecological community and creating a positive and attractive image of ecological communities through the help of marketing approach could be a good start.

2. Preparation of Manuscripts

2.1 Fonts and Formatting

As you read these guidelines, please refer to the sample layout at the end of this document. Place all text, figures, and tables within an area measuring 170 mm wide and 240 mm high. On A4-size paper (210 mm x 297 mm), this is equivalent to left and right margins of 20 mm and top and bottom margins of 25 mm.

Do not number the pages; the organizer will arrange the page numbering later. Use only the fonts (typefaces), character point sizes, and line spacing specified in the subsections below. ***Do not use any font other than Arial***. Do not use characters from two-byte character sets such as Chinese, Japanese or Korean. For special characters such as Greek letters, use symbol fonts.

For numerical expressions, we recommend that you use the Equation Editor tool included with Microsoft Word or MathType (Design Science, Inc.). Unless indicated otherwise, use single line spacing (10-point) for all paragraphs, noting the number of blank lines to be inserted between the main elements of the paper.

We suggest that you use the Microsoft Word template file provided. It contains pre-formatted styles for each of the components of the paper. If you apply these styles to the respective components of your paper, it will be formatted automatically according to these guidelines.

The names of the styles to be applied to each component of the paper are indicated in the formatting instructions below.

2.2 First Page

On the first page, include the title, information about the authors, the keywords, and the summary. The Title (11-point Arial bold, all capital letters, centered, style name “Title”) should be a maximum of 25 English words, without any abbreviations. Please use the same title used for the abstract you submitted previously. Leave two blank lines after the title (10-point Arial, style name “Body Text”).

List each Author on separate lines with the given name(s) followed by the FAMILY NAME (10-point Arial, centered, style name “Author”). ***Indicate the speaker’s name only in bold*** (style name “Speaker”). Append a superscript footnote number after each author’s name that will be linked to the author’s affiliation. Leave one blank line after the authors’ names (10-point Arial, style name “Body Text”). List the authors’ Affiliations comprising the academic or institutional/company affiliation, city and country followed by e-mail address (10-point Arial, flush left, style name “Affiliation”). Do not include mailing address and telephone or facsimile numbers. Start each affiliation on a new line, preceded by the superscript footnote number linked to the author’s name. Leave two blank lines after the last affiliation (10-point Arial, style name “Body Text”).

Choose up to eight Keywords from your paper and list them as shown in the template file, separating each word with a comma and single space (10-point Arial, style name “Body Text”). Insert two blank lines after the list of keywords.

Begin the Summary with a level-1 heading (11-point Arial, bold, flush left, 11-point line spacing, style name “Heading 1”). Insert one blank line (5-point line spacing) after the heading (this space is automatically inserted when the style “Heading 1” is applied). The body of the Summary (10-point Arial, flush left, style name “Body Text”) should total about 200 words in English. Insert one blank line (5-point line spacing) between paragraphs in the body of the Summary. (This space is automatically inserted when the style “Body Text” is applied to the preceding paragraph.) Do not indent the first line of any paragraph.

2.3 Full Text of the Manuscript

Follow the summary with the **Full Text** of your paper (10-point Arial, flush left, style name “Body Text”). Insert one blank line (5-point line spacing) between paragraphs in the body of the Abstract. (This space is automatically inserted when the style “Body Text” is applied to the preceding paragraph.) Do not indent the first line of any paragraph.

2.4 Headings

Limit headings to three levels and number them according to the decimal system when appropriate.

2.4.1 Main heading: **1. Heading Level 1** (11-point Arial, bold, flush left, 11-point line spacing, 10-mm hanging indent, style name “Heading 1”). Capitalize the first letter of all major words.

2.4.2 Subheading: **2.1 Heading Level 2** (10-point Arial, bold, flush left, 10-point line spacing, 10-mm hanging indent, style name “Heading 2”). Capitalize the first letter of all major words.

2.4.3 Third-level heading: 1.1.1 Heading level 3 (10-point Arial, flush left, 10-point line spacing, 10-mm hanging indent, style name “Heading 3”). Capitalize the first letter of the first word.

Insert a single blank line (10-point line spacing) before all headings (the three heading styles provide this space automatically). Insert a half-space blank line (5-point line spacing) between all headings and the text, graphic or table that follows. Position heading numbers flush left, followed by a tab and the text indented 10 mm. To avoid leaving a heading stranded at the bottom of a page, force the heading to the top of the following page by inserting a blank line.

If you apply the styles provided, all these formatting requirements are provided automatically.

2.5 Graphics (Drawings and Photographs) and Tables

Insert graphs, line drawings, and photographs into the finished document as digital objects. Use a resolution of at least 300 x 300 dpi (dots per inch) for photographs and drawings. Center the figure on the page, placing it as close as possible to the text in which it is mentioned; do not append figures at the end of your paper.

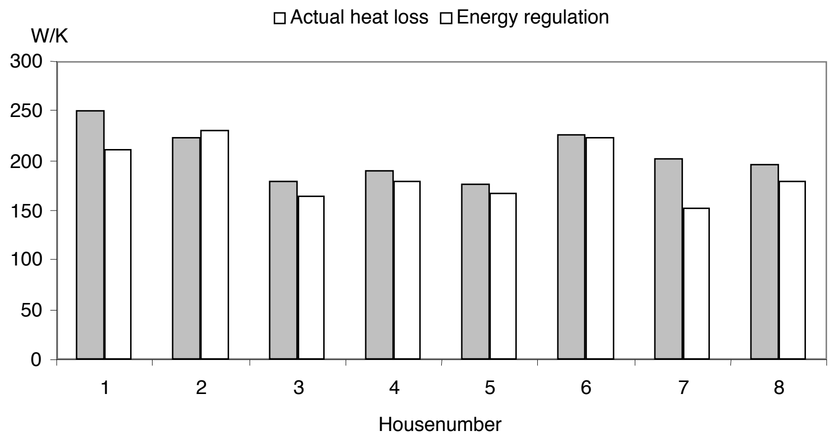

Figure 1 Comparison between actual heat loss and maximum allowed heat loss in 8 Norwegian log houses.

Provide a figure number (in consecutive Arabic numerals) and caption below each figure and photograph. For the captions of figures and tables, use 10-point Arial italic with 10-point line spacing (style name "Caption"). To ensure legibility, do not use point sizes smaller than 8 points for text appearing within figures and tables. See the sample layout at the end of this document.

Provide a table number (in Arabic numerals) and caption centered above the table (10-point Arial, centered, 10-point line spacing, style name "Table number"). ***Avoid vertical lines in tables where possible***. See the sample layout below. For ease of file transfer, use compact formats for images. The following image has satisfactory resolution in jpeg format (137 KB).

Table 3 Results for Axial Load

Yield Line Number	Normal BM (Nmm)	Yield Line Length (mm)
1	-13.793	5.771
2	-25.058	11.660
3	-18.315	11.832
4	-10.334	11.813
5	-4.335	11.638

2.2.2 Heading Level 3

Use the equation editor (integrated within Microsoft Word) to insert equations as text wherever possible. Alternatively, insert equations as images. When using the Windows platform, apply either Arial or Symbol fonts in equations; when using the Macintosh platform, apply Times, Helvetica or Symbol fonts. Reference each equation with a number in parentheses at the right margin of each equation. Insert one blank 10-point line (style name "Body Text") above and below each equation. See the sample layout below.

$$w = \frac{M}{Q}\left\{\frac{\sin\left[k\left(h-x\right)\right]}{\sin\left(kh\right)} + \frac{x}{h} - 1\right\}$$
(1)

2.7 Units

Use SI units exclusively. Indicate decimal locations with a period; do not use a comma.

2.8 Using References

List references in the text according to the author-date method. When the author reference is a natural part of the sentence, you can indicate the reference as follows:

Nørstrud (1990) described a similar format which was used for the second Symposium on Building Physics in the Nordic Countries.

When a paper has many authors, mention only the principal author followed by "et al." instead of listing them all. If an author appears in the reference list with different publications from the same year, the publication years may be modified as follows: 1990a, 1990b, etc.

Append a list of references (note: no heading number is used) to the end of the document. Authors are listed alphabetically with the first author's surname and initials followed by the initials and surnames of co-authors. Authors' names are separated by a comma except for the last two authors' names, which are separated by "and." Include all authors in the reference list. The year of publication follows the authors' names, followed by the title of the article, paper, book or report and either the name of the periodical in which the article is printed, the name of the conference and location at which the paper was presented, or the name of the publisher or the institution behind the publication. If the reference is to a monograph, indicate the title in italics. If the reference is to an article in a periodical, indicate the name of that periodical in italics. Complete the reference to periodicals with volume and page numbers. Also indicate the editors of conference proceedings. Use a full stop to separate all entries used to describe a reference. Format the reference list as body text (style name "Body Text"), inserting a blank line between each entry in the reference list (provided automatically if the style is used).

An example of a reference listing is provided below.

Appendix A. Submission Guidelines

You may submit your paper via email to SB08papers@asnevents.net.au between 02 January 2008 and 30 March 2008. If you want to revise the file after you have submitted it to our website, you can do so by re-submitting the file (with the same name) to the same address *before* 20 March 2008.

Submit your paper as a Portable Document Format (.pdf) file. Note that Microsoft Word does not make this conversion, but will direct you to third party software to make the conversion. Name your file "SB" followed by your abstract number (one to four digits) followed by the file extension ".pdf". For example, given the abstract number "1024", you would name your file as follows:

SB1024.pdf

Please note the file size must not exceed 1 MB.

When creating your PDF file, please do not include any characters from two-byte character sets such as Japanese, Korean, or Chinese. You may embed all fonts in your file. When using Acrobat Distiller, select "Print Optimize" or "Print" in the job option. Check the status of the fonts with Acrobat or Acrobat Reader as follows: Open the PDF file with

Acrobat and choose "File" –> "Document Properties" –> "Fonts" to display the list of embedded fonts.

We recommend that you print your PDF file to confirm the quality of the PDF conversion.

MILDURA RIVER HOUSE: PERFORMANCE A "LUXURY" SUSTAINABLE HOME

Luke MIDDLETON[1]

[1] EME Group, Middle Park, Melbourne, Australia, luke@emegroup.com.au

Oral presentation preferred

Keywords: sustainable housing, thermal performance measurement, thermal performance computer modelling, thermal mass vs. insulation

Abstract

This is a twelve month monitoring project; this paper will present the first five months of measured data of environmental conditions in new luxury home and compare this with computer simulated predictions of two types of software: the housing industry standard rating tool, First Rate and the more sophisticated modelling software EnergyPlus.

The aim for this house is to reduce energy consumption by at least 50%, improve air quality and provide significant reductions in mains water usage. The premise is that intelligent efficiency is holistic focusing on an interaction between site, people, landscape, building envelope, seasons, activities and orientation. Ecological sustainability can only succeed when underpinned by an active participation with these systems, and this project sets out to encourage and make this participation convenient and enjoyable.

This project addresses the challenge of achieving sustainable function in a 'luxury' home. This is a timely opportunity as more people aspire to the costly environmental qualities of size and grandeur. This project is a symbiosis of sustainable design with a luxurious living, underpinned by embedded environmental design components including: in ground Labyrinth cooling with night heat purging, insulated and non insulated rammed earth walls and low e double glazing with strategic window positioning.

This paper illustrates two major issues when using energy modelling software. Firstly, regarding the 'FirstRate' software, the actual building performance is significantly better than what was predicted by the software, which rated it as 5.5 Star. Secondly, regarding the more sophisticated simulation software EnergyPlus, the actual performance still outstrips the predictions.

1. Introduce project

The project is located in the township of Mildura on the banks of the Murray River. The climate is semiarid, experiencing large fluctuations between day and night time temperatures. In summer the temperatures can reach in excess of 42C, whilst in winter sub-zero temperatures are experienced overnight. On average throughout the year the night time temperature can be 15-20C below the day time temperature. (figures obtained from Special Services Unit of the Bureau of Metrology)

The clients brief was heavily steeped in Asian aesthetics and Feng Shui principles. A report prepared by a local Feng Shui consultant stipulated in detail the location and orientation of functions throughout the home. The obvious appeal of Murray River views were also a priority of the client. This required expansive views to the east thereby necessitating large areas of glass along the east elevation.

The design response was to provide large framed views to the east, reducing the area of window to less than 60%. Generous glazing was provided to the northern end of the building. Western and southern facades are massive insulated rammed earth walls with minimal glazing. Internally the public and private spaces were divided with a long rammed earth wall running north south, providing good internal thermal mass (^).

Other integral design components include, roof profiled to improve heat stratification, Labyrinth cooling with night heat purging, landscape design to provide mediation zones and shading, low energy diffuse lighting throughout and Rain water harvesting

Figure 1 Mildura House

1.1 Aims of the paper

This paper will present the performance of the home over five months. These results will be compared with the results predicted by computer modelling software. The paper will compare two types of computer simulation evaluation software, First Rate and Energy Plus with the actual performance of the home.

The aim is to demonstrate the limitations of computer simulated thermal performance for a luxury home with a creative non-typical design located in a semi arid climate. In particular, the performance of the various thermal mass objects, the labyrinth cooling system and thermal stratification.

With the advent of increased regulation regarding the performance of buildings, namely 5 star energy ratings in the instance of housing, there has been and will continue to be a significant growth in the use of computer modelling software. For real reductions in housing energy consumption it is essential to continually test against the actual performance of homes. This paper adds to previous research in this area such as the monitoring of the Ecohome at Cairnlea estate Melbourne between June 2004 and May 2005 prior to its occupation. The results of this research will assist in the improved understanding the computer climatic modelling software, it's benefits and limitations. Without this vital auditing process inefficient homes and cities will continue to be built.

Furthermore, this research focuses on creative non-standard design solutions that cannot be realistically and fairly assessed by industry standard rating tools.

2. Data collection

2.1 Physical Monitoring

Sensors were obtained from Cornerstone Technologies and programmed to take temperature and humidity readings at half hour intervals.

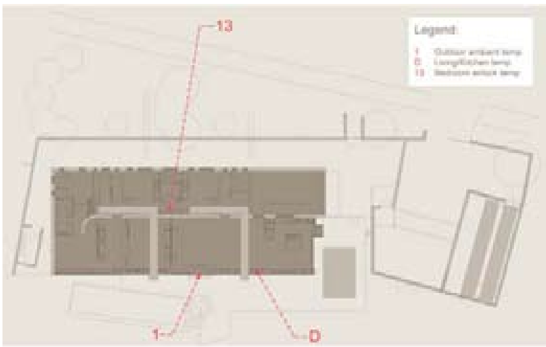

Figure 2 Sensor locations

Half hourly measurements of temperature and humidity were obtained at strategic locations. Internally two sensors monitored the air temperature and humidity. As can be observed in Fig. 2, Logger D was located within the living space on the eastern wall to represent the peak temperatures that would be likely to be experienced within the space due to the large windows in the vicinity. Logger 13 was located in the predicted coolest zone of the house in-between the guest bedrooms. This zone has minimal glazing and is surrounded by the thermal mass of rammed earth walls. Sensor 1 was located outside above the bay window (2.6m metres above floor height).

LOGGER GENERAL SPECIFICATION

Center 340 thermorecorder -

Measurement Range: -30°C ~ 70°C ; -22°F ~ 158°F

Response time: 20minutes to 95% under slow air.

Accuracy: ±0.7°C(± 1.3°F)

Resolution: 0.1°C / 0.1°F

2.2 FirstRate software

The house energy rating is the method used to measure the energy efficiency of a house.

The house energy rating measures the energy efficiency of a house by allocating a point score to each element of the house e.g. floors, walls, windows, etc. and provides an overall rating on a scale from 0 to 6 stars, with half star increments.

An energy efficient house rates 5 stars or higher. The house energy rating is independent of the size and type of housing. This means that large and small houses, attached and detached dwellings each have the potential to achieve a good energy efficiency rating.

2.3 EnergyPlus software

The building was modelled in ECOTECT and outputted to EnergyPlus.

The model was constructed from detailed plans and elevations of the finished home. All as built materials were included in the model, including actual configuration of floor, wall and ceiling insulation, construction materials, window frames and double glazing units. The surrounding landscaping including significant river red gum trees to the east were modelled to emulate the shading of the building that occurs.

The Labyrinth Night Purge Cooling system was added in Energy Plus.

3. Results

3.1 Physical Monitoring

The results contained in this report are for the period 16 October 2007 until 26 March 2008. During the five month testing period the house was vacant during the period 10th - 25th November and 13th - 30th January.

The occupants were pleased with the comport levels for the majority of the time. During prolonged heatwave periods the backup air-conditioning system was used. Over the 162 day period of monitoring the backup air-conditioning was required for less than 6 percent of the time the building was occupied.

This summer period was unusually hot and there was one period of six consecutive days and another period of eight consecutive days with day time temperature reaching 40+ degrees Celsius (refer figure 3 and 4).

3.2 First Rate

The building was rated by Gary Kruithof of Dynamic Design. It achieved a 5.5 star rating with a score of 14 points including a deduction of 4 points from the Area Adjustment. The rating assumed Climate Zone 27. The winter score was 32, whilst for summer it scored -14.

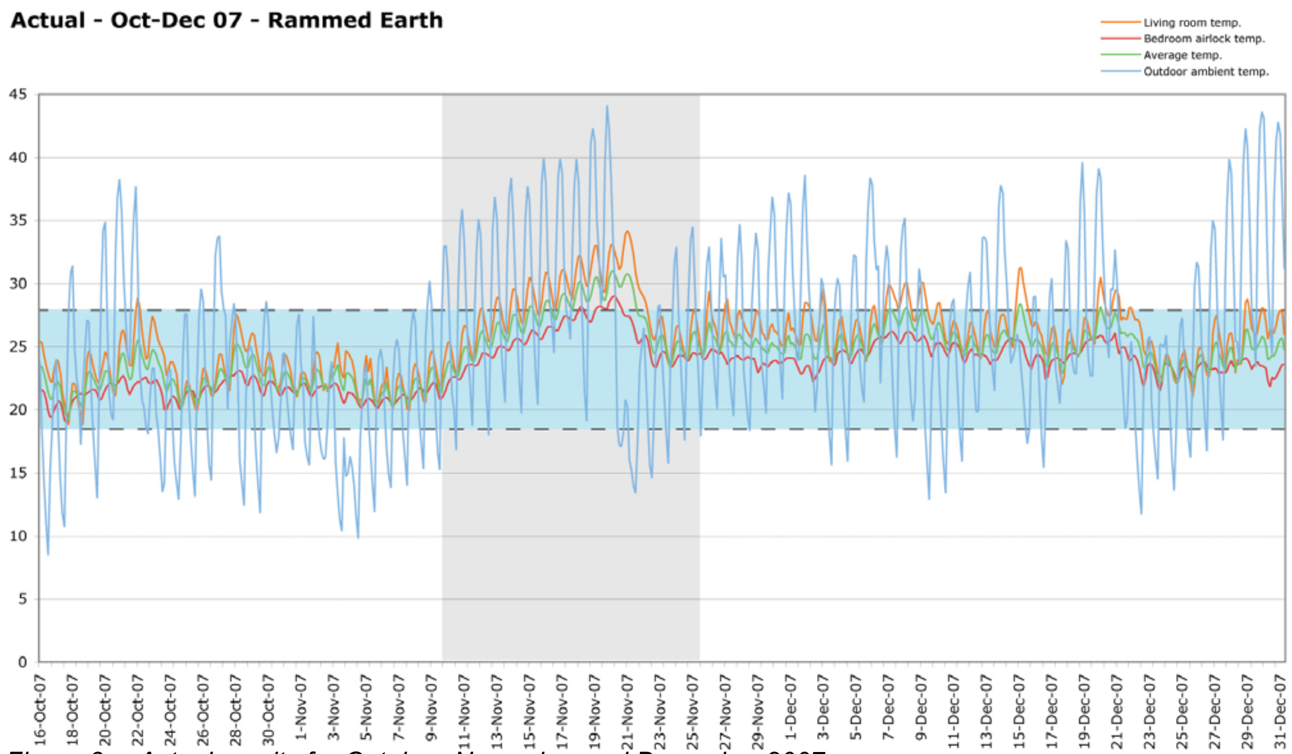

Figure 3 Actual results for October, November and December 2007

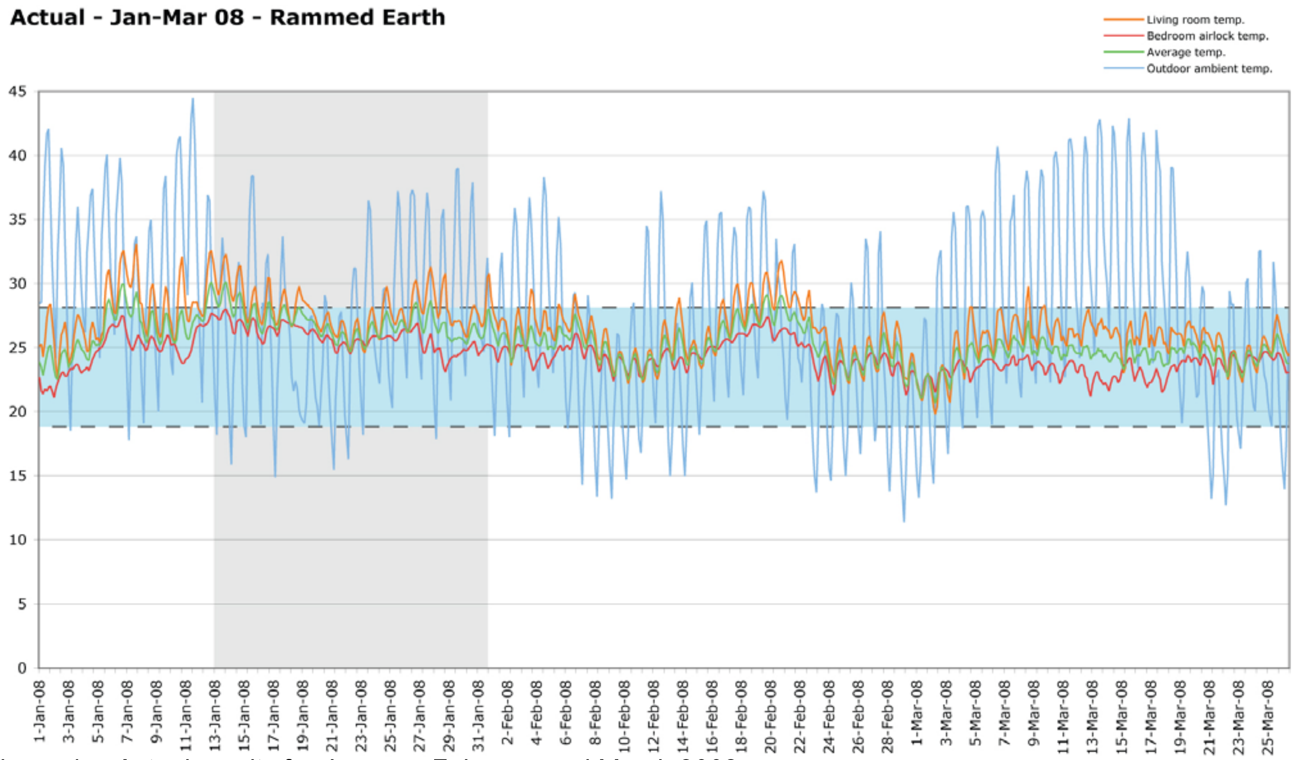

Figure 4 Actual results for January, February and March 2008

3.3 Energy Plus

The EnergyPlus results predict that the building significantly mediates the extreme outdoor temperatures providing a comfortable environment for the majority of the summer months (refer figure 5 and 6). It can be seen in figure 5 and 6 that consecutive hot days and warm nights force the internal temperature up as the thermal mass has no chance of purging heat energy.

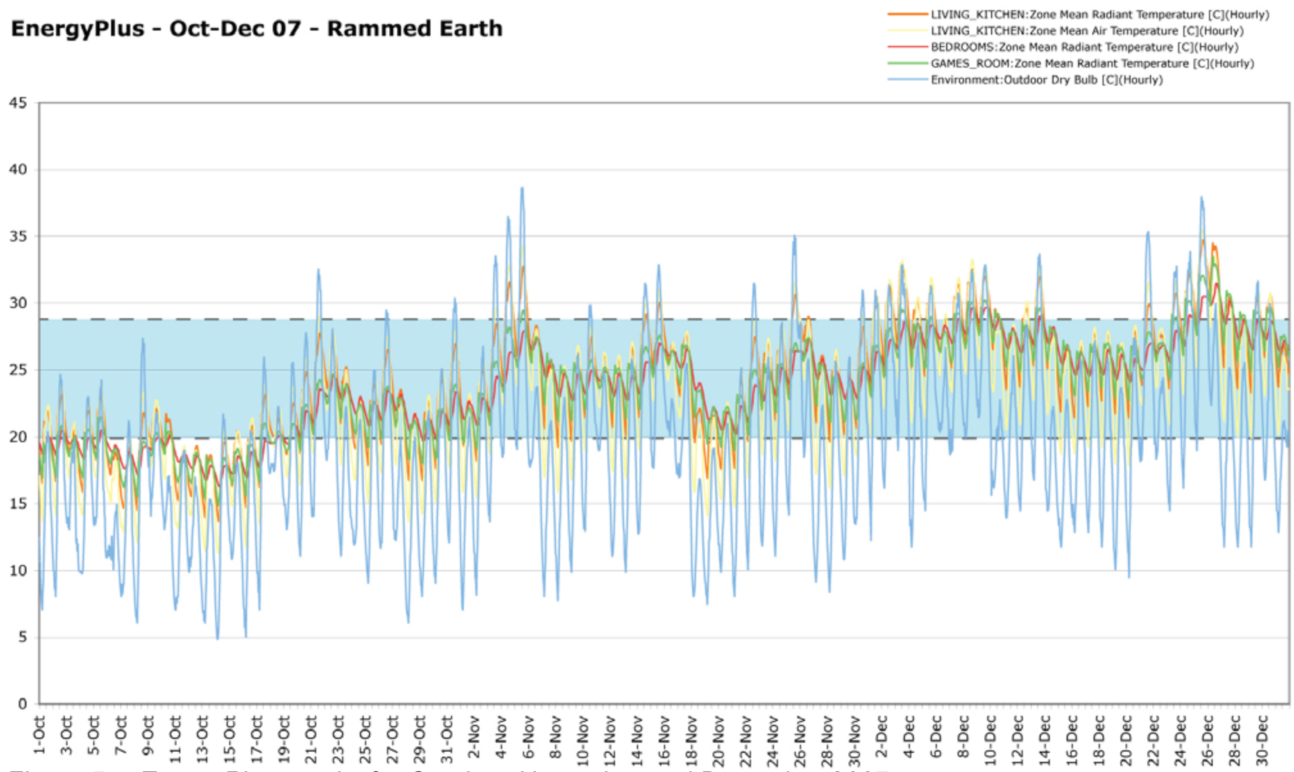

Figure 5 EnergyPlus results for October, November and December 2007

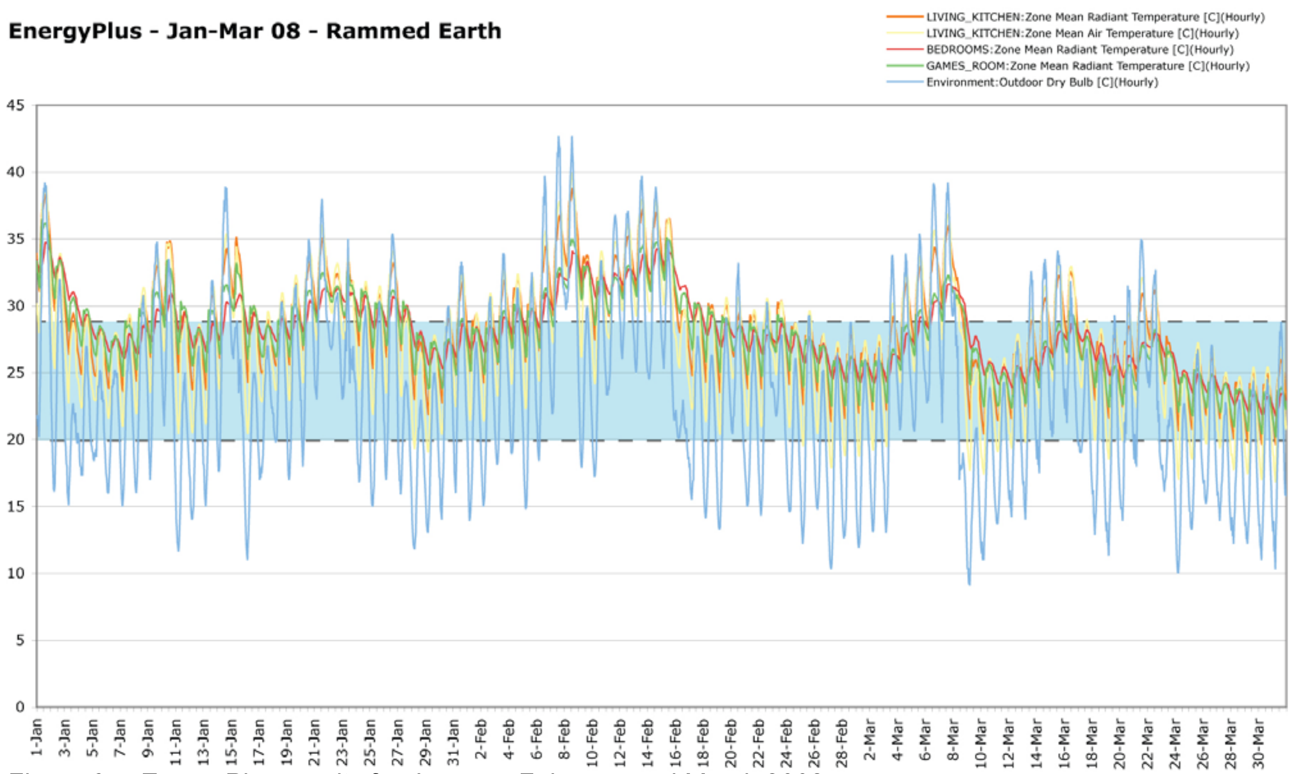

Figure 6 EnergyPlus results for January, February and March 2008

4. Discussion

The results clearly illustrate that the building performs better than the EnergyPlus modelling. Further it is obvious that the FirstRate software vastly under estimated the thermal performance of this home. Especially if you consider it's performance against the Ecohome at Cairnlea estate Melbourne.

4.1 Analysis of results

During the October period the actual outside ambient temperatures, seen in Fig. 3, were on average 5 degrees higher than the weather file inputs for the EnergyPlus model that can be observed in Fig. 5. Despite this, the measured internal temperatures remained within the comfort range. The EnergyPlus model predicted greater day to night temperature fluctuations and higher peak temperatures than actually occurred. During October there was no backup air-conditioning used.

A comparison of Fig. 3 and Fig. 5 also shows the simulated and actual results for November. For the majority of November the house was unoccupied and no night purging occurred. It can be observed that from the 13^{th}-16^{th} the increase in outdoor temperature triggered a steady rise in the internal temperature as there was no chance for thermal mass to cool through night purging.

The EnergyPlus model, in Fig. 5, provides for night time purging with the labyrinth from 8pm to 6am. When a period of similar outdoor temperature, is compared with the actual results it can be observed that despite the provision of night purging, the simulated indoor temperatures are higher than those observed in the actual results. For instance in the simulated results when the temperature rose to 36.5C outside the internal living room temperature was 31.6C whereas the actual results show that when the outside temp rose to 36.9 the internal living room temperature was 28.9C.

The results observed in December followed a similar pattern to October. Whilst the actual outdoor temperatures (Fig. 3) were far higher than the EnergyPlus weather file (Fig. 5), the internal temperatures were lower than were predicted by the computer model. It should be noted that during the excessive and prolonged heatwave experienced at the end of December the occupants utilised the backup air-conditioning. The air-conditioning thermostats are located within the guest bedroom precinct (i.e. the cooler part of the building) and were set at 25 degrees to provide a temperature of 26-7^{o}C in the living spaces.

4.2 Actual versus predicted comfort

It can be seen from these results that the passive systems provide a greater level of comfort than predicted by the modelling software. Within the zones surrounded by thermal mass day to night temperature fluctuations were reduced to less than 3 degrees (outdoor temperature fluctuation 20^{o}C). In the living spaces where the design criteria necessitated significant areas of glazing the internal temperature variants was generally limited to less than 5 degrees. By contrast, the EnergyPlus model predicted the living spaces to fluctuate by up to 7.5 degrees.

Actual results show that during the majority of the monitoring period the temperature remained within comfort levels. The most significant increases occurred during periods when the house was unoccupied when no night purging occurred or on consecutive days of extreme heat where the temperature was over 35^{o}C for a prolonged period as in Fig. 4 from 2^{nd}-5^{th} and 15^{th}-19^{th} February. During some of these periods backup air conditioning was used to obtain comfortable indoor temperatures. In March Mildura experienced 16 days over 35^{o}C, 8 of which exceeded 40^{o}C, this is the longest period that backup air conditioning was required. It is important to note that whilst the temperature exceeded comfortable levels on some days it was still several degrees cooler than external temperatures. For instance Fig. 3 shows that on 15^{th} November when the outdoor temperature reached its maximum of 37.7^{o}C it was only 29.6^{o}C in the living room and only 25.5^{o}C in the bedroom. On 16^{th} when the outdoor temperature reached its maximum of 40^{o}C it was 30^{o}C in the living room and 26.6^{o}C in the bedroom.

The measured results include extended periods when the building was not occupied. It can be seen during these periods that the thermal mass gradually increased in temperature, as it had no chance to purge the heat energy at night. Even during these periods the actual results are far better than the predicted EnergyPlus results (which also included for the operation of the labyrinth for heat purging over night).

4.3 Advantages and limitations of EnergyPlus

The complex nature of algorithms within the simulating software provides far more data about what is contributing to the outputs, than could have been obtained by physical measurements.

For example the contributions to the temperature of a zone can be broken down into solar gain, ventilation gain, conduction/convection gains, ventilation and so on. Simulation provides useful design insight, as parameters can be varied one at a time and the corresponding change observed in the data output.

The hypothetical (simulated) results are reliant on the accuracy of the inputs. They are also limited by the algorithms, which are approximations of physical circumstances. In some cases the modelling software outputs are limited as they provide more general information. For example, the EnergyPlus outputs are limited to average temperatures within a zone as opposed to temperatures at a specific point within that zone.

The EnergyPlus software cannot attempt to predict the habits of occupation that could improve or inhibit the performance of the building.

4.4 Advantage and limitations of physical monitoring

The measured data represents the true, all-inclusive physics of the situation, including the physics of the sensors (accuracy, calibration, lag etc). It shows the true measurement at that time and represents everything that is going on, much of which is likely to be uncontrollable and often unknown.

The physical monitoring of air temperature and humidity within a room or zone can include logging devices at various locations with in a zone close to windows such as at the ceiling level and at occupation level to provide a better understanding of real comfort levels. (Unlike the Energy Plus results which have only average temperature outputs)

A sensor may provide distorted outputs due to unplanned circumstances such as sunlight directly hitting the sensor or a heat source such as a computer being placed near the sensor (although careful analysis of the figures combined with common sense should reveal such anomalies.

The sensors provide raw data according to temperature and not a breakdown of the energy sources such as solar radiation, radiant heat and shade air temperatures that make up the resultant temperature.

4.5 Comparative modelling

There is some correlation between the actual performance and energy plus output, so, to discover a further level of insight we modelled the same building in lightweight brick veneer construction, no labyrinth and single glazed comfort plus glass (rating the building as 5 star). The actual building has double glazing with one layer being low e. This exercise revealed a massive difference in the predicted energy consumption between the as built home (5.5 star) and the alternative modelled (5 star) (refer Table 1)

Table 1 Predicted Energy Consumption of Home as Built (5.5 star) versus Standard Brick Veneer Construction (5 star)

summary

	heating	cooling	total energy	
rammed earth	3,645,201	6,262,071	12,576,956	
lightweight w comfort plus clear glass	10,417,755	11,850,640	22,268,395	
saving in energy	7,051,662	4,056,098	11,107,759	watt hours per year
percentage reduction in energy	293.5%	145.4%	188.3%	
saving in energy with earth tube		4,398,410		watts per yr

5. Conclusions

It is clear from the measured results that the computer modelling of passive building design has significant limitations. The effectiveness of thermal mass and insulated thermal mass does not seem to be accessed effectively by First Rate and even the more detailed modelling capacity of EnergyPlus does not accurately predict the actual performance of this home.

Moving beyond the success of this project, the ongoing monitoring aims to inform and improve the occupants' operation of the building. With more detailed understanding of specific temperatures throughout the house and within the labyrinth and rammed earth walls, the occupant can make informed decisions about the opening and closing of windows and the operation of the labyrinth duct system. From a design point of view these results are invaluable in consolidation of the original principles and will provide information to improve similar design approaches.

Further studies include: additional temp loggers to understand temperatures in and along labyrinth, temperature within the rammed earth wall versus surface temperature, and air temperature adjacent to better understand thermal lag and the effect of air temp versus solar radiant energy on the thermal mass, and internal temperature loggers at high and low level to better understand the effectiveness of heat stratification within the roof form.

SUPPORTING DEVELOPMENT TOWARDS MORE SUSTAINABLE BUILDING: PERSPECTIVES ON THE DEMONSTRATION PROJECT AS A STRATEGY FOR CHANGE

Paula FEMENIAS Dr. Arch.[1]
Michael, EDEN Prof. Arch.[1]
Barbara RUBINO Arch. PhD Student[1]

1 Department of Architecture, Chalmers University of Technology, Göteborg, Sweden, femenias@chalmers.se, eden@chalmers.se, rubino@chalmers.se

Keywords: sustainable building, demonstration projects, development processes, market transformation, practice-based learning, ecological modernisation, Sweden

Summary

This paper explores the mechanism for development towards more sustainable building in Sweden. The proposed mechanism is based on a retrospective study of the evolution of more sustainable building practices during the last decades, with focus on the west of Sweden and using elements from theories on ecological modernisation as a way to understand change. The retrospective study presents actors, networks and important break-points. Three conceptual pairs have been used to discuss factors that make sustainable building practices progress: governance and learning, exemplifying and legitimising, and symbol and performance. It is argued that we might experience a shift towards governance and voluntary action developed through practical experiences. Catalysing successful demonstration projects lead the way, set up visions and goals and influence development of policy and regulation. The focus on energy efficiency has led to a broad acceptance with a rebound synergistic effect back to other building qualities. However, it is important to look beyond current achievements and to reconsider other important aspects of sustainable building: water and material issues, renewable energy and social issues.

1. Introduction

The aim for this paper is to contribute to a framework for understanding the evolution of sustainable building practices, and eventually to support these processes. The focus is on learning processes at a building project level and the system boundary is the building. The study underlines the importance of experiments and demonstrations for the development.

A tentative retrospective study of sustainable building practices in Sweden from the 1960s until today outlines important events, identifies actors and networks and recognizes institutional, societal, political and individual motivations to engage in more sustainable building. The study draws on the authors' personal experiences and their research on sustainable building in Sweden (e.g. Rubino, 2007, Eden 2008), on interviews with influential actors (Femenías, 2004), and on literature studies. Our theoretical framework draws on theories of innovation in construction (e.g. Fernie et al, 2005), ecological modernization (Fudge and Rowe, 2001; Jensen and Gram-Hanssen, 2008); and social theories (e.g. Guy and Shove, 2000). The study has a normative approach to sustainable building recognising environmental limits and natural carrying capacity, demand management, environmental efficiency as well as social welfare issues and equity (Fudge and Rowe, 2001). A systems approach provides an understanding of the continuous (exogenous and endogenous) processes of change and development. The study does not take a normative approach to ecological modernisation which is used as a means to understand change.

2. The Building Sector in Sustainable Development

The slow uptake of energy efficient measures has been discussed in Sweden (e.g. Nässén and Holmberg, 2005) and in other parts of the world (e.g. Lovins, 1992). These articles point to the potential for increased efficiency, although a gap still persists between what is achievable through best available practice, and that which is considered mainstream building practice. New technologies are available but are not adopted on a larger scale. The reasons behind this slow uptake are numerous and complex referring to widely differing factors from problems inherent in the organisation of work in the building sector, i.e. heterogeneous actors in unique project settings, to low-energy prices or contemporary non-sustainable architectural ideals. The perceived impression is that the sector is unable to handle the necessary changes and that change can only be through incentives and stronger regulation. However, it has become widely accepted that the implementation of sustainable building is not only a technical question but is also dependent on social acceptance and institutional factors (Guy and Shove, 2000; Jensen and Gram-Hanssen, 2008).

2.1 Reconstructing Building Practices

The building sector, in Sweden and other countries, has in recent years been in focus for general reconstruction programmes initiated by the perceived image of the sector as inefficient and reluctant to adapt to modern demands. It is interesting to observe that the sector was described in the same way in 1947. A document of that year, SOU 1947:7, states that the Swedish building sector is not investing in research and development by their own means and suggests governmental funding for building related research as this will have strategic importance for the society as a whole.

> Building activities produce mainly articles to be used during a very long time. It is therefore understandable that clients and contractors show some reluctance to try new and relatively unknown materials and methods, and prefer to proceed under known conditions and with known materials. Considering these foundations, the building industry could with good reason be characterized as one of the most conservative of industries.
> SOU, 1947:7, pp 10-11, (in Swedish, the above is the authors' translation from Swedish)

The above should be placed in a historical perspective. At the time of the establishment of the Royal Swedish Academy of Sciences in 1739, scientific research was focused on everyday practical implementations of results (www.kva.se). The development through the industrial revolution led to a distinct separation and in many cases antagonism between science and practice. Many of the epoch-making industries were the result of practical developments combined with good organisation and management. However, scientific research has since become increasingly important for industry. Early governmental investigations point to the problem of transferring laboratory results to practice, a process that will profit from small scale experiments and later full-scale tests before being diffused in practical implementations. Based on a neo-classical economy perspective of markets, the persistent idea has been that scientific results automatically will lead to innovation (e.g. TSERC, 1987). This instrumental approach to energy efficiency has not been efficient and is partly explained by the R&D chain in the building sector seldom being chronological or linear and that development is seldom triggered by science but through the search for solutions to problems in practice.

2.2 Ecological Modernization in Sweden

The Swedish government has since the late 1990s developed a policy framework based on ecological modernisation as a means to respond to environmental pressure and the need for a socio-economic revival (Fudge and Rowe, 2001). Ecological modernisation is described as a framework to explain increasing environmental considerations in society and the changes caused by these processes. Ecological modernisation is often linked to the mainstreaming of sustainable development based on continued economic growth and the use of environmental technology without fundamental changes to individual actions and beliefs. The concept can be a paradox as structural changes are argued to be necessary while only selective remedial measures are promoted (Hajer, 1995 quoted in Smith and Kern, 2007). Jensen and Gram-Hanssen (2008) see no link between ecological modernisation and models for weak or strong sustainability arguing that ecological modernisation can lead to either depending on the actual actors and processes.

Fudge and Rowe (2001) in their study of ecological modernisation in Sweden found this process to be mainly codified as environmental protection and that norms may favour unduly expert focused and even ‘technocratic’ paths to the pursuit of sustainable development. The industry has always been a key player in Sweden’s pursuit of sustainable development and the building sector has been given a key role in the aim to rebuild society for sustainable futures.

Fudge and Rowe (2001) refer to three major stages in the maturation of ecological modernization, which are recognized in Sweden although not chronological. The first stage focuses on technological innovation, a critical attitude towards the state, and a bias towards market solutions. The socio-economically successful economic expansion in the late 1980s and early 1990s had a strong technological and environmental drive. The second stage, from the late 1980s to the mid-1990s, took a more moderate view on technological innovation, the state, and the market instead emphasizing on institutional and cultural dynamics supported by the emergence of the ‘Brundtland report’ in 1987. The second stage has in Sweden found difficulties gaining support in the conservative and rather expert-led governmental institutions. In the third and current stage the debate has broadened to include the role of consumption and global processes, in which market dynamics and economic agents are increasingly important. At the same time the nation-state is transformed towards a more decentralised and consent style of governance. The third stage thinking, which can be identified in governmental aims and policies, has proved to have difficulties in practice. The relatively few enlightened individuals have not been able to catalyse the broader shift.

Similar critics of an overly technocratic ecological modernisation have been made in the Netherlands (Smith and Kern, 2007). What is now observed in the Netherlands is a transition discourse to reinvigorate ecological modernisation, a process based on a more reflexive approach that institutionalises processes for deliberative social choice between alternative scenarios of development. This transition approach combines long-term visions, policy learning, and adaptive governance. The transition discourse proposes: multi-stakeholder civic arenas for debate and progress towards sustainable socio-technical systems; practical niche elements for exploring potentials; institutions that promote social learning; and supportive policy development and innovation. The innovation model is based on evolutionary economics and perceived as more institutionally complex and varied and results less automatic, than in technology push-models. The transition approach has not managed to influence radical change and reinvigorate the Dutch ecological modernisation. Incremental reforms persist and older discourses seem solidified.

3. Reconstructing the ‘History of Sustainable Building’ in the West of Sweden

As a background to this tentative history of sustainable building the comparatively good quality of the Swedish building stock seen in an international perspective must not be underestimated, both in terms of environmental and social aspects. Already in the 1950s the Swedish building regulations prescribed 10 cm of insulation in outer walls. And when other European countries only just start to discover the advantage of exterior insulation of walls (instead of interior insulation) this had been praxis in Sweden for decades. Another example is car free housing areas which have been built in Sweden since the 1960s. Social perspectives on housing and living qualities for everybody has been studied and implemented through governmental policy and regulation since the 1930s as part of the ‘Folkhems’ project of making Sweden a modern state.

3.1 The 1960s – The Seeds

The environmental movement of the 1960s can be linked to the social movements of the era. The publication of Rachel Carson’s book *Silent spring* in 1962 is widely accredited to be one of the starting points of the environmental movement in western countries.

Nature as source of inspiration in architectural design and vernacular building traditions can be traced back long in history. Architects such as Frank Lloyd Wright have been renowned for their environmental inspiration. However, the claim that all good architectural design is essentially ecological has been proven weak if implemented as the single strategy to achieve a resource efficient design. Still, these ideas of an environmental architecture taught to architect students in Sweden in the 1960s are the seeds of current development (Interview with Hans Eek, 2001 – the architect of Sweden’s first passive housing and founder of The Passive House Centre in Sweden).

3.2 The 1970s – The Experimental Era

The 1970s were marked by the oil crises resulting in a broad awakening for energy issues. In Sweden, the energy crises led to massive governmental campaigns which aimed for oil independence and resulted in strengthened building regulation, subsidies, and low interest loans for up-grading of building envelopes. National programmes funded experiments and demonstration projects for developing energy efficient building and renewable energy technology. The strategy was to replace oil mainly with electricity (direct heating in buildings) or nuclear power (for district heating). The decision to invest in and continue to use nuclear power is still debated.

The period is usually described as an era of experimentation. Inspired by developments in USA, France and Germany., Swedish pioneering architects became involved in low-energy building, solar buildings and in socially responsible architecture. Experiments received finance through national programmes but they were also the result of individual investments. One of the pioneers at the time, Hans Eek made important experiences in Mrs Henriksson's house. Mrs Henriksson decided to support the development of ecological building by asking Hans Eek to design a highly experimental private house. Mrs Henriksson's house was very unsuccessful – the many and untried technical solutions never worked. Hans Eek says that the main problem was the architect behaving as a miserable engineer.

In 1972, the first and pioneering UN conference on human environment was held in Stockholm. The conference laid the framework for future international cooperation on environmental issues. In the summer of 1976 an influential exposition was held in Stockholm. The ARARAT (Alternative Research in Architecture, Resources, Art and Technology) exposition, organized by a group of architects, displayed and discussed alternative technologies and ecological housing experiments.

3.3 The 1980s – The Transition Era

The early 1980s experienced a backlash for the broader interest in low-energy building and renewable energy caused by an economic downturn and the election of conservative governments in many countries. A reduction in demand and an overproduction of oil also resulted in falling energy prices. In the US, Jimmy Carter was succeeded by Ronald Reagan who basically stopped the experimental era in low-energy technology. In 1987, the publication of the Brundtland report re-launched the politically driven development and contributed to a wider use of the concept of sustainable development as a new approach to environmental policy. The key was to link environmental concern with socio-economic development and this opened the door to the coming transition from low-energy to sustainable buildings.

The Swedish Government continued to invest in experimental and demonstration programmes for energy efficient building concepts in the 1980s. The well-known Stockholm project involved the construction and monitoring of some 200 apartments between 1983 and 1985 (Guy and Shove, 2000). The project provided exemplification through cases, but without any practical implications.

As a contrast to such mainstream and more realistic approaches, the grass-roots and pioneers of the 1980s contributed to the emergence of the Swedish eco-villages. In 1991 the Swedish National Board on Housing, Building and Planning made a definition of the concept eco-village stating the importance of local perspective, small scale, social aspects as well as an eco-cycle perspective on material and energy resources (e.g. www.ecoby.org). The eco-villages have a strong grass-roots perspective engaging the community in the realization of the project. The first eco-village built in Sweden was Tuggelite, completed in 1984. The eco-village can be seen as emerging from the collectivist movement of the 1960s and 1970s, as reactions against contemporary urban and semi-urban lifestyles (Jensen and Gram-Hanssen, 2008).The initiators of the first eco-villages experienced a lack of documented knowledge and practical experience which led to problems. Several Swedish eco-villages has reported high energy use but claimed other less tangible qualities such as every-day aesthetics and strong social networks.

The Swedish National Housing Exhibition, Bo85, opened in 1985. Inspired by ecological influences of the time Bo85 promoted individual conservatories, combining passive energy and social space. However, this resulted in poor energy efficiency. In 1987, an important experiment with air-solar collectors was completed in Göteborg (architect Christer Nordström), in the refurbishment of a housing block from the 1950s. The project showed good results in terms of reduced energy use and important experiences were made connected to the social benefit of a collective green house attached to the house, but not part of the energy system. The project remained a one-off project partly due to the reorganisation of the public housing company.

During the 1980s the sick building syndrome highlighted the problems of building materials with emissions to the indoor environment and the problem with ineffective ventilation which probably contributed to the increased interest in naturally ventilated and ecological buildings.

3.4 The 1990s – The Eco-Cycle Era

The 1990s marked a broader awakening to environmental issues and ecology. The Rio de Janeiro Earth Summit 1992 and the resulting Agenda 21 document led to a shift from ecological building to sustainable building, which has proved to be a more broadly acceptable concept, turning to resource efficient technological solutions and not primarily life-style changes. During this decade environmental issues gradually became institutionalised and part of the daily routines in Swedish construction through voluntary environmental management systems and through deregulation of construction. Larger architectural offices, developers and contractors built up in-house environmental expertise. Some measures, such as waste separation, became praxis.

In the 1990s new examples of ecological building emerged based on eco-cycle ideas for recycling of wastewater, the use of locally produced and natural materials, and an increasing interest in naturally ventilated buildings. The scale of the examples that are built is still single-buildings and housing but the decade also revealed an increasing interest in urban issues. A wave of naturally ventilated schools was initiated through the example of Fredkullaskolan built in 1992. In 1995, the eco-village Understenshöjden outside Stockholm was completed. The project received significant attention for its living qualities and aesthetics. Later the project was subject to a partly erroneous and biased accusation of large energy use and technical problems in the Swedish media (Gluch and Femenías, 2002). This was probably to be the last project where non-professional actors (the community) had the main influence in planning and realisation.

At the end of the decade a number of larger public housing companies and building contractors engaged in environmental issues and produced a number of demonstrational projects without great influence on mainstream practice. The projects mixed tested and untested technology, usually in relation to occupant behaviour. The lack of systematic thinking in briefing, planning and follow-up and the lack of performance indicators make those experiences difficult to systemise.

The Swedish Government has also invested in large demonstration programmes to stimulate environmental technology. The Local Investment Programme, 1998 – 2002, supported several retrofit projects of housing from the 1960s and 1970s in relation to socioeconomic regeneration of the areas. The results from these projects show good results in environmental terms and social sustainability with less vacancies and satisfied tenants. However, due to insufficient planning for learning, among professional actors and tenants, and diffusion of experiences the investments have not contributed to long-term change (Stenberg et al, forthcoming).

3.5 The Current Decade – The Passive House Era

The new decade has shown the continued legitimacy of sustainable building practices. An important feature of this evolution is the governmental initiative, Building-Living Dialogue a cooperation between leading private and public organisations with voluntarily agreements to take concrete measures for sustainable building and educational actions towards practitioners. A vision was established in 2000 with goals for reduced energy with at least 30% by 2025, goals for reduced use of fossil fuels, declaration of building materials and phasing out of chemicals.

In the early 2000s two larger flagship projects were built: Hammarby Sjöstad in Stockholm and Bo01 in Malmö, aiming at sustainable housing on brownfield close to the city centres. Although using programmes and assessment tools, the projects failed to reach high environmental performance although resulted in other lasting qualities, including a good urban design.

Recently a new upswing of the local development of sustainable building in Göteborg has occurred, with public-private investments and co-operation between research and practice. One example is Universeum, which is a science centre (completed in 2001) with innovative technology for cooling/heating. The project planning involved researchers and practitioners building local capacity for continued design. The spectrum of environmental measures in Universeum include urine-separating toilets, local wastewater treatment, renewable building materials and solar energy. Two projects in Göteborg (completed 2000 – 2001) have been of large national and international importance: First, the retrofitting of a housing area from the 1970s in Gårdsten, addressing social and environmental issues (design by Christer Nordström). The project has resulted in 40% less energy use and 30% less water use and socio-economic benefits, and received the World Habitat Award in 2005. Second, Sweden's first passive housing, a terrace housing project in Lindås (initiator Hans Eek). Measurements show that both projects approach the energy goals for 2025 set by the Building-Living Dialogue. The factors for success include committed clients, the early involvement of actors, education of all actors to understand set goals, cooperation with researchers, and the focus on performance, evaluation and dissemination of results. After a few years without follow-ups, the projects seem to be catalysts for the wave of interest in energy-efficiency and passive building methods which Sweden is experiencing today.

An on-going research project Demo04/06 at Chalmers University of Technology connects researchers and a network of professional actors involved in five local case studies with demonstration capacities. Demo04/06 provides an arena for mutual exchange and learning, on the one hand between practitioners and on the other hand between practitioners and researchers, and reaches beyond the arena boundaries. Two of the evolving cases connected to the arena develop the passive house concept. The Harbour house is a new multifamily housing project by a commercial developer owned by Göteborg municipality. The developer and all their consultants are engaged in the Building-Living Dialogue. Brogården in Alingsås, outside Göteborg, is a retrofit and regeneration project with social ambitions of housing from the 1970s. Important factors in that project is a strong political engagement in the municipality, an enlightened client, Hans Eek as consultant, and partnering contracts for involved actors. Both passive house concept projects have goals for energy use below those set up in the Building-Living Dialogue vision for 2025.

4. Discussion

Jensen and Gram-Hanssen (2008) in their study of sustainable building in Denmark base their discussion on three elements: governance (new types of cooperation and roles for actors), standardisation (use of standards, tools to define and legitimize) and visibility (measurement of energy and material flows). Governance and visibility can be traced as important elements in ecological modernization processes. The authors define standardization as a central concept for construction and for the modernisation of processes in general. Based on our retrospective study, we have found three pairs of elements important to the Swedish development: first, governance and learning; second, exemplifying and legitimising; third, symbol and performance.

4.1 Governance and Learning

The study shows that development of sustainable building in Sweden has a strong basis in bottom-up activities even though with time these activities have benefited from government support. It is the individual project and the learning produced by practice that has pushed development forward. Seen in a wider perspective than that of immediate commercial success, the contribution of earlier projects to the development, although often unsuccessful as individual projects, cannot be underestimated. Later years show a clear shift from government driven processes towards market led governance for change. Important thresholds have been reached through the intensified focus on energy efficiency and the success of contemporary demonstration projects which has legitimised the interest in sustainable building practices.

Some elements inherent in a reflexive ecological modernisation described as transition (Smith and Kerr, 2007) can be observed in recent development in Sweden with voluntary agreements and multi-stakeholder arenas for exchange and progress. It could be discussed if the strong reliance on government actions in earlier decades created dependence and a weakened innovative force. Further studies will be needed to see if the current development will manage to overcome commercial competition and sustain a self-supporting evolution.

Experimental activities and demonstration projects have an important role in the development even though these investments could be more efficient. Evaluations of government support for earlier experiments and demonstrations claim positive advance in the accelerated introduction of new energy efficient technology although recognising deficiencies in explicit knowledge accumulation and dissemination (e.g TSERC, 1987). The transfer of results over organisation boundaries will also need a process of experimentation in which the external and explicit evolution of knowledge will have to be internalised by new actors and tested in a new context. However, the implementation gap, i.e. insignificant impact from demonstration projects on mainstream building practices, is more than a knowledge problem. There has often been an overestimation of the influence of key individuals and rational choice on decision-making. This overlooks the complexity and unpredictability of the implementation process and fails to provide reliable explanations regarding the relationship between practice, performance and context (Fernie *et al.,* 2006, Rubino, 2007).

4.2 Exemplifying and Legitimating

What this paper highlights is that sustainable building is defined through practice, through building projects. Contemporary successful commercial projects show what is possible and consequently legitimise those kinds of investments. New visions and goals for the advance of sustainable building are formulated in innovative projects, not in policies or through regulatory systems. Contemporary projects prove that considerably higher energy efficiency can be reached than is prescribed in current Swedish building regulations.

This retrospective study reveals different approaches to sustainable building. Even if different approaches, by different actors have been emphasized in different historical periods, these varying approaches co-exist at the same time. Jensen and Gram-Hanssen (2008) argue that the lack of a common definition of green building is not necessarily bad. Instead, a variety of approaches can be useful as it can motivate different kinds of actors and more easily adapt to differing project contexts. However, it could also be argued that these varying and sometimes competing approaches have impeded development as pioneers and more realistic actors have acted independently and have not wanted to learn from each other.

The study also point to the importance of emerging tools for legitimising more sustainable building practices, including building material declarations, environmental programmes, environmental policies and life cycle costing. Furthermore, the study reveals a shift from solution fixed and closed concepts of sustainable building towards function, quantitative performance and systems thinking. This is supported by a change in Swedish building regulation s from prescriptive solutions to system goals. The strong sense of place, local solutions, and homogenous and closed concepts in earlier examples has limited the broad transferability. This development also points to a shift from product issues to process issues recognising the importance of good quality process ingredients, i.e. the participation of a larger range of actors and stakeholders through all stages of a project in an integrated approach and the recognition of extra time for innovation, in the making of successful sustainable building. However, one should probably not overestimate the unduly positive outcome of a specific process or ideal design process.

4.3 Symbol and Performance

What can be considered as more sustainable building? The definition is evolving through time and as was discussed earlier it has to be defined in relation to normal praxis or norms in each national or regional context. In Sweden, some measures e.g. water-efficient appliances are normal procedures and do not have to be emphasised as part of sustainable building practices.

The importance of tangible dimensions of sustainable building has often been discussed, as a means to raise awareness that will lead to action (Guy and Shove, 2000; Jensen and Gram-Hanssen, 2008). Recently, the tangibility of sustainable building has gone from the often criticized symbolic attributes to performance indicators, a shift that has further supported the legitimacy of sustainable building. However, there are still problems connected to indicators such as kWh/m^2, and in the comparison between different locations (e.g. difficulties in delimiting flows or including household electricity use or not) and their accuracy to actually indicate sustainable development (e.g. in relation to the increasing space occupied per person). It has also been observed that individual measurement of energy as a means to stimulate lifestyle changes is not as effective as was planned as occupants experience difficulties in understanding the figures (Stenberg *et al*, forthcoming).

5. Concluding Remarks

This explorative study points to increasing governance in developing more sustainable building in Sweden and this may be an indication of a transition to a new phase in the ecological modernisation of Swedish building practices. The successful performance of contemporary low-energy buildings should not be seen as the ultimate goal of this development, we have to proceed beyond the passive house era. Energy, even though important, is not the only aspect of sustainable building. We see a need to reinvent and further study other important aspects of sustainable building such as water use, building materials, transport, renewable energies etc. as well as health, well-being and social issues linked to democracy and participation (Stenberg *et a*l, forthcoming) qualities in the built environment that are more difficult to assess, defend and motivate. Furthermore, the sector should be encouraged to innovate more, invest in experiments and demonstration to learn and establish new routines. The Government has to rethink their role in these processes, how they could support bottom-up initiatives and learn from them. Finally, the holistic approach in this study is motivated as sustainable building cannot be seen as one technology, which makes it more difficult to study but in fact responds to a complex reality.

Keywords: Integral design, self-sufficiency, fine wire heat exchangers, very low temperature heating, aquifer, seasonal heatstorage, parabolic multipurpose solar collectors, vacuum sewer

1. Abstract

Every decade the Dutch horticulture has a great exposition event, the 'Floriade'. The next Floriade 2012 will contain a greenhouse characterised by ergonomic office workplaces in a green surrounding. Normal offices are located within the greenhouse in different climates including particular vegetation.
This literally and environmentally greenest office is also the greenest building in the Netherlands, lacking public utilities, except ICT. The size of the building is 42,500 m2. A low glasshouse roof on the south side climbs up till six floors of office on the north side. Large parabolic solar collectors dominate the silhouette of the building. (Figure 1) The seasonal surplus of heat and cold from the solar power system is stored in the aquifer approximately 50 m beneath the building. The building is equipped with a heating system based on very low-temperatures (24-25˚C), enabled by fine wire heat exchangers recently invented. The cooling of the indoor climate in summer is based mainly on the same system. The vacuum sewer system and organic waste collection are aspects of ecological innovation. By means of an anaerobic bioreactor and a micro-turbine, electricity can be produced on location with addition of organic waste. The filtered exhaust gases are used as nutrients up till 1,000 ppm, in order to take care of the CO_2 balance. Pure water can be retained within this process, which takes two or three days. An important, little known aspect of the greenhouse/landscape office is the healthy work environment. It appears from research that houseplants have a surprisingly wholesome effect. We know the process of purifying the air of CO2 and producing O2 from the biology lessons, but reducing stress, skin irritations and headache are a little known contribution of plants to the improvement of the living environment. The parabolic solar collector roof construction is the most striking innovation.

Figure 1 Artist impression – The forest is reflected in the glass by the forward tilted glass north facade and thus camouflaging the height of the building. Parabolic solar collectoring are skyline from a far.

During a 24 hours period a new coating on mirrors enables the harvesting of boiling water and PV electricity on a sunny day and cold and condensing water by clear night sky. In a country of regulation the Dutch government needs to decide on the building permit for this building that will not be plugged into public utilities. The paper will discuss most issues related to the Floriade 2012 greenhouse.

2. Definition of a problem

The export of Dutch greenhouse horticulture products amounts to 7 billion euros a year. In the Netherlands greenhouse cultivation largely depends on natural gas. These greenhouses account for almost 10% of the national natural gas consumption. A greenhouse uses 50 m3 natural gas/m^2 year. With increasing environmental awareness and rising fuel prices new innovative methods had to be found. This paper presents the results of this innovation in horticulture translated integral design into a multipurpose greenhouse/office building. Office islands in the different climate zone with corresponding spheres have to adduce proof that working in glass and green is healthy and relaxing. The offices in the Middle East and the Amazone climate will have 'stand alone' climate working places.
Does the greenhouse/landscape office have any weak points then? Certainly, the metabolism of the sedentary human being and that of the plant is very different. So how do we make pleasant green workplaces in various climates? This is a very special problem, the biggest challenge of the greenest office.

3. Statement of requirement

The ambition of the initiator/client is the most important design factor of each building. Two clients design a spear point project to surprise the International Floriade visitor in the year 2012. A special program point was the greenhouse/office – healthy work places in the green as part of the 10,000 m^2 exhibition greenhouse on the ground floor. (Figure 2) The groundbreaking innovation of the recently developed "Zonneterp" Greenhouse Village was to serve as a footing – the beginning of the Edible City.

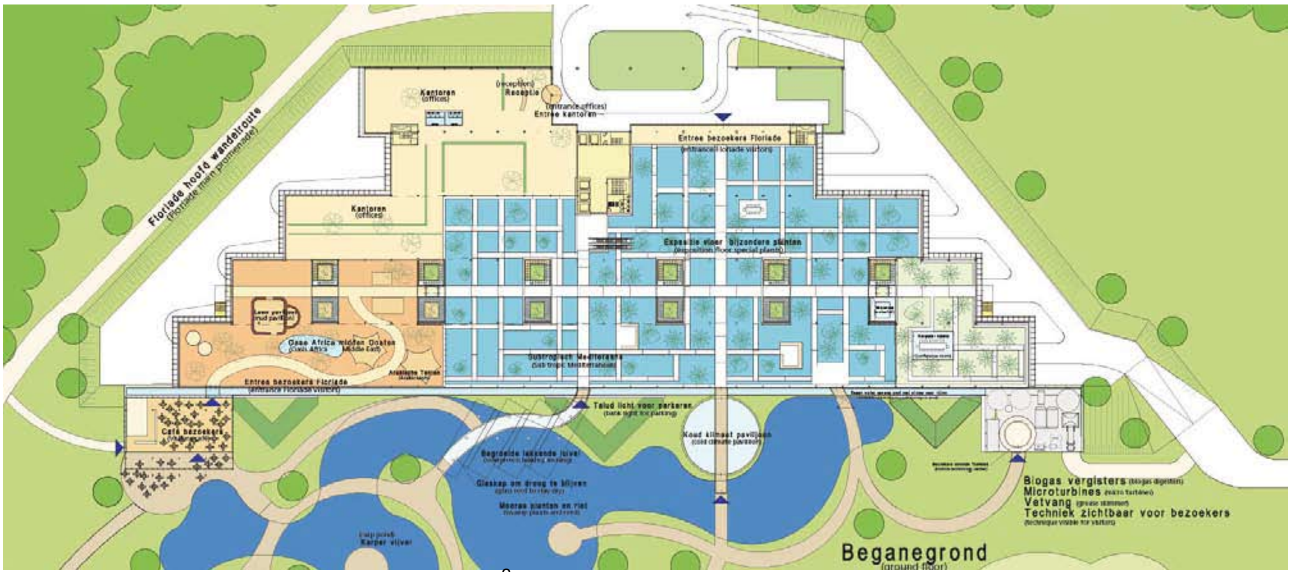

Figure 2 Floor plan – ground floor 15,50 m^2 with four indoor climates.

4. Integral design

Integral design is the lifting of all building functions with an added value by weaving into a permanent entity. In order to be able to elucidate in the space of eight pages "the greenest building", illustrations are more efficient than written text; a drawing tells more that a thousand words.

4.1. Location

The location is a natural environment (setting) close to the city of Venlo at a junction of two highways towards Germany and Belgium. This needs to become the "Genius Loci" of the Floriade. In addition, the invisible location-properties of the sand layers and groundwater are important for installing seasonal heat storage of 8 ˚ to 28˚C in the aquifer. (Figure 3)

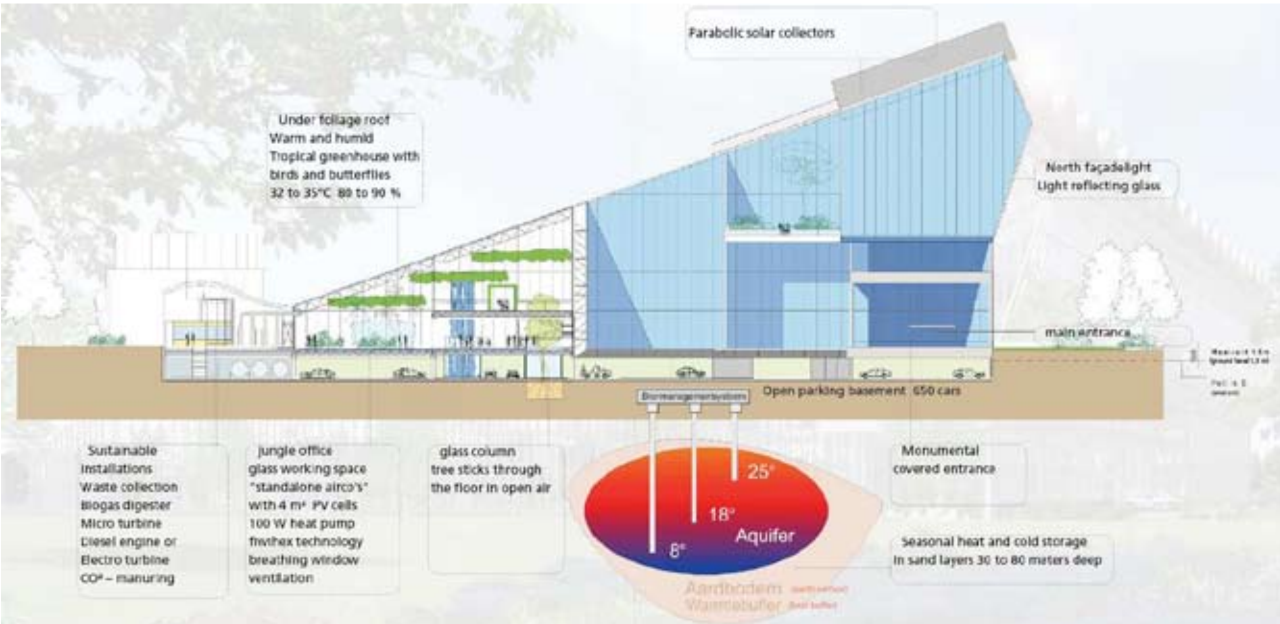

Figure 3 Section – installation – tropical zone – parking – aquifer = seasonal heat / cold storage

4.2 Energy self-sufficiency

The sun is the source of heat and the radiation at night towards the clear sky the cold source. The characteristic properties of sustainable installations are that they are based on the physics of the open country more than on mechanical engineering. New fine-wire-heat exchangers enable very low temperature heating and cooling within the closed greenhouse. Two fine-wire-heat exchangers have been developed; water/air and air/air heat exchangers.
The ø 1/10 mm copper wire is around 8 x as efficient as a plate heat exchanger. A greenhouse receives around 7x as much solar-energy heat as the thermal loss at night and in winter. Each greenhouse functions as a hothouse, and the closed greenhouse certainly functions as a solar collector, which needs to be cooled down by means of the aquifer.

Figure 4 Longitutional section 250 m

4.3 Parabolic solar collectors

Multifunctional parabolic solar collectors as supporting reflecting roof plates have a vertical solar collector for hot water of 70 to 80˚C in the bent focus of the parabola. (Figure 4 and 5) On this solar collector black thin-walled "Helianthus" pv-cells are pasted on both sides (1,20 m wide). The solar collector also cools down the pv-cells (max. 80˚C) that provide more electricity and promotes a longer, useful life span. By applying spectral selective coating on the mirrors, more IR (infrared) radiation can be achieved on clear nights. This yields more cold for the aquifer, but also condensation and glazed frost, i.e. drinking water and irrigation water in dry climates. A closed greenhouse requires little irrigation water.

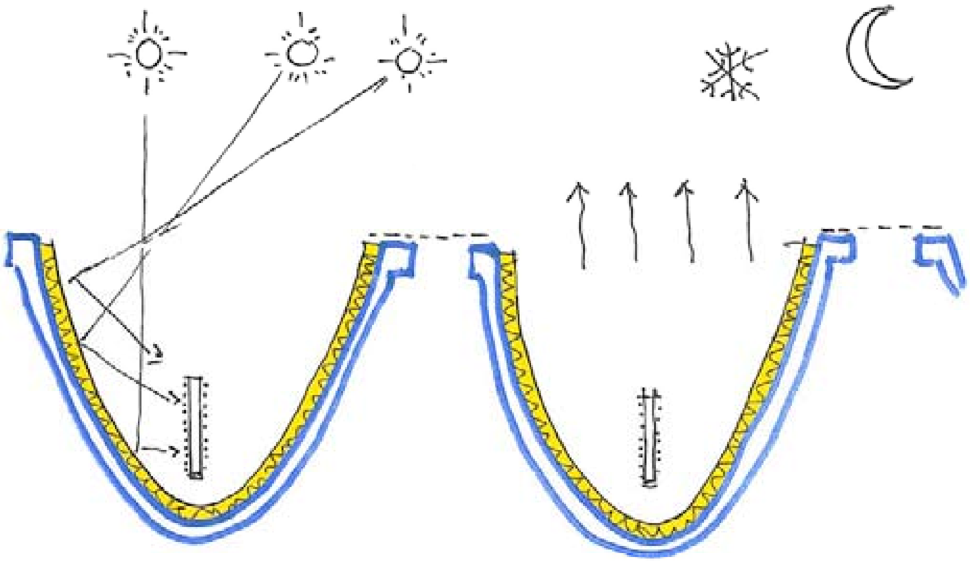

Figure 5 Schematic section parabolic solar collectors; deliver heat output during the daytime and cold output and water from condensation during the night (glazed frost)

4.4. Organic waste

Vacuum sewerage (faces and urine) and a complete organic waste collection and- disposal is a condition for closed carbon -nitrogen cycles. (Figures 6, 7, 8, 9, 10) By means of anaerobe fermenting methane gas is made for the drive of a micro turbine during a period of 2,5 days in a bioreactor that provides itself with electricity. The filtered exhaust fumes are used as fertilization for the greenhouse plants. With CO_2 concentration of 1,000 ppm the plants growth within the closed greenhouse increases by 20% and the building is totally CO_2 neutral. Apart from the cooling, which can be limited by adjustable outside awning a closed greenhouse has two advantages: the relative humidity can be kept high and equable without appreciable water from the outside and there is considerable less bother from insects. The end product is compost that can be used as mould.

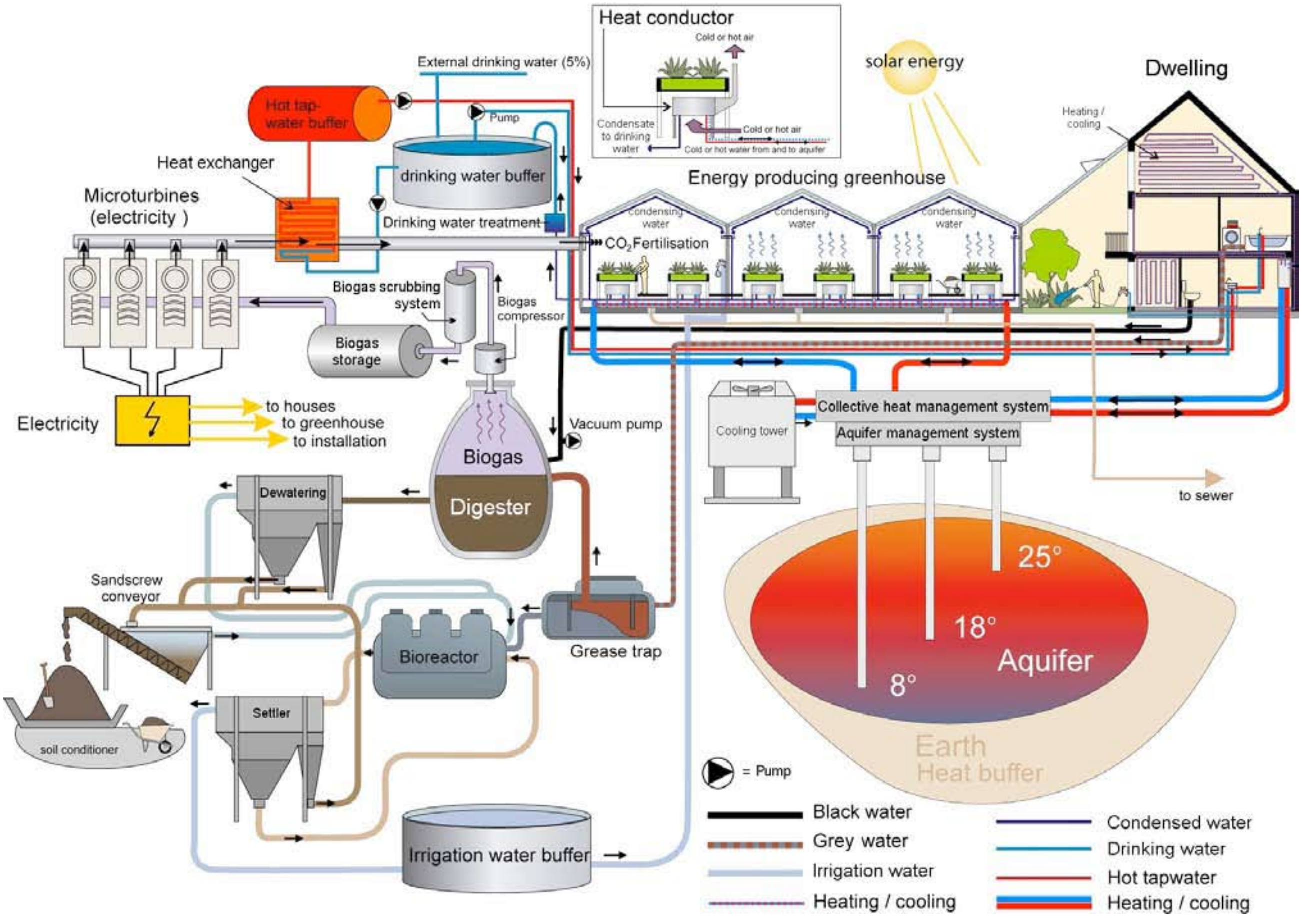

Figure 6 The complete installation of heat and cold in the closed organic waste processing inclusive of CO2 neutral greenhouse. The dwellings will be replaced by offices in the integral design.

4.5. The edible city

In the Netherlands 2 ha of closed greenhouse with aquifer and energy storage is adequate to heat 8 ha equivalent of a neighborhood of some 200 houses. A greenhouse of 8 ha produces sufficient organic waste to also provide these houses with electricity. “The Edible City” requires new town planning and development plans.

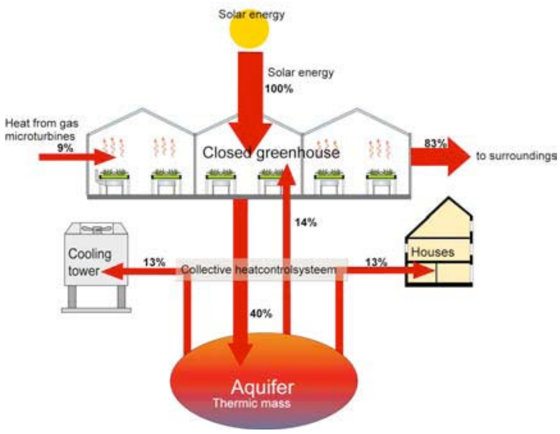

Figure 7 Energy balance

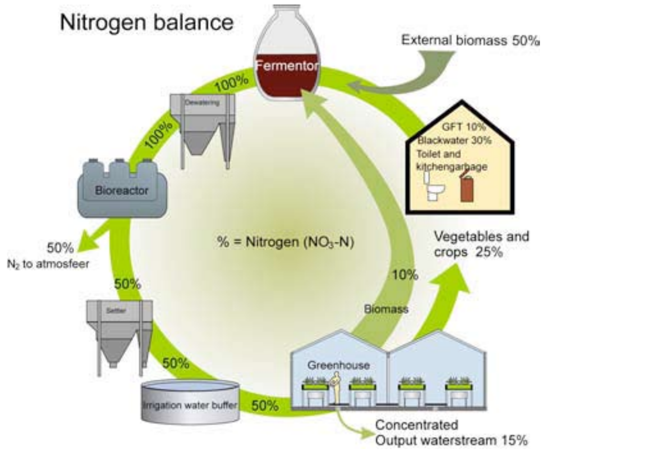

Figure 8 Nitrogen balance

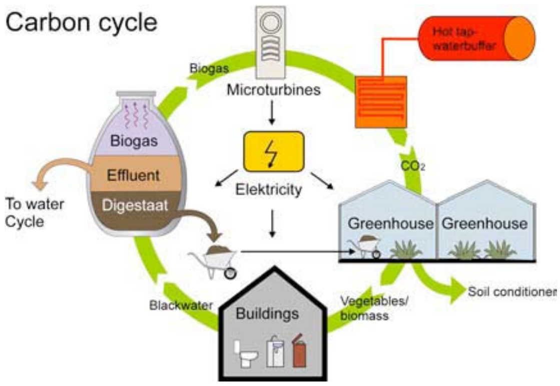

Figure 9 Carbon Cycle

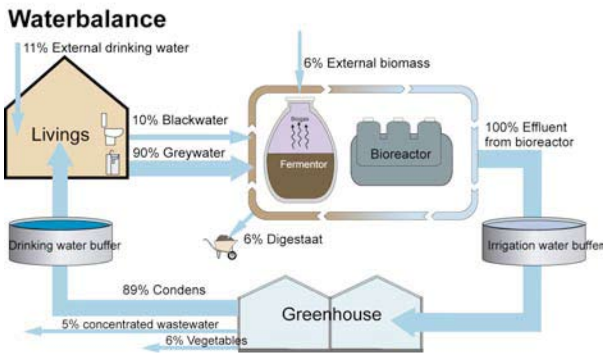

Figure 10 Water balance

5. Indoor climate

5.1. Air heating

The desired indoor climate, the temperature, humidity and ventilation with four diverse continental climates is achieved by complete design without heat pumps and cooling machines. The basic heating and cooling is the slow radiation heating, supplemented with fast reacting air heating and air cooling which is also used in “Zonneterp” Greenhouse Village. However, a transition is needed from the effective utilitarian fine-wire-heat exchanger in the closed greenhouses to silent heating and cooling on office work places with a noise level of < 25 dB in the cell offices. (Figure 11 and 12)

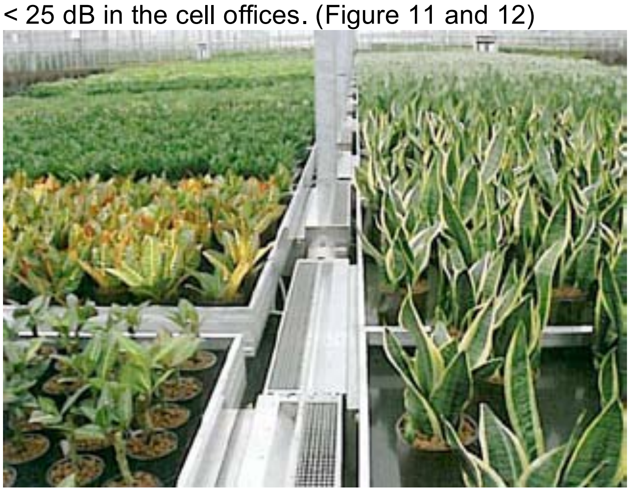

Figure 11 Fiwihex – heating / cooling

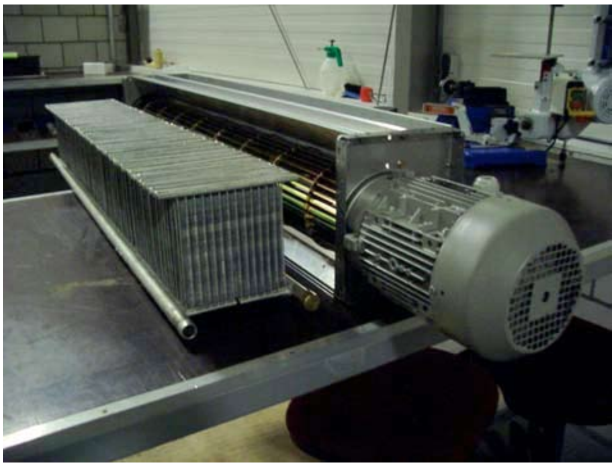

Figure 12 Fiwihex box of heat exchanger and a tangential blower

5.2 Radiant heating

The temperature control for radiant or air heating takes place from the seasonal heat storage in the ground. For the benefit of the concrete core activation heat and cooling the weather forecast can sometimes offer help during big weather changes. The concrete core activation by oxygen tight floor heating pipes in floor and ceiling. The concrete core activation is relatively fast and effective in a new, very stiff, hollow concrete floor, which can span 18 m. wide of the garage in the basement. The 18 m has also become a plan size with a large degree of freedom for layout. This new floor has as its characteristic a large cavity of 0,6 m with diagonal reinforcement bars, which connect 100 mm top slab walking floor and 100 mm bottom slab ceiling floor. The large cavity is reachable from above for wires and the underneath has a sound-absorbent structure. No false ceilings are required. The equable indoor temperature benefits from the thermal mass of the concrete. The auxiliary quick heating / cooling by means of air. (Figure 16)

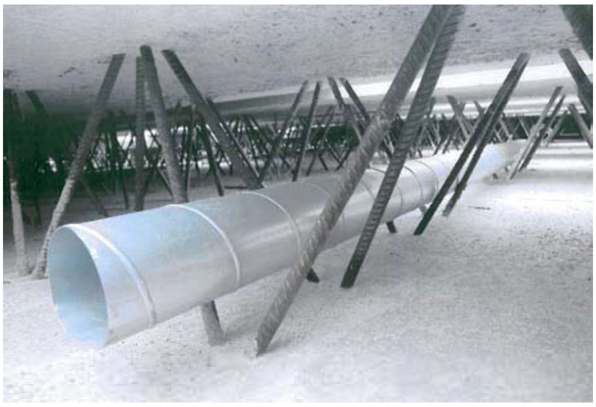

Figure 13 New type of concrete double floor has an extraordinary span of 18 to 20 meters

5.3 Ventilation

The greenhouse has four artificial indoor climates, subtropical, Middle Eastern, Amazon, and the polar circle area. Research has proven that plants have a beneficial effect on patients. The plants produce carbon dioxide but the offices have “breathing windows” ventilation (BW) as a supplement (Figure 14, 15 and 16). This is an intelligent, balanced way of ventilation, which measures the CO_2 of the indoor climate and ventilates according to one’s needs. Adjustable, but at f.i. a CO_2 level of 600 ppm the ventilation stops. The fine-wire-heat exchanger in BW exists of 15 km ø 1/10 mm copper wire and weighs 500 gr. The dimensions of the heat exchanger are 100/200/450 mm, so that it can be cleaned in the shower or in a dish washing machine.

Figure 14 First prototype of a Breathing Window

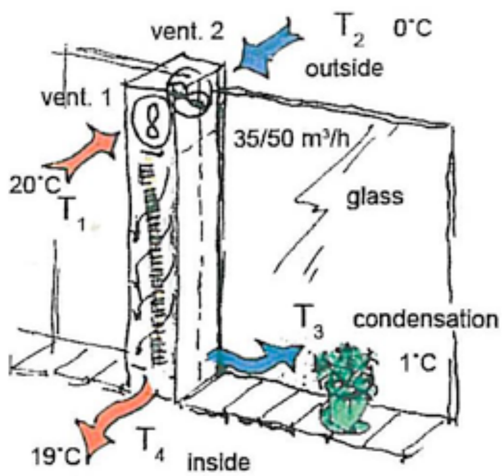

Figure 15 - the Concept of a Breathing Window

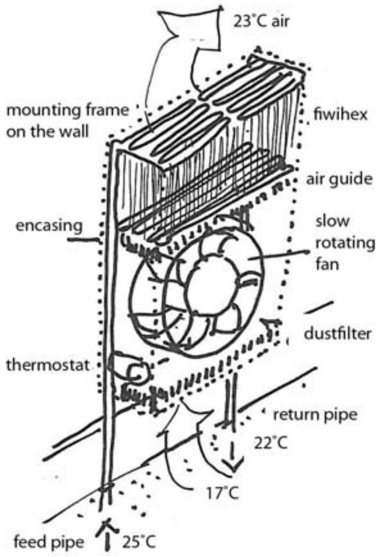

Figure 16 new Very- Low- Temerature Heating Device

5.4 Characteristic values in metabolism

By far the most difficult condition is the sustainable indoor climate. The metabolism of a sedentary person and a standing plant are different, this is also the biggest challenge for the architect. (Figure 17,18 impressions).

Figure 17 Interior

Figure 18 Exterior

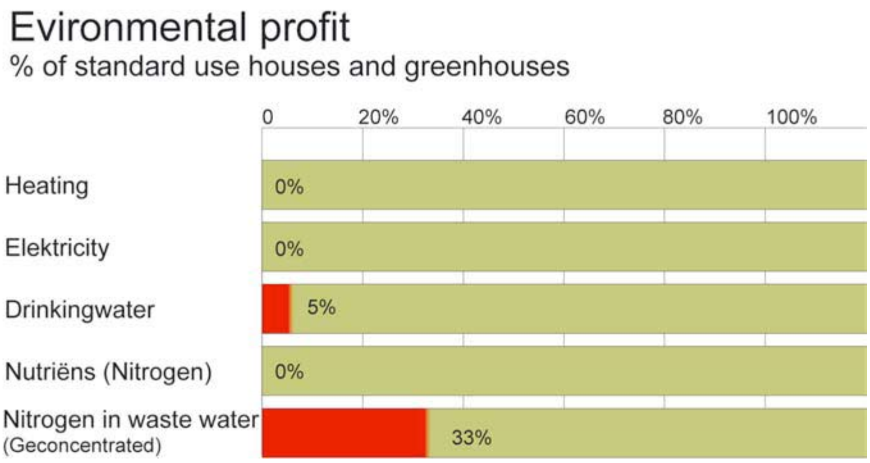

Figure 19 Self-sufficiency or general utilities

6. Conclusion

By innovation in various fields and the integral designing, a self-supporting building can come into being without general public utilities.

Evaluation of Ecobalance Performance of Building Composite Materials by LCA Multi- Eco-indicators

Toshio FUKUSHIMA Dr.Eng.[1]

[1] Department of Architecture, The University of Kitakyushu, Kitakyushu, Japan, fukushima@env.kitakyu-u.ac.jp

Keywords: building composite material, short- cut fiber, carbon fiber, glass fiber, LCA multiple eco-indicators, ecobalance performance, global environmental impact analysis, radar chart visualization

Summary

Carbon, and glass short-cut fiber reinforced cement composites (FRC), and glass short –cut fiber reinforced plastics (FRP), both among advanced composite materials are becoming widely used in building field. In order for these composite materials to be “ecomaterial” gentle both to the global environment and to the human beings, supporting sustainable buildings, an appropriate evaluation should be made from various points of view. This paper deals with research on evaluation of ecobalance performance for these FRC and FRP, based upon LCA multi-ecobalance-indicators such as long service life, resources circulation, reduction of harmful substances, resources and environmental capacities, health safety, and materials efficiency, each of which are quantified as five rating indices. Comparison and evaluation of the environmental load of total materials requirement and energy consumption per unit volume in production based upon LCA fundamental data of fibers and matrix component materials. Global environmental impact analysis is also done from the viewpoint of the global warming and acid rain. Radar chart visualization is shown for typical FRC. Although PAN based-CFRC and GFRP are both excellent composites from the viewpoint of tensile strength and long service life, GFRC is considered to be the best ecomaterial from the viewpoint of the global environmental impact analysis.

1. Introduction

The establishment of sustainable buildings and housings taking into account the balance among the environment/landscape, safety/long service life and economy is the premise of the realization of environmentally harmonized sustainable society in which the flow of rational resources circulation is made possible, and the global environmental problems are becoming resolved. As fundamental materials supporting sustainable buildings and housings, building materials have to be “ecomaterials “gentle both to the global environment and to the human beings. In order for us to supply from the materials side for the basis to establish sustainable environment-conscious buildings, cities, and societies (eco-buildings, eco-cities, and eco-societies), we have to convert building materials into ecomaterials (ecomaterialization) or develop ecomaterial-type building materials (Fukushima (2003a), Fukushima (2004a)). A number of ecomaterial-type building materials have been gradually developed. When we select them as building materials, the judgment of how to evaluate the degree of environmental harmony or ecobalance performance is required (Fukushima (2006). On the other hand, environment-conscious materials design (ecomaterials design) for the selection of ecomaterial-type building materials, and environment-conscious life-cycle design (eco-life-cycle design) as the design considering life- cycle processes, paying special attention to the balance among long service life , resources circulation, and ecobalance performance, are as well important for application of ecomaterial-type building materials for sustainable buildings and housings(Fukushima(2003b) and Fukushima(2004b) .

The concept of composite materials was known empirically from old age. However, technology of composite materials has drastically progressed recently with the development of advanced artificially fibers such as carbon, aramid, and glass. Fiber reinforced composite materials as masterpieces of artificial materials, are becoming more and more important in building field. Due to their excellent material properties such as lightweight, high strength, high corrosion-resistance, carbon, aramid, and glass short-cut fiber reinforced cement composites (FRC) are used as excellent exterior materials, for example, for external thermal insulation systems in sustainable buildings, replacing asbestos fiber reinforced cement composites, which are becoming prohibited due to the problems of causing, for example, mesothelioma and lung cancer. On the other hand, short –cut glass fiber reinfoeced plastics (FRP) are becoming widely used for kitchen units, bath units, and water supply tanks etc. In order for these advanced composite materials to be ecomaterial, supporting sustainable buildings, an appropriate evaluation should be made from various points of view (Fukushima (2005) and Fukushima (2007)). Part of the results of this research was reported in 7th Ecobalance conference in Tsukuba, Japan (Fukushima et.al. 2006b)).

This paper deals with research on evaluation of ecobalance performance for these FRC and FRP, based upon LCA multiple eco-indicators. As the part of the quantification of the resources and environmental capacities of these composites, comparison and evaluation of the environmental load of total materials requirement and energy consumption and per unit volume in production, based upon LCA fundamental data of fibers and matrix component materials, are shown. Global environmental impact analysis is also done from the viewpoint of the global warming and acid rain. Based upon six items of ecobalance performance, radar chart visualization is shown for GFRC as typical FRC.

2. Research Methods

2.1 Six evaluation indicators of ecobalance performance

In order to evaluate ecobalance performance, it is necessary to set LCA evaluation indicators from various points of view. For example, only the life-cycle inventory (LCI) as an integrated evaluation method of energy consumption and carbon dioxide (CO_2) generation rate in the total life cycle is insufficient. Comprehensive evaluation based on other LCA indicators as well as LCI is required. Ecobalance performance can be evaluated by the quantitative expression of six evaluation indicators of service life, resources circulation, reduction of harmful substances, resources and environmental capacities, materials efficiency, and health safety. LCI indicators are included into the category of the improvement of resources and environmental capacities. The objective of this research is also to evaluate quantitatively evaluate the characteristics of this category of fiber reinforced composites.

Table 1 Setting Methods of Rating Numbers of Various Evaluation Indicators

Evaluation Indicator	Rating number				
	1	2	3	4	5
Characteristics of Long service life					
1) Structural materials and Components	15-30year	30-45year	45-60year	60-75year	75-100year
2) Exterior and interior materials	5-10year	10-15year	15-20year	20-25uear	25-30year
Characteristics of Resources Circulation					
Recycling Indicator = Recycling Ratio× RecyclingNumber	0-1	1-2	2-3	3-4	4-5
Reduction of Hazardous Substances					
Rate of Generation of Dioxin （ppm）	8-10	6-8	4-6	2-4	0-2
Characteristics of Resources/Environmental Capacities					
Improvement Ratio of Resources/Environmental Capacities	0-3%	3-6%	6-9%	9-12%	12-15%
Characteristics of Materials Efficiency					
Improvement Ratio of Materials' Efficiency	-10- -5%	-5-0%	0%	0-5%	5-10%
Characteristics of Health Safety					
Number of Human Race Feeling Health Damage per 1,000 ones	80-100	60-80	40-60	20-40	0-20

In BEES4.0 of National Institute for Standards and Technology of U.S.A (Lippiant 2007), 10-12 evaluation indicators including the global warming, acid rain and solid wastes etc. are set to evaluate comprehensive environmental performance of many building materials. Although six evaluation indicators shown here are partly correlated with these 10-12 indicators of BEES, these are selected, paying special attention to life-cycle ecobalance, not limiting only to the environmental performance in production. For example, if we can expect long service life, we can reduce the amount and number of generation of solid waste, so that the environmental load is greatly improved. On the other hand, if we can expect the resources circulation after designed service life, the environmental load is greatly improved as well. From the viewpoint of the conservation of natural resources, the improvement of materials efficiency or resources productivity using recycled or unused materials contribute to the reduction of mass consumption of natural resources. As the other three most important evaluation indicators, we have also to taking into account the reduction of hazardous substances, the improvement of resources/environmental capacities, and the health safety. Table 1 shows the stetting methods of rating numbers of various evaluation indicators by five indices. For example, standard service life of structural materials such as concrete is set as 45-60years, and that of exterior and interior materials such as FRC and FRP as 15-20years （Fukushima 2006）.

2.2 Conditions of sustainable production of building materials

For pursuit of the environmental harmony, we consider the general concept of ecobalance performance, paying special attention to life-cycle processes of building materials as follows:

Ecobalance Performance = Demanded Performance and Service× ｛Service Life(SL)｝ / {(Life Cycle Cost(LCC))×(‘Total Materials Requirement（TMR）)×(Life Cycle Environmental Load(LCEL))}

(1)

This means that we endeavor to obtain the demanded performance and service of building materials and components, and/or system by minimizing life–cycle cost, total materials requirement and life cycle environmental load, and also making service life as long as possible, on the contrary to the previous concept of industries that pursuit for the maximum performance and service by minimizing only initial cost in the 20th century (Fkushima2005). Various evaluation indicators of ecobalance performance are treated based upon this rather comprehensive concept. In this paper, TMR and LCEL are specially considered in order to quantify the LCA indicator of the improvement of sources /environmental capacities.

3. Research Results and Discussion

3.1 Characterization of total materials requirement of composite materials

Based upon unified mix proportion of the same water cement ratio of 40%, cement sand ratio of 25% shown in Table2 , and the same fiber length of 6mm, and various fiber volume content(V_f) of 1,2,3%, properties of PAN –based carbon and glass short-cut fiber reinforced cement composites (PAN-CFRC and GFRC) are characterized. On the other hand, total materials requirement (TMR) per tensile strength and TMR per compressive strength are also calculated for E-glass short-cut fiber reinforced plastic (GFRP for SMC bath tablet use), and for ordinary concrete, based upon their mixed proportion shown in Table 3and 4. Characterization of TMR of composite materials is summarized in Table 5. Fig.1 shows the comparison of TMR of PAN-CFRC, GFRC, and GFRP.

Table 2 Unified Mix Proportion of Matrix Mortar of FRC

Water cement ratio W/C (%)	Sand cement ratio S/C (%)	Unit Mass (kg/m³) Water（W)	Cement（C)	Sand（S)	High Performance Water Reducing Reagent (C×1.0%)	Defoamer (C×0.05%)
40	25	488	1220	305	12.2	0.6

Table 3 Mix Proportion of GFRP

Unit Mass (kg/m³) E-glass	Unsaturated Polyester Resin	$CaCO_3$	Other Additives
600	589	665	46

Table 4 Mix Proportion of Ordinary Concrete

Slump (cm)	Water Cement Ratio W/C (%)	Air Content (%)	Sand Gravel Ratio S/G (%)	Unit Mass (kg/m3) Water (W)	Cement (C)	Gravel (G)	Sand (S)	Admixture (g/m^3) High Performance Water Reducing Reagent (C×0.6%)
18	60	4	46	180	300	968	818	1,800

Table 5 Characterization of Total Materials Requirement (TMR) of Composite Materials

Type of composite	Fiber Volume Content (%)	TMR (kg/m^3)	Tensile Strength (N/mm^2)	Compressive Strength (N/mm^2)	TMR per Tensile Strength (kg/m^3/(N/mm^2))	TMR per Compressive Strength (kg/m^3/(N/mm^2))
PAN-CFRC[1)]	1	2,052	2.14	—	959	—
	2	2,040	2.89	—	706	—
	3	2,012	3.84	—	524	—
GFRC[2)]	1	2,049	2.10	—	975	—
	2	2,047	2.66	—	770	—
	3	2,050	3.35	—	612	—
GFRP[3)]	24-28	1,900	3.43	—	554	—
Ordinary Concrete[4)]	—	2,264	—	23,900	—	0.095

Notes:1) PAN-carbon short-cut fiber reinforced cement composite (Fiber Length: 6mm, Fiber Density: $1.75cm^3$) 2) Alkali-resistant glass short-cut fiber reinforced cement composite (Fiber Length: 6mm, Fiber Density: $2.55cm^3$) 3) E-glass Short-cut fiber reinforced Unsaturated Polyester Resin (Fiber Length: 2-3mm, Fiber Density: $2.5g/cm^3$) 4) Structural Design Strength: $F_c=24N/mm^2$, Durability Design Strength :$F_d=24N/mm^2$

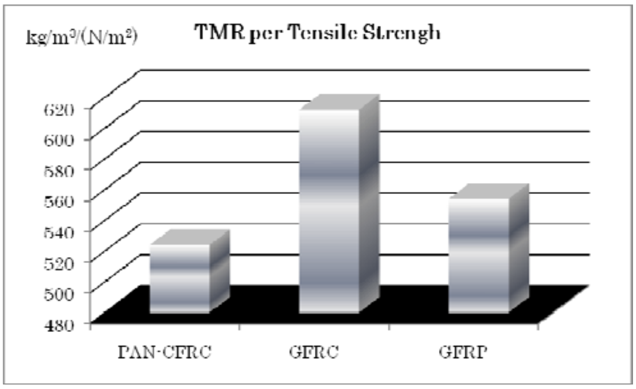

Figure 1 Total materials requirement (TMR) per tensile strength of composite materials

We can find out the tendencies of characteristics of TMR of various composite materials as follows:

1) TMR based upon unified mix proportion is almost the same value of about $2050kg/m^3$ both in PAN-CFRC and in GFRC, but become smaller with fiber volume content (V_f). TMR of GFRP is smaller value of 1,900 kg/m^3 than those of FRC, but that of ordinary concrete is rather greater value of 2,264 kg/m^3 than those of FRC.

2) TMR per tensile strength has the tendency of the decrease with V_f in each FRC. When we think about the case of 3% of V_f, however, PAN-CFRC has the smaller value of 524 $kg/m^3/(N/mm^2)$ than that of 612

kg/m3/ (N/mm2) of GFRC. TMR per tensile strength value of 554 kg/m3/ (N/mm2) of GFRP is smaller than those of PAN-CFRC and GFRC.

3) TMR per compressive strength value of 0.095 kg/m3/ (N/mm2) of ordinary concrete is much smaller than TMR per tensile strength of FRC and FRP.

4) Materials efficiency obtaining demanded compressive strength is rather greater in concrete than that obtaining demanded tensile strength in FRC and FRP.

3.2 Characterization of energy consumption and hazardous gas generation of composite materials

Based upon unit energy consumption and waste gases of various component materials shown in Table6, and mixed proportion of composite materials as shown in Tables 2, 3, and 4, unit energy consumption and unit waste gas amounts are calculated. Results are shown in Table 7.

We can find out that PAN-CFRC and GFRP have rather greater UEC compared with ordinary concrete and GFRC. On the other hand, the amount of SO_x and NO_x generation of GFRC becomes comparable to PAN-CFRC.PAN-CFRC has the greatest amounts of UEC waste gas generation in other composite materials.

Table 6 Unit Energy Consumption (UEC) and Waste Gas Generation of Component Materials of Composites

Type of Component Material	Energy Unit (MJ/kg)	CO_2 (kg/kg)	SO_x (kg/kg)	NO_x (kg/kg)	Data Resource
PAN-Carbon Fiber	478.5	29.7	0.00682	2.00946	The Japan Carbon Fiber Manufacturing Association
Alkali-Resistant Glass fiber	29.8	1.85	0.000926	0.00069	The Japan Glass Fiber Manufacturing Association
E-Glass Fiber	474.81	32.42	0.03855	0.21259	Japan Reinforced Plastic Society

Table 7 Unit Energy Consumption (UEC) and Waste Gas Generation of Composite Materials

Type of Composite	UEC (GJ/m3)	CO_2 (kg/m^3)	SO_x (g/m^3)	NO_x (g/m^3)
PAN-CFRC	62.4	4117.08	4073.86	123653.66
GFRC	40.0	2698.63	2898.63	18153.13
GFRP[1)]	65.0	4802.00	599.56	20893.61
Ordinary Concrete	19.5	1176.88	1176.88	8183.88

Notes:1): E-glass Short-cut Fiber Reinforced Unsaturated Polyester Resin

3.3 Global environmental impact analysis

Results of evaluation of global environment impact of composite materials based upon Table 7 are shown in Fugues 2, 3, and 4. Evaluation of the global environmental impact by acid rain was done by the reduced amount of SO_x waste gas generation by the following equation:

Reduced Amount of SOx waste gas generation = SOx waste gas generation+0.7 NOx waste gas generation (Lippiant 2007)

(2)

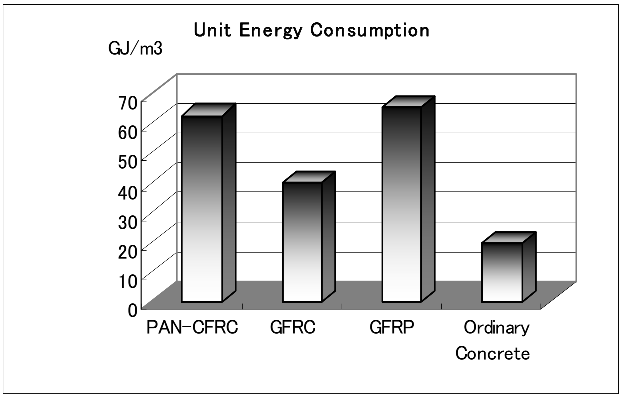

Figure 2 Evaluation of global environmental impact of composite materials (Part 1:unit energy consumption).

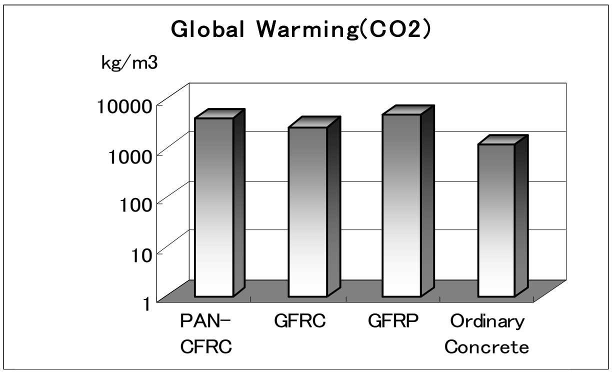

Figure 3 Evaluation of global environmental impact of composite materials (Part 2: Global warming).

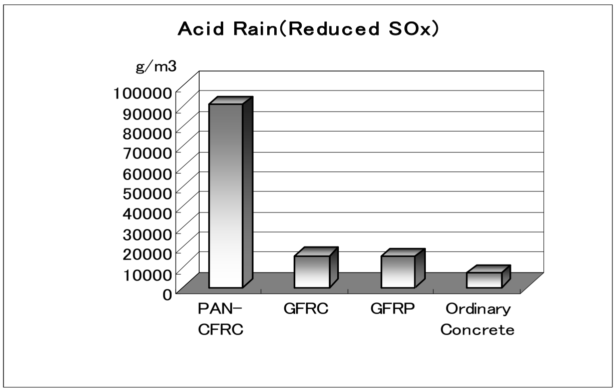

Figure 4 Evaluation of global environmental impact of composite materials (Part 3: Acid rain).

.

From these results, we can say as follows:

1) PAN-CFRC and short-cut GFRP are excellent composite materials. From the viewpoint of the ecobalance performance, however, they give the considerably greater environmental burdens to the global environment, compared with GFRC and ordinary concrete.

2) From the viewpoint of the gentleness to the global environment, GFRC is the best among various fiber reinforced composite materials.

3.4 Evaluation of six items of ecobalance performance by five rating indices

Each item was evaluated by the following consideration:

3.4.1 Long service life

Standard service life of reinforced concrete as structural composite component is 60years, so that its rating index is 4.また、Those of external CFRC and GFRC are 30years, so that their rating indices are 5. Service lives of carbon and glass continuous fiber reinforced plastic reinforcements as structural materials are 100 years, so that their rating indices are 5.

3.4.2 Resources circulation

Resources circulation was evaluated by the product of recycling rate by recycling number. Recycling rate of external GFRC is 70%, and recycling number is 5, and evaluation of resources circulation is 3.5, so that its rating index is4.

3.4.3 Materials efficiency

If we replace the binder of CFRC from ordinary Portland cement to 90% ecocement and 10% waste GFRP powder, comparable flexural strength is obtained with that of CFRC only using ordinary Portland cement as the binder, and materials efficiency is improved about 10 %. Consequently its rating index is 5.

3.3 Visualization of ecobalance evaluation by radar chart of GFRC

Figure 5 shows the visualization of ecobalance performance by radar chart of GFRC. From this figure we can say that GFRC has balanced ecobalance performance except for rather low rating number in the items of resources circulation and materials efficiency.

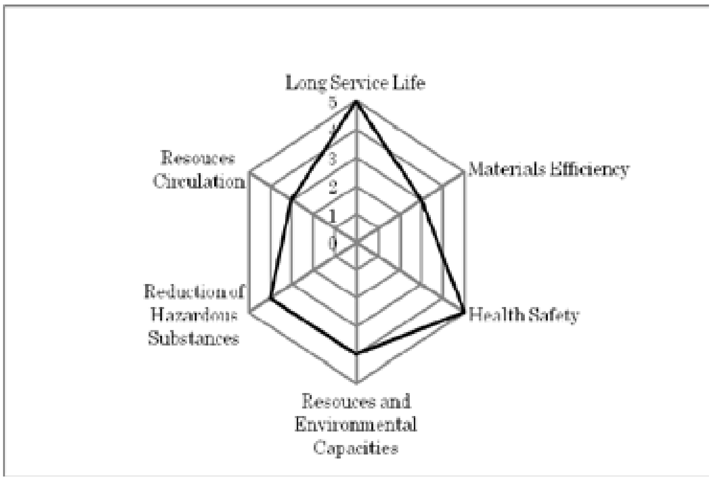

Figure 5 Visualization of ecobalance evaluation by radar chart of GFRC

4. Summary and Conclusion

In order to begin with estimate the environmental load in production of various short-cut fiber reinforced composite materials(FRC and FRP), based upon LCA fundamental data of fibers and matrix component materials, comparison and evaluation are done for these composite materials, from the viewpoint of total materials requirement and energy consumption and waste gas generation, compared with the case of ordinary concrete. The following remarks can be made:

1) Total material requirements per tensile strength have the tendency of the decrease with fiber volume content in each FRC.

2) Although PAN-CFRC and short-cut GFRP are excellent composite materials from the viewpoint of total materials requirement obtaining demanded tensile strength, from the viewpoint of the gentleness to the global environment, GFRC is the best among various short-cut fiber reinforced composite materials.

Acknowledgement

I would like to express heartfelt thanks to many Japanese associations and societies such as Ecomaterial Forum, The Japan Carbon Fiber Manufacturing Association, Japan Glass Fiber Manufacturing Association, Japan Reinforced Plastic Society, Japan Cement Association, and Japan Environmental Management Association for Industry, for their kind help to supply data of unit energy consumption and waste gases of various composite component materials.

ABSTRACT

Recently the pollution of indoor air in newly built houses by noxious gas emitted from construction materials, adhesive, furniture, etc. is emerging as a serious social problem. Thus, the present study purposed to prove the effect of purifying polluted indoor air using plants and natural materials. For this purpose, we measured the effect of purifying indoor air of HCOH, CO, CO_2 using a 1/3 size mock-up model composed of a living room and a balcony. According to the result, plants and natural materials were highly effective in purifying polluted air in the balcony space and the effect reached the living room adjacent to the balcony. The results suggest that air pollution in newly built houses called sick house syndrome can be solved through natural purification using plants and natural materials and, based on the results, we may develop a system for pleasant indoor environment in the future.

KEYWORDS: Sick house syndrome, Indoor air pollution, Plants, Natural materials, Balcony, Natural purification

1. INTRODUCTION

Recently sick house syndrome is emerging as a social problem in Korea. That is, most of construction materials, adhesive and furniture used in newly built houses emit volatile organic chemicals (VOCs) such as formaldehyde and pollute indoor air, threatening the residents' health.

Recognizing the seriousness of the problem, the government is making efforts to establish relevant systems and environmental standards, and house constructors are also examining various ways of reducing indoor air pollution.

Thus the present study purposed to examine how effective plants and natural materials in apartment balconies is in purifying polluted indoor air of construction materials, furniture and the outside air. For this purpose, we manufactured two 1/3 size mock-up models, placed selected plants in the balcony, and measured and analyzed changes in the balcony and the living room temperature, humidity and noxious elements such as HCHO, CO, CO_2.

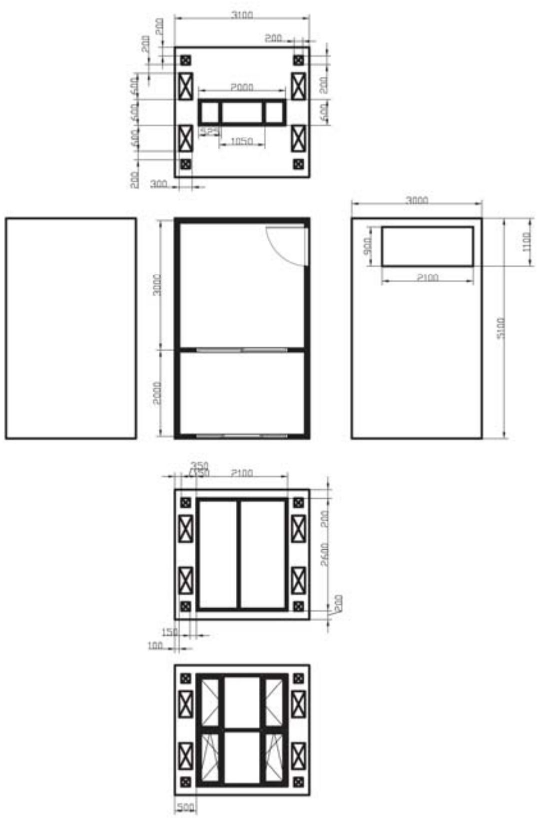

Figure 1. Floor plan, elevation of mock-up model

Figure 2. Actual appearance of the model

2. STRUCTURE OF MODEL AND EXPERIMENT METHOD

As in Figure 2, 3 and 4, the structure of the mock-up model has dampers (C, D, E, F) and vents for natural ventilation (A, B, G, H) to control air flow between the balcony and the living room so that the environmental condition of the balcony can affect the living room. The design intended to reduce noxious elements and create pleasant environment in the living room through the systematically organized environment-friendly plants and natural materials in the balcony.

2.1 Experiment 1: Measuring change in formaldehyde content

The names and layout of plants in the experiment chamber are as in Figure 2. In Figure 1, the balcony with plants in a chamber was named AT and the living room AR, and in another experiment chamber of the same size and condition, the balcony was named BT and the living room BR.

In the model, we opened and volatilized a bottle containing 10cc of formaldehyde at the rear part of the middle of AR and BR at 6:00 pm on June 22 2004 and measured the concentration of formaldehyde at 10:00, 14:00, 18:00 on the next day (23rd of June), at 8:30 on the 24th) and at 9:00 on the 25th. Each measuring was made in order of AT-BT-BT-AT-AR-BR-BR-AR (the same hereinafter). Each space was measured five times, and the means of the results was used in analysis. The measuring device used was PPM formaldehyde meter TM400(PPM Technology, U.K.).

2.2 Experiment 2: Measuring changes in temperature, humidity and formaldehyde, carbon monoxide and carbon dioxide contents

The composition and structure of the experiment chambers are identical with those in Experiment 1. The names and layout of plants in the experiment chambers are as in Figure 3. Experiment plants were placed on the 19th of September. Until the 17th of September before the experiment, the chambers were ventilated by opening the windows and water and nutrition were managed.

In order to measure changes in temperature, humidity, CO and CO_2, we obtained their base levels at 10:00 on the 17th with the windows opened and, at 10:30, injected 100% CO gas at 1kgf/cm2 for a second into six times into the center of the two living rooms. We used a solenoid valve that can adjust the concentration of gas injected through electric control (the same hereinafter).

Measuring was made at 10:00, 11:00, 14:00, 17:00 and 22:00 on the 17th, 4:00, 8:00, 11:00, 14:00, 17:00 and 22:00 on the 19th, and 4:00, 8:00, 11:00, 14:00, 17:00 and 22:00 on the 20th. The order of measuring was identical with that in Experiment 1. The measuring device was GRAY WOLF (gray wolf sensing solutions, USA).

Next, 1ml of formaldehyde was injected into the center of the living rooms using a pipette at 13:00 on September 17 2004, and its concentration was measured at 14:00 and 17:00 on the 17th, 8:00, 14:00 and 22:00 on the 18th, 8:00, 14:00 and 22:00 on the 19th, and 8:30 and 14:00 on the 20th. The measuring device was identical with that in Experiment 1.

2.3 Experiment 3: Measuring changes in temperature, humidity and formaldehyde, carbon monoxide and carbon dioxide contents

The composition and structure of the experiment chambers are identical with those in Experiment 1. The names and layout of plants in the experiment chambers are as in Figure 4. Experiment plants were placed on the 20th of September. On the 24th of September, the chambers were ventilated by opening the right and left window and water and nutrition were managed. Next, base levels were measured at 8:30 with the windows opened.

In order to measure temperature, humidity, CO and CO_2, we closed the windows at 9:40 on the 24th and injected 100% CO gas at 1kgf/cm2 for 6 seconds into the center of AR and BR at 9:50 on the 24th. Measuring was made at 8:00, 10:00, 11:00, 13:00 and 17:00 on the 24th, 9:00, 14:00 and 17:00 on the 25th, 9:00 and 17:00 on the 26th, 14:00 on the 27th and 18:00 on the 28th.

In the experiment with formaldehyde, 1ml of formaldehyde was injected using a pipette at 10:00 on September 24 2004, and its concentration was measured at 11:00, 12:30 and 18:00 on the 24th, 9:00, 14:00 and 17:00 on the 25th, 17:30 on the 26th, 14:00 on the 27th and 18:00 on the 28th.

3. EXPERIMENT RESULTS AND DISCUSSION

3.1 Experiment 1: Changes in formaldehyde content

As for changes in the formaldehyde content after 18 hours from the volatilization of formaldehyde as in Figure 5, the content in the balcony with plants (AT) was lower by 2ppm than that in that without (BT), and it lowered by around 5ppm after three days (25th of July). The content in the living room adjacent to AT (AR) was not much different from that in the living room adjacent to BT (BR). The reason that the effect of AT did not decrease the content in AR was that formaldehyde continued to volatilize from the formaldehyde bottle in the living room and as a result, plants removed only formaldehyde in AT.

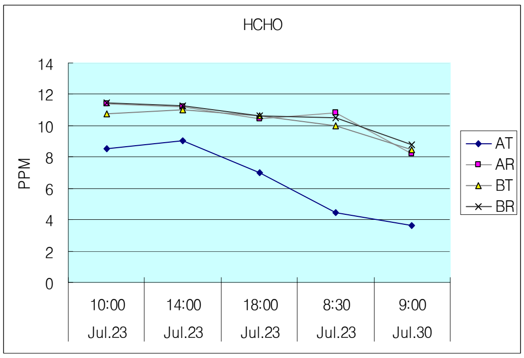

Figure 5. Changes in formaldehyde (HCHO) content in the model (7/23-7/25)

3.2 Experiment 2: Changes in temperature, humidity and formaldehyde, carbon monoxide and carbon dioxide contents

As for changes in the formaldehyde content after 1 hour from the volatilization of 1ml of formaldehyde in the living room` at 13:00 on the 17th of September (Figure 6), the content in the balcony with plants (AT) was 5ppm lower (reduced by 50%) than that in the balcony without (BT), and the content in AR adjacent to AT was also 3ppm lower than that BR, suggesting that it was affected by AT probably because a limited quantity of formaldehyde was volatilized in the living room. The content was high during daytime when temperature was high and low in morning and evening. In addition, it was low on rainy days (14:00 on the 18th) and cool days and high on sunny and hot days (14:00 on the 19th) (Figure 5).

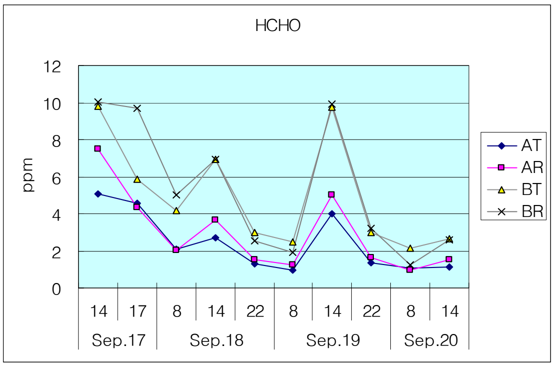

Figure 6. Changes in formaldehyde (HCHO) content in the model (9/17-9/20)

On the other hand, the temperature of the closed experiment chambers (AT, AR, BT, BR) was 5-7℃ higher than that of the open air during daytime but was not much different at night (Figure 7). There was no notable difference in temperature among the chambers. At the early stage of measuring, the temperature of AT (with plants) was 1-2℃ lower than that of BT (without plants) but soon the difference disappeared.

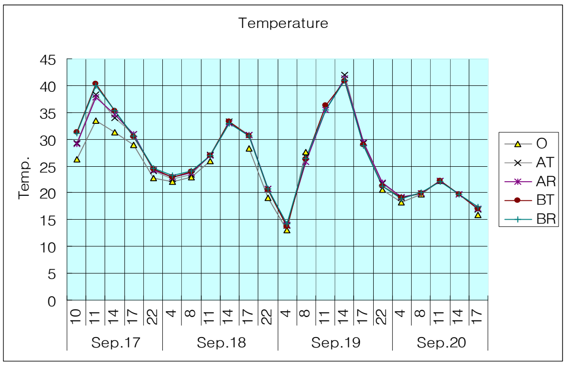

Figure 7. Changes in the temperature of the experiment chambers (9/17-9/20)

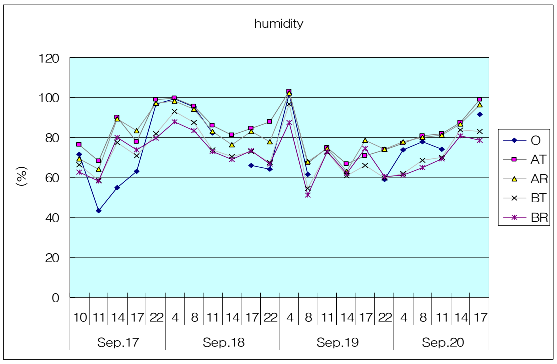

Figure 8. Changes in the humidity of the experiment chambers (9/17-9/20)

Humidity was 5-10% higher in AT (with plants) and AR than in BT (without plants) and BR. This is probably because of continuous evaporation of water by the hydroponics system and the transpiration of water in the culture media of the plants in AT (with plants) (Figure 8).

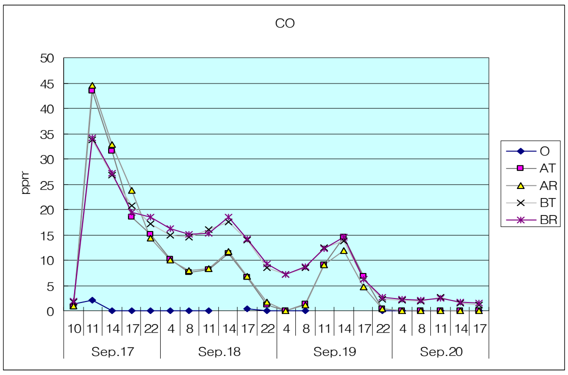

Figure 9. Changes in the carbon monoxide content in the model (9/17-9/20)

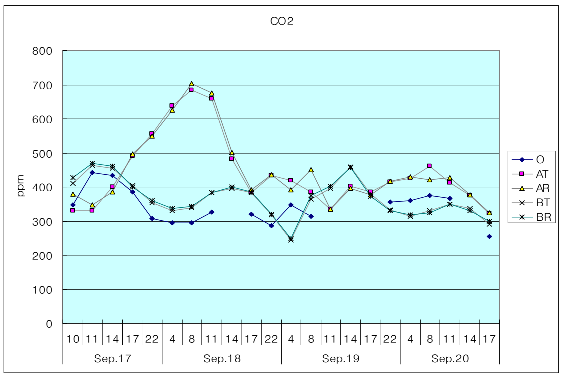

Figure 10. Changes in the carbon dioxide content in the model (9/17-9/20)

At the early stage of treatment (11:00), the CO content was around 45ppm in AT (with plants) and AR and around 35ppm in BT (with plants) and BR. However, after 8 hours (17:00) it became similar among the chambers (19-24ppm) and, from 22:00, fell down sharply to 14-15ppm in AT and AR and to 17-18ppm in BT and BR (Figure 9). It rose during daytime when temperature was high (14:00 on the 18th and 14:00 on the 19th) and fell down to 0ppm from around 22:00 on the 19th. However, the CO content in BT and BR continued to remain 2-3ppm.

The CO_2 content was 90-120ppm lower in closed AT (with plants) and AR than in the open air and closed BT and BR at the early stage (11:00 on the 17th) but became higher by 350ppm at night (4:00 on the 18th). The concentration of carbon dioxide after a day (after 14:00 on the 18th) varied within 30-100ppm regardless of time (day and night).

3.3 Experiment 3: Changes in temperature, humidity and formaldehyde, carbon monoxide and carbon dioxide contents

As for changes in the formaldehyde content after 1 hour from the volatilization of 1ml of formaldehyde in the living rooms at 10:00 on the 24th of September (Figure 11), the content was 5ppm lower (reduced by 50%) in the balcony with plants (AT) than in that without plants (BT) and 1-3ppm lower in AR adjacent to AT than BR, suggesting that AR was affected by AT.

The content was high during hot daytime (14:00-17:00 on the 25th and 14:00 on the 27th) and low in morning and evening. The result was similar to that in Experiment 2, but differences in the content among the chambers with different plant layout were more obvious in Experiment 3 (Figure 2 and 3).

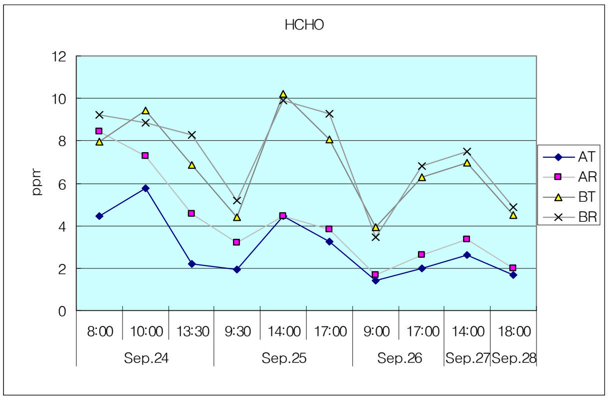

Figure 11. Change in the formaldehyde (HCHO) content in the model (9/24-9/28)

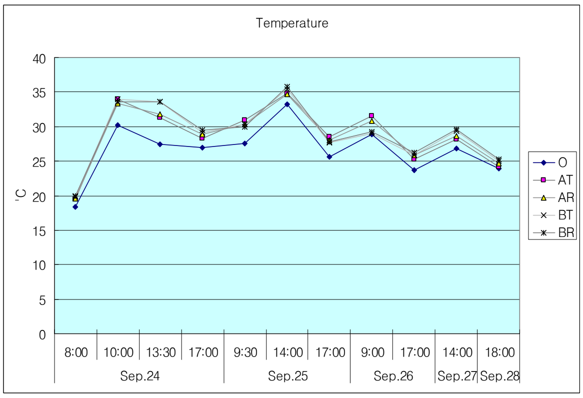

Figure 12. Changes in the temperature of the experiment chambers (9/24-9/28)

Temperature in the closed experiment chambers (AT, AR, BT, BR) at day and night was 2-7℃ higher than that in the open air. Temperature was not significantly different among the chambers but during daytime it was 1-2℃ lower in AT (with plants) than in BT (without plants) (Figure 12).

Humidity was 10-20% higher in AT (with plants) and AR than in BT (without plants) and BR. This was probably because of the continuous evaporation of water by the hydroponics system and the transpiration of water in the culture media of plants (Figure 13).

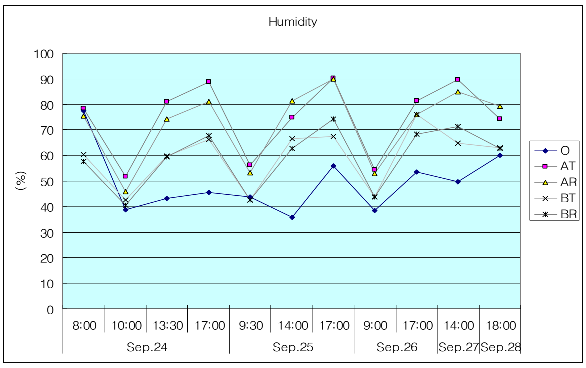

Figure 13. Changes in humidity in the model (9/24-9/28)

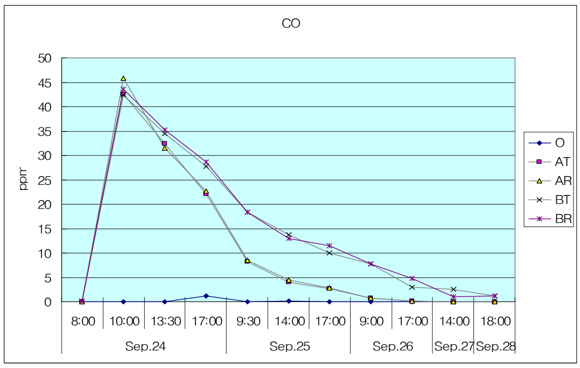

Figure 14. Carbon monoxide in the experiment chambers (9/24-9/28)

When measuring was made immediately after the injection of CO into AR and BR as in Experiment 2, the CO content in the four spaces was all around 43 ppm and then a clear difference was observed between the concentration in AT and AR and that in BT and BR. After two days had passed the concentration reached nearly 0ppm in AT and AR, but a small amount of CO was detected in BT and BR even after four days (Figure 14).

The concentration of CO_2 was around 80ppm lower in AT (with plants) than in the open air and BT at the early stage after plants were placed

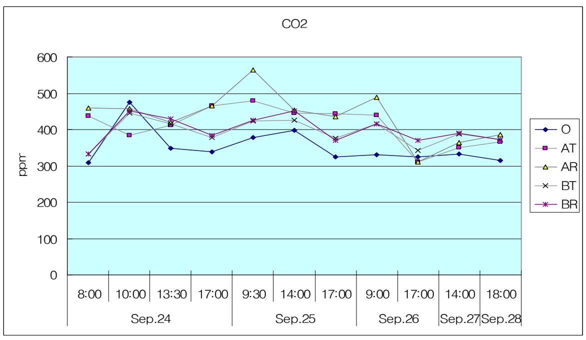

Figure 15. Carbon dioxide in the experiment chambers (9/24-9/28)

(10:00 on the 24th) but, over time, it became around 90ppm higher in AT than in BT at around 17:00, became similar at around 14:00 (daytime) on the 25th and became 60ppm lower at 14:00 on the following day (26th). That is, the concentration of CO_2 was low during daytime when carbon dioxide assimilation was active and high at night when plants respired (Figure 15).

4. CONCLUSIONS

As the three experiments above show, the reduction of formaldehyde was clear in the balcony with plants, which in turn reduced formaldehyde in the living room. However, if formaldehyde occurs continuously, it has to be removed continuously through appropriate deployment of plants and natural materials.

In these experiments with a reduced-size model, the temperature of the balcony with plants was affected by the temperature of the open air, and it went up to some degree in AT (with plants) due to the respiration of plants in the small closed space on hot days compared to rainy or cloudy days.

Due to the transpiration of plants, humidity was generally higher in AT (with plants). This was because of the continuous evaporation of water and the transpiration of water contained in the culture media of plants at high temperature by the hydroponics system in the balcony.

As shown by the results of three experiments, the concentration of CO in AT and AR was clearly different from that in BT and BR. This was because plants have the physiological function of reducing carbon monoxide and reduction in the balcony affected the living room.

When temperature was not so high and the weather was sunny, carbon dioxide assimilation was active and as a result the level of carbon dioxide went down, offsetting or exceeding the increase of carbon dioxide from respiration in evening and at night.

As expected, CO_2 decreased as plants in the small closed space absorbed carbon dioxide through carbon dioxide assimilation during daytime or when temperature was low in the rainy season. On hot days, however, plants lost their function as respiration was more active than carbon dioxide assimilation, had problems in their growth and withered to death due to high temperature. In this case, however, the concentration of carbon dioxide was not high enough to be harmful to the human body.

In this study we proved the purification effect of plants and natural materials against formaldehyde, carbon monoxide, carbon dioxide but this study has limitations in that it used a reduced-size model and was carried out only in summer and autumn.

Thus, in order to generalize the effect of experiment, it is necessary to carry out an experiment throughout the four seasons using a real-size model and a larger number of noxious substances and to study the application of the results to actual houses.

DOES THE BUILDING SYSTEM PREDEFINE THE CUMULATED LIFE CYCLE ENERGY DEMAND?

András ZOLD Professor[1]

Keywords: cumulated energy demand, life cycle assessment, statistical evaluation

Summary

Cumulated life cycle energy balance components of single family houses, built with four different building systems have been analyzed. The components include the embodied energy, the energy need of maintenance and demolition of those building elements which directly influence the operational energy need and those, but only those components of the operational energy need which depends on the building – thus, on one hand the envelope of the building, on the other hand the transmission heat losses and the utilized solar gains have been considered. Statistical population of randomly generated technically feasible houses have has been calculated and compared. Significant differences between the mean values of cumulated energy demand of different building systems have been proven by statistical method, nevertheless the overlapping of the confidence intervals shows that the building system itself does not completely predefine the final result, only the higher or lower likelihood of the expected cumulated energy demand can be spoken of. Unlike the comparison of the data of a few arbitrarily selected sample buildings the applied statistical method facilitates the evaluation of the multitude of buildings.

1. Introduction

Many analysises, national regulation as well, as the Energy Performance of Building Directive of the European Commission and European Parliament focus on the operational energy demand of buildings. The requirements become more and more strict. Nevertheless the less is the operational energy demand the more important will be in both absolute and relative sense the energy need of the erection, maintenance and demolition of the buildings. Neglecting them the risk of false decision may become considerable.

One of the main subject areas of the recent research at the BUTE is the life cycle energy balance of buildings.

The analysis (Szalay 2008) of the relationship between the energy demand and other environmental indicators proved that energy demand is a suitable screening indicator in the environmental assessment of buildings. For typical building systems and heating fuels, energy is highly correlated with the global warming potential, the resource use in eco-indicator 99 and with the non-renewable cumulative exergy demand.

The life cycle of buildings consists of four phases:

- Production: acquiring raw materials, manufacturing and transporting building products to the site and erecting the building.
- Maintenance: small repairs and changing the building elements at the end of their useful life, this includes the production of the new elements.
- Operation: energy demand for heating, domestic hot water and lighting.
- Disposal: disposal of the old building materials in the maintenance phase and demolition of the building at the end of the effective life, separation, transport and processing of materials for reuse/ recycling/ incineration/ landfill and recultivation of the deposit site.

As far as production, maintenance and disposal is spoken of, distinction should be made between those building elements which have direct relationship with, and those elements, which have no or only an indirect influence on, the operational energy use. The first category includes the walls, roofs, exposed windows and movable shading or night insulation – in one term the envelope. Their thermal characteristics (U-value, transmittance, decrement factor….) govern the transmission and radiant heat flows between the building and environment. Considerable may be the embodied energy of the internal floor slabs, foundation and partitions, however they have no or only moderate effect on the operational energy by the heat storage capacity.

The operational energy must be divided in two categories, as well. These are its building related and user related components. Transmission heat losses and utilised solar gains depend on the size, shape and thermal properties of building elements (the solar access on the surrounding obstructions, too), providing climatic conditions and standard indoor temperature are given. The other components depend on the user behaviour. This is self intended in the case of domestic hot water consumption, whilst ventilation heat losses seem to be disputable. Nevertheless, if the air tightness of the envelope fulfils the requirements and the building is properly used, the air change rate depends on, and is adjusted to, the number and activity of the habitants.

Encompassing the rational use of energy in the followings the energy need of the building envelope and the building related operational energy will be analysed, thus the interrelated components of the life cycle energy balance.

2. Method

Based on architectural and functional considerations, the realistic ranges of the parameters describing the geometry of the “technically feasible” buildings and the relationships of these parameters have been defined (Szalay 2008). Thus, the building sample is neither arbitrarily selected, nor based on statistical data of existing buildings, but covers the population of the “technically feasible” buildings, since there is no guarantee that the data of the future buildings will coincide with those of the previous era. For this, the parameters describing the building geometry and the realistic ranges of these parameters based on functional and architectural considerations have been determined. The parameters were the floor area, the number of storeys, the perimeter to floor area ratio, the window ratio and frame factor and the density of partition walls in the layout. An algorithm has been developed for the random generation of a large building sample based on the realistic ranges of the geometric parameters. In each category 1000 buildings have been generated. Based on the geometric parameters the area of the building elements and the surface to volume ratio (ΣA/V) describing the dimensions and compactness of buildings have been calculated. In the base scenario, the buildings were built with an unheated cellar and unheated attic, the window ratio was 10-30 % of the façade area, 10 % of the windows faced North, 30-30-30 % South, East and West, respectively, and the windows were partly sunlit.

Several calculations have been carried out - here the interrelated components of the life cycle energy balance for four building system and for one and two-storey residential buildings are analysed. The results are presented for 1 year and 1 m^2 net heated floor area over a 50-year period in Hungary (basic climatic data: 72 000 heating degree hours, 2000 sunshine hours per year, 48 N latitude, continental temperate zone).

With regard to the embodied energy basically the Swiss ecoinvent database has been used, with certain modifications. The composition of the Swiss and the Hungarian electricity mix and the source of the natural gas differ significantly, hence these modules were changed. For products missing from the database new datasets were developed based on the material composition (Tiderenczl et al, 2006).

For the analysis, we have chosen four building systems, typical for new buildings in Hungary:

- insulating brick system;
- brickwork with external insulation;
- autoclaved aerated concrete system;
- timber stud system.

Although mixed systems cannot be excluded (for example, insulating brick walls can be combined with a wooden floor), in this study we always considered external and partition walls and floors as belonging to one system. It corresponds to the real market situation: the suppliers offer, and the builder usually prefer, complete packages and compatible elements.

Insulating bricks are specially designed porous hollow clay bricks that reduce heat flow. These bricks are suitable as a load-bearing structure up to 3-4 storeys and can just fulfil the new national energy performance requirements without additional insulation, issued in 2006 (the U value is between 0,35 – 0,43 W/m^2K, depending on the thickness). The brick density is between 600-800 kg/m3, depending on the number and arrangement of the voids. The porosity of these bricks is increased by adding materials that burn during firing (e.g. saw dust). The thermal transmittance of the brickwork can be further decreased by applying mortar and/or plaster with perlite, expanded clay or expanded polystyrene.

The system includes partition walls, lintels, girders etc. made of burnt clay. The floors are made up of pre-stressed reinforced concrete beams with clay covering, clay hollow blocks filling between the beams, and 4-6 cm concrete topping with reinforcement.

Clay bricks with a density of 1200-1400 kg/m^3 are suitable from energy point of view as external wall only if an insulation layer is added. Blocks with a thickness of 30 cm are applied in load-bearing walls. This system is not linked to any special floor constructions, the walls can be combined with all kinds of floor. We considered prefabricated reinforced concrete beams with hollow concrete blocks between them, typically used in the practice.

Autoclaved aerated concrete (AAC) is made from sand, lime, cement and water with an aerating agent with autoclaving. AAC is a lightweight material of low heat conductivity. The current Hungarian thermal requirements for external walls can be fulfilled with single-layer AAC walls of 30 cm. The aerated concrete system includes load-bearing and partition walls, lintels and reinforced wall or roof boards. Reinforced concrete beams with AAC block filling with concrete topping was considered as floor system.

Among the industrially prefabricated systems, applied for single family houses the most common one is the timber stud system. Wall panels consist of solid timber studs with a usual spacing of 60-80 cm connected with top and bottom plates. The spaces are filled with mineral wool insulation. Wood-based panel sheating provides bracing. The thermal bridge effect of the wooden studs can be decreased if an additional insulation layer with battens perpendicular to the studs is applied. The spacing of the floor joists is adjusted to the walls. Wood-based subflooring ensures the stiffness of the floor. This system is suitable for low-rise buildings up to 2 storeys.

In the study, for all building systems the same building service systems were chosen which are typical for new buildings in Hungary and comply with the current energy regulation. For heating and domestic hot water production a low temperature modulating gas boiler was considered, with radiators and indirectly heated hot water storage tank. This is also the reference system defined in the current regulation on building energy performance (TNM 7/2006). Mechanical ventilation is not common in residential buildings in Hungary. No mechanical cooling was taken into account: in a properly designed and used residential building the summer overheating remains tolerable.

3. Discussion

Professionals as well as potential builders frequently raise the question, which building system is the more preferable from energy point of view? The answer is not going to be a simple one, since differences in all phases of the life cycle have to be pondered – and the answer may not be free of interest of different confronting lobbies. Certainly, increased thermal insulation can be argued for and everybody accepts, that the more efficient insulation decreases the operational energy use. On the other hand the opponents argue with the higher embodied energy which – according to their opinion – does not compensate the operational energy saving. Similar is the case of high quality glazing and windows. It is easy e.g. to understand that timber construction is environmentally friendly and due to constructional reasons, ab ovo has an insulation layer of considerable thickness – and even so the higher need of maintenance can be mentioned. Even if the interest of the market actors can be excluded, it is impossible to have a clear picture unless the subject of the discussion is not well defined, and the user related operational energy and the embodied energy of the foundation and internal partitions are mixed with the relevant components of the life cycle energy balance.

The aim of the analysis is to define the absolute difference and the proportion of the cumulated energy need of the envelope and the building related operational energy demand, using statistical data (mean value, standard deviation, confidence intervals) of the investigated “populations”, consisting 1000 randomly generated buildings in each category. Comparing the statistical data of the different categories - each corresponding to a building system, we examined, whether the differences are significant or of random character.

Based on the central limit theorem we determined that the results follow a normal distribution. The central limit theorem states that any sum of many independent and identically-distributed random variables will be approximately normally distributed if the sum of the variables has a finite variance. A chi-square test was performed to test for normal distribution. We proved that normal distribution provided a good fit to the observed data in most cases.

The results are shown in Figs. 1. and 2, for one storey and two storey single family houses, respectively. It can be seen that the density functions, expressing the sum of the building related operational energy and the embodied energy, influencing directly the operational energy need for the life cycle of the building overlap each other.

It has been proven by statistical analysis that disregarding the overlapping the differences between the mean values are significant at a confidence level of 99 % at any paired comparison of the building systems.

First, an F-test was performed to prove that the standard deviations of the two normally distributed populations do not show a significant difference. Then a t-test was necessary to analyse whether the means of the two populations were equal.

The building systems can definitely be differentiated, nevertheless the difference of the mean values does not exceed $\pm$ 6 % of the overall average in the case of one storey and $\pm$ 8.5% in the case of two storey houses. The dispersion seems to be higher, thus the scewness of the density functions is less (they cover a “wider” interval) in the case of insulating brick system, the narrowest functions belong to the timber stud system for both one and two storey houses. This is clearly reflected in the quartiles values. The upper and lower pairs of them border the interval which includes half of the population, whilst at the given level of confidence they mark the intervals which include 90% of the houses. Nevertheless these differences are of random character only, as it has been proven by F-test at 95%..

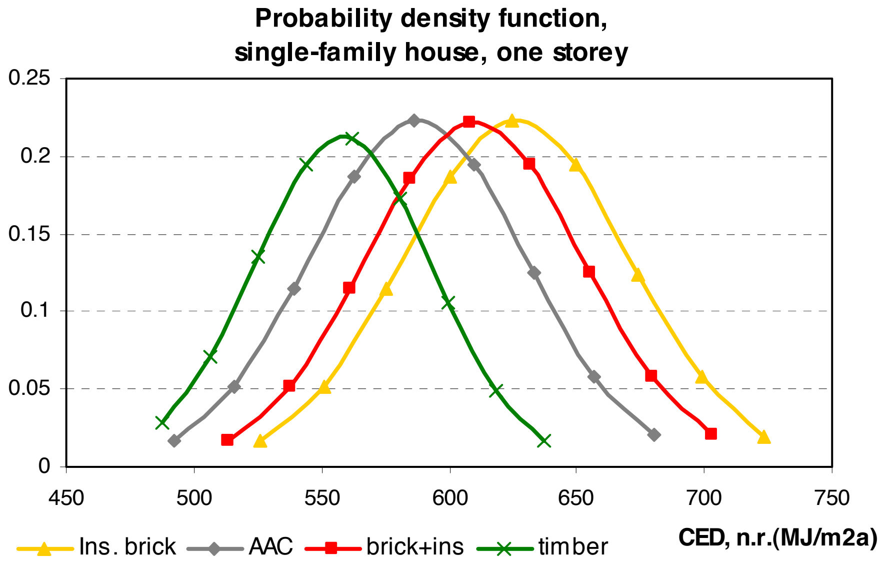

Fig. 1.

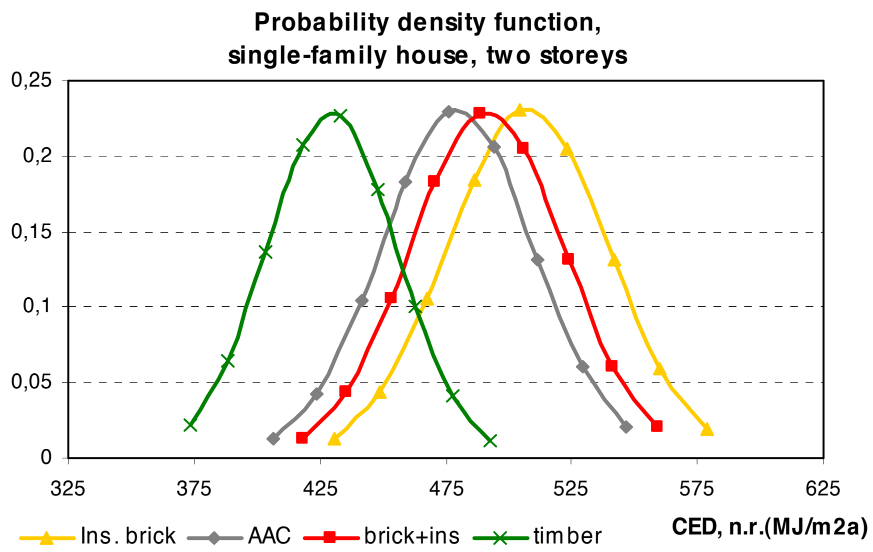

Fig. 2.

These intervals, as well as the density functions overlap each other. In the case of a section from 570 to 630 MJ/m^2a houses of all building systems appear. Taking the middle of this interval 600 MJ/m^2a one can see, that the most of the houses of insulating brick have higher, most of the timber houses have lower energy need, whilst in the case of aerated concrete this is roughly the mean value, nevertheless any of the analyzed building systems may be chosen if a cumulated energy demand between 570 – 630 MJ/m^2a is acceptable.

The chance to have a building of a cumulated energy demand less than 570 MJ/m^2a is very limited if insulating brick system is applied, whilst the risk that the cumulated energy need exceeds 630 MJ/m^2a can be neglected in the case of timber stud system.

More considerable difference in favour of the timber stud system is found if two storey houses are evaluated. It is due to the fact that the area of the floor slabs is smaller in comparison with that of a one storey building of the same total floor area, thus the role of the exposed walls prevails. Here the overlapping interval of all four density function is narrower: from 450 to 470 MJ/m^2a, however if the three silicate based systems are taken into account any of them can be chosen if 450 – 530 MJ/m^2a cumulated energy demand is acceptable.

As it could be foreseen, considerable is the difference between the one and two storey houses, due to the lower specific transmission heat losses and the lower mass of the envelope

Table 1 Statistical characteristics of one-storey single family houses (MJ/m2a)

	ins brick	AAC	brick	timber
mean	626	588	610	558
median	625	587	609	557
st. dev.	44	42	42	35
1. quartile	595	558	580	532
3. quartile	656	616	638	582
90 % lower	553	518	540	500
90 % upper	700	658	680	616
conf. int. +-	73	70	70	58

Table 2 Statistical characteristics of two-storey single family houses (MJ/m2a)

	ins brick	AAC	brick	timber
mean	508	480	492	430
median	508	480	492	429
st. dev.	32	30	30	26
1. quartile	485	458	470	412
3. quartile	531	502	514	448
90 % lower	455	429	441	387
90 % upper	561	530	542	473
conf. int. +-	53	50	51	43

More pragmatic data can be obtained from the cumulative distribution functions (Fig 3. and 4.). Taking a threshold value of the cumulative energy demand one can see, how many % of the population is to the left (i.e. the demand is less than the threshold) - the complementary % has higher demand. In the opposite way: if we want to know the threshold value, belonging to a given likelihood we should start from the vertical axis.

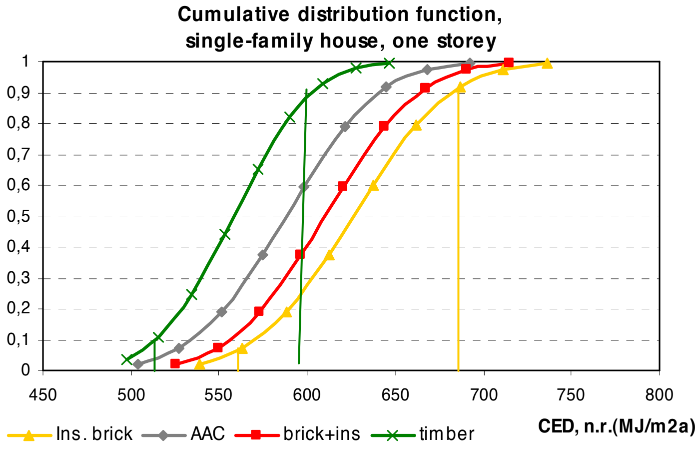

Fig.. 3.

It is possible to mark the confidence intervals: in Fig. 3 those for insulating brick and timber stud systems are shown, marking the intervals in which 80 % of the houses can be found. Even in the case of these two systems it can be seen, that they overlaps each other from 520 to 590 MJ/m^{2}a: about 15% of the houses built with insulating brick and about 35% of houses with timber stud system are in this interval. Self intended the confidence intervals of the other two systems ("in-between curves") overlaps with those of the very left and right curves.

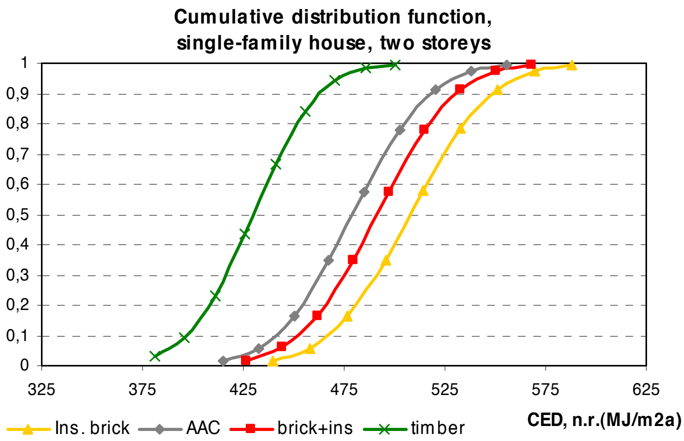

Fig.4.

4. Conclusions

Although the sum of building related operational energy and the embodied energy, directly influencing the operational energy need for the life cycle significantly depends on the building system, the average energy needs per system are in a relatively narrow interval. Thus as far as the building envelope is concerned from energy point of view, the difference between the mean values of insulating brick and timber stud systems is 12 % in the case of one storey and 17 % in the case of two storey houses if the total population of all feasible houses between 60-180 and 120-240 m^2, respectively are taken into account.

The overlapping of the confidence intervals shows that the building system itself does not completely predefine the final result, only the higher or lower likelihood of the expected cumulated energy demand can be spoken of.

It has been proven that the timber stud system offers the best chance to achieve low cumulated energy demand, nevertheless it is not excluded that its average value can be achieved with other building systems.

Taking into account the silicate based systems only, it can be stated that although the differences are significant, they are small and a given cumulated energy demand can be achieved in many cases with any of these building systems.

Unlike the comparison of the data of a few arbitrarily selected sample buildings the applied statistical method facilitates the evaluation of the multitude of buildings.

Keywords: sustainable, building, development, investment, risk, financial, feasibility, assessment

Summary

There is increasing demand within the construction industry for sustainable building development but there are many perceived barriers to its implementation, predominately financial, even though the benefits can be shown. The current challenge is not convincing stakeholders of these benefits but in providing evidence of the financial feasibility of sustainability.

Williams Boag Architects (WBa) has developed a simple-to-use software tool that enables building design professionals to assess the financial feasibility of a project at its outset, reassuring investors and developers that an ESD solution will provide equivalent or better net financial returns than a conventional development, thereby reducing the investment risk. The two key characteristics of the “SIFT” tool are that it assesses the financial potential of a high aspiration green development project; and the assessment occurs at the project’s inception, before any design work is undertaken.

SIFT can be used to define the potential for capitalising on life-cycle cost savings; inform clients at project inception stage before decisions are made; and as a powerful tool for assessing and comparing alternative building investment choices. With its core purpose to facilitate the implementation of ESD at the earliest stage of the process, SIFT considers the total cost of ownership, demonstrating the link between the recurrent and capital costs.

1 Introduction

Of all the challenges to implementing sustainability in building development the hardest ones for a consultant team to counter must be the perceptions that it will cost more and that there is a financial risk. These become constraints that undermine otherwise good intentions. By minimising the risks and identifying the associated financial feasibility at the outset of a project, some of the uncertainty about sustainable development can be reduced, reassuring potential investors and engendering greater confidence in innovative solutions so that a project commences with the best possible chance of achieving its green goals.

This paper presents a method that Williams Boag Architects (WBa) believes will answer this need. It is a simple-to-use software-based tool that enables building design professionals to assess the financial feasibility of environmentally sustainable buildings based on the limited information available at the inception of a project. It assumes that buildings are developed to their full ESD potential and assesses the investment implications. A report is produced for interpretation by the design team to prioritise sustainability opportunities for both environmental and financial success.

The tool has been developed in collaboration with Deakin University and Cundall Australia and, in an Australian first for an architecture practice, supported by an AusIndustry Start Grant.

We will look briefly at why we felt such a tool is needed, describe the tool and its reports, then demonstrate it against a real building to test its ability to identify and prioritise opportunities for sustainable development.

1.1 Context

Generally, sustainable buildings are considered to cost more to design and construct than conventional buildings (Williams, 2004). However, many studies have shown that not only is it possible to design a sustainable building that costs no more than a conventional building (Davis Langdon, 2007), but the additional financial savings and other benefits over the life-cycle of these buildings can be significant (Kats, 2003; GBCA, 2006; CoStar, 2008).

Traditionally, most emphasis has been placed on the upfront or capital costs. The design of buildings to take a more sustainable approach requires that clients and design teams take a more holistic approach. A sustainable building will have, by its nature, consideration for the life-cycle impacts associated with its construction and its operation.

1.1.1 Financial Constraints And Risks

Barriers to sustainable design are also significant barriers to innovation. Perceived issues include capital cost premiums, the risk of reduced long-term investment returns and building performance, lack of available information, hidden costs and split incentives (Sorrell *et al.*, 2004). These are all predominately financially driven and any attempt to promote sustainability must address them.

1.1.2 Client Needs

Hence the current challenge is typically not convincing stakeholders of the benefits of sustainable building, but in providing evidence of its financial feasibility, especially considering the emphasis given to financial aspects of projects (Higgins *et al.*, 2004). Clients are often unwilling to allocate funds to unproven or seemingly unnecessary technologies or design solutions (RICS, 2005, p.13). The lack of built examples creates uncertainty and reluctance. It is not until clients become aware of the life-cycle implications of design decisions that the financial benefits become convincing.

According to Williams (2004), the dilemma faced by clients is finding the right group of sustainable design strategies that are financially attractive, provide operating costs advantages and deliver benefits to occupants. A method is needed to demonstrate the potential benefits and financial viability of taking this approach. If the potential can be assessed at the pre-design stage, when minimal costs have been expended and at the lowest risk level, then development proponents are in a better position to evaluate the viability of the project.

1.1.3 Life-Cycle Approach And Benefits

By taking a life-cycle approach a client or financier is able to capture the many benefits that are associated with a sustainable building. Although developers may be reluctant to invest additional capital into a project if they have no interest in the building once it is complete, they may find that potential purchasers and tenants will pay more for buildings that will save them on operating costs throughout its life (McCartney, 2007; CoStar, 2008).

There is an opportunity to significantly increase the return on investment by capitalising on the life-cycle operating cost savings, however design teams need to be confident that any extra capital investment will be recouped within a reasonable investment cycle. By identifying the strategies that have an acceptable level of return the perceived risks are reduced. It has also been suggested that the risks associated with not taking a sustainable approach to building development may be even greater than the risks of doing so (Wasiluk, 2007).

1.2 The Task

So we have studies and reports that confirm costs for building green do not need to be higher, that value is often higher and that the predicted benefits exist, but there is a need to demonstrate these benefits for each particular project to those who make the ultimate decision on whether or not it will proceed, the financiers, investors and developers, sufficient to get the commitment and financing to progress with strong ESD goals.

2 SIFT

WBa has developed a tool that can be used prior to any design work being undertaken, to assess the financial feasibility of a sustainable outcome for a particular building proposition, that also indicates the extent of risks associated with the approach. In addition, it is possible to identify where the greatest potential exists within the project, allowing design teams and clients to prioritise and target these opportunities.

Traditionally, the judgement of the feasibility of a sustainable building approach has been on an intuitive basis, using the knowledge held by a handful of senior consultants, gained through past experience. WBa has formalised this knowledge and decision-making process into a tool that, wherever possible, is based on objective data.

2.1 Assessment Model

The purpose of the model is to unlock the financial potential of the recurrent costs of a building (e.g. energy and maintenance savings, rebates, income opportunities etc.) so that it can be used to benefit its initial capitalisation. It links ESD strategies with monetary returns, making the proposal attractive to financial institutions.

The model (illustrated in Figure 1) provides an assessment of the potential to create a best-practice sustainable building. The opportunities across various parameters (see Figure 2) are identified. The numerical outputs of this assessment are converted into an overall project score which indicates the likelihood of a good return on investment. This score is presented to clients and financiers, together with a report describing the areas of greatest opportunities and also where greatest risks lie. Clients and design teams can use this information to prioritise their efforts towards the desired outcome.

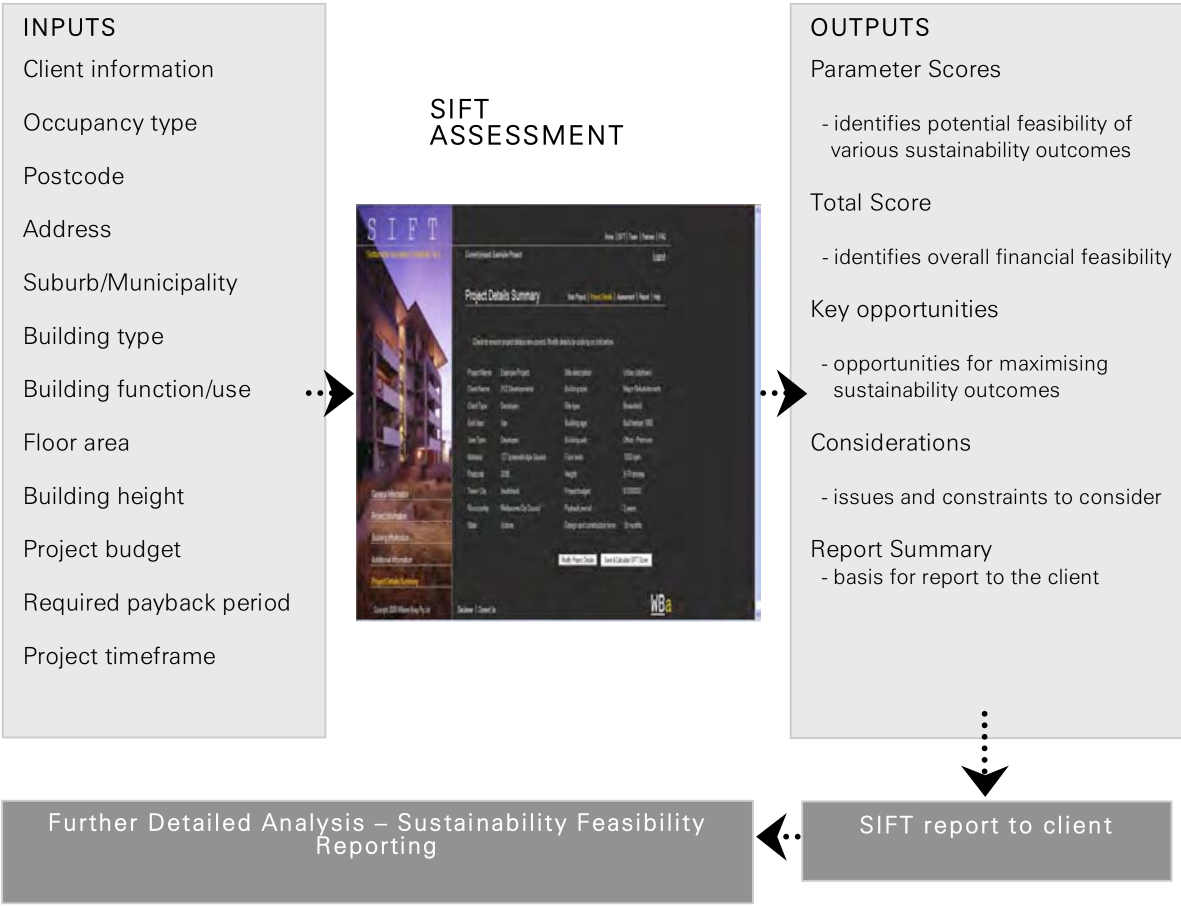

Figure 1   The SIFT assessment model

Initial validation has been performed by comparing the tool's outputs to the opinions of expert design team members for over ten projects. This process showed a close correlation between the opinions provided by the team of the likelihood for creating a best-practice, financially feasible sustainable outcome, and the outputs of the tool. Still in its late testing stages, the tool needs to be validated against built outcomes, however due to the long nature of building projects this process is likely to occur over an extended period of time.

2.2 Sustainable Innovation Feasibility Tool

The model has been realised in a web-based tool, the Sustainable Innovation Feasibility Tool or SIFT. SIFT is simple to use, requiring easily obtained inputs and enables the assessment of a project at its outset, and well before any design work is commenced. SIFT does not assess designs or design options for the level of sustainability attained. There is an underlying assumption that the design team has the expertise and drive to implement best-practice. The test is for financial feasibility only.

The assessment is performed at the earliest possible stage of a project. This may be at an initial client meeting or based on an advertised tender. Only limited information is required to perform an assessment, such as: the project budget, floor area, building function and location details (as shown in Figure 2). Using these very basic details, additional information can be gleaned, for example the climate is known based on the site address, usage patterns can be assumed from the building's function. Eighteen assessment parameters form the basis of the SIFT evaluation process. They were identified as key factors influencing sustainability and also as having a financial impact, either as a cost or an income potential. They are rated on a scale from zero to ten with a score of ten representing a maximum long-term financial benefit to be gained from implementing a high aspiration sustainable solution. These individual parameter scores are weighted and combined into an overall score for the project. The financial risks associated with a project with a higher score are thus considered to be lower.

• energy conservation	• reduced recurrent costs
• water conservation	• reduced replacement costs
• waste minimisation	• reduced maintenance costs
• reduced car-parking	• promotional/incidental use
• improved rental return	• external funding

Figure 2 Some of the SIFT model parameters of assessment

The tool contains benchmark data specific to particular building types and locations, obtained from various industry and government sources. This data is used to make the connections between each of the key inputs and the subsequent relationships with each of the assessment parameters.

For example, energy consumption data per square metre of gross floor area is used to determine the potential for integrating innovative energy saving solutions into the design. The quantity of energy consumed within a building is typically dependant on the purpose for which the building is used, the size of the space being heated/cooled/lit, the climate in which it is located and hours of operation. These inputs for a specific project (building type, GFA, location and occupancy hours) are used to determine the likely energy consumption for the proposal, based on the benchmark data within the tool, for a conventional building. If this energy use is considered to be high then the potential for cost savings from reducing energy consumption would be correspondingly high and so the higher the likelihood of achieving a financial return from implementing strategies, such as active or passive systems, to reduce this energy consumption.

The outputs of the tool include a detailed report that is used to inform the project of the possible environmental outcomes that can be achieved at minimal risk and maximum return, whilst also identifying those areas where potential for a financial return is unlikely or risky. Key opportunities or constraints specific to the project are also identified by the tool at this stage. This may include information relating to problems with availability of infrastructure to the specific site that may influence the ability to provide innovative, feasible design solutions. It may also include the identification of funding available for implementing otherwise cost prohibitive technological solutions. By identifying the areas with greatest sustainability potential, time and effort is saved by design teams, who can focus on those areas where greatest financial return can be achieved.

The tool is simple to use and some of the reporting is automated, but its benefit cannot be optimised without an understanding and committed design team to interpret the results and follow its guidance.

2.3 Case Study

As a demonstration of the application and benefits of SIFT, the tool has been applied to a building case study (shown in Figure 3). The project was selected because it has been substantially built and has been recognised by national and international awards for its sustainability initiatives. It was tested by SIFT as if it were a new unknown proposal, using the key project details available at its outset.

Project name: Oasis Housing Development

Building type: Multi-unit residential

Location: Inkerman Street, St.Kilda

Budget: $45m

Gross floor area: 9 100m^2

Local government: City of Port Phillip

Figure 3 Case Study – Oasis Housing Development, Melbourne

Figure 4 shows the SIFT assessment result for Oasis. With a SIFT score of 6 out of 10, this project is considered to have reasonable potential to be developed as a financially feasible best-practice sustainable building. SIFT finds it has potential across most of the assessed parameters. One reason why the potential may have been slightly reduced across some of the areas of assessment was due to the building not being owner-occupied. Clients are typically more willing to invest in innovative sustainability strategies if they are also likely to benefit from the consequent ongoing operational cost savings, and occupant behaviours are more reliably predictable when the occupants can be identified and included in a development's genesis.

Whilst certain factors may have reduced the overall financial feasibility from ideal, potential for the overall project still remained relatively high. The areas that were identified as having the greatest potential to contribute towards achieving a best-practice sustainable outcome, whilst maximising the financial feasibility of the project, included:

- conservation, re-use and collection of water;
- reducing construction and operational waste;
- reducing replacement costs of services, central plant and services reticulation;
- reducing recurrent costs;
- incorporation of natural ventilation;
- maximising the use of public transport;
- local regulatory requirements, including sustainable design assessment using the local authority's STEPS assessment tool.

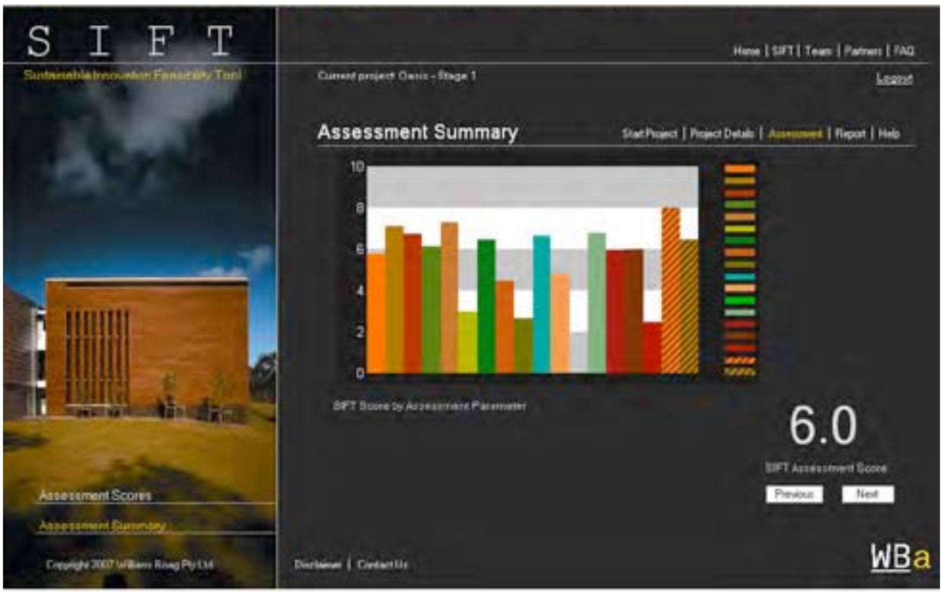

Figure 4 Assessment results of Oasis Housing Development case study

The SIFT tool allows a range of different building types to be assessed: residential, educational and commercial. Particular building types may have greater or lower potential than other building types due to factors such as level of servicing required for the function, hours of operation, scale or adaptive use possibilities. SIFT considers this variability and thus the score for particular building types will fall within a set range. For example, multi-unit residential projects are only capable of achieving a total score between two and eight (as shown below in Figure 5). A score of six is therefore quite high for this type of building.

Figure 5 Total score and possible score range for Oasis Housing Development case study

2.3.1 Built Outcome Validation

The SIFT assessment of the Oasis Project identified that it had reasonable potential and numerous opportunities for creating a financially feasible sustainable outcome. The assessment also identified the areas of greatest strength. The opportunities for integrating water conservation and re-use strategies and potential for achieving a significant return on investment for implementing them was assessed as being maximum (ten points out of ten). It is interesting to note that the built project includes an extensive grey-water treatment and recycling system, for which it has won numerous awards, including the United Nations World Environment Day Award 2000 and the Stockholm Partnership for Sustainable Cities Award 2002.`

Potential for incorporating strategies for natural ventilation was also found to be high and financially beneficial. In the actual buildings, the use of natural ventilation has been maximised through a system of vertical shafts and open areas throughout the building. This system allows every apartment to be naturally ventilated with hot air exhausted at the highest point of the building (Figure 6).

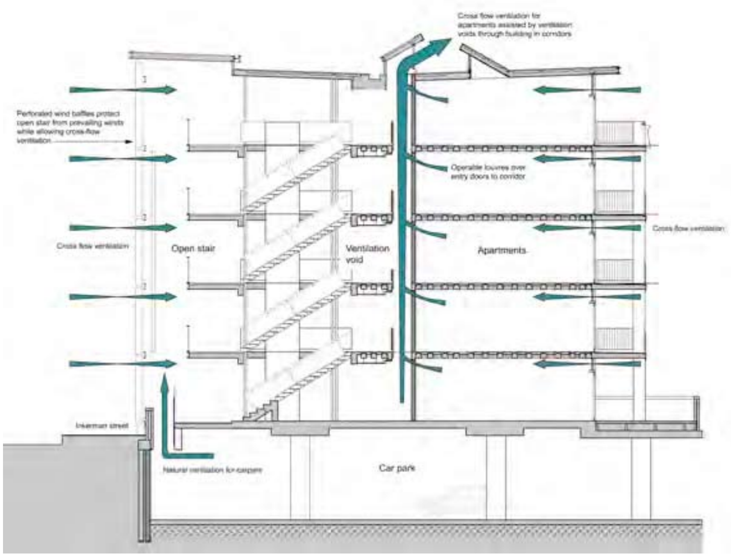

Figure 6 Oasis Housing Development ventilation strategy

The potential for a significant reduction in recurrent and replacement costs was rated high. One of the strategies used in the built project that embodies this is a centralised hydronic heating system. The advantage of this type of system is that it reduces operating, or recurrent, costs and also the costs associated with replacement of parts (Figure 7).

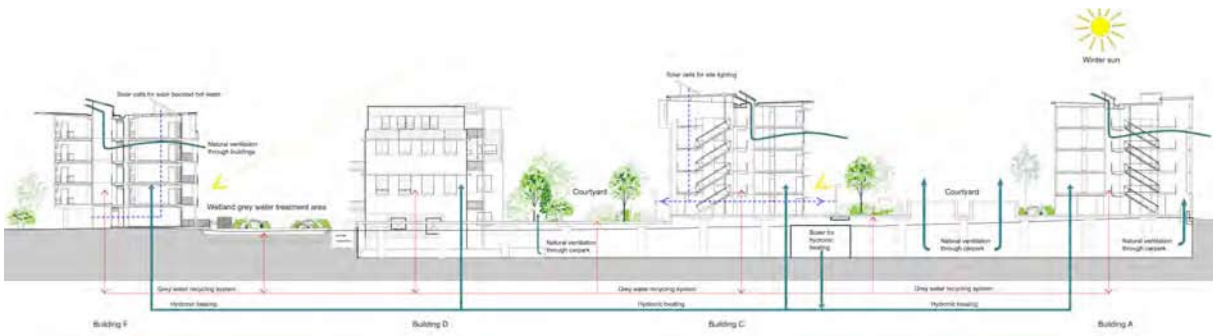

Figure 7 Oasis Housing Development centralised hydronic heating strategy

These examples illustrate a good correlation between what SIFT predicts is feasible and what was realised in the final commercial development.

2.4 Assessment Reporting

The tool provides an assessment of a project based on a total project score between zero and ten, and similar scores for each of the parameters. Whilst this output is useful in the first instance for identifying overall potential, it doesn't provide the level of information and detail required to address project opportunities or constraints and set realistic project goals. For this reason, it is necessary to expand these numerical values into a more descriptive explanation. The report is presented to clients and used by design teams to set project goals and focus on particular strategies. An excerpt of this report is shown below in Figure 8.

Detailed Opportunities

The following indicates potential opportunities that exist for maximising the financial feasibility of a sustainable building solution for this project.

Water

- The potential to reduce water use is high due to the large quantity of water traditionally consumed by this type of building.
- The potential for on-site rainwater collection is high due to the high availability of rainwater for this site chosen for the project and/or the large roof area of the proposed building.
- The potential for process water re-use is high due to the large quantity of water consumed and suitable for re-use.

Figure 8 Excerpt of report used to detail project opportunities

The final stage of the SIFT process involves the consultant team conducting detailed feasibility assessments of the possible solutions by quantifying the extent of life-cycle financial, social and environmental benefits associated with each and prioritising these for consideration in the building design.

2.5 Benefits

SIFT reduces some of the risks that are typically associated with sustainable building development by providing clients, investors and design teams with an understanding of the likely success factors for a particular project. By identifying these factors and areas of greatest and least potential at the earliest stage of a project, time and costs can be saved through the adoption of realistic and achievable project goals. It will help to avoid the common practice of overstating project goals only to have them dropped later in favour of capital cost savings when detailed analysis of a design proposal indicates the expected cost.

SIFT assessments can facilitate comparison of feasibility options or alternative building investment choices such as competing locations, such as different municipal areas or climate zones, the impact of varying payback period expectations and therefore rate of return, or alternative green building investment opportunities. SIFT assumes that a development is as environmentally progressive as possible so it is not a method of comparing the detail of a design.

The SIFT database captures the information and knowledge that is held by all members of the design team so that this information can be accessible to a much wider audience and applied to any project. The expertise and knowledge gained from previous projects is used to inform the database and improve future projects.

Initial validation has been performed by comparing the tool's outputs to the intuitive opinions of design teams for over ten projects. This process showed a close correlation between the opinions provided by the expert design team members of the likelihood for creating a best-practice, financially feasible sustainable outcome, and the outputs of the tool. Still in its late testing stages, the tool needs to be validated against built outcomes, however due to the long nature of building projects this process is likely to occur over an extended period of time.

2.6 Limitations

SIFT assumes a competent design or consultant team to interpret and implement results. It is not a checklist that guarantees results. SIFT does not rate how green a development may be; the base assumption is that the team will be striving for a high level outcome.

The outputs from SIFT are a numerical rating and descriptive advice. Although the assessment is a financial one it is about feasibility not actual cost so SIFT does not provide costings.

SIFT is currently only able to assess offices, multi-unit residential developments and primary, secondary and tertiary educational buildings across Victoria, Australia. Its coverage, of building functions and geographically, will be extended as data becomes more readily available and as the early stages are proven. A more streamlined tool is currently being developed that will enable the assessment of buildings worldwide.

3 Conclusion

Through considering of the whole-of-life consequences of design decisions, WBa's SIFT tool will enable clients, financiers and designers to identify early on the financial feasibility of achieving a best-practice sustainable development project. The tool makes it possible to identify the potential for creating a sustainable building, whilst prioritising the particular areas in which greatest potential exists for taking a sustainable approach to the design of buildings and systems that are also financially feasible. If the possible financial barriers and opportunities within a project are known, the risks associated with developing a sustainable building can be reduced.

SIFT differs from other ratings tools currently in the development industry in two key characteristics:

- It assess financial potential not green potential; and
- The assessment occurs before any design work is undertaken, on minimal data.

It is our hope that reducing risk will lead to increasing confidence and hence will encourage a greater number of building developers to take an uncompromising best-practice sustainable approach to their projects.

Keywords: CASBEE, $LCCO_2$, Assessment, Global Warming

Summary

Comprehensive Assessment System for Building Environmental Efficiency (CASBEE-2006) in Japan was already capable of assessing efforts to reduce the energy needed to operate buildings, utilize existing building structural frames and recycled construction materials, and extend the service life of buildings.

Such efforts can reduce CO_2 emissions from the production of construction materials (embodied CO_2), and reduce a building's Life Cycle CO_2 ($LCCO_2$) emissions, respectively. But Lifecycle CO2 was not directly counted in BEE (Building Environmental Efficiency) and CASBEE Rating.

New CASBEE-2008 incorporated a new item, "Measures for Global Warming," that can be rated by $LCCO_2$ emissions. $LCCO_2$ emissions are assessed in the simplified manner described in this report and reflected in item 1, "Measures for Global Warming" under "LR-3: Off-site Environment." These results also affect the radar chart, Building Environmental Efficiency (BEE), and CASBEE ranking directly.

As described above, new CASBEE is changed to explicitly assess measures for global warming. Further efforts to prevent global warming are expected to be promoted by the building sector.

1. Introduction

Global warming has become a very important issue. CASBEE-2006 was already capable of assessing efforts to 1) reduce the energy needed to operate buildings, 2) utilize existing building structural frames and recycled construction materials, and 3) extend the service life of buildings. Such efforts can reduce CO_2 emissions from the production of construction materials (embodied CO_2), and reduce a building's Life Cycle CO_2 ($LCCO_2$) emissions, respectively. Former CASBEE also had a column for optionally indicating $LCCO_2$ emissions, which was calculated separately by other LCA tool.[1)] But Lifecycle CO_2 was not directly counted in BEE (Building Environmental Efficiency) and CASBEE Rating.

New CASBEE-2008 incorporated a new item, "Measures for Global Warming," that is rated by $LCCO_2$ emissions. This paper outlines the new assessment.

2. Basic policy for reporting CASBEE efforts to fight global warming

An international trend in the building environmental efficiency assessment field is to require a more quantitative Life Cycle Assessment (LCA).

The LCA assesses various environmental aspects that are simultaneously related to multiple environmental impacts. For example, CFC emissions are related to ozone layer depletion and global warming, while energy consumption is related to the depletion of fossil fuels and global warming. The LCA assesses these impacts by integrating them into a single index in the result (such as the Life-cycle Impact assessment Method based on Endpoint modeling (LIME)).

Though CASBEE assessed energy savings using the Energy Reduction Ratio (ERR) in the "LR-1: Energy," which is related to the depletion of fossil, considering global warming is now a major concern, it was absolutely necessary to add new item "Measures for Global Warming" to the "LR-3: Off-site Environment" assessment.

3. Changes to the assessment steps in CASBEE

When the item "Measures for Global Warming (Global Environmental Measures)" was added to the "LR-3: Off-site Environment" assessment, the six items that comprised the LR-3 were re-organized and reduced to "Local Environmental Measures" and "Surrounding Environmental Measures " (Figure 1 and Figure 2). This allows explicit assessment of measures against global warming (reduction of $LCCO_2$ emissions) without significantly changing CASBEE's structure. It also allows these measures to be included in the calculation of Building Environmental Efficiency (BEE) and the evaluations of sustainable ranks "S: five stars" to "C: single star" (Figure 3).

4. Development of a simplified method for assessing $LCCO_2$ emissions in CASBEE

CASBEE aims to become as simple to use as possible, because many users for many types of buildings employ it. Accordingly, simplified "Standard Calculations" has been developed, which can estimate $LCCO_2$ emissions primarily based on items that already have been assessed in CASBEE. Moreover, if $LCCO_2$ emissions already have been accurately calculated using the published LCA tool,[1)-3)] then the calculated $LCCO_2$ emissions can be listed as "Individual Calculations."

The specific procedure for calculating $LCCO_2$ emissions is summarized below using an office building as an example.

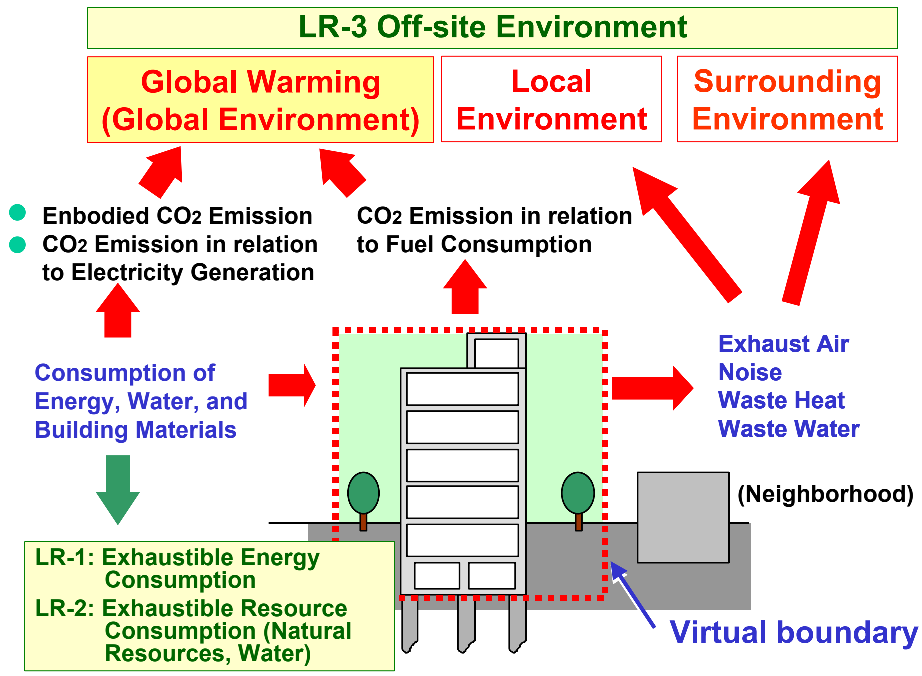

Figure 1. Arrangement of "Efforts to address global warming" and other items in the LR assessment

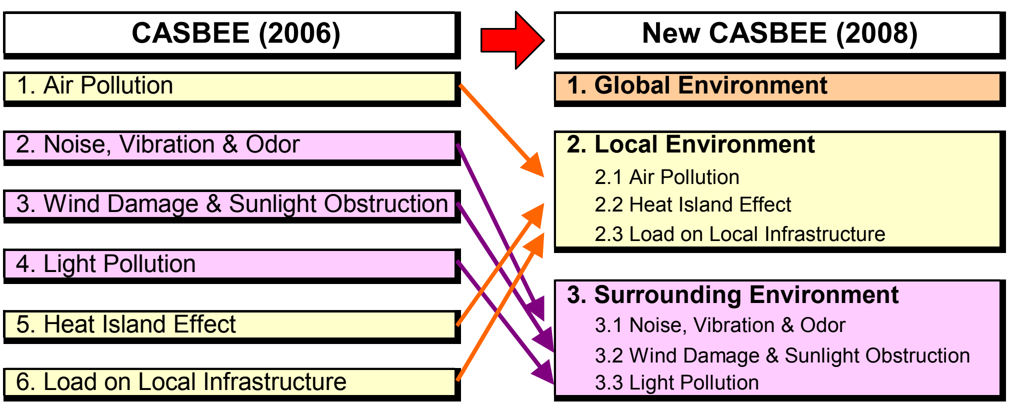

Figure 2. Re-arrangement of items in the "LR-3: Off-site Environment" assessment

Note: The ozone layer depletion is also a serious global environmental issue, but Japan already has implemented measures to this issue, so "measures for ozone layer depletion" falls under "2. Materials of Low Environmental Load" in the "LR-2: Resources & Materials" assessment.

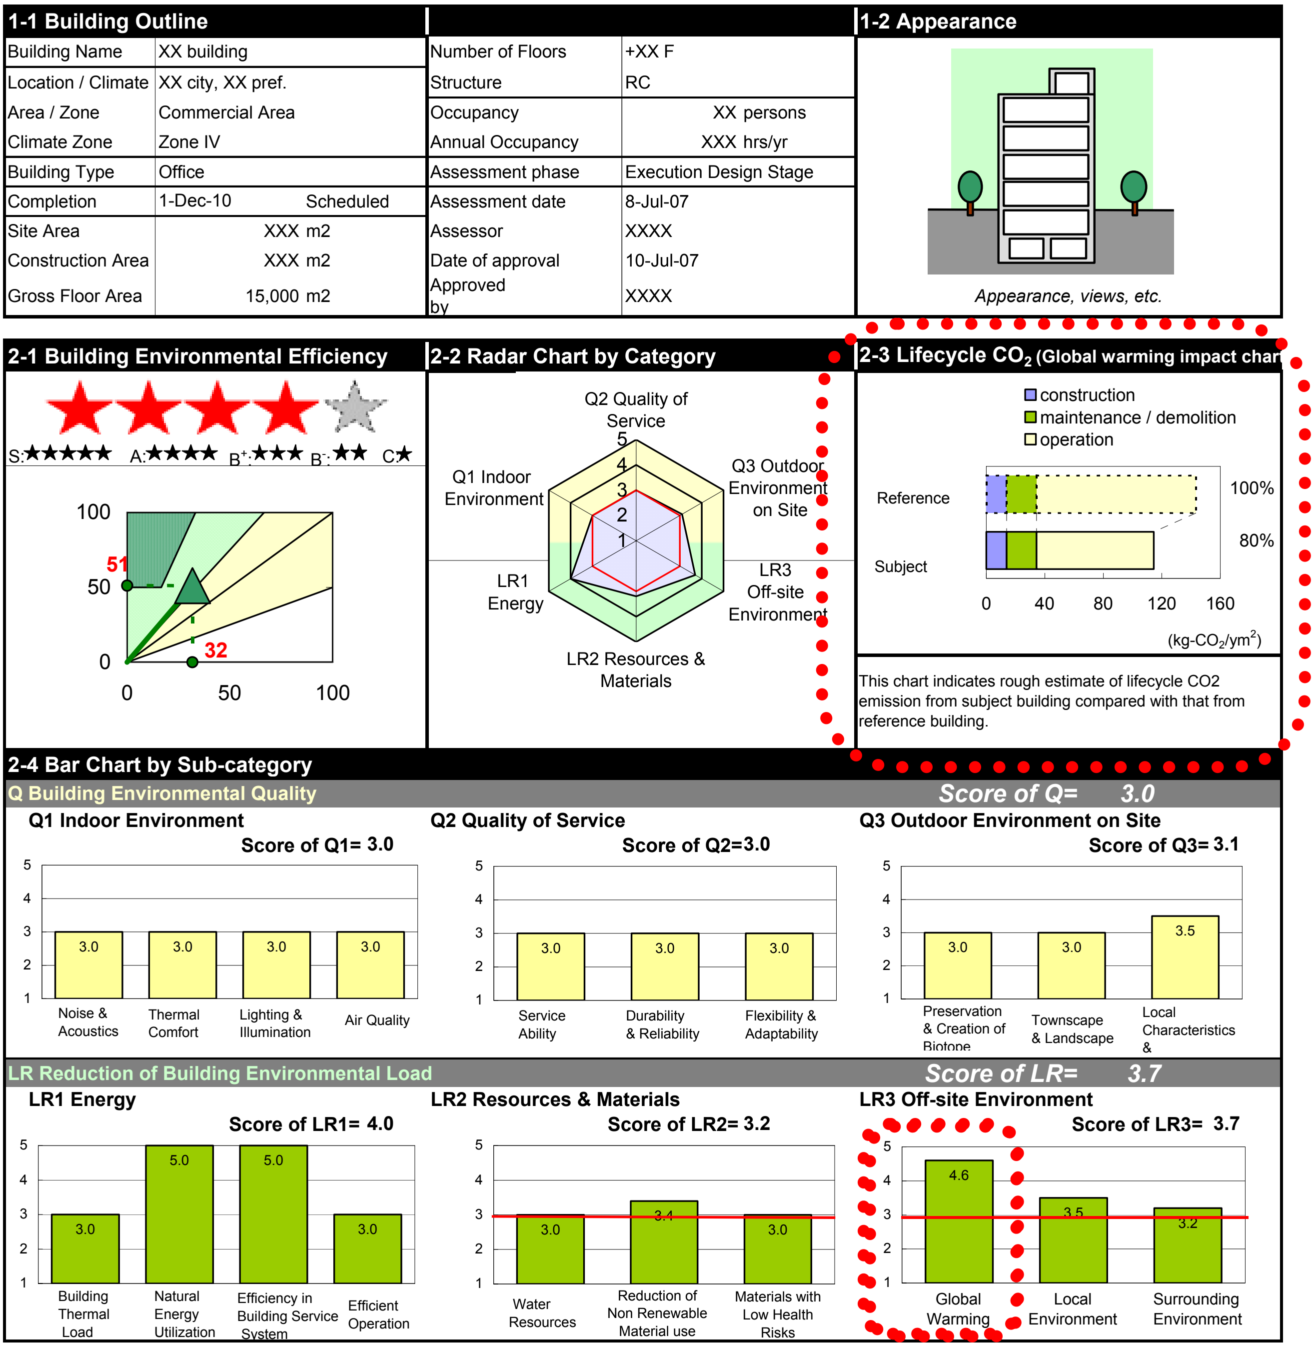

Figure 3. CASBEE (2008) Result sheet and Life Cycle CO_2 presentation

4.1 CO_2 emission units for building materials and energy

The CO_2 emissions units for building materials are listed in Table 1. Those for energy are listed in Table 2.

Table 1 CO_2 emission units for main building materials

Building Materials	CO_2 Emission Unit
Portland Cement Concrete	282.0 kg-CO_2/m^3
Blast Furnace Cement Concrete	206.0 kg-CO_2/m^3
Steel-frame	0.9 kg-CO_2/kg
Reinforcing Steel	0.7 kg-CO_2/kg
Mold Form	7.2 kg-CO_2/m^2

Note:

The data that is used for the Architectural Institute of Japan's LCA tool is also used for the CO_2 emission units for building materials.

Four types of emission units based on an inter-industry relations analysis are defined for the tool. This paper uses the "CO_2 emission units based on domestic consumption expenditures," which take into account the narrowest range of the ripple effect.

Table 2 CO_2 emission coefficients for energy

Energy	CO_2 Emission Coefficient		
Electric	0.555	kg-CO_2/kWh	
	0.0569	kg-CO_2/MJ	1kWh=9.76 MJ (primary energy)
City Gas	0.0506	kg-CO_2/MJ	
Kerosene	0.0678	kg-CO_2/MJ	
Grade A crude oil	0.0693	kg-CO_2/MJ	

Note: The CO_2 emission coefficients are based on the Law Concerning the Promotion of Measures to Cope with Global Warming.

4.2 Calculating $LCCO_2$ emissions for a reference building

(1) Factors assumed for the reference building

CASBEE uses a five-level rating system for each item and sets Level 3 as the standard level in Japan. The ideal standard building, in which all of the items in the CASBEE assessment are at Level 3, is assumed. $LCCO_2$ emissions from a subject building are compared to the reference value for this reference building.

(2) Service life of buildings

The service life of office buildings is set at 60 years. Efforts to extend the service life of buildings other than residential buildings are not considered.

(3) CO_2 emissions from construction materials

The quantity of construction materials used for ordinary buildings in Japan is determined from statistical data[4)] for each type of building and structure. The typical quantity of major construction materials used for the structural frames of office buildings is listed in Table 3 by the type of structure.

CO_2 emissions from construction materials during the construction, operation, renovation, and demolition phases (Table 4) are calculated using the Architectural Institute of Japan's LCA tool.[2)] The default values of the tool are used for the quantities of interior and exterior finishing materials, the equipment used, and the conditions for renovation and repair.

Table 3 Quantity of major structural materials

Building Type	Structure	Concrete m^3/m^2	Steel-frame t/m^2	Reinforcing Steel t/m^2	Mold Form m^2/m^2
Office	SRC	0.696	0.100	0.078	0.668
	RC	0.772	0.038	0.103	1.050
	S	0.567	0.136	0.070	0.433

Table 4 CO_2 emissions during construction, operation, renovation, and demolition phases

Building Type : Office Building	Structure			Measures
Phase	S	RC	SRC	
Construction Phase	817	831	835	kg-CO_2/m^2
Value per Durable Years (60 Years)	13.61	13.85	13.92	kg-CO_2/(m^2.a)
Operation, Renovation and Demolition Phase	1,214	1,240	1,223	kg-CO_2/m^2
Value per Durable Years (60 Years)	20.23	20.67	20.39	kg-CO_2/(m^2.a)

(4) CO_2 emissions due to energy consumption in the operation phase

Using statistics[5)] to determine the amount of primary energy consumed during building operations, the standard value of a CO_2 emission unit per floor area during operations is determined. The following values are used for an office building.

Primary energy consumption unit = 1,936 MJ/(m^2.a)

CO_2 emission unit = 109 kg-CO_2/(m^2.a)

(5) Calculating $LCCO_2$ emissions

Based on the conditions described above for a reference building, $LCCO_2$ emissions for the reference building are calculated using the Architectural Institute of Japan's LCA tool and applied as reference values according to building use and type of structure.

4.3 Method of calculating $LCCO_2$ emissions for the subject building

(1) Extension of service life

In item "2.2.1 Service life of building structural frames" of the "Q-2: Quality of services" assessment, apartment buildings are assessed in accordance with the "Rating of buildings for measures against deterioration" of the Japan Housing Performance Indication Standards. Based on the results of the assessment, the service life of an apartment building is set at 30, 60, or 90 years.

Because it is difficult to assess quantitatively and concretely the results of measures to extend the service life of a building, the effects of such measures are considered only for apartment buildings.

(2) Reuse and recycle

Reusing and recycling construction materials can reduce $LCCO_2$ emissions. Typical examples of this are the reuse of an existing building's structural frames and blast furnace cement.

The effects of reusing/recycling 100% of an existing building's structural frames and blast furnace cement are calculated using the LCA tool described above. The values are stored in a database, as shown in Table 5. In a practical sense, the effects are calculated from the ratio of utilization of an existing building's structural frames and blast furnace cement.

Table 5 CO_2 emissions after reusing/recycling building materials

Building Type : Office Building	Utilization Ratio	Structure			Measures
		S	RC	SRC	
Construction Phase					
In Case that Existing Structure is Reused	100%	392	400	394	kg-CO_2/m^2
Value per Durable Years (60 Years)		6.54	6.67	6.57	kg-CO_2/(m^2.a)
In Case that Blast Furnace Cement is Reu	100%	763	756	769	kg-CO_2/m^2
Value per Durable Years (60 Years)		12.71	12.60	12.81	kg-CO_2/(m^2.a)

(3) Energy savings in the operation phase

CASBEE assesses the energy savings of buildings using the Perimeter Annual Load (PAL) and the Coefficient of Energy Consumption (CEC) under the Energy-saving Law. CASBEE also assesses the Energy Reduction Ratio (ERR) of primary energy consumption of an entire building using the denominator and numerator of the CEC for the air-conditioning, ventilation, lighting and hot water supply systems, and elevators. The CO_2 emissions from energy consumption during building operations are estimated using the following procedure.

(i) Calculate the reference value of the CO_2 emission unit from the primary energy consumption unit using the statistical data in Section 4.2 (4).

(ii) The thermal insulation performance and sunshine shielding level of a building's exterior walls under the Energy-saving Law are specified by the PAL (MJ/(m^2.a)). Estimate the reduction in primary energy consumption due improvements in the performance of the subject building's exterior walls based on the difference between the reference value of the PAL and the calculated value for the subject building.

(iii) The energy efficiency of building equipment is prescribed by the CEC for the air-conditioning, ventilation, lighting and hot water supply systems, and elevators under the Energy-saving Law. Determine the ERR of the entire building using the CEC.

(iv) Estimate the reduction in primary energy consumption (MJ/(m^2.a)) due to the use of natural energy systems, such as solar power generation.

(v) An additional reduction (5% maximum) of primary energy consumption can be assumed by improving the monitoring and operational management systems so that building operations are more efficient.

(vi) Estimate primary energy consumption in case of taking measures for energy-saving by this procedure, and then convert this value into CO_2 emissions (kg- CO_2/(m^2.a)).

The factor for converting primary energy consumption into CO_2 emissions is determined from the average ratio by energy type for each building type and the appropriate CO_2 emission coefficient of energy from Table 2. For example, the conversion factor for an office building is 0.0563 kg-CO_2/MJ.

(4) Method of rating buildings for "global warming" impact according to $LCCO_2$ emissions

The subject building is rated on a 1-to-5 scale according to $LCCO_2$ emissions. A score of 5 (the highest) is given when the $LCCO_2$ emissions of the subject building are 75% or less of those of the reference building, while a score of 1 (the lowest) is given when the $LCCO_2$ emissions of the subject building are 125% or more of those of the reference building.

5. Case Study

Before New CASBEE-2008 was formally released, the case study was executed in 18 buildings. The relation of LCCO2 emission and BEE is shown in Figure 2. BEE value is relatively small in buildings of large LCCO2 emission, i.e. such buildings are un-sustainable.

Some buildings are able to reduce LCCO2 emission to about 70% and become "S" rank sustainable buildings. However, when there are little approaches in other issues, BEE is not necessarily high ranks even if the LCCO2 emission rate is low.

6. Conclusions

(1) A "Standard Calculation" function is added to CASBEE to estimate $LCCO_2$ emissions in a simplified manner based on input data that is similar to conventional data.

(2) As per the basic concept of CASBEE, the standard method of assessing $LCCO_2$ emissions is simplified wherever possible.

(3) A new item, "Measures for Global warming," has been added to CASBEE. This item allows $LCCO_2$ emissions to directly affect BEE value and CASBEE's sustainable ranks "S: five stars" to "C: single star."

(4) If $LCCO_2$ emissions already have been accurately calculated using the published LCA tool [1)-3)] then the calculated $LCCO_2$ emissions can be listed as "Individual Calculations."

CASBEE quantitatively determines $LCCO_2$ emissions and explicitly assesses measures to prevent global warming. Further efforts by the building sector are expected to promote them.

Keywords: Sustainability framework, energy strategy, renewable energy, carbon neutral, ecological footprint.

Summary

During the past two decades, China's GDP has been rapidly increasing. This achievement, however, has given rise to problems of net energy imports, environmental pollution and ecological destruction at home, cross-border pollution, and mounting carbon dioxide (CO2) emissions. To reduce the impacts of development on the physical and social/cultural environment, a sustainability approach is needed to be adopted.

Green building design is becoming mainstream in China. At policy and regulatory level, China has implemented mandatory building energy standard throughout country, aiming to reduce the energy use in buildings by 20% by year 2010. Recently, China has also implemented voluntarily its green building standard issued by the Ministry of Construction, the Assessment Standard of Green building. Yet implementing this standard into the design and construction details is difficult within the context of China. This paper addresses the detail approaches on design strategies and construction site management to achieve the requirements of sustainable development through case study.

Cases for study for Sustainable development of are the Changxindian in Beijing and TangShan in Beijing and Dongtan in Shanghai developments. These projects symbolise the commitment of China to the environment and the society, and showcases the integrated approach to green building, energy planning, utilization of renewable energy to support the principles of the Sustainability Framework developed.

1. Introduction

Due to the rapid urbanisation in recent years, China is now one of the biggest consumers of oil, gas and coal and the government is eager to see the country back away from a growing dependency on imported energy (THUBERC, 2007). Recent studies have also shown China to be the least energy-efficient of the world's major economies, using several times as much fuel for each unit of output as the United States, Japan or European countries according to the China Energy Statistical Yearbook 2006. China is also home to several of the world's most polluted cities – mostly due to power plants burning vast amounts of dirty coal to power the country's rapidly growing cities.

In order to change the situation, all of the efforts are being made to build a stable, economical, safe and clean energy supply system which safeguards China's energy security efficiently. The Central government, led by Premier Wen Jiabao and Vice Premier Zeng Peiyan, has setup a team tasked with ensuring the country's energy consumption and pollution reduction targets stated in the Chinese government's 11th (year 2006-2010) Five-Year Plan are met. China has set a goal of reducing energy consumption per unit of GDP by 20 percent by 2010. The National Development and Reform Commission is taking this lead on (1) allocating the target among provinces and industrial sectors, and (2) adopting energy efficiency improvement criteria for evaluating the job performance of local government officials.

As building industry is one of the biggest energy consuming sectors, improving energy efficiency of buildings is pivotal for China in achieving its goal of creating a resource-saving society, according to Minister of Construction (MOC). The MOC indicated that the country will focus on the building energy conservation, targeting at the energy resources, land uses, water and building materials (the four savings) (Wang, 2005).

In fact, the implementation of the energy law and the green building standards in the market has encouraged the adoption of energy efficient designs and renewable energy for building design. Green or sustainable buildings are now a key consideration in new building developments in China. State-of-the-art technologies have been tested and adopted in this biggest building market.

2. Cases Study of Eco-city

Figure 1 Planning of 21st Century Cities.

The overarching vision for both Tangshan, Changxindian and Dongtan is to create a world-class sustainable city that is responsive to the needs of economic growth, accommodates demographic trends and, at the same time, places environmental and social sustainability at the core of the developments objectives. These objectives are summarised as follows:

- To preserve the natural habitat
- To create an integrated, vibrant and evolving community
- To improve quality of life and create desirable lifestyles
- To create an accessible city
- Managing the use of resources in an integrated manner
- Working towards carbon neutrality
- Utilising governance to achieve long term economic, social and environmental sustainability.

3. Strategies to Make Eco-City Sustainable

3.1 Sustainability Framework

The early stages of the sustainability strategy has involved the following: the identification of high level objectives and prioritized themes; the development of design targets and feasibility studies to support the masterplan; testing the feasibility of achieving the targets; and producing integrated design solutions which include sub-strategies for topics such as energy, water resources, waste and materials. A set of specific sustainability objectives relating to social issues, economics, the environment and natural resources was identified. These objectives are detailed in the sustainability framework document, which provides a strategic decision making tool for the project (Fig. 2). In particular, energy management is the key aspect to be considered.

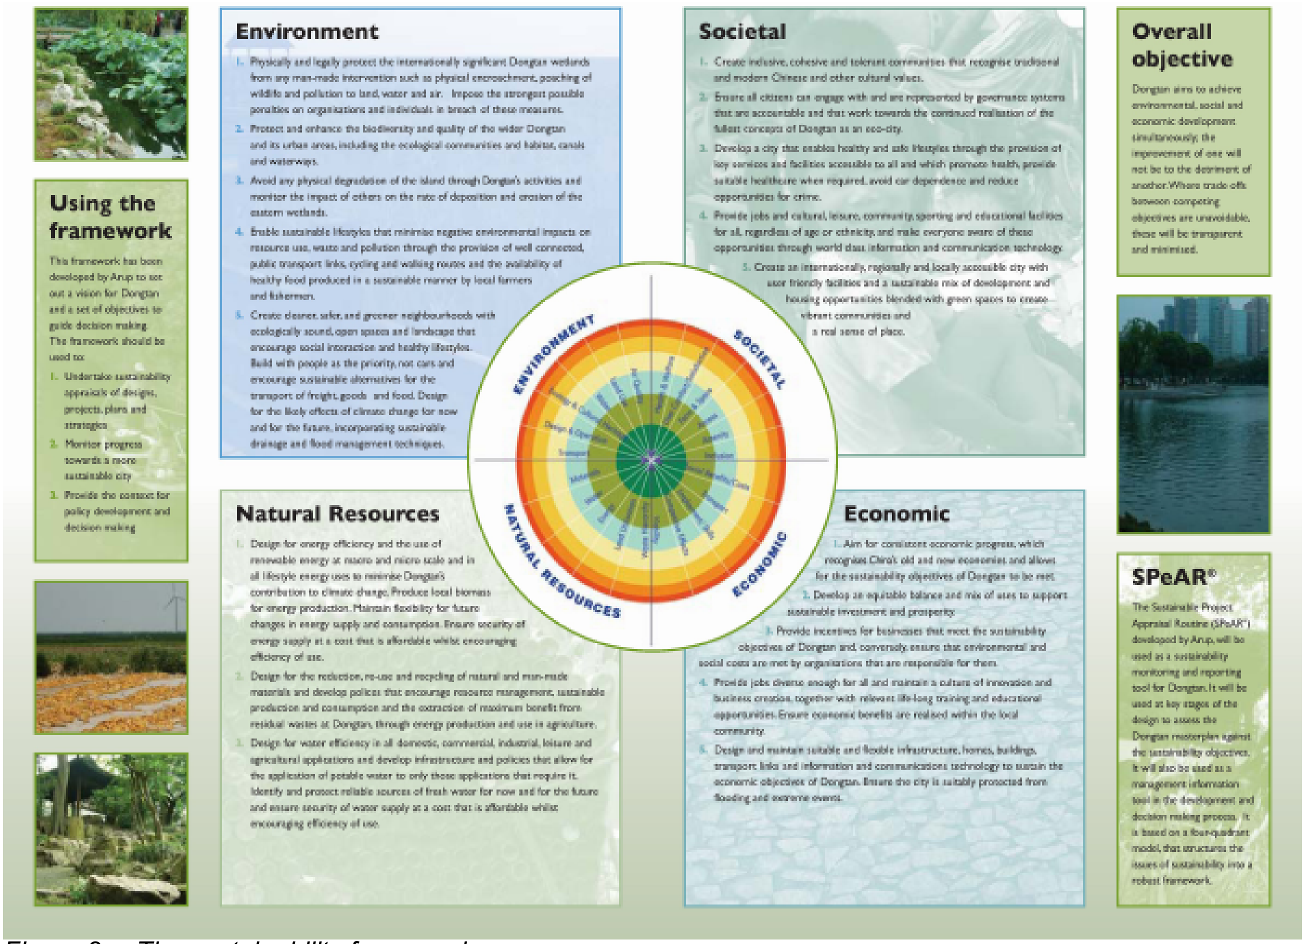

Figure 2 The sustainability framework.

3.2 Energy Strategy

The following specific targets for energy strategy have been set:

- To limit energy demand levels to a level representing a fair "Earth Share" as assessed using the Eco-Footprint methodology.
- An average reduction in overall electrical & transport energy demand of at least 66% across all energy consuming sectors compared with a defined "baseline".
- To provide Carbon Neutral Energy supply to all sectors.

The demand reduction target is based on the need to reduce the Business As Usual (BAU) new-build Eco-Footprint of Shanghai down to a fair "Earth Share". For the energy use within the Eco-city, this means a demand reduction of the order of 66% as compared wit the current standards in China. There will be other energy uses off site consumed by the manufacture of products, and for off-site services used by Eco-City occupants that are not covered by this target. The development will seek to influence the choice of these latter energy uses by Eco-City occupants, and may contribute to off-setting these to some degree by exporting energy generated onsite from renewable sources.

In addition to the above targets related to macro scale sustainability, it is intended to maximise air quality in the urban areas of Eco-city. This would require the elimination of combustion emissions, whether from heat generation plant, electricity generation plant, vehicle internal combustion engines or from open flame cooking (due to the adverse effect on indoor air quality) in the built up areas. This is subject to continuing discussions, and may need a phased introduction with the targets for the first phase being the elimination of building emissions from heat and electricity generation plant, and from public transport vehicles.

3.3 Implementation of Energy Strategy

Achieving successful implementation of low and renewable energy developments relies to a large extent on correct implementation of an energy hierarchy. The priorities, in terms of achieving the ultimate goal, are set out below in the order in which they should be implemented:

- Reduce demand (in particular for electrical energy).
- Maximise efficiency (by fully exploiting the heat by-product of electricity generation).
- Generate energy from renewable sources.

In addition to the above electrical energy demand, the design of Eco-city also intends to meet the energy needs of on-site transport from renewable sources. In strategic terms the energy reductions are achieved as follows:

- Reducing energy demand through best practice architectural design.
- Limiting the areas provided with energy intensive systems, and limiting the allowable installed capacity of energy intensive systems.
- Switching where appropriate to heat powered systems, instead of electrical powered systems.
- Influencing the product purchasing and lifestyle choices of the occupants.

3.3.1 Reducing energy demand

The buildings will be designed to reduce demand using best practice design for low energy buildings, including the following features.

- Modest window areas.
- Building orientations optimised for the type of building, e.g. more glazing to the north to reduce cooling requirements.
- Shading overhangs to avoid most of the direct solar gain in the summer.
- Passive cooling techniques using night ventilation provision coupled to room exposed thermal mass to minimise cooling needs (Fig. 3).
- An airtight building envelope to reduce summer hot air infiltration and winter heat loss through draughts.
- Entire structure contained within thermal insulation “overcoat” building envelope to enhance thermal insulation, and to avoid envelope thermal bridging.
- Internal heat gains minimised to reduce direct electricity use and to reduce the amount of air-conditioning needed.
- Low energy rated domestic & commercial appliances, and labeling systems to help purchasers and installers to select products that achieve sufficiently low energy demand.
- All electronics will have low standby power requirements.
- Lighting will have low energy fittings, “low voltage” & tungsten lamps will be avoided, and automatic daylight sensing will be used for non-domestic room lighting.
- Centralised air-conditioning systems will have low ductwork pressure, very good fan efficiencies, and hence low fan powers.

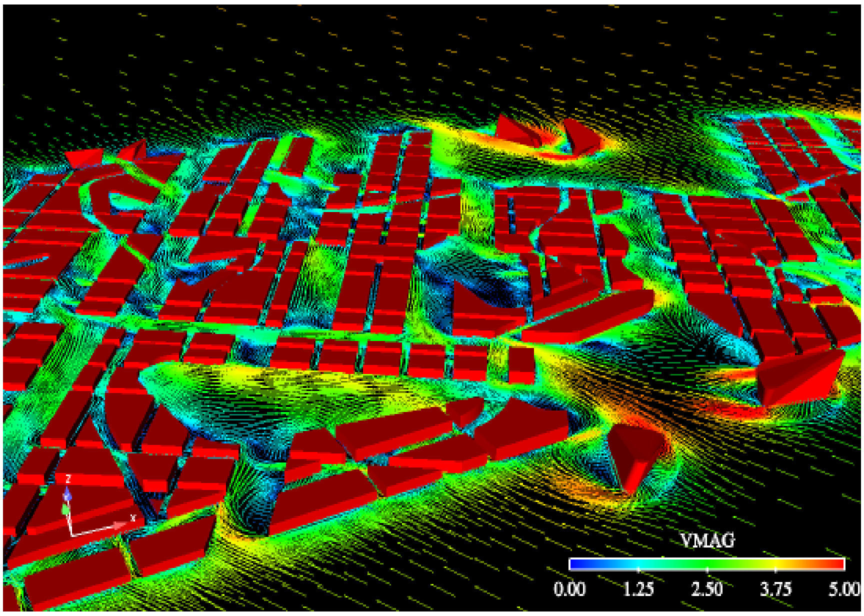

Figure 3 Wind analysis on different building disposition scheme.

Energy used in transportation also accounts for a great portion of energy demand. The target reduction is also 66% for on-site transport energy. This scale of reduction is needed for it to be practical for all on-site transport energy to be sourced from renewable energy power generation centre. Much of the transport energy reductions are related to “modal switch” created by the masterplaning, in other words, designing Eco-City in such a way that occupants and visitors regard walking, cycling and public transport as more convenient for access to facilities than private car use.

The aspiration for “Zero Tailpipe Emissions” from transport seeks to avoid local particulate and gaseous pollution. This may be achieved using either electrically powered vehicles, or hydrogen-powered vehicles, assuming current technology has developed sufficiently for a proportion of public transport to be hydrogen powered. The Eco-City Combined Heat & Power (CHP) plant has been sized so it has sufficient renewably generated electricity capacity to serve all the projected on-site transport: either as electric powered vehicles, or by using the electricity to create hydrogen.

In practical terms this way of manufacturing hydrogen may have to be done at a specialist facility remote from the Eco-city using electricity that is fed via the Grid from the CHP plant.

If some selected transport types prove unsuitable for running on direct electricity or hydrogen for Eco-City’s first phase, then the renewably generated CHP electricity intended for transport would be available for export. It would, in effect, become a carbon offset for any fossil fuelled vehicles.

A further renewable energy proposal worthy of more investigation is the provision of a bio-diesel vehicle service station at the car parks immediately outside Eco-City. If the bio-diesel were to be sold at a price that slightly undercut normal fossil fuel diesel price in China, it would encourage use of bio-diesel in vehicles traveling outside the eco-city: particularly for Eco-City occupants with a car, as well as for visitors and anyone making deliveries to the Consolidation Centre.

3.3.2 Efficient energy generation

Typically, buildings are demanding increasingly large amounts of electricity, and less heat; yet the former is the most inefficient form of energy to generate. Generating “high-grade” energy in the form of electricity from any source is inherently relatively inefficient due to basic laws of physics. Power stations have typical efficiencies ranging from 15% to 45%. Higher conversion efficiencies can be achieved when the by-product of electricity generation, namely “low-grade” energy in the form of heat, is produced and then used immediately. This makes much better use of the primary fuel.

The most efficient conversion is achieved when a large proportion of useable heat is produced alongside the electricity using a Combined Heat and Power plant (CHP). This can allow efficiencies of as high as 80% to be achieved. In practical terms the limitation is the extent to which the heat is useful and compatible with building demands. This means that wherever possible building systems that operate on heat should be chosen, and the amount of electricity needed should be minimised. In order to use this heat the power station needs to be in close proximity to the buildings, as they have to be linked with district heating pipework.

Thus, in principle the buildings for Eco-City will be designed to use heat for all space cooling, space heating and hot water demand. Systems that only use electricity will be restricted as far as possible.

Figure 4 Electricity supply infrastructure.

3.3.3 Renewable energy sources

The target of carbon natural can be achieved by employing renewable energy source. The primary energy sources have been prioritised as follows:

- Maximise large-scale on-site renewable electricity generation. This takes the form of large scale wind turbines positioned and PV farm. This reflects the fact that the largest proportion of energy demand is in the form of electricity.
- Maximise small-scale renewable electricity generation which is integrated into buildings. This is expected to be in the form of building mounted photovoltaic solar panels and micro wind turbines (Fig. 5).
- Energy from a centralised Anaerobic Digestion (AD) sewage treatment plant is expected. It is expected that the electricity generated will be sufficient to serve the energy demands of the water supply and distribution, and the sewage collection and treatment. This means that both these systems will be “net zero energy”.
- The majority of the electrical needs of the development will be met by a biomass fuelled Combined Heat & Power plant located in the Energy Centre. The low-grade heat produced as a result of this electrical power generation should satisfy all the developments heat requirements.

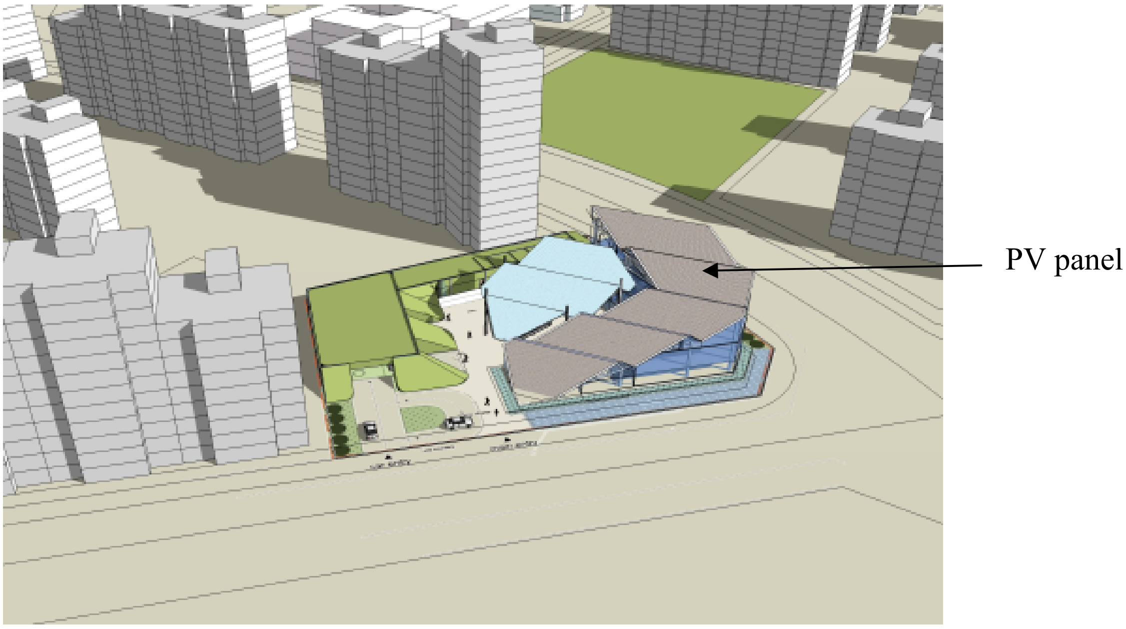

Figure 5 Local small-scale renewable electricity generation.

The aim is to use any surplus CHP renewable energy capacity to contribute to a “Carbon Offset” fund. It can contribute to reduce CO2 emission (Haeseldonckx, 2007). This might then be used to offset the carbon emissions incurred during construction and in the manufacture of materials for eco-city. Alternatively, this might be used to offset to some degree the carbon emissions identified in the Eco-footprinting related to off-site goods and services used by Eco-City occupants. In practical terms this means that the CHP would be able to sell its excess renewably generated electricity onto the Grid for supply to areas outside the Eco-city.

3.3.4 Occupant Influence

Eco-City occupants and their lifestyles will have a significant impact on the eventual energy use in the city. The proposed building design energy demand reductions will result in the majority of the remaining energy demands being directly influenced by occupant lifestyle.

Experience form around the world suggests that in practice the actual operational energy use of buildings is often much higher than estimated by the design energy use calculations. Therefore, to establish a more accurate benchmark, additional energy allowances have been included, based on monitored building energy data, in the operational energy use estimates for the BAU case.

Occupants normally choose their own entertainment systems, and there is a growing trend for large format televisions and music systems in main living spaces, and secondary televisions in other habitable rooms. These are often left on for extended periods, and even when not in use can consume significant energy in standby mode. Likewise, occupants tend to choose white goods, hot water appliances, showers, supplementary lighting, AC and cooking appliances, all of which have a significant impact on overall energy use. Most occupants are unaware of the significance of their choices: a key factor to achieving the Eco-City will be educating occupants. This will need to be combined with co-operation from product supply chains who need to ensure there is a full range of clearly labelled, and well marketed low energy products available. This may need to be managed through governance by introducing appropriate incentives and penalties.

It should be noted that the targets have been set against a baseline of actual demand including the Operational Rating of the buildings. The Operational Rating reflects the way buildings are constructed and operated, and is normally higher than the building design calculated energy consumption. The building design calculation, termed here as the Asset Rating, often uses local construction regulations and tends to simplify energy use in buildings. The difference between these two energy consumption figures comes about for a number of reasons: what is built is not to the standard anticipated by the building designer, and construction regulations tend to simplify energy use, often ignoring such aspects as building envelope air tightness and thermal bridging, and the way occupants use the buildings which rarely represents the idealized assumptions used in building design.

3.3.5 Overall

The overall targets have been set to achieve a 66% reduction in annual energy use compared with typical new build in China. To achieve this, the buildings are expected to reduce their electrical consumption by more than 75% and extensively use waste heat available from the electrical power generation. This energy will be provided from renewable sources such as biomass and wind, which is expected to result in negligible fossil fuel use, and also negligible net CO2 emissions. The electrical power generation is also intended to deliver some excess renewably generated electricity for use elsewhere in Shanghai, thereby providing an additional ‘carbon offset’.

3.4 Ecological Footprint Assessment

Aforementioned, the city has an objective to be zero-carbon in operational energy from the outset, through a combination of energy efficiency measures, renewable energy generation, a hydrogen powered transport, methane collection from organic waste, and self-sustaining local food production. In order to assess the level to which the city will achieve its zero-carbon objectives, a comprehensive Eco-footprinting calculation (Chamber et al, 2004) has been carried out using Integrated Resources Modelling (IRM), which was developed from the outset as a decision support tool based on resource supply and demand. The results from the assessment shows that Eco-City reduces the ecological footprint to 2.7 global hectares per person (gha/capita), which is 56% lower than BAU (6.2 gha/capita).

Energy demand for buildings and transport within the city limits will not require the use of fossil fuels apart from for cooking. Moreover, the energy centre will generate an on-site renewable off-set. In other words it exports spare site-generated renewable electricity for use by others in Shanghai so reducing their carbon emissions by an amount equivalent to the carbon emission of the cooking gas used in eco-city. Consequently CO2 emissions are entirely sequestrated into the renewable fuel sources and do not contribute to greenhouse gas effect, as they are part of a closed loop exchange cycle.

4. Conclusion

Due to the rapid urbanisation in recent years, China is now one of the biggest consumers of oil, gas and coal and the government is eager to see the country back away from a growing dependency on imported energy. Recent studies have also shown China to be the least energy-efficient of the world's major economies, using several times as much fuel for each unit of output as the United States, Japan or European countries. In order to change the situation, all of the efforts are being made to build a stable, economical, safe and clean energy supply system which safeguards China's energy security efficiently.

Eco-city symbolises the commitment of China to the environment and the society, and showcases an example of an integrated approach to green building, energy planning, utilization of renewable energy are incorporated to support the principles of the Sustainability Framework developed. Specific improvements have been made to Energy, these are:

- To provide carbon-neutral energy supply to all on-site sectors.
- To reduce overall electrical and transport energy demand by more then two thirds, shared across all energy consuming sectors compared with a defined "baseline".
- To provide net 100% of energy demand from renewable sources.
- To limit on-site operational energy demand levels to a level representing a fair "Earth Share" as assessed using the Eco-Footprint methodology.

Based on the results from the Ecological Footprinting Assessment, Eco-City reduces the ecological footprint to 2.7 global hectares per person (gha/capita), which is 56% lower than BAU (6.2 gha/capita). Energy demand for buildings and transport within the city limits will not require the use of fossil fuels apart from for cooking. Moreover, the energy centre will generate an on-site renewable off-set. In other words it exports spare site-generated renewable electricity for use by others in Shanghai so reducing their carbon emissions by an amount equivalent to the carbon emission of the cooking gas used in eco-city. Consequently and CO2 emissions are entirely sequestrated into the renewable fuel sources and do not contribute to greenhouse gas effect, as they are part of a closed loop exchange cycle.

Keywords: residential and non-residential sectors, suburban, low-carbon society, simulation

Summary

In Japan, CO_2 emissions from the residential and non-residential sectors have increased significantly. This paper focuses on reducing CO_2 emissions in suburban areas, where little attention has been paid to the management of CO_2 emissions even though the building stock in suburban areas accounts for a large percentage of the country's total. In this paper, we conduct a case study to estimate potential reductions in CO_2 emissions from the residential and non-residential sectors of Toyonaka city, Japan, considering technological advancements and dissemination of energy-saving technologies as well as the management of building stocks. This study on Toyonaka city, a typical suburban city, is relevant to addressing future challenges in finding ways for shifting Japanese suburban areas toward a low-carbon society. The results of the case study show that a CO_2 emission reduction by more than 50% of the current levels is achievable by combining these measures for the residential and non-residential building sectors and managing building stocks, along with an expected population decrease in Toyonaka city, which account for one-fifth of the reduction.

1. Introduction

Reducing CO_2 emissions has become an urgent challenge. The management of energy demand in the residential and non-residential sectors is imperative in Japan, as these sectors have been the main contributors to the current increase in national CO_2 emissions. The total floor area in the non-residential sector in major cities (23 wards in Tokyo, Osaka, and Nagoya) occupies 15% of the total floor area in Japan, while households in major cities account for 12.5% of households in Japan (Statistics Bureau. 2000). This means that the majority of buildings in the residential and non-residential sectors are built in suburban cities. Thus, it is important to find a vision for a future low-carbon society in Japanese suburban areas and pathways to realize the vision.

When we imagine the future of a suburban city in Japan, we cannot ignore the trends in decreasing and aging population and decreasing number of households. These changes might result in a decrease in the demand for housing and changes in the demand for businesses and services. In addition, due to the decades-long lifetime of buildings in the residential and non-residential sectors, buildings that are constructed in the next few decades are likely to still exist in 2050. While adapting to these trends, we have to manage our building stocks and infrastructure to reduce CO_2 emissions to a large extent. It is important to find development pathways with synergy between the management of carbon emissions and building stocks. For example, we can avoid declines in the quality and efficiency of administrative services that can be expected due to a decrease in the density of residents per land area by managing housing locations and density appropriately.

The purpose of this paper is to quantitatively evaluate various energy-saving measures and implementation strategies for building stock management, with the objective of creating future visions of a low-carbon society with CO_2 emissions reduced by more than 70% from the current level. For this purpose, we developed a simulation model that estimates energy use in the residential and non-residential sectors of Toyonaka city. We estimate CO_2 emissions in 2050 based on assumptions regarding technological advancements, dissemination of energy-saving technologies, and management of building stocks, with the purpose of quantifying potential reductions in CO_2 emissions by pursuing different pathways in the next decades. In this paper, we first introduce Toyonaka city and the current situation of its building stocks. We then describe the methodology of this study, including simulation models and cases designed in this study. We finally derive some implications based on the results of the case study.

2. Case study area: Toyonaka city

Toyonaka city has an area of 36.6 square kilometers with a population of 390,000 in 159,000 households. This city has prospered as a bedroom suburb of the Osaka urban area. The population size is decreasing, while the number of households has increased, especially those housing families with few members. The residential and non-residential sectors account for 58% of the current emissions from the city. The authority of Toyonaka city has currently explored the feasibility of reducing CO_2 emissions by more than 70% compared with 1990 levels by 2050 (Toyonaka city. 2007).

Figure 1 shows the regional partition of Toyonaka city. The city is divided into seven regions according to the Master Plan of the Toyonaka City (Toyonaka city. 2000). Table 1 shows the total floor area of buildings in the residential and non-residential sectors for each region. The North-central, Central, and East regions of Toyonaka city can be characterized by their high proportion of building stock in the residential sector. The Northeast and Western regions have a business district, while approximately 70% of the building stock is occupied by residential sector buildings.

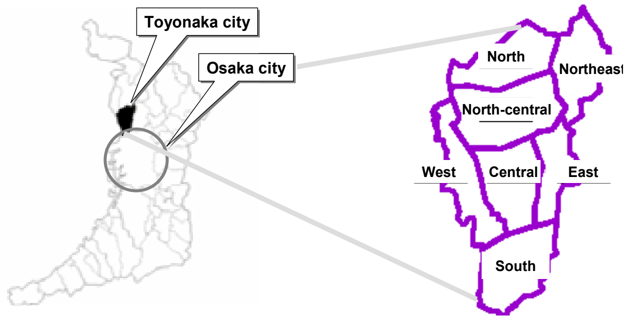

Figure 1 Location of Toyonaka city, Osaka, and regional partitions

Table 1 Seven regions of Toyonaka city

Regional Partition	Ratio of total floor area			Total floor area [1000 m^2]	area [km^2]
	Detached houses	Apartments	Non-residential sector		
North	38%	42%	19%	2,091	5.0
Northeast	15%	54%	31%	2,562	4.8
North-central	52%	35%	12%	3,930	7.0
Central	43%	42%	15%	3,414	5.2
West	31%	32%	37%	1,052	5.0
East	22%	67%	11%	1,605	3.9
South	46%	30%	24%	2,724	5.7

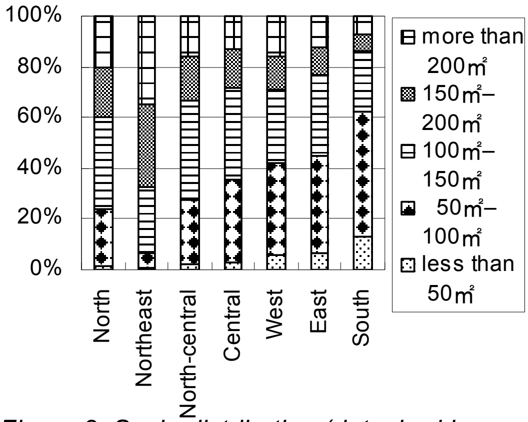

Figure 2 Scale distribution (detached houses)

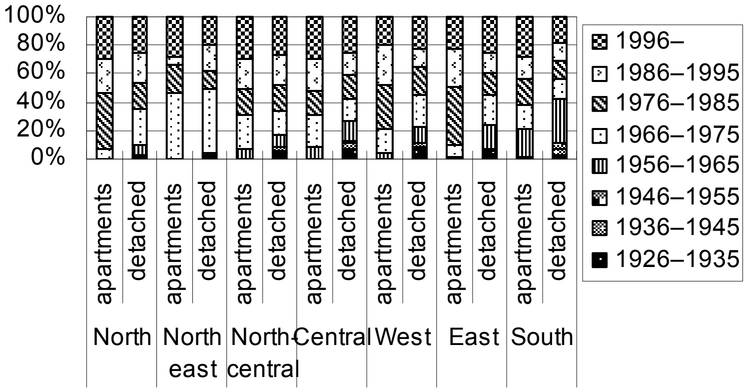

Figure 3 Distribution of the construction date houses in the residential sector

The existing building stock in each region has distinctive characteristics in terms of scale and age, as shown in Figures 2 and 3. Figure 2 shows the scale distribution of detached houses. Figure 3 shows the distribution of the construction date for houses. Differences have arisen as a result of the way these regions have been developed. In the North region, the building stock constructed after 1976 occupies approximately 80% of the total, as the region has been developed since 1976. The Northeast region is characterized by Senri New Town, which has many large apartment buildings constructed in the 1960s and 70s. This region has a business area consisting of high-rise office and commercial buildings, where the first Japanese district heating and cooling (DHC) system was introduced. The percentage of large buildings here is the highest in the city. The North-central and Central regions have the longest history in Toyonaka city. Approximately 40%

of the building stocks have accumulated in these regions, and they have been renovated at fixed intervals. In the West, there is less building stock because there is an airport in this region (Itami Osaka Airport). The East region, like the North region, has been developing since 1976. In this region, however, apartment buildings have dominated regional development, while relatively large detached houses were provided in the North region. The South region is characterized by a high proportion of small and old buildings, as the region rapidly developed from 1930 to 1960 and has been slowly renovated.

3. Methodology

In this study, we estimate CO_2 emissions from the residential and non-residential sectors of Toyonaka city in 2050. We develop five simulation cases in order to quantify the potential reduction due to stepwise improvements in home appliances and insulation performance as well as the incorporation of more radical actions for CO_2 reduction, or the implementation of building stock management that would lead to the development of a different landscape from that existing. We first explain the business-as-usual (BAU) case of this study in Section 3.1. We then explain the simulation cases in Section 3.2. We finally introduce the simulation model developed for this study in Section 3.3.

3.1 BAU case

Figures 4 and 5 show the population and household estimates of the National Institute of Population and Social Security Research (National Institute of Population and Social Security Research. 2004, 2005). For all cases, we assumed that population and the number of households will follow Figures 4 and 5 until 2050.

Table 2 lists the total floor area in the non-residential sector assumed in the BAU case. We assumed that the total floor area in all the principal usages except hospitals and schools will remain at 2000 levels until 2050. We assumed that the total floor area of the hospital building stock will increase according to increases in patient beds. Similarly, we assumed that the total floor area of schools will decrease according to the estimated decrease in the number of children. We also assumed that the geographical distribution of the residential building stock will remain as it is in 2000 until 2050.

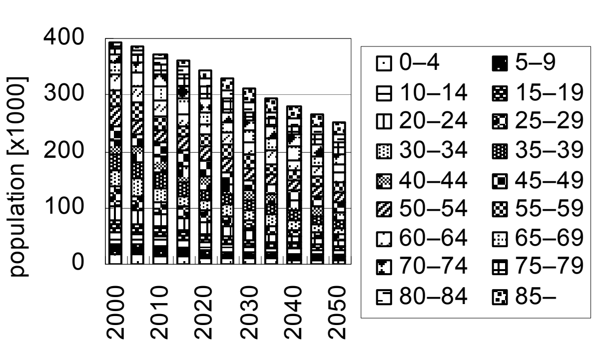

Figure 4 Estimated population

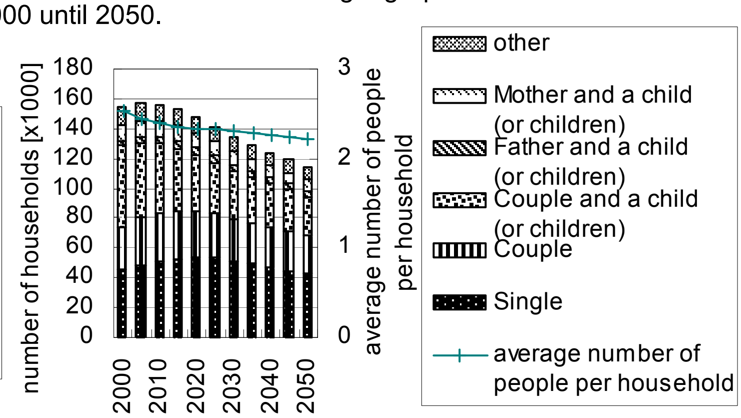

Figure 5 Estimated number of households

Table 2 Method of estimation

Item		Method of estimation
Population*		Followed the estimation of national Institute of Population and Social Security Research
Households*		Same as above
Area distribution of households		Constant
Total floor area in the non-residential sector	Offices	Constant
	Commerce	Constant
	Hotels*	Constant
	Hospitals	Estimated based on the capacity of a hospital bed
	Schools	Decrease due to the number of children in each region

*suppose that it stays constant in this city in 2050

3.2 Simulation cases

Table 3 lists the simulation cases. In Step 1, we assumed stepwise improvements in the energy efficiency of home appliances for the residential sector, and of lighting, office equipment, and heat source machinery for the non-residential sector (explained in Subsection 3.2.1). In Step 2, we assumed improvements in the insulation performance of building envelopes for both the residential and non-residential sectors (explained in Subsection 3.2.2). In Step 3, we assumed the incorporation of the building stock management such that the accumulation pattern of the building stock in each region will vary until 2050 (explained in Subsection 3.2.3). We designed three cases in Step 3 in order to examine the effect of different building stock management strategies on CO_2 emissions.

Table 3 Simulation cases

			Residential sector	Non-residential sector
Step1		Technical advance-ments	Improvements in the efficiencies of air conditioners, televisions, refrigerators	Energy-saving measures are introduced to all buildings when rebuild
Step2			Insulation performance gain (all buildings after 2010)	Insulation performance gain (less than 2,000 m^2)
Step3	Case 1	Manage-ment of building stock	Housing stock locating in South and West regions will be replaced with new stock in the other regions with the same shape and scale when they are disposed	In South and West regions, the total floor area of offices, commerce, and schools will be reduced according to the decrease in the number of households
	Case 2		Housing stock locating in South and West regions will be replaced with apartment buildings in other regions when they are disposed	Same as above
	Case 3		In addition to the changes assumed in Case 1, all the detached houses will be replaced with apartment buildings	Buildings for offices and commerce with a total floor area less than 2,000 m^2 will be replaced with a building larger than 2,000 m^2 while the total amount of the building stock remain constant as that in Case 2

3.2.1 Efficiency of available technologies (examined in Step 1)

Table 4 shows the efficiencies of air conditioners. The future efficiencies of TVs, personal computers, refrigerators, VTR/DVDs, and air conditioners were estimated by taking their lifetime function and volume of sales into account, and those of other appliances were kept constant.
Table 5 shows efficiencies of appliances in the non-residential sector.

Table 4 Efficiency of air conditioners

	COP of air conditioners									
	Cooling					Heating				
	2.2 kW	2.5 kW	2.8 kW	3.6 kW	4.0 kW	2.2 kW	2.5 kW	2.8 kW	3.6 kW	4.0 kW
2000	3.65	3.73	3.78	3.40	3.16	3.96	4.10	4.08	3.93	3.47
2050	6.22	6.10	6.21	4.89	4.99	6.71	6.53	6.52	5.70	5.58
2050Step1	6.47	6.25	6.36	5.26	5.19	6.76	6.51	6.60	5.68	5.65

Table 5 Available technologies in the non-residential sector

System alternative	Heat source					
	Cooling	Cooling COP		Heating	Heating COP	
		2000	2050		2000	2050
Absorption	Direct gas-fired absorption chiller	1.00	1.65	Same as cooling	0.83	0.83
Turbo/boiler	Water-source turbo refrigerator	4.50	8.00	Boiler	0.83	0.83
AHP	Air-source heat pump driven by electricity	2.89	5.00	Same as cooling	3.12	5.4
Individual	Individual air-conditioning system	2.60	4.00	Same as cooling	3.12	5.4
GHP	Heat pump driven by gas engine	0.95	1.60	Same as cooling	1.19	2.00
		Annual system COP				
DHC (Senri chuo area)		0.57	0.80			

3.2.2 Thermal insulation performance (examined in Step 2)

We distinguished four levels for thermal resistance of exterior walls in the residential sector, as listed in Table 6, based on Japanese government standards first established in 1980 and upgraded two times. Figure 6 shows the current proportions of the four insulation levels, as well as those assumed in the simulation cases that were estimated based on trends of newly constructed houses. For the estimation, we distinguished house types, insulation levels, and the date of construction, since the share of the four insulation levels depends on these elements. In the non-residential sector, we assumed two levels of thermal insulation of external walls, “No insulation” and “Insulated.” Current statistical data shows that approximately 15% of newly constructed buildings with more than 2,000 m^2 of total floor area are insulated. We assumed that all the newly constructed buildings after 2000 more than 2,000 m^2 will be insulated.

Table 6 Thermal resistance of exterior wall insulation

	Thermal resistance [m^2 K/W]	
	Detached houses	Apartments
Below 1980	-	-
1980 Standard	0.60	0.50
1992 Standard	0.86	0.77
1999 Standard	2.20	1.10

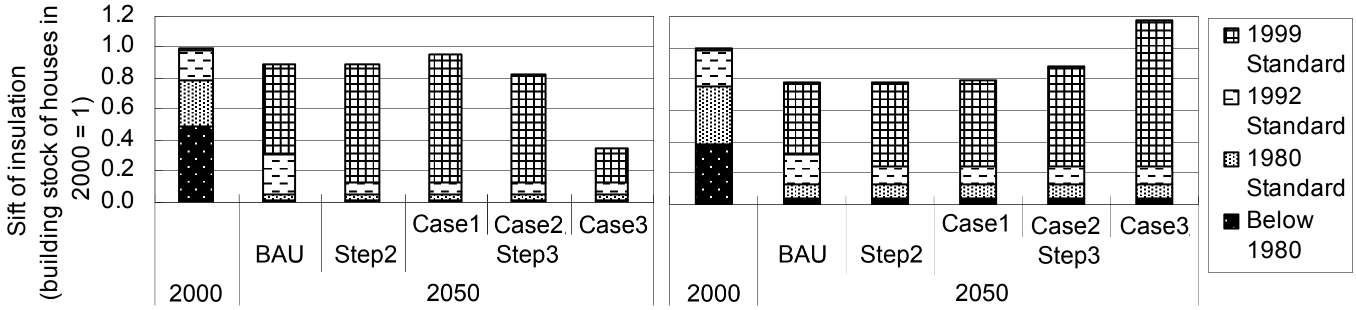

Figure 6 Shift in heat insulation of houses (Left: detached house, Right: apartment)

3.2.3 Shift in total floor area

As shown in Figures 4 and 5, the population and number of households in Toyonaka city will decrease in the next decades. If people continue to live where they currently live, the density of residents per land area will decrease considerably, possibly resulting in declining quality and efficiency of administrative services. We thus propose to implement the management of urban areas in the city so as to limit the space for new buildings. We assumed that the housing stock in the South region, where there are many old houses highly likely to be destroyed in the near future, and in the West region, where there is little housing stock (as explained in Section 2), will be replaced by construction in other regions.

In this study, we identified the following three directions that possibly contribute to reducing CO_2 emissions:

- Increasing multifamily housing in the residential sector
- Replacing detached houses with apartment buildings, due to a higher energy efficiency of apartment buildings than detached houses
- Replacing small buildings with large buildings in the non-residential sector (larger buildings have higher energy efficiency)

We designed three cases in Step 3, each considering one of these directions in order to quantify the potential benefit of the management of the building stock in Toyonaka city. Figures 7 and 8 show the estimated total floor area in the residential and non-residential sectors, respectively.

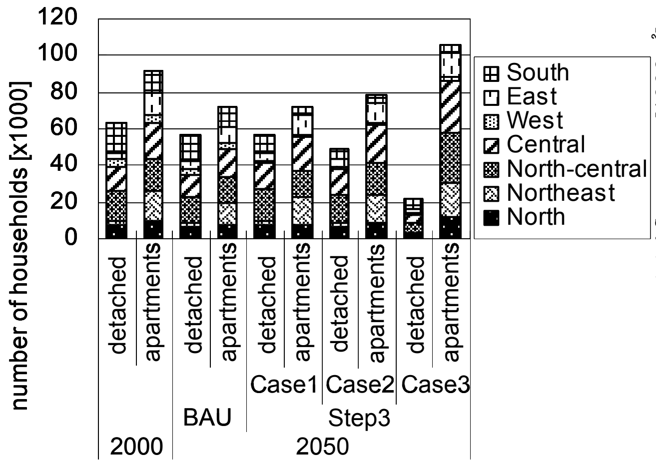

Figure 7 Estimated total floor area of buildings in the residential sector

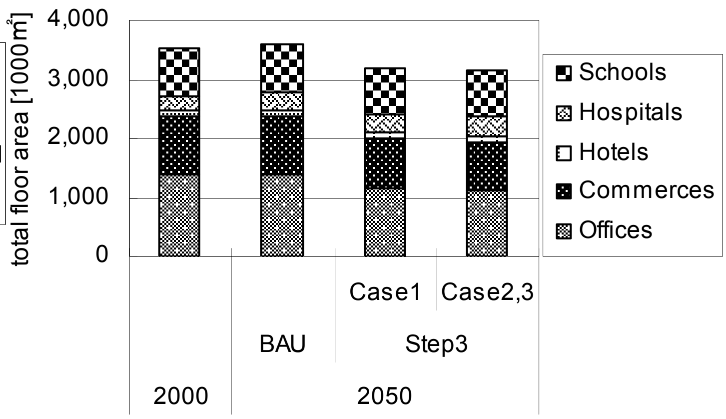

Figure 8 Estimated total floor area of buildings in the non-residential sector

In BAU scenarios, we assume that people continue to live where they do now. The total floor area of hospitals will increase by 36% from 2000. The total floor area of schools will decrease by 4% from 2000, because 5 elementary schools (from 41 in 2000 to 36 in 2050) are closed due to a decrease in the number of children.

In Case 1 of Step 3, we assume that the housing stock located in the South and West regions will be replaced in other areas. In the non-residential sector, the total floor area of office buildings, commercial buildings, and schools decreases according to the decrease in the number of households. The total floor area of office and commercial buildings will decrease by 17%. The total floor area of schools will decrease by 6% from 2000, because 7 elementary schools (from 41 in 2000 to 34 in Case 1 of Step 3) are closed.

In Case 2 of Step 3, we assume that the housing stock in South and West regions will be replaced by apartment buildings in other areas. In addition, office and commercial buildings with a total floor area less than 2,000 m^2 will be replaced by buildings with more than 2,000 m^2. The total floor area of both office and commercial buildings will be constant, as in Case 3 of Step 3.

3.3 Simulation model

We developed a simulation model for estimating the energy consumption and CO_2 emissions of the residential and non-residential sectors of Toyonaka city. The models for both sectors are developed based on the building clustering modeling approach (Yamaguchi et al. 2007). This methodology can be summarized as follows:

- Designing building prototypes, each representing a building stock category with particular characteristics in terms of energy use
- Performing simulations using these prototypical building models as input in order to predict the energy use in each building stock category
- Aggregating the total energy use by summing up the predicted energy use of all the building stock categories

Subsections 3.3.1 and 3.3.2 explain how this methodology is applied to the residential and non-residential sectors in this study.

3.3.1 Simulation model for the residential sector

The residential building stock is divided into 912 categories that are arranged under 19 household categories and 12 building categories—six for detached houses and six for apartment buildings—as well as four levels of insulation performance of building envelopes. For each building stock category, a prototypical building model was designed as input for the simulations. We then performed simulations to quantify end-use energy consumption, or electricity, city gas and kerosene, for each category, considering occupants' behavior, operation and performance of energy-consuming appliances, and requirements for air conditioning and ventilation. A detailed explanation of this model is given elsewhere (Shimoda et al. 2007).

3.3.2 Simulation model for the non-residential sector

The building stock in the non-residential sector was divided into 864 categories considering the principal usage (offices, retail, hotels, hospitals), size (4 categories for each principal usage), zoning of floor plan (9 categories), and heating systems used in buildings (6 categories). For each building category, a prototypical building model was developed as input for a simulation model that predicts the end-use energy consumption, or electricity and city gas. In the simulation model, the cooling, heating, hot water, and electricity demand profiles are simulated on an hourly basis. The end-use energy consumption is then quantified by simulating the operation of heat-source systems. A detailed explanation of this model is given elsewhere (Yamaguchi et al. 2007).

3.3.3 Validation

Figures 9 and 10 show the simulation result of the total end-use energy consumption of the residential and non-residential sectors of Toyonaka city, respectively. The simulation results show good agreement with the statistic score in both the residential and non-residential sectors.

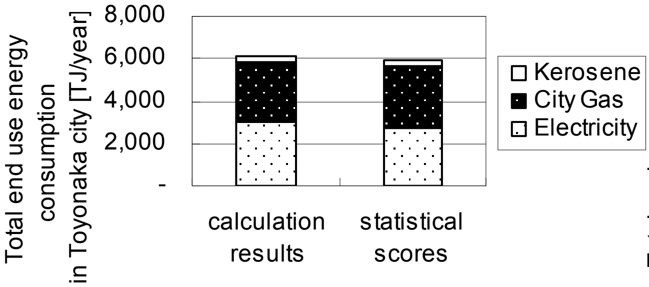

Figure 9 Comparison of calculation results with statistical scores in the residential sector

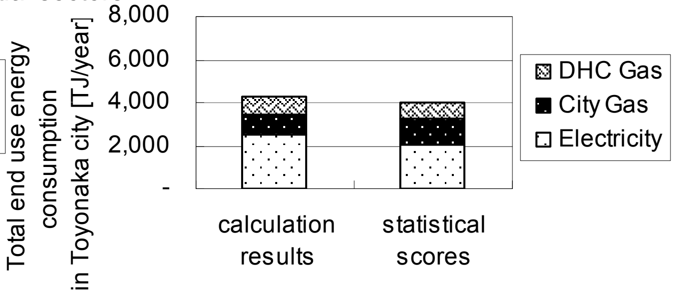

Figure 10 Comparison of calculation results with statistical scores in the non-residential sector

4. Results

4.1 BAU case

In the residential sector, the annual primary energy consumption in 2050 is estimated to decrease by approximately 40% from 2000. Figure 11 shows the decomposition of this decrease. The decrease results from decreases in both the population and number of the households, as well as improved energy efficiency in energy-consuming appliances and improved performance of insulation in building envelopes. The improvement in appliances and insulation performance is likely to be realized, as national standards have been established. This implies that these standards will contribute significantly to reducing CO_2 emissions. Regarding the number of households, although it decreases by 26%, the annual primary energy consumption will decrease by only 13%. This can be attributed to an increase in the proportion of elderly people and households with a small number of family members that have a higher energy demand than average.

In the non-residential sector in 2050, the annual primary energy consumption decreases by approximately 13% due to improved efficiency in energy-consuming appliances and heat source machinery as well as increases in DHC energy performance. Figure 12 shows the decomposition of the decrease.

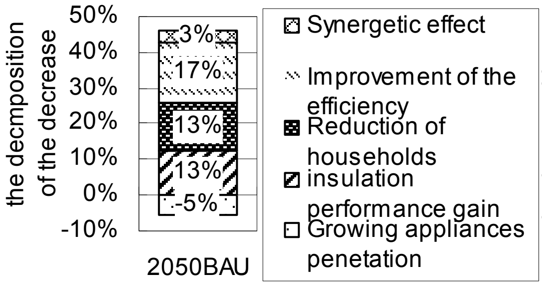

Figure 11 Results of factor analysis in the residential sector

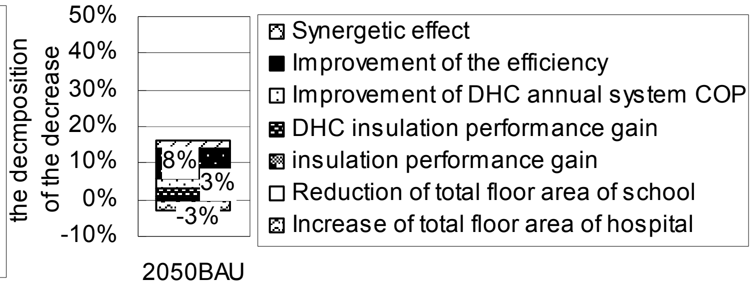

Figure 12 Results of factor analysis in the non-residential sector

4.2 Results of case study

Figures 13 and 14 show the annual primary energy consumption of the case study in the residential and non-residential sectors, respectively.

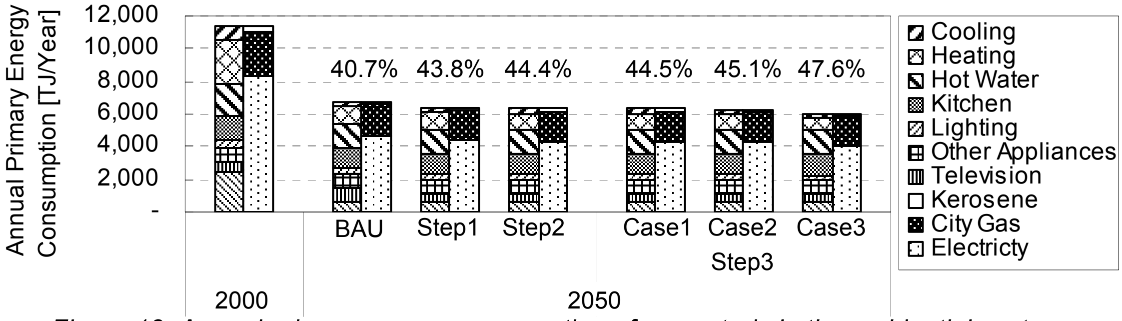

Figure 13 Annual primary energy consumption of case study in the residential sector

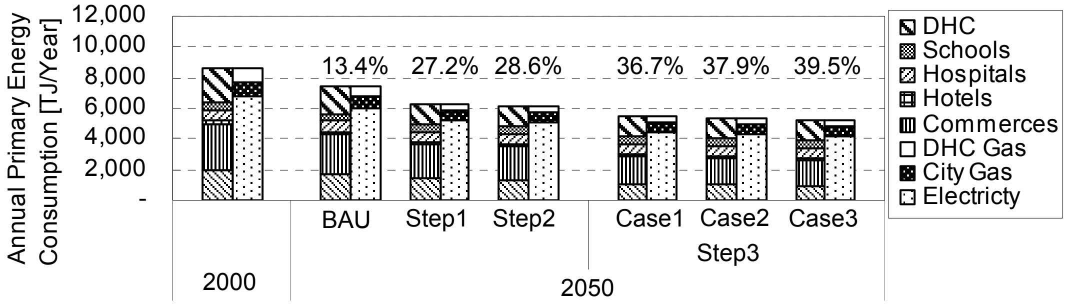

Figure 14 Annual primary energy consumption of case study in the non-residential sector

In Step 1, the additional reduction from the BAU case in the residential sector is 3.1%, based on the consumption in 2000. The gain is small because the improvement in the efficiency assumed in Step 1 is much smaller than that assumed between the BAU case and the baseline. In the non-residential sector, the improvement in the efficiency of energy-consuming appliances assumed in the BAU case results in an approximately 13% reduction in primary energy consumption. An additional 14% is gained by dissemination of energy-saving measures assumed in Step 1.

In Step 2, we assumed the accelerated adoption of the highest-level insulation standard in newly constructed buildings in addition to the BAU case following the current trend in the adoption of building insulation standards. The gain in saved energy is small. In the non-residential sector, as the improvement in the insulation performance is assumed to occur in all buildings, the increase in the saving ratio is not so large.

In Case 1 of Step 3, where we assumed a reduction in the total floor area of office and commercial buildings for the non-residential sector, the energy reduction ratio increased by 7.9%. In Case 2 of Step 3, in the non-residential sector, primary energy consumption decreased by 1.2% due to the decrease in the total floor area of office and commercial buildings. In Case 3 of Step 3, where we assumed that all the houses that are destroyed will be replaced by apartments for the residential sector, the annual primary energy consumption decreases by 2.5%. We assumed the replacement of small buildings with large buildings with more than 2,000 m^2 of total floor area in the non-residential sector, and the annual primary energy consumption decreased by 1.6%.

Figure 15 shows CO_2 emissions in 2050 for each simulation case, where the CO_2 emission rates of city gas and kerosene are 51.3 t-CO_2/TJ and 68.5 t-CO_2/TJ, respectively. The horizontal axis shows the CO_2 emission rate of grid electricity. While it is currently 0.358 kg-CO_2/kWh (Kansai area in Japan), the value in coming decades is uncertain. As shown in the result for Case 3 of Step 3, CO_2 emission can be reduced by approximately 44%, if the CO_2 emission rate of grid electricity remains at the current value until 2050. To achieve a 50% reduction in the total CO_2 emission, the CO_2 emission rate of grid electricity must be lower than 0.299 kg-CO_2/kWh even in Case 3 of Step 3. This value is not unrealistic because the local electricity company has provided electricity with an emission rate of 0.277 kg-CO_2/kWh, although great effort will be required to achieve this value.

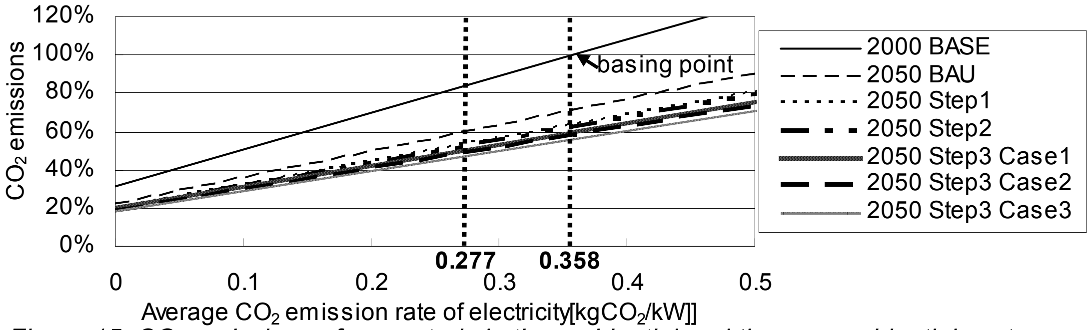

Figure 15 CO_2 emissions of case study in the residential and the non-residential sectors

5. Implications

We show that a 50% reduction in total CO_2 emissions in the residential and non-residential sectors is achievable by combining available options including implementing technological advances, improving insulation performance, disseminating energy-saving technologies, managing building stock, and improving the CO_2 emission rate of grid electricity. At least the first three options have a substantial direct potential for reducing carbon emissions. While policy instruments have been applied and are expected to be effective, it is important to enhance and widen the effort. The management of the building stock is less effective than the technical measures. However, it is must be implemented in order to achieve a 70% reduction in total CO_2 emissions. To achieve such a substantial reduction, we must consider more radical changes in buildings and infrastructure, e.g., further dissemination of photovoltaic and fuel cells. Although we did not consider these technologies in this study, it can be expected that there is a synergy between dissemination of these technologies and management of the building stock.

Conclusion

In this paper, we quantified the potential reduction in CO_2 emissions from the residential and non-residential sectors of Toyonaka city, a typical suburban city in Japan. The result of this study showed that in the residential sector, a substantial reduction in CO_2 emissions is feasible by implementing technological advances in home appliances and improving insulation performance, in addition to the smooth decrease in the number of households expected in the next decades due to the population decrease. For the non-residential sector, technological advancement, and dissemination of energy-saving technologies could lead to a substantial reduction in CO_2 emissions. This study also showed that a CO_2 emission reduction by more than 50% of current emissions is achievable by combining these measures for the residential and non-residential building sectors and managing the building stock. The management of the building stock would play a more important role, together with dissemination of emerging technologies (e.g., photovoltaic and fuel cells), if the city sets a higher target than a 50% reduction in CO_2 emissions. This study addressed key challenges for suburban cities in Japan that account for a large portion of the building stock.

Keywords: city, new equilibrium, superposition of uses, healthy neighbourhood, self-sufficiency, agriculture, reduction in trip length, intensity

Summary

Cities do not necessarily represent an unsolvable problem for a sustainable planning of life- they can even be part of the solution. Referring to determined parameters there is proposed a district that achieves a maximum self-sufficiency in water, energy and food supply and covers also with the resulting wastes on local level. For this purpose we chose a busy part of the town of Barcelona that currently runs a transforming process.
The strategies, to accomplish the objectives exposed, are:

- Creation of a new equilibrium among the built-up and the free areas.

- Intensive net occupation of the building.

- New relation among the different uses of the territory with the proposal of not bringing about any types of mobility.

- Spatial and functional integration of the agriculture as an urban use of fundamental necessity.

All these together objectives can also bring good connections with the adjacent neighborhoods and the city with its surrounding area in general. Moreover it will represent an environment of integrative and healthy characteristics for its inhabitants. This comes up from a wide range of yet existing initiatives of sustainable development in Barcelona.

1. Introduction

The concept of sustainability was originally defined in 1987 in the Brundtland Report in 1987 as ''development that meets the needs of the present without compromising the ability of future generations to meet their own needs'', becoming a cornerstone of global environmental discussion. In the framework of sustainable development, there has been an interdisciplinary approach towards environmental problems. This created an understanding of the mutual influence between natural and social processes on the one hand and between the interaction of nature and biophysical elements of the society on the other hand. Material and energy flow (called also social metabolism) and therefore influence natural processes like colonization. Cities often are an excellent example of these relations. It is expected that large urban centres will be a field of great interest in sustainable development studies.

Barcelona, the capital of Catalonia takes advantage of its strategic situation alongshore the Mediterranean Sea and close to the French border. It has not only managed to become the principal commercial and industrial centre of Spain, but gained international recognition as well. Having one of Europe's most important and busy ports and a big variety of industrial activities ranging from light to the high technology, it is nowadays one of the twelve most successful manufacturing cities in the world and the Mediterranean's most important trading and shipping route centre. Barcelona's Metropolitan Area is currently formed by 36 municipalities. Covering an area of 633 km2, the area was populated by almost 3 million inhabitants in 2004. The BMA is at present one of the 10 most densely populated metropolitan areas, with 4.785 habitants per km2, and the second most densely populated built-up area in Europe after Paris. Furthermore, its development in industrial and commercial terms is to such an extent that it contributes approximately 70% of the Catalonian GDP, hosting 58% of Catalan industrial sites.

2. Objective

The first objective of the proposal is the design of a neighbourhood, understood as a backdrop to daily life. It is conceived as part of an integrated system in which the pursuit of the maximum level of self-sufficiency in the provision of water, energy and basic foods and in the management of waste products. This will not imply the renunciation either of contemporary expectations of comfort nor of a strong urban character.The establishment of the proposal is realised in an urban area on which there are in motion diverse municipal plans of renewal or partial rehabilitation but without no strong criterion of coherence among them. It is tried to have a size of sufficient proposal to be able to investigate which is the most efficient scale of resolution of the problems that is tried to approach (energy, water, wastes, mobility, integration of the agriculture, social inclusion, …) in line with the parameters that historically have governed the growth and evolution of the city and with the current initiatives that the City council already has in motion (bets by a dense urban model, promotion of new habits of mobility for low environmental impact, experimentation with new forms of collection and valuation and appreciation of wastes, campaigns for the saving in the water consumption , …) with the following objectives:

1º to minimize the energy environmental impact and, especially, in those critical sections in its distribution (fossil fuel for mobility and thermal consumption for air conditioning) that, in Spain, occupies the 84% of this impact developing the established in the solar Decree that, among others things forces to obtain a ratio of cover in hot water sanitary production of 60% like minimum

2º to rationalize the uses of to water in a country with cyclic droughts and in process of sharpening that, in April of 2008, obliged the implementation of all kinds of measures to alleviate to water deficit of the City included the maritime transportation of to water

3º to manage the residues so that its revaluation returns them to include in the service life as Contract of "Neteja i Recollida de Residus 2009-2017 " already scores in the Nova that puts the emphasis in selective collection i, especially, of the organics fraction with less noise, minor environmental contamination and smaller consumption of water and in the development of law 15/2003 on no domiciliary collection of urban residues with the creation of a hierarchized network of Garbage (Green Points) based on the served population.

4º to facilitate a massive mobility of very under environmental impact i that guarantees a universal inner mobility and sufficient an outer connectivity dissipating the inequality that bring about the possession or not of a private car.

Barcelona and Catalonia are in an important process of change in all the aspects related to this project. Every some month new steps for a more sustainable city are approved.

The Mobility plan for Barcelona (and that for Greater Barcelona) has approved a prevision on reduction of driven car kilometres in the city for the next years. For new promotions equilibrium of emissions (micro-particles and NOX) is required and the promoter must finance new needs for public transport.

Limitations for free car parking are increasing. The Mobility Law (2003) has as principle priority of more sustainable transport modes over less sustainable.

Barcelona has worked during decades with mobility plans which restrict the free use of private car. Superblocks and local streets with very low traffic volumes. A principle of 75 % of all streets as local streets and speeds (if presence of vehicles) not superior of 30 km/h.

A new balance between use of public transport and private vehicle is related to equality of access at trip ends. Direct access from parking to dwellings and offices shall change to practice the walking at street surface. A local street with activities, human beings and better attraction as is found inside the parking.

5º to integrate the agriculture in the life and the urban form to assure an eating provision according to the nutritious needs and the local possibilities; to obtain the inclusion of the agricultural landscape in the urban landscape for being the possible receiving premises of gaseous, liquid, and solid wastes produced in the city once revalued and optimizing, at the same time, the production (so much of vegetable eating as not eating products) and for effects, on the health, by-products of the viewing, in the city, of the "weather" of the agricultural cycle and its seasonal demonstrations (sowing, growth, maturation, collects, …)

6º to establish the physical bases that facilitate the social inclusion, the sensation of ownership, the easy access to the basic rights (dwelling, schooling, health, mobility, …) to the services and the equipment generally and the promotion of the equality of opportunities. The used principles of planning are those lead that us to the attainment of the objectives indicated with the greater of possible means economy media and that cause the greater amount of possible synergies (definition of the new balance between the free ground and the occupied by the construction; qualification of the agricultural like entirely urban and consolidated ground like so; intensive use of the ground occupied by the construction; systematic and obligatory mixture the different city-planning uses in the construction on a same occupied ground; size of the unit of accessible action to I chirped in reasonable times; clear reading of the proposed set; respect by the local conditions of cultural, historic, geographical order, …

The general strategy considers the impact of the development during its various stages: during construction; the activity generated during its useful life (the quality of living space, interior mobility and exterior connectivity, provision for all social classes, work, and leisure) and its possible transformation as and when it should become obsolete.

3. Methodology

3.1 Description of the study area

3.1.1 Location

This study proposes the implantation of a new neighbourhood in one of the extremes of the city, in an area delimited by the railway which connects the centre of the city with its north-eastern periphery (Maresme and Vallès Oriental), and the Besòs river. The area is triangular in form and amongst its characteristic features is the planned location of a new high-speed rail terminal in one of its extremes and the lineal park of the Besòs River which acts as an important biological corridor between Barcelona and outlying towns. The site has an area of 166.40Ha, comprised of predominantly ex-industrial land.

Figure 1 Situation of the district inside Barcelona

3.1.2 Physical environment characteristics

Barcelona enjoys a typical Mediterranean climate, with mild temperatures whose annual average is around 16º C (30ºC in summer, 8ºC in winter). The average rainfall in the local area is of 628 annual mm. Despite this, the last ten years have been relatively dry, as it has rained above the average rainfall from the reference period in only one year. 2006 was no exception, as there were 476 mm of rain. The relative humidity is annually between 70-90%. Drought 2008

3.2 The creation of a multidisciplinary planning team

A team must be created that covers the fields of knowledge implied in urban planning. It was formed with the participation of experts in different areas: architecture, urban planning, mobility, landscape, agriculture, environmental chemistry, ecological economy, waste management, public health, physical environment, natural resources and energy management.

3.3 Definition of the variables which define a sustainable district

The variables that define a sustainable neighbourhood include the urban structure (urban characteristics, land use and skyline), the integration of agriculture and nature into the district, the sustainable management of water and energy resources, and the adequate management of wastes and emissions, and the mobility.

The detailed strategy contemplates the efficient use of scarce resources and proposes the implementation of passive solutions before active solutions based on renewable resources. The use of active solutions based on non-renewable resources will be employed as a last resort. Always bearing on mind the aim of being as much self-sufficient as possible and closing cycles.

4. Proposal

4.1 Neighborhood structure

The following assumptions have been considered in order to achieve the objectives: a scale of development with a critical mass such as can guarantee the viability of the operation; the balance between open space and built mass; a highly intensive net occupation with a balance between residential and non-residential uses; and a strong integration of agriculture in the urban fabric.

The neighbourhood has been designed for a population of 40,000 inhabitants. The 166.40Ha of the proposal are occupied as follows: 49.40 Ha. (30%) construction; 44.70 Ha. (27%) roads; 35.70 Ha. (21%) public green space, 36, 60 Ha. (22%) agriculture.

The implantation of the buildings in the territory follows an intensive model, with a high net population density similar to that of many areas of the existing city (240 inhabit/Ha). The equilibrium between residential and non-residential uses is sought through the systematic superposition of differentiated uses, at the same time liberating the individual from an imposed dependence on the private motor vehicle. The distribution of uses is: 800,000 m2 housing; 400,000 m2 public services; 560,000 m2 offices and tertiary; 50,000 m2 for light industry with other uses and 90,000 m2 for hotels.

The area occupied by buildings and roads constitutes slightly more than the half of the proposal and comprises uses compatible with residence, in their turn differentiated in *urban* and *non-urban* uses. Urban uses are those that, by their nature, support the definition of the city as a space of exchange (equipment, commerce, offices, small industry, hotel, business...) creating and receiving flows of people and/or merchandise and generating tensions between the interior, private world and the external public space.

The distribution of the built mass is realised in two distinct though complementary ways. The ‘urban’ uses occupy the level of the public space in predominately horizontal volumes, the continuity of the facades, the preponderance of the solid one set against the empty one and the clear separation between public space and private space with what a great effect of urban continuity is obtained, a great exterior-interior tension is created, the encounter is facilitated on the land and its possible accidents (topography, wooded masses, courses or sheets of water, ...) and with the existing urban weavings, being constituted in a continuous one with the wooded masses and in the base of the building in height that resolves its delivery to the floor. Besides the places of work these volumes should be capable of containing any of the habitual equipment of a neighbourhood.

In this part of the buildings, the use of dwelling is prohibited, but not other residential forms as the hotels that are integrated easily in the urban dynamics. The assembly of this part of the building will have space for the job more the school positions for the 70% of the population that resides in the unit more its spaces of provisioning and routine leisure.

The second distribution locates the dwellings, in the space superimposed upon the urban uses and with a typology in which predominates the vertical dimension, geometrically independent of the determining factors of the land, thus permitting the optimization of the orientation and the facilitating the conditions of habitability and privacy that the use of dwelling requires whilst also facilitating the adoption of passive strategies for the energy efficiency: direct solar contribution, natural lighting and ventilation

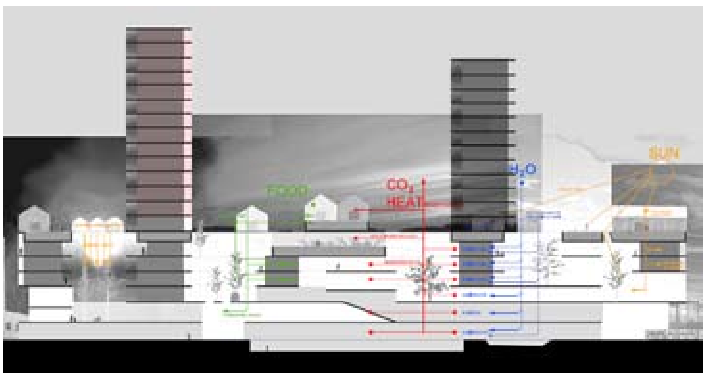

Figure 2 Superposition of uses and cycles

Figure 3 Neighborhood structure

4.2. The integration of agriculture

The project includes the agricultural land use as part of the urban set; planned with the concept of proximity agriculture and alimentary sovereignty (each community has the right –also the necessity- to provide themselves with all the possible food according to their agricultural capacity).

This relationship between agriculture and city is proposed due to several factors:

- Agriculture is the basis of human feeding. It is advisable, from all points of view, **to locate the agricultural production close to the consumption focus** in order to reduce transportation and middlemen.

- Agriculture within the city makes possible **to close the life cycle of organic wastes** (not only solid but also liquid) **and atmospheric emissions**, both produced in the urban environment. The organic fraction from the municipal solid wastes, together with black wastewaters, would be subjected to anaerobic digestion processes. From those, it could be obtained sludge (rich in nutrients), which would be composted to obtain water and manure (compost). Water could be used to irrigate the vegetation areas not used for alimentary purposes and compost could be used to enrich the soils.

- Agriculture facilitates **the visualisation of a *tempo* in the city** in the sense that it constitutes a **live landscape** which changes throughout the year, highlighting the passing of time through the seasons and the agricultural tasks (sowing, growth, blossom, harvesting…).

The project considers a **double spatial integration**. From one hand, non-residential buildings' roofs will host **greenhouses** dedicated to the **bulk production of vegetables**, and on the other hand, some well-lit areas dedicated to the **cultivation of ornamental and aromatic** plants will be inserted to higher residential towers. In both cases, the air from the activity in the buildings, enriched with CO2 due to human activity, will be injected in the agricultural spaces. This air is produced in the buildings (offices, shops, workshops, dwellings) and it will be recirculated into the greenhouses and the inserted cultivation areas, since the CO2 will favour the plants' growth, preventing the emission of this gas to the open atmosphere.

Furthermore, the project has assigned a total of 36,60Ha of land to **exclusively agricultural uses**, preferably **fruit trees** and also grape trees, in combination with some vegetable plants that have difficulties to grow in greenhouses or from the summer season.

The double combination of open-air crops and 'protected' crops, with a desirable distribution of them, implies many advantages: crop diversification which reduces business risks, possibility to combine profitable crops with less productive ones, assuring part of the crops in case of undesirable weather conditions (frost, hail…), more commodity in the execution of agricultural tasks and more capacity to plan the sowing tasks because crops in greenhouses grow more regularly.

Taking into consideration that the vegetable nutritional needs are a minimum of 0.4 kg of vegetables and 0.4 kg of fruits per person and day and that the double combination of greenhouses and open-air crops assures the availability of all kinds of vegetables and fruits (amounting to 450 Ton of vegetables per Ha in the greenhouses complemented with 40 Ton/Ha in the open-air crops), the local vegetable and fruit consumption would be satisfied in a high percentage. **Vegetables would be produced in a surplus** (with only 13 Ha of vegetables greenhouses the demand would be coped) and the surplus could be exported to neighbouring areas in the city. **The fruits demand (5.840 Ton/year) would be satisfied in a 25%.**

The commercialization of fresh products, which should be done in markets and establishments within the neighbourhood (but not in the production location), will promote the social activity and will induce to collateral consumption (bars, restaurants…), shaping an important focus of activity in the city.

The waste management system in the district would yearly provide the agricultural and green areas with approximately 5.840 Tm of compost, which would be enough to cope with their fertilizing demands.

Other benefit of agricultural plantations within the city, apart from the economic and productive, will be disposing of a landscape which will provide the territory with structure, colours and even smells. This landscape will change throughout the year, making possible the identification of the seasons and become a distinguishing element for the neighbourhood. The vast agricultural land area will make possible also the availability of familiar orchards or vegetable gardens of reduced dimensions (200 m2) and also keeping aside some agricultural lands for pedagogic purposes related with schools. The combination of plants growing at ground level (grape trees) with taller plants (trees) growing at higher levels, and the high availability of several tree varieties, will make possible multiple combinations between agricultural areas, buildings and green areas.

4.3 Water management

The basic principle of water management is to adequate the quality of water to the several water uses. In this sense, several strategies are proposed as follows: the use of rainwater harvesting systems (which priority is to be used for domestic water uses), ground water catchments (for vegetables irrigation) and treated wastewater (for other green areas). Moreover, efficiency in water use is also a premise, and grey water reuse is considered in all dwellings.

Table 1 Relation between water demand and supply

WATER DEMAND (m3/year)	WATER SUPPLY (m3/year)
Domestic uses: 730.000 Public services, offices, tertiary, light industries and hotels: 404.000	Water Harvesting Potential: 531.853 m3/year
Vegetables irrigation: 374.860	Ground water available
Gardens and ornamental plants irrigation: 114.240	Treated waster water available: 730.000

These results indicate a **DWSS of 0.73**, which means that 73% of the domestic water demand could be supplied by rainwater harvesting within the district. The irrigation demand could be easily satisfied with ground water and treated wastewater.

4.4. Waste Management

Waste water and organic solid wastes are sent together to anaerobic digestion. This process would make possible the obtaining of water (used later for irrigation), methane in the form of biogas and also sludge. The biogas is a form of energy recovery. Sludge could be used for agricultural purposes after being transformed into compost (process which reduces 30 % of its volume), applicable to the agricultural lands and green areas of the city. It is assumed that each person produce 1200gr/day.The waste treatment chain would provide the district with 7.920 m3/day of biogas, 5.840 Ton/yr of compost and 730.000 m3/year of treated wastewater.The waste management self-sufficiency indicator is expected to achieve values of 0.9, according to the municipal waste treatment facilities projected for the area. This would mean that 90 % of the wastes can be treated within the district.

4.5. Energy management

The energy consumption of the district would achieve figures of 145.920.000 kWh in domestic uses, 231.000.000 kWh in the other buildings uses and 1.788.000 kWh in street lighting each year.

Solar photovoltaic energy production on the area would provide about 730.000 kwh/Ha.

To the solar energy supply it should be added the embodied energy in the biogas produced from wastes (7920 m3/day) would have as much as 33.533.280 kWh of embodied energy.

4.6 Mobility

The scale of neighbourhood permits to undertake the diverse activities in a way unit seeking the synergies that contribute to the solutions. The equilibrium and proximity between the residential ceiling and the not residential one permits that, in a very high percentage, the displacements by mobility obliged and great splits of the doctor they can be carried out to I chirped, bicycle,… or, in its defect, with a brief journey of public transportation and reduction of parking places.

During the last years the trend in car use in the centric areas in Barcelona starts to decrease. The new Mobility Plan for the region and for the city has taken option for a reduction in the whole area of a first 6 % for 2012. This makes it probable to manage mobility in a new quarter with less car use and higher non motorized trips. As general Barcelona show 45% of pedestrian trips. The pedestrians rise to 70 % of the internal trips, in several mayor neighbor towns.

The new quarter of 40.000 inhabitants shall generate a total of 128.000 daily trips, most internal in the zone between dwellings, offices, industry and service functions.

Table 2 Associated mobility

Land use	Construct M2	Trip Generation	% internal trips	total trips	Internal trips	External trips
Dwellings	800.000	0,16	85%	128.000	108.800	20.000
Services	400.000	0,15	80%	60.000	48.000	12.000
Offices	560.000	0,1	75%	56.000	42.000	14.000
Industry	50.000	0,05	60%	2.500	1.500	1.000
Hotel	90.000	500 rooms	10%	2.000	200	1.800
Green area	360.000	0,05	90.5%	18.000	16.300	1.700

With a moderate modal split (13 % internal + external car trips) a total of 34.000 trips in cars are estimated or 26.400 car movements. 8950 cars will leave the quarter per day and come back again. This is equivalent of capacity of one lane per direction. (Table 2)

The external car trips are estimated to a mean length of 8 kilometers and the internal to 3 kilometers. The prevision of car use for the Sant Andreu quarter of half of the general objective of the mobility in the city and surroundings shall result in a saving of 13,5 million of car kilometers and 2322 T of CO2.

The modal split can be achieved by several options of city and public transport design.

- Integrated public transport within 250 meters from dwelling and workplace.
- No through streets in the quarter.
- No direct access from buildings to underground parking. The way to parking includes a short on street pedestrian trip.
- Automatic car parking from street level (50% saving of parking M2) and max.200m from arterial street.

The external trips in public transport rise to 36.400 (18.200 per direction) shall be distributed by train, metro, tram and bus in a proportion of 10 %, 40 %, 15 % and 35 %. (see service areas on graph 2). With 130 buses/day and direction or a bus every 6 minutes entering and leaving the area the demand shall be attended. The internal bus trips shall need an internal shuttle service of a bus every 4 minutes. To this must be added bus service to metro and train stations.

The pedestrians shall be stimulated by groups of living streets with concentration of activities, public transport access and way to parking entrances and exits. Every 250 to 300 m a square with this activity concentration shall be adapted to assure that pedestrians can feel in company.

Cyclists shall share the internal street area with pedestrians, goods distribution and cars to parking access, due to low speed local streets (20km/h).

4.7. Healthy neighborhood

Nowadays, the relationship between urbanism and human health is well-known. There are some hygienic principles perfectly assumed which tend to improve the sanitary conditions in dwellings and cities and also to minimize the urbanization impact on the health.

The project we propose involves a reduction of the atmospheric pollution, especially due to the expected reduction of the private car movements. An important part of the neighborhood citizens will be able to work in nearby places, many trips with shopping or leisure purposes will be done by foot and the use of public transportation systems, less polluting, will be enhanced.

There will also be a reduction of traffic accidents. Running over passer-byes will tend to zero since people and vehicles will not share the same physical space (at least there will not be highways at the same level). The accidents among vehicles will also be minimized since there will be a reduction in the number of crossroads and two-way routes.

The project strengthens the systematic contact with nature, facilitating the access to green and agricultural areas, which will be located nearby dwellings. The access to areas assigned to sport practices will be also facilitated in order to favour physical aerobic activities. The district will be designed to promote displacements by foot or bicycle through the idea of services proximity and walking distances This is according to the promotion of the use of the bicycle in the urban displacements and the enlargement of the areas pedestrian that carries out the City Hall as well as the actions to promote walking as a healthy activity developed the Catalonian health administration

It is important to highlight the relationship between urbanism and mental health. In cities, compared to rural areas, there is a higher incidence of some mental disorders, such as anxiety and depression, related with the urban life style: high levels of stress and less social support. Recently, it has been suggested that there is a relationship between living in urban areas and suffering serious mental disorders such as schizophrenia. In this sense, it has been stated that as the urban density increases, the schizophrenia prevalence also rises. It is probably a multifactor phenomenon affected by environmental and social aspects, all of them related, to a certain extent, to the urban form. In our project, the population density is low enough to favour the interpersonal contact and the proximity of nature, but not that low to difficult the existence of services and economical activity. In this sense, the dwelling modules are also designed to constitute small (or medium) communities, endeavoring the natural creation of social nets that can help vulnerable people and support them.

Keywords: city, sustainability, collaboration, design, architecture, landscape, planning,

Summary

HASSELL is an interdisciplinary design practice operating in 11 locations throughout Australia and Asia (Sydney, Melbourne, Brisbane, Perth, Adelaide, Darwin, Hong Kong, Bangkok, Shanghai, Chongqing, and Beijing). HASSELL has four core design disciplines: Architecture, Landscape Architecture, Planning and Interior Architecture

HASSELL has undertaken a design and research based project to compare and contrast the key issues facing these cities if they are to embrace a sustainable future. Key sustainability indicators were established for each location

Collated indicator data includes information on economic and demographic statistics, private vehicle usage and the ecological footprint of each city to form the basis of the study. Whilst the scope of the collated data is identical, large variations in different cities were immediately obvious.

The collated 'indicators' were then used as the basis for a three dimensional design response for each city. The design proposals have been developed collaboratively in a multidisciplinary environment to ensure holistic, visionary design responses emerge to the following question - *What could each city become by 2030 to make a meaningful contribution to reducing the impacts of climate change whilst creating vibrant 'liveable' urban environments?* The design schemes are deliberately provocative to reinforce the notion that significant shifts in attitude are as important as appropriate infrastructure models. The project highlights a variety of robust design outcomes each

suited to differing cultural contexts and climatic regions. The project has served not only as a vehicle to test leading edge design theory, but also celebrate the way in which a shared design culture can nurture a broad range of culturally appropriate responses.

1. Research Basis - methodology

Cities across the globe currently consume vast quantities of resources and produce enormous amounts of waste in a linear relationship that pays little heed to the ability of the planets biosphere to sustain such practices. This linear model is then matched with pressures associated with extraordinary migration from rural areas to cities as today's global population chooses to inhabit cities in proportions never seen in the history of our species.

Current development patterns follow a highly inefficient 'western' model based on a presumption that resources are infinite and the planets ability to absorb waste streams unlimited. This issue needs to be addressed by finding ways in which city development can be based on a more holistic 'metabolic' type model where resources and waste streams are integrated in a cyclical symbiotic system.

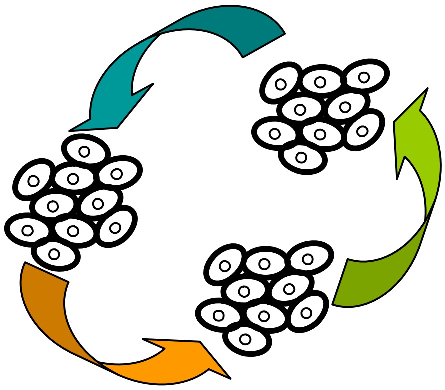

Figure 1 – A metabolic model for City Design.

Given this premise, a set of key indicators were established for each studio location to explore and allow immediate comparison across locations. This served to highlight differences between studios and geographic regions and allow a platform from which design responses could be developed.

The research deliberately represents collated data as 'indicators' because this allowed the study team to look at general trends rather than striving for precise information. The wide spread of data sources often meant specific comparison of detailed issues was difficult as much data was from disparate sources who had collated data for a wide range of differing purposes. This issue was often accentuated by the difficulties faced by our China based studios in gaining data that was collated in a manner to allow detailed comparison. This impediment was mitigated by ensuring that 'trends' were used as the basis for design proposals. The overriding purpose of the research was to permit exploratory design work that was aspirational in nature. In addition to allowing robust design responses, the indicators also permitted individual studios to focus on specific issues pertinent to each location. This approach has allowed different studios to better understand the context in which each design office operates and thus look to different regions for ideas and solutions to ongoing city evolution.

The collated data was organized on a per capita basis to acknowledge the fact that the impact of climate change is a challenge to be equally borne by all the citizens of the planet. Whilst the impacts of climate change differ from region to region, responsibility to act to mitigate damaging trends is best recognized when data is presented in a per capita manner. This is especially relevant to city design as cities are by their very nature a reflection of the collaborative industry of their citizens over any given period. Changes in individual behavior are as important as major alterations to infrastructure and development patterns.

2. Research Results

The indicators selected as part of this study for each city were:

- CO_2 emitted per capita
- Transport – Private car use per capita

- Population density
- Average Income
- Water use per capita
- Ecological Footprint per city

The tabulated results for each of these categories follow below.

	Adelaide	Bangkok	Beijing	Brisbane	Chongqing	Hong Kong	Melbourne	Perth	Shanghai	Sydney
CO_2 tons per person per year	**18**	**12.6**	**5.8**	**24**	**4.8**	**6.5**	**15**	**20**	**7.6**	**14**

Table 1 – CO2 per person per year. Key Issue – developed cities produce unacceptably high levels of CO_2 per capita.

	Adelaide	Bangkok	Beijing	Brisbane	Chongqing	Hong Kong	Melbourne	Perth	Shanghai	Sydney
Car Ownership Per 1000	**475**	**165**	**40***	**458**	**40***	**42**	**446**	**478**	**40***	**412**

Table 2 – Transport, private vehicle ownership. Key Issue – China has the highest aspiration index for car ownership in the world. Western vehicle ownership rates are unacceptable on a global scale.

	Adelaide	Bangkok	Beijing	Brisbane	Chongqing	Hong Kong	Melbourne	Perth	Shanghai	Sydney
Population Density per km^2	**1300**	**3631**	**3700**	**950**	**3200**	**6211**	**1500**	**1200**	**2590**	**2100**

Table 3 – Population Density. Key issue – low Australian population densities are matched with sprawling suburbs and transport networks dominated by the private motor vehicle.

	Adelaide	Bangkok	Beijing	Brisbane	Chongqing	Hong Kong	Melbourne	Perth	Shanghai	Sydney
Average income $US	**44,500**	**10,000**	**5,800**	**48,250**	**2,000**	**30,000**	**54,500**	**53,700**	**11,500**	**62,000**

Table 5 – Average incomes, Key Issue – the benefits of higher income are tempered by greater resource use and CO_2 emissions.

	Adelaide	Bangkok	Beijing	Brisbane	Chongqing	Hong Kong	Melbourne	Perth	Shanghai	Sydney
Water Use kL/person	**90**	**215**	**158**	**130**	**27**	**140**	**75**	**180**	**170**	**80**

Table 6 – Water use per capita, Key Issue – differing locations receive different amounts of rainfall that don't necessarily reflect annual scarcity.

	Adelaide	Bangkok	Beijing	Brisbane	Chongqing	Hong Kong	Melbourne	Perth	Shanghai	Sydney
Ecological footprint	**7**	**3.4**	**3.1**	**7.7**	**1.3**	**4.9**	**6.2**	**9**	**3.4**	**7**

Table 7 – Ecological Footprint. Key Issues – developing nations footprints are escalating as incomes increase. Australian cities must find ways to start reducing total footprint areas.

2. Research Conclusions

The collated indicators reinforced a well understood premise – that 'developed' Australian cities have evolved in a manner that sees high average incomes directly correlate to high CO_2 outputs based on having lower population densities and greater average travel distances by private car. Water use varies from city to city and tends to be an issue for local management depending on rainfall intensity and when the rain occurs. The indicators allowed our studios to examine their situation in direct comparison to other studios. This assisted in the selection of specific areas for the individual designs to focus. The ecological footprint indicator allows a range differing issues to be directly correlated. It provides an overall indicator of the total sustainable performance of each city.

From the collated indicators it is clearly demonstrated that the increased wealth evident in the developed Australian cities is directly linked to excess CO_2 production and very high ecological footprint measures. The need for a development model that decouples wealth generation and the opportunities associated with first world 'western' cities from environmental degradation is evident.

The design solutions seek to explore the individual issues facing each city and allow responses that are situation and site specific to emerge.

3. Design Response

HASSELL is a multidisciplinary firm and the design responses that form the basis of this study have been developed by personnel from across our core disciplines: architecture, landscape architecture, planning and interior design. The design responses have evolved in response to the following provocateur, "*What could each city become by 2030 to make a meaningful contribution to reducing the impacts of climate change whilst creating vibrant 'liveable' urban environments?*

In the quest for a metabolic city design model, it became immediately clear that sustainable cities will need to develop holistically in a manner that allows for substantial sharing of opportunity and resources across the traditional real estate boundaries that have been one of the core attributes of contemporary city development. Key design drivers included the following:

- Integrated landscape – making landscape a 'participatory' element within city-scapes. Moving beyond landscape driven solely by visual amenity to landscape that can act to filter air, water and waste. How will landscape and design support substantial energy generation systems and food production whilst providing opportunity for recreation and visual amenity?
- How can the ideals of industrial ecology be integrated into new city design? What city infrastructure needs to evolve around decentralized models to allow for better efficiencies and distribution networks? What systems could be better centralized for the same reasons? Key utilities require consideration – electricity generation, sewer networks, storm water control and collection, carbon minimization.
- Healing damaged natural systems – what natural systems have been disrupted by the current city model? Can these systems be identified and reintegrated to assist in nutrient filtration, waste management and visual amenity?
- Transport systems for minimum carbon waste. How could drastically reducing private car use positively benefit new city design? Design teams were cognisant of the many negative spatial impacts cars have on urban form and city spaces –exhaust pollution and greenhouse gas contribution are not the only issues associated with high private car ownership and usage rates.
- How can city design contribute to a sense of place and community? Diversity, equity, opportunity for employment, access to services, affordable housing and 'delightful' spaces all contribute to making up the matrix of a great city. Design solutions seek to be cognisant of these issues and ensure monoculture single zone approaches are avoided.
- Efficiency / density – there are many efficiencies to be gained by increased population densities in contemporary city centers. These include high quality transport options, efficient distribution of

resources and collection and redistribution of waste streams. However, the adverse impacts of extreme density matched with inadequate accommodation, sanitation and inequity need to be acknowledged.

- Integrated technology – it is recognized that industrial ecology and integrated design will be able to resolve many of the problems associated with resource and waste cycles within cities. However, integrated technological solutions are going to be required to assist and support natural systems to ensure local biological networks are not overwhelmed.
- Policy frameworks – design solutions must have the potential to be supported and encouraged by appropriate policy structures. Developing cities in a 'metabolic' manner will require adjustments to the jurisdictions of traditional city planning and development control to ensure an integrated approach to design and infrastructure provision.

Whilst the above mentioned issues shaped the design outcomes, our basic premise is that a collaborative approach that encompasses all the traditional urban design disciplines is going to need to be supplemented by a range of skills not commonly utilized by traditional linear city development models. Information from ecologists, sociologists, psychologists, agricultural scientists, futurists and many many others is going to be required to build robust sustainable cities. It is the role of design to evaluate the inputs from all these sources and develop outcomes suited to a sustainable future.

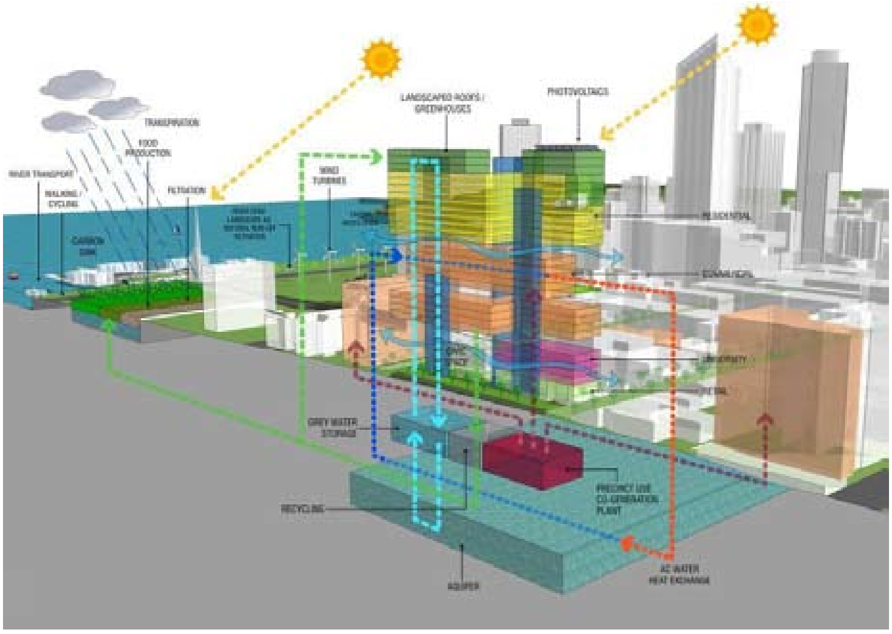

Figure 2 – An integrated approach to resource sharing and waste stream management.

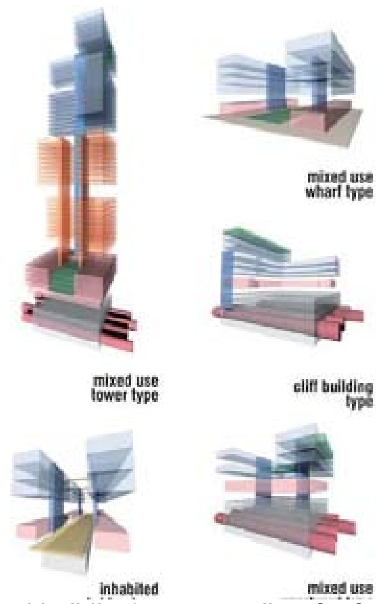

Figure 3 – exploring 'universal building' types to allow for future re-use and adaptation

.

Figure 4 – Future Sydney? An integrated sustainable opportunity.

4. Comparisons and Conclusion

The design outcomes of this project have focused on central city areas as this tends to be the crucible of opportunity and where HASSELL have the most ability to influence new development models. This is not to say that there are not many issues at the fringes of rapidly expanding cities that are worthy of careful consideration.

This exercise has illustrated that the issues that face our 'northern' studios tend to be related to extraordinary population expansions in very short time frames. (Chongqing is experiencing approximately 10% population growth per annum). Putting plans in place to manage this type of growth is problematic as often no clear development framework is in existence. The growth of Australian cities appears to be deceptively manageable, however, old development models still control this growth and encourage wasteful, ecologically damaging systems to continue. The opportunity exists in Australia to start incrementally changing city development control systems to set up a sustainable future. Lessons learnt can be quickly shared to ensure a wide audience can be the beneficiaries of this experience.

Sharing experiences and articulating lessons learnt was a key project driver. The design outcomes are merely a first step on a journey to share knowledge across our studios and ensure our people better understand the issues facing our different locations. By sharing this knowledge we believe we ensure a holistic integrated design approach will develop better city outcomes.

Real change in city development is going to require new thinking and skills from across the design spectrum. For cities to aspire to development along 'metabolic' lines, policy and development controls are going to have to be modified to allow for decentralized access to services and resource flows. Sustainable cities will embrace the opportunities these new relationships offer. New cities will offer the opportunity for built form, open space, landscape, utility infrastructure and transport networks to act in a 'participatory' and restorative manner where each element acts to enhance the livability and sustainability of the overall city. We believe this project has presented the type of approach necessary to achieve such outcomes across a range of different regions. Further to this, the design solutions have demonstrated the manner in which a shared design approach can foster a broad range of culturally diverse solutions suited to a specific local context.

VANCOUVER'S OLYMPIC VILLAGE: DESIGNING A SUSTAINABLE COMMUNITY AT SOUTHEAST FALSE CREEK

Roger BAYLEY P.Eng.[1]

[1] Merrick Architecture, Vancouver, BC, Canada, roger@rogerbayley.com

Keywords: Olympic village, community, accessibility, passive design, LEED™, mixed-use, energy, brownfield

Summary

Millennium Water is a model sustainable community that is being built on the last remaining large tract of undeveloped waterfront land at Southeast False Creek near downtown Vancouver. The Vancouver Organizing Committee for the 2010 Winter Olympic and Paralympic Games has designated the site as the Athletes' Village for the duration of the Games, at which time the area will temporarily house approximately 2,800 competitors.

Prior to its redevelopment, the site was considered a brownfield and underwent extensive environmental remediation. Following construction, Millennium Water will be a complete community, offering a variety of goods and services, transit options, and employment opportunities within walking distance of the residences. The development is based on environmental, social and economic sustainability principles.

The neighbourhood will be a leading edge community while maintaining heritage ties to the past, having been for many years an important urban industrial site. The area will be home to a diverse population, offering a mix of subsidized, rental and market accommodations. Housing will be designed to accommodate singles, families, seniors and people of varying physical abilities. With a target of LEED® Gold, Millennium Water is being built to meet a high standard of sustainability.

Figure 1 Digital rendering of Millennium Water, community centre in foreground.

1. Project Overview

1.1 Sustainability Highlights

The new neighbourhood will offer a variety of long-term environmental, health, social and economic benefits to the community. Building occupants will enjoy enhanced indoor environmental quality via fresh air ventilated from the outdoors and non-toxic finishes to minimize off-gassing of materials. Buildings will be heated by renewable resource - sewer heat recovery - distributed by a neighbourhood energy utility. Energy consumption will be reduced through passive design strategies. Potable water consumption will be reduced by way of rainwater collection and a greywater recycling system. Stormwater management strategies include a system of swales, retention ponds and cisterns.

There will be employment opportunities and day-care facilities within the neighbourhood with the goal of propagating a vibrant community. The project promotes alternative transportation and active living through proximity to transit, designated bicycle and pedestrian areas, and car share vehicles. Parks, gardens, green roofs, and urban agriculture will enhance local ecology, provide recreational opportunities and be a source of local food production. Community life is supported through public amenities: public art, a non-motorized boating facility, community centre, pedestrian plaza and commercial district.

1.2 History and Background

Millennium Water comprises seven hectares and is the first phase of the redevelopment of Southeast False Creek (SEFC) which totals 32 hectares. Beginning in the late 1800s, the SEFC site was for many years an industrial yard – its activities included sawmills, foundries, shipbuilding, metalworking and salt distribution – and in recent years the site has lain vacant, awaiting clean up and redevelopment. The Millennium Water project will begin the process of bringing life back to the area, transforming the site that was once a hub of industrial activity into a thriving community: a commercial, residential, and recreational hub in the heart of Vancouver.

Millennium Water will offer 130,000m² of commercial and residential space. The project will see the construction of 1,100 housing units. 250 are to be subsidized housing, 110 will be rental housing, and the balance regular market housing. The project is slated to be completed by the end of October 2009 at which time it will be temporarily handed over to Vancouver's 2010 Olympic Organizers (VANOC) for a six-month period. Following the event, the site will be returned to the owners for permanent occupancy. As the site has been designated as Vancouver's Athletes Village, construction must adhere to a very strict timeline – a significant challenge for design and delivery of a development of such a scale.

By 2020, the remainder of SEFC will be complete and its projected 7,200 residential units are expected to become home to between 12,000 to 16,000 people. The neighbourhood's approximate 560,000m² of development will include a full size community centre; a non-motorized boating facility; three to five licensed childcare facilities; an elementary school; five restored heritage buildings; public plazas and promenades; community gardens and 10 hectares of parkland.

Figure 2 Millennium Water Site within SEFC Official Development Plan Area

2. Olympic Athletes' Village

For six months following construction of Millennium Water, the neighbourhood will be used to accommodate athletes competing at the 2010 Winter Olympic Games. As Vancouver's Olympic Village, Millennium Water will temporarily house approximately 2,800 athletes for the duration of the Games. The neighbourhood will become a lively centre of activity, celebration, and ceremony in honour of the event, while meeting the daily needs of visiting athletes and their delegations.

Adaptability was necessary in designing the Olympic Village, since buildings had to meet VANOC's overlay requirements in addition to the conditions of the Official Development Plan for the area (ODP). The overlay applies to a six-month 'exclusive use period' in which the site will be controlled by VANOC. The overlay includes provisions for temporary housing, dining, fitness, and health care facilities and security among the numerous operational requirements of the Olympic Village. The design team had to find flexible solutions for creating buildings that would serve two distinct purposes: accommodating the event and also the residential legacy.

All of the ground floor commercial spaces will be fitted out to accommodate operational facilities for the athletes. Residential suites will be temporarily protected for the duration of the exclusive use period, in order to safeguard the furnishings such as hardwood floors and kitchens from damage.

Legacy features that have been included in project design include silhouettes of ski jumpers, hockey players and other athletes that will take shape in the vegetation on the buildings' green roofs. Street names in the new neighbourhood, including Athletes' Way will also evoke the legacy of the event and the Athletes' Village.

3. Design Standards & Regulatory Tools

3.1 Official Development Plan

The design for Millennium Water was subject to a number of stringent regulations. The project had to comply with standards and guidelines detailed in the Southeast False Creek Official Development Plan (ODP) bylaw, which was adopted by Vancouver's City Council in July 2005. The focus of the Plan is to develop a complete community that will serve as a learning experience for the application of sustainability principles to large-scale neighbourhood design. According to the ODP vision, the area will be transformed into a community 'where people live, work, play and learn in a neighbourhood that has been designed to maintain and balance the highest possible levels of social equity, liveability, ecological health and economic prosperity.'

The ODP describes general land-use parameters and regulations under which the project can proceed. The Plan mandates a set of environmental standards to govern the site's redevelopment including a Green Building Strategy, and specific design principles and targets for landscaping and urban agriculture, water and energy efficiency, alternative transportation, and waste management.

3.2 Green Building Strategy

The SEFC Green Building Strategy was developed by the City of Vancouver in order to mandate a level of sustainability in building design and to set a new precedent for local sustainable design. The Strategy applies to all new buildings that fall within the boundaries of the 32-hectare SEFC site. The Strategy sets a target of LEED® Silver for new construction according to the Leadership in Energy and Environmental Design Green Building Certification system. In addition to the LEED® qualification, the strategy outlines a number of criteria under the following categories: energy, parking, landscape, water and waste management. Any person applying for a building permit within the SEFC boundaries is required to provide documentation outlining their approach to meeting the requirements of the Green Building Strategy. The acceptance of development and building permit applications by the City of Vancouver is contingent upon the applicant's commitment to meeting the Strategy's requirements.

3.3 LEED® Green Building Certification

Millennium Water is targeting a higher standard than the mandated LEED® Silver. The project is targeting LEED® Gold at a minimum for all buildings, and the community centre is being designed to achieve LEED® Platinum certification. One of the multi-unit residential buildings, an affordable housing block for seniors, is targeting NET ZERO annual energy consumption and will likely achieve LEED® Platinum.

The SEFC redevelopment area is participating in the US Green Building Council's LEED® for Neighbourhood Development (LEED®-ND) pilot program. LEED®-ND integrates the principles of Smart Growth, New Urbanism, and environmental building design into a new standard for sustainable neighbourhood design. The study will evaluate neighbourhood development against a number of criteria under the following categories: Smart Location & Linkage; Neighbourhood Pattern & Design; Green Construction and Technology; Innovation & Design Process.

3.4. Safer Home™ Certification

Millennium Water is being built to meet criteria set by the Safer Home™ Certification Program, a home building standard that provides safety, comfort and adaptability for people of varying ages and abilities. This voluntary standard improves accessibility for people with diverse needs and provides the opportunity for aging-in-place. Safer Home™ design criteria comprises 19 points including widened hallways and stairwells, lowered light switches, removable under-sink cabinets, pressure/temperature control valves on shower faucets to name a few.

Safer Home™ is linked to the principles of Universal Design, allowing homes to be usable by all people to the greatest extent possible without adaptation or specialized design. Universal Design is based on the premise that people have changing needs throughout their lives. Safer Home™ is the only certification program in Canada that addresses the application of Universal Design in our homes. Building life is extended through the application of these guidelines as the design is adaptable to changing needs over time.

4. Passive Design

In order to reduce overall energy demand in buildings at Millennium Water, the design team focused on passive design strategies. The mechanical engineer took a systems approach to design, emphasizing sustainability by looking for synergies that would help reduce the need for mechanical systems. Passive design was seen as the first step in creating buildings that are thermally comfortable, efficient and provide a pleasant indoor environment for occupants. By including passive design techniques the design team reduced heating and cooling loads, lighting and mechanical ventilation systems.

Passive strategies on the project include enhanced envelopes, efficient glazing systems, wrapped balconies, through-suites with exterior access ways, light and shading controls, operable windows and natural ventilation. Building orientation was taken into account when designing the exterior facades to take advantage of, or respond to exterior environmental factors such as sun, wind and rain. Enhanced envelopes reduce energy loss. Rain screen systems were specified to insulate buildings from Vancouver's notoriously wet climate. Heat gain is controlled using operable shading devices and deep balcony overhangs on south and west facades. Double glazed windows with low-e coatings reduce heat gain and loss through the window systems. The project compromised with a 70:30 glazed to non-glazed ratio, which is low for Vancouver buildings, which often prefer 100 percent glazing in order to maximize views.

4.1 Passive Design Area Exclusions

The project paved the way for future sustainable design in Vancouver through an unprecedented agreement between the City and the developer. In order to encourage passive design strategies such as thicker walls for improved insulation, wider circulation areas, deep balconies for shading, and exterior corridors for improved air quality, the City granted area exclusions for any additional area required to meet passive design requirements. Specifically, any additional floor space area that was included in the design as part of a passive strategy was excluded from the calculations of floor area. The developer was thus able to include passive strategies without forfeiting developable area.

5. Energy Systems

5.1 Neighbourhood Energy Utility

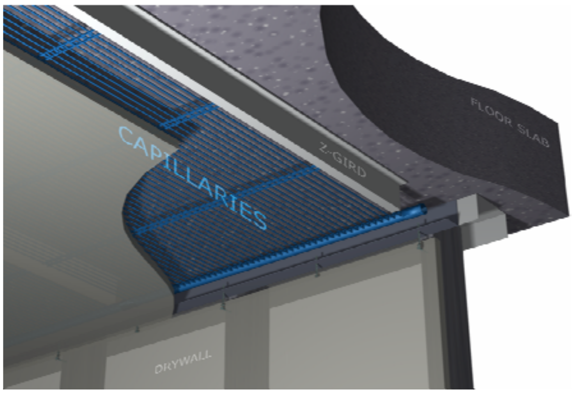
Buildings at Millennium Water will be heated by way of Southeast False Creek's neighbourhood energy utility (NEU). The NEU is a community energy system that will provide space heating and domestic hot water to all buildings in the Southeast False Creek redevelopment area.

The NEU is being designed with leading-edge technology to use a sustainable heat source – it will recover heat from the municipal sewer system. Sewage waste heat will be captured and used to heat water at the SEFC Energy Centre. The system uses heat pumps to upgrade low-grade heat to high temperature water, which is then distributed to buildings throughout the site. The Energy Centre will be designed as an interpretive facility to showcase the innovative use of sustainable technology, and is expected to achieve LEED™ Platinum certification.

This will be the first use of this technology in North America, and one of only four such projects in the world. The system, when completed in May 2009, will produce heat at a cost that is competitive with traditional building heat and hot water systems, but in a more sustainable manner. Emissions of greenhouse gases will be significantly lower and the NEU will have long-term flexibility to adopt new alternative heat sources to keep pace with anticipated technology advancements.

5.2 Ceiling-mounted capillary heating and cooling

Buildings at Millennium Water will be heated and cooled using what will be North America's largest in-ceiling radiant capillary heating and cooling system installation. Capillary heating employs the circulation of cold or warm water through narrow (3-4mm) plastic capillary tubes. Capillary tube mats allow large amounts of energy to be transferred with no draught or noise, even with low temperature differences between active room surfaces and room air. Capillary heating was preferred by the design team as it provides optimum thermal comfort with the added benefit of cleaner indoor air quality due to a reduction in airborne particles such as dust and allergens as compared to conventional forced air systems. Radiant systems exchange heat using water rather than air. Water is a better heating and cooling transport agent than air as it requires less volume to transport the same amount of heating and cooling capacity. The system is self regulated based on the room load. If the room is empty, no energy transfer happens, thus saving energy.



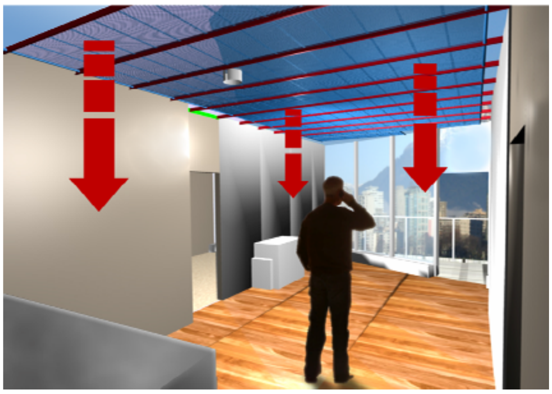


Figure 3 & 4 Ceiling capillary mat installation delivers radiant heating and cooling.

6.0 NET ZERO Housing

6.1 The Concept

The term NET ZERO is used to describe buildings that are designed to produce as much energy as they consume on an annual basis. Millennium Water will feature Canada's first NET ZERO multi-unit residential building. The design team is working with the City of Vancouver and Canada

Mortgage and Housing Corporation to support this project. The proposed NET ZERO building at Millennium Water comprises an approximately 6,900m², 68-unit social housing project for seniors.

6.2 Project Objectives: A model for carbon-neutral development

NET ZERO housing is a design approach that integrates five key principles of sustainable design: Health, Energy, Resources, Environment and Affordability. The Millennium Water NET ZERO project will be a test bed to promote practical, cost-effective energy efficiency and onsite energy production measures in a way that is transferable to future projects. The project will demonstrate how the combination of energy use reduction and efficiency measures integrated with renewable energy production can result in an annual zero net energy balance.

6.3 Design Strategies

The NET ZERO building required an ongoing integrated design process in order to meet its target. The primary strategy in reducing building energy demand in this building is through the application of advanced building technologies and passive design techniques including enhanced envelope design (triple-glazed windows, R-20 walls and R-30 roofs), rain screen envelope, high performance glazing systems and shading devices. The design team focused on an efficient, tight envelope as a starting point in order to reduce the need for mechanical systems.

The building is ventilated naturally using fresh air that enters through the slab and is released behind the refrigerator in order to temper the air on its way into the interior spaces. Fresh air ventilation, efficient insulation, through suites and shading devices eliminate the need for mechanical air conditioning in the building.

6.4 Renewable Energy

The building will rely on renewable energy systems to provide its own supply of clean, 'green' power. Heating loads will be met using waste heat from an adjoining supermarket. The remainder of the building's energy use will be offset using two rooftop solar thermal arrays – one on the roof of the building, and the other on an adjacent building. Solar thermal was found to be both the most cost effective and appropriate technology for Vancouver's climate, and as such, was the chosen technology that will allow the SEFC NET ZERO building to achieve its target performance.

6.5 Monitoring & Evaluation

Following occupancy, building energy performance will be extensively monitored in order to evaluate the achievement of the project and to inform future projects. As this project incorporates a combination of new technologies and strategies, it is imperative that the project be properly documented and its performance be evaluated once the building is in use. While the design and energy strategies were carefully modelled and strategically implemented based on assumptions about building performance and occupant behaviour, the success of the project will only become evident once the building is up and running. The performance of the building depends on its design but also largely upon the behaviour of its occupants and therefore considerable education will take place one to two years following regular occupancy.

6.6 Education and Public Engagement

NET ZERO building occupants will be educated about the building's systems and design so that they are aware of the goals for the building and how their individual choices can influence the building's performance. An awareness program will be implemented which is likely to include a video as well as a manual for occupants which will outline the building's design targets and demonstrate the importance of behaviour change and occupant buy-in in order for the building to meet its desired performance level. This includes information about the building design, renewable energy systems and the role of the occupant. Behavioural recommendations will amount to tips on how to reduce personal consumption through actions such as, for example, turning lights off when leaving rooms and not leaving the television running all day.

6.7 Meters

All Millennium Water suites will include metering devices that provide feedback on per unit electricity, heating and cooling and water consumption. The meters also show the associated cost of electricity and will predict the amount of monthly electricity bills. Greenhouse gas emissions associated with electricity use is also displayed. The meters are designed such that the user can set consumption targets. The devices include two strips that light up in green if you are within range of your target and red if you are exceeding your target consumption level.

In-suite meters are expected to help reduce individual occupants' electricity and hot water consumption significantly. Research shows that awareness programs and in-suite metering devices can influence users to reduce their consumption rates by 20%. Occupants, once armed with the knowledge of how many resources they consume and how small behaviour changes can reduce their consumption, their personal footprint (in GHG emissions) and in turn affect their monthly utility bills, are liable to commit to new patterns of use and reduced consumption.

Figure 5 Meters will be installed in every residential unit; display showing unit cost of electricity.

7. Land Use and Site Planning

7.1 Water Use Reduction

The development aims to reduce the use of potable water by at least 30% below conventional levels. Low flow fixtures and appliances will be installed universally throughout the buildings. Stormwater runoff will be reduced by 25% through a site-wide system of green roofs, swales and retention ponds. Building plumbing includes a greywater system in which rainwater is harvested and stored in a below-grade cistern, then treated and circulated through the building for reuse in irrigation and toilet flushing.

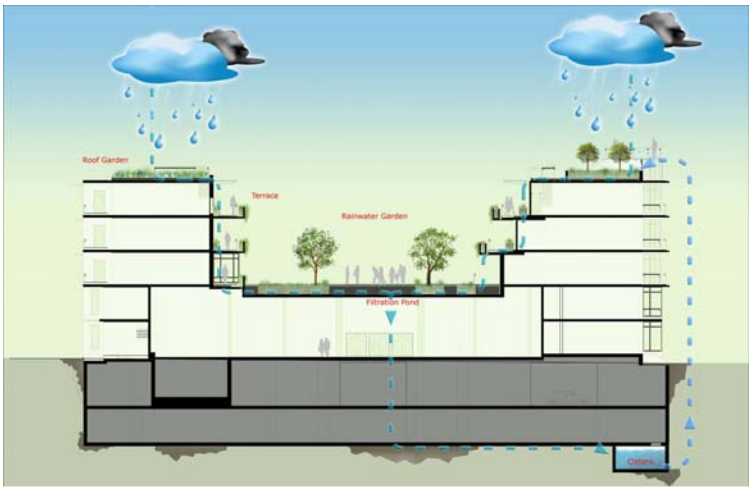

Figure 6 Rainwater harvest, storage and recycling schematic.

7.2 Landscape Design

Courtyard cooling ponds containing collected rainwater will contribute to passive design strategies through evaporative cooling. The landscape at Millennium Water is being designed to thrive without use of potable water, to control stormwater runoff, enhance native habitat, and provide opportunities for gardening. All buildings will have a minimum of 50% green roof coverage, with plantings arranged into motifs that celebrate the Olympic Games theme.

7.3 Urban Agriculture

Urban agriculture is incorporated into the landscape design, with the intent of creating opportunities for onsite food production and distribution. The City commissioned an extensive study on urban agriculture opportunities for SEFC. The report findings include recommendations for locations where food production might take place including community gardens, on private plots, rooftop gardens, balconies and window boxes, school gardens and inside buildings. Food distribution outlets could include farmers markets, home delivery, buying clubs, grocery stores and an emergency meal program.

7.4 Sustainable Transportation

The site is located adjacent to what will be Vancouver's newest major public transit infrastructure project, a light-rail line called the Canada Line that will connect Vancouver's airport to the city's central business district. In addition, the site is within walking distance of at least three regular bus routes. Streets and pathways are designed to encourage cycling and walking, with links to the city's system of cycling paths. In addition, most basic amenities (food & drug) will be available within walking distance of residences. 100 percent of residential parking will be in underground lots and priority spaces are designated for car-sharing vehicles. The waterfront will feature a non-motorized boating facility and connections to Vancouver's aqua-bus systems.

8. Green Marketing

The market suites at Millennium Water are being sold by North America's top condominium marketing firm, Rennie Marketing Systems (RMS). Through involvement with this project, RMS has come to see the value of green design and to recognize the growing demand for sustainable design in the marketplace. RMS devised a 'Green' version of its widely recognized logo as an endorsement of green design and the added value of sustainability. The Green logo is one way in which this project is a beacon of a larger market transformation that is taking place as consumers grow increasingly aware of how their buying decisions impact their environmental footprint. This particular development is an important vehicle for the future of sustainable building design because, largely owing to its link with the 2010 Olympic Games, Millennium Water is a high profile project, and as such, promises to garner significant media attention the world over. The new neighbourhood will demonstrate new technologies and large-scale application of sustainable design principles. It will show successes of applied sustainable design and inspire future planners and designers to adopt similar objectives at the outset of project development.

9. Conclusion

The vision for Southeast False Creek and Millennium Water required an unprecedented level of commitment to sustainable urban design for a development of such scale in Vancouver. Meeting this commitment presented a considerable challenge for the design team, one that was exaggerated by the strict deadline imposed by the timeframe of the Olympic Village exclusive use period. In order to rise to the challenge, the team had to make a concerted effort not only to meet established targets, but moreover, to approach the design process from the perspective of sustainability from the earliest stages of concept design.

Despite challenges, the integrated design process undertaken by the design team was successful and produced two notable results: established sustainability targets were achieved (and some exceeded); and team members, regardless of their level of expertise in sustainability, learned a great deal from the experience about the interplay between buildings, energy systems and the environment. Once completed, the neighbourhood will continue to be a source of learning to designers from around the world, and to the City of Vancouver and its residents, and will pave the way for future urban sustainability on a local and global scale.

DO CONSTRUCTION MANAGEMENT GRADUATE SKILLS MEET THE NEEDS OF A GREENER BUILDING INDUSTRY?

Carolyn HAYLES PhD [1]
Barbara de la HARPE PhD[2]
Ron WAKEFIELD PhD[3]

[1] School of Planning, Architecture and Civil Engineering, Queen's University, Belfast, UK, c.hayles@qub.ac.uk
[2] Design and Social Context Portfolio, RMIT University, Melbourne, Australia, barbara.delaharpe@rmit.edu.au
[3] School of Property, Construction and Project Management, RMIT University, Melbourne, Australia, ron.wakefield@rmit.edu.au

Keywords: generic skills, sustainability, employer conceptions, construction industry

Summary

Construction professionals with knowledge and understanding of sustainability and sustainable development are in increasingly high demand. This is as a result of the push to implement more environmentally sustainable management policies, practices and operations to meet current environmentally-focused legislation. It is, therefore, imperative that construction managers understand sustainability issues and adhere to increasingly stringent environmental policies. However, a study undertaken in 2001 showed that an understanding of environmental issues was near the bottom of a set of skills industry representatives thought important.

In this paper we present findings of a study aimed at establishing what priorities construction employers now place on environmental awareness and sustainability skills. We report whether an understanding and knowledge of environmental issues is considered to be more important now than previously. We explore the sustainability skills (knowledge and understanding) that graduates are expected to have, and contrast these with the expectations employers have of construction managers with 10 years or more experience. Lastly, we present employer views on the current and future trends in sustainability and the associated skills they believe that graduates will need to ensure that construction practices benefit society as a whole.

1. Introduction

The construction and building industry is an industry where employees with environmental awareness and a knowledge and understanding of sustainability and sustainable development are in increasingly high demand. This is as a result of advances and new technologies and methodologies in the industry and the push to implement more environmentally sustainable management policies, practices and operations to meet current environmentally focused legislation (Tinker & Burt, 2003); and green building accreditation schemes. Examples of such schemes include the UK's Building Research Establishment (BRE)'s Environmental assessment method (BREEAM), the Leadership in Energy and Environmental Design (LEED) in the US and Canada, and Green Star in Australia.

Construction professionals are involved in the oversight of a wide variety of construction projects. They design, engineer, coordinate and supervise the construction process from the conceptual development stage through to final construction. More specifically, construction and project managers oversee the delivery and use of materials, tools, and equipment; and the quality of construction, worker productivity, and safety. They are responsible for obtaining all necessary permits and licenses and, depending on contractual arrangements, direct or monitor compliance with building and safety codes and other regulations (Manthe & Smallwood, 2007; Smallwood, 2003). Therefore, it is imperative they understand sustainability issues and adhere to increasingly stringent environmental policies. Those who have grasped the concept of sustainability understand that human actions have complex environmental and normative consequences, in addition they display an ability to comprehend inter-relatedness; they also show an attitude of care or stewardship, and have the necessary skills to act on knowledge and feelings (Orr, 1992). Similarly, according to Strauss (1996), sustainability behavior is characterised by the motivation and knowledge to investigate and pursue courses of action that contribute to a more sustainable future. The importance of an in-depth knowledge and understanding of sustainability and building green practices has been steadily increasing over the last decade, despite this however, a study undertaken in Melbourne Australia, by Love, Haynes and Irani (2001), showed that an understanding of environmental issues was near the bottom of a set of skills industry representatives thought important for future construction managers.

In terms of generic skills, employers, professional bodies, governments and students themselves are looking for programs that develop skills relevant to employment (ACNielsen, 2000 Harvey, 2006; Hager & Holland, 2006; Precision Consulting, 2007). It is now also well accepted that universities are engaged in attempts to ensure that their graduates are equipped with the skills "… that are highly regarded by employers and are seen to contribute to the country's prosperity and social capital" (Precision Consulting, 2007, p. 1). Furthermore, lifelong learning skills are particularly important for staff ongoing professional development (Candy, Crebert & O'Leary, 1994). The literature on generic skills for the construction industry suggests that supervision and communication skills, motivation and leadership are the most sought after by industry. Research on construction manager skills by Smallwood (2003) found that working with others; integrating efforts of people and technical expertise were the most important skills for construction managers. In addition, administration, oral communication, controlling, coordinating, decision-making and leadership skills were important for all managers. In terms of graduates, Frame and Canter (2001) found that the graduate skills employers most valued were information technology, teamwork and personal and professional skills. Smallwood (2001) recommends that university programs should help students develop skills in resource management and expertise relevant to the construction industry and should "...empower graduates to improve the construction process i.e. customer service, health and safety, productivity and quality management"(p.11). However, no research has been undertaken that focuses in-depth on construction mangers' perceptions of environmental and/or sustainability skills sets of construction graduates.

Obtaining information about environmental awareness and sustainability skills is now imperative for higher education institutions dedicated to ensuring that graduates meet the needs of a greener construction industry; an industry that is now outwardly committed to sustainable development. The results of this research will be used to inform the value of what is currently being taught within Property, Construction and Project Management (PCPM) degree programmes at RMIT University in Melbourne Australia. It will assist in establishing the focus of topics that should be addressed within the curriculum to ensure that industry relevant sustainability issues are embedded within the degree programs.

In this paper we present the outcomes of a study aimed at establishing whether employer perceptions of environmental awareness skills, included in a list of 18 generic skills, have changed and specifically whether employers see environmental awareness as being more important now than 7 years ago; given the increased awareness of the need to focus on sustainable construction and building 'green'. As part of the survey a selected group of major employers were also asked to rank their perceptions of recent graduates and employees' (with 10 or more years experience) knowledge and awareness of sustainability issues. Next we outline the research methodology, discuss the findings and make suggestions about what skills are seen as important by employers to inform university curriculum development.

2. Method

A group of major construction and property employers (n=12) based in Victoria, Australia were invited to participate in a survey exploring their perceptions and expectations of the skills of graduates and employees with 10+ years experience. Respondents were sent the survey in advance by email. The survey was then conducted by telephone. The survey comprised four sections:

The first section looked at the generic skills of construction graduates and asked employers to consider both the level of importance they would attach to a number of skills using a likert scale of 1-5 and their perceptions of the current skill levels of construction graduates (see Table 1 for list of skills). This section was informed by the list of generic skills generated by Love et al. in 2001.

The second and third sections addressed sustainability skills, and asked employers to rate the importance of a number of factors for recent construction graduates (first year in industry) and then for construction employees (with 10+ years experience), using the same scale of 1 to 5. The sustainability criteria included social, economic and environmental sustainability issues relating to the building and construction industry (See Table 2 for list of sustainability skills).

Table 1 List of generic skills including environmental awareness

	Skills
1	Academic achievement
2	Accepting responsibility
3	Adaptable to changing working environment
4	Computer literacy
5	Time management
6	Exercise professional judgment
7	Practical building knowledge
8	Interpersonal
9	Leadership capability
10	Numeracy
11	Oral communication
12	Problem solving
13	Environmental awareness
14	Teamwork
15	Trust and honesty
16	Update professional knowledge
17	Work autonomously
18	Written communication

Table 2 List of sustainability-related skills

	Skills (subdivided into 5 themes)
	Management issues including corporate social responsibility
1	Drivers for sustainability within the industry
2	The importance of social impacts associated with construction
3	Awareness of stakeholders associated with a construction project
4	Communicating issues to stakeholders
5	Managing stakeholder concerns
6	Implication of mismanaging risks
7	Ethical, social & cultural requirements of diverse workforce/supply chain
	Procurement issues
8	Business case for sustainable procurement
9	Financial benefits of integrating sustainability into procurement
10	How to evidence sustainable development
11	Environmental and social risks within the supply chain
12	Risk-based approaches to sustainable supply chain management
	Water Management issues
13	Global and national water issues
14	How water impacts and affects the construction sector
15	Key legislation relating to water management on site
	Energy issues
16	Global and national impacts associated with energy use and production
17	How energy impacts and issues affect the construction sector
18	Key energy legislation
19	Managing energy on site
20	reducing energy use within the workplace
	Waste issues
21	waste management and waste minimisation
22	How waste impacts the construction sector
23	Key legislation relating to waste
24	waste management on site

The fourth part gave employers the opportunity to provide additional information by completing four open ended questions:

1. Do you want to make any comments on graduates' generic or sustainability skills?
2. What are the current trends in sustainability that you are experiencing in your industry?
3. What kinds of skills will graduates need to meet these trends?
4. What do you think will be the future trends in sustainability for your industry?

All responses were anonymous and confidentiality was guaranteed.

Eleven of the 12 employer organisations approached took part in the survey. Two of the 11 employers who agreed to be surveyed chose not to respond to the four open ended questions (Section 4 of the survey).

3. Findings

In this section we present the analysis of the quantitative and qualitative survey data.

3.1 Perceived level of importance of graduate skills

Employer perceived rankings of environmental awareness is presented in Table 3. Results highlight that the perceived importance of environmental awareness has not significantly shifted since 2001 where it was ranked 14th (Love et al, 2001).

Table 3 Perceived level of importance of graduate skills

Rank	Generic Skill
1	Trust and honesty
2	Teamwork
3	Accepting responsibility
3	Computer literacy
5	Time management
5	Exercising professional judgment
5	Interpersonal skills
5	Leadership capability
9	Numeracy
9	Oral communication
9	Problem solving
9	Written communication
13	Updating professional knowledge
14	Adaptability to changing working environment
15	Academic achievement
15	**Environmental awareness**
17	Practical building knowledge
18	Working autonomously

3.2 Perceived skills of current graduates

Employer perceived rankings of the skills of current graduates, including environmental awareness, are presented in Table 4. Results show that actual graduates' environmental skills are ranked higher (see Table 4) than their perceived importance (see Table 1 above).

Table 4 Perceived skills of current graduates

Rank	Generic Skill
1	Computer literacy
2	Trust and honesty
3	Numeracy
4	Teamwork
5	Academic achievement
6	Exercising professional judgment
6	Interpersonal skills
6	Oral communication
6	**Environmental awareness**
6	Working autonomously
11	Adaptability to changing working environment
12	Leadership capability
12	Written communication
12	Accepting responsibility
15	Time management
16	Updating professional knowledge
17	Problem solving
18	Practical building knowledge

3.3 Perceived sustainability skills of current graduates

Employer perceptions of sustainability skills of current graduates are presented in Table 5. Results show that management and waste issues are ranked highly and are the top 5 sustainability skills.

Table 5 Perceived sustainability skills of current graduates

Rank	Skills associated with sustainable construction	Theme
1	Implication of mismanaging risks	Management
2	How energy impacts and issues affect the construction sector	Energy
2	Awareness of stakeholders associated with a construction project	Management
2	Waste management and waste minimisation	Waste
5	Communicating issues to stakeholders	Management
6	Managing stakeholder concerns	Management
7	Drivers for sustainability within the industry	Management
7	How waste impacts the construction sector	Waste
7	Waste management on site	Waste
10	Key legislation relating to waste	Waste
10	How to evidence sustainable development	Procurement
10	Global and national impacts associated with energy use and production	Energy
13	Global and national water issues	Water
13	Financial benefits of integrating sustainability into procurement	Procurement
15	Ethical, social & cultural requirements of diverse workforce/supply chain	Management
15	Environmental and social risks within the supply chain	Procurement
17	Key legislation relating to water management on site	Water
18	The importance of social impacts associated with construction	Management
18	Business case for sustainable procurement	Procurement
18	Key energy legislation	Energy
18	Managing energy on site	Energy
22	Risk-based approaches to sustainable supply chain management	Procurement
22	How water impacts and affects the construction sector	Water
22	reducing energy use within the workplace	Energy

3.4 Perceived sustainability skills of employees with 10+ years experience

Employer perceptions of sustainability skills of employees with 10+ years industry experience are presented in Table 6. Again, results show that management issues in particular are highly ranked.

Table 6 Perceived sustainability skills of employees with 10+ years experience

Rank	Skills associated with sustainable construction	Theme
1	Implication of mismanaging risks	Management
2	Managing stakeholder concerns	Management
3	Awareness of stakeholders associated with a construction project	Management
3	Financial benefits of integrating sustainability into procurement	procurement
5	Communicating issues to stakeholders	Management
6	How energy impacts and issues affect the construction sector	Energy
7	Drivers for sustainability within the industry	Management
7	How to evidence sustainable development	procurement
7	Key legislation relating to waste	Waste
7	waste management on site	Waste
7	Managing energy on site	Energy
7	reducing energy use within the workplace	Energy
7	Key legislation relating to water management on site	Water
14	Risk-based approaches to sustainable supply chain management	procurement
15	Business case for sustainable procurement	procurement
15	Environmental and social risks within the supply chain	procurement
15	Waste management and waste minimisation	Waste
15	How waste impacts the construction sector	Waste
15	Key energy legislation	Energy

21	Global and national impacts associated with energy use and production	Energy
22	Ethical, social & cultural requirements of diverse workforce/supply chain	Management
23	Global and national water issues	Water
24	The importance of social impacts associated with construction	Management

3.5 Reponses to the open-ended questions

In response to the question "*Do you want to make any comments on graduates'* sustainability skills?", 5 of the 9 respondents mentioned that they believed that current graduates were more aware than previous graduates of sustainability issues, as illustrated by the following comments:

- Graduates are now more aware of the issues than the older guys…with sustainability skills, the new generation are far more aware than the past generation and this is a good thing; and
- Because it is an emerging area graduates' knowledge is better than predecessors – generally good and better than more experienced colleagues on the whole

While two respondents stated that they expected that graduates should be aware of sustainability, two were of the opinion that graduates did not require a great depth of knowledge in the area, as illustrated by the following comments:

- I would expect graduates to be GENERALLY aware of it [sustainability]; and
- Sustainability – they need only a broad understanding of it.

In response to the question *"What are the current trends in sustainability that you are experiencing in your industry?"*, the most often mentioned trend was the ecological sustainable design (ESD) requirement or green star rating (6 stars) initiative/legislation (5 instances). This was followed by general sustainability issues (4), responding to an increase in consumer demands (3), developing new ways of measuring a building's performance (1) and managing energy and waste during construction (1), as illustrated by the following comments:

- Buildings are becoming Green Star rated – 5-6 stars, and this has turned things around overnight; and
- Clients are requesting greener buildings i.e. ABGR and Green Star rated.

In response to the question *"What kinds of skills will graduates need to meet these trends?",* the skill most mentioned to meet emerging trends was for graduates to have thorough technical knowledge and expertise in sustainability, including knowledge of Australian Building Greenhouse ABGR ratings and AGBC building ratings (3); this was followed by negotiating skills (3) for example, to facilitate agreement on what constitutes innovation; and to manage trade-offs to meet minimum required ratings. Knowledge of local and overseas requirements and future trends in sustainability (2), improved understanding of operating costs lifecycle costing analysis (1), an ability to apply management skills generally and to manage others (2); as well as skills to manage the moral/ethical implications of sustainability (1) were also mentioned.

In response to the question *"What do you think will be the future trends in sustainability for your industry?",* the future trends mentioned by respondents included increased consumer demand for high quality and energy efficient greener buildings (3); more and more onerous requirements to be met, more pressure, and specialized, expertise required (2); adopting carbon neutral approaches; ensuring closer links between design, construction and operational factors; meeting the demand for retrofitting for efficiency; increased pressure on energy reduction during construction; managing environmental aspects and that sustainability will be high on the agenda of any future project.

4. Discussion and conclusions

In this section the findings presented above are used to answer a number of questions:

1. *Have priorities changed given the increased awareness of the need to focus on the environment and on building 'green'?*

The results of this current survey show that for this group of employers the answer is no. In fact the data reveals that they rank environmental awareness slightly lower than the group of employers did in 2001 (n=27).

2. *Is understanding and knowledge of environmental issues considered to be more important now than it was in 2001 and if not, why not?*

Although the results of the quantitative data suggest that this group of employers do not consider environmental awareness to be more important now than it was in 2001, the qualitative data clearly illustrates that they are highly engaged in sustainability, see as critical to the industry and are pleased that current graduates are demonstrating higher skills levels in sustainability awareness than existing employees. However one employer expressed tension in the industry surrounding sustainability and specifically leadership as suggested by the following comment: "still a lot of skeptics (about sustainability) and these people are controlling the finances….contrary to that, we are starting to see a lot of grass roots support – from below the power if you like….".

3. *Do current graduates meet the needs of the industry in terms of their current knowledge and understanding of environmental awareness?*

Both the quantitative and qualitative data show that the employers surveyed believe that current graduate demonstrated an understanding of environmental awareness. Data showed that employer perceived level of importance of environmental awareness (rank = 15) was lower than their perceptions of graduate actual demonstrated skill levels (rank = 6).

4. *Which sustainability skills do employers value in recent construction graduates (first year in industry) compared with construction employees with 10+ yrs experience?*

In both instances the management skill of understanding the implications of mismanaging risks was the most important skill for both recent construction graduates and employees with 10+ yrs experience. Other skills in common at the top end of the scale were awareness of stakeholders associated with construction projects and communicating issues to stakeholders. Where they differ is that the focus for current graduates included more operational-focused skills such as how energy impacts and issues affect the construction sector and waste management and minimisation. Whilst for those with 10+ years experience, issues were the higher-order leadership skills of managing stakeholder concerns and understanding financial benefits of integrating sustainability into procurement.

Issues surrounding the management of risk, waste, stakeholders and energy, as well as the drivers for sustainability legislation were consider core to the skills required of both graduates and employees.

5. *In light of the above findings, what implications do these perceptions of employers have for curriculum development of university construction management programmes?*

The findings from the study reported in this paper reinforce that we cannot ignore the importance and growth of sustainability and sustainable development within the construction sector (Tinkler and Burt 2004). It is imperative that university programmes respond to employer perceptions and continue to ensure that students graduate with requisite sustainability knowledge and skills. Given the importance placed on the design stage for embedding sustainability by employers as demonstrated by the qualitative results of this study, this requires opportunities for students to work in interdisciplinary teams with architects, planners and engineers, where they "embrace the concept of sustainability as a process; one which starts well before construction (in the planning and design stages) and continues long after the construction team have left the site: a process that takes in the design, construction and on-going maintenance of what is being referred to as a 'green' building" (Hayles and Holdsworth, 2005, p 2). In this way built environment students from every discipline can gain an understanding of the different roles other disciplines play in the process and consequently, are educated with a 'whole building' mentality.

There is also a need to ensure that the moral and ethical drivers for sustainability are understood by built environment students, as highlighted by one of the employers surveyed who stated that "[g]raduates have to know the drivers of sustainability and have to know the legislation and [that] there is a moral side to it as well".

In conclusion, this paper shows that whilst employees may not be attaching the level of importance to environmental awareness that we would like see, their comments suggest that sustainability as a whole is high on their agenda and has permeated the everyday life of construction professionals. It is now up to universities, with regard to environmental awareness and sustainability, to continue to educate graduates who exceed the expectations of employers and who become industry leaders implementing sustainable approaches to construction that have yet to be imagined.

Acknowledgment: We would especially like to thank James Harley for the work he did gathering the data.

SUSTAINABILITY AND THE STRUGGLE FOR HEGEMONY IN AUSTRALIAN ARCHITECTURAL EDUCATION

Dr. Peter M. Graham

Architecture Program, The University of New South Wales, Sydney Australia

Keywords: architectural education, sustainable design education, ideology, hegemony, curriculum reform

Summary

This paper describes the outcomes of PhD research into ideological barriers to the implementation of sustainable design curricula in Australian architectural education. More specifically I describe ideological positions within the contested fields of architectural education and sustainable development and explain the dimensions of ideological resistance manifest in the values (ethos), structure (eidos) and implementation (praxis) of Australian architectural curricula.

The research has identified strategies of hegemonic struggle which affect the relative dominance of ideologies in Australian architectural education and the positioning of sustainable design curricula within this contested field. I have found that sustainable design curricula are currently marginalised in Australian architecture courses and that this marginalisation has been historically constructed. I have also exposed hegemonic strategies that reproduce such marginalisation within curricula.

1. Introduction

The discipline of architecture has a long history of engagement with environmental issues and environmentalism. Recently there has been rhetorical support from professional organisations for the broader sustainability agenda (eg UIA, 1993; RAIA, 2005; RIBA 2006). Despite this, it appears that architectural education has been slow to integrate the concept of design for sustainability, rather perpetuating the view of sustainable design as being for architecture (Fletcher & Dewbury, 2002). The latter position reinforces the hegemony of professional ideologies of architecture and the vocational intent of architectural education rather than challenging the status quo and educating architects to change the profession so it can better contribute to the ideals of sustainable development Influential advocates of education *for* sustainability suggests that most formal education teaches us how to be unsustainable (Milbrath, 1989; Orr, 1994; Huckle and Sterling, 1996; Sterling, 2001; Fien, 2003; Thomas, 2004; Tilbury & Wortman, 2004; UNESCO, 2005). Can this criticism be levelled at architectural education? Are the dominant ideologies shaping curricula in our architecture schools teaching only how to better replicate an unsustainable status quo? Are the ideologies which have been dominant in shaping architectural curricula at odds with the ideologies of sustainability education? If so how can knowledge of ideology inform curricula reform?

1.1 The Problem of Ideology in Sustainable Design Education

To affect curriculum change it is necessary not only to have a design for a desired state, but also to gain the power to implement it. This assumption demands both an understanding of the power relations that support the status quo and an acceptance of curriculum development as a process of ideological struggle. Hence, efforts to reform architectural education need to be informed by an understanding of the hegemonic struggles which shape architectural curricula. To understand resistance to such reform we must go beyond identifying the problem of integration, and look more closely at the problem of how to gain the power to influence change.

Existing research in the field of sustainable design education has not focussed on such issues. Research in the fields of sustainability education and sustainable design education has commonly stated this problem in terms of integration i.e. how can sustainability be fully integrated into curricula? Conclusions of such Investigations have often identified ideological conflict as a potential barrier to integration, but have left it uninvestigated (Alabaster & Blair, 1996; Thomas *et al*., 1999). Contemporary international studies have not considered curricula as manifestations of a history of ideological struggle (Fletcher & Dewbury, 2002; Fowels *et al*, 2003; Wright, 2003; McDonald, 2004;). Nor have detailed studies of sustainable design education in schools of architecture been conducted in Australia.

This paper presents a summary of the findings of PhD research which has addressed these knowledge gaps by investigating such issues through a critical history of ideas within the contested fields of architectural education and sustainable development. It summarises ideological positions within discourses related to these fields in order to explain documented resistance to the integration of sustainable design curricula in architectural education in Australia.

Using critical discourse analysis I have tested the hypothesis that dominant ideologies shaping architectural education in Australia prohibit rather than support the sustainability agenda. The outcomes of the discourse, content and analyses of curricula support this hypothesis. The following section briefly explains the methodology adopted for this research. The findings which support this conclusion are then presented.

2. Research Methodology

This study focussed on the influence of concepts of ‘sustainability’ and ‘sustainable design’ on discourses in architectural education in general and Australian architectural curricula in particular. The intention of this research was to better understand the power relations and strategies that lead to the dominance and subordination of certain ideas in architectural curricula. Developing an adequate method for investigating ideology in discourse was approached by first addressing the fundamental questions; What is ideology?; How can ideology be identified in architectural education?; and How can ideology in architectural education be understood?

I adopt the view that ideologies are lived systems of values which have a material existence in the practices of institutions (Heywood, 1992). I also consider ideologies to be tacit theories and ideas that shape the language, actions and values that exist within a discourse (Gee, 1990). According to these definitions, identifying ideologies can help explain the unconscious acts and conscious social practices of people and institutions (Marshall, 2000). More specifically, studying ideologies can explain the establishment, maintenance and dynamics of the social relations of power, domination and exploitation within a field as well as forms of resistance and conflict (Foucault, 1984; Fairclogh, 2003).

In summary ideology is subconscious systems of belief which are manifest in the discursive practices of institutions. Because people’s ideology is ‘sub-conscious’, interview and survey methods were not deemed the most appropriate methodology for investigating the dynamics of ideology. Changes in discourse are a more reliable indicator of hegemonic struggle than people’s opinions, particularly over long periods (the total period under consideration in my thesis covered more than 2000 years of ideas in architectural education).

Historical and contemporary analyses of such practices were conducted using a synthesis of the concepts of ‘field’ (Bourdieu, 1985) and ‘discourse’ (Fairclough, 2003; Gee, 1990; Foucault, 1984). A historical discourse analysis (Weiss and Wodak, 2003) was conducted of the handbook descriptions of architectural courses in Sydney over the last thirty years, in addition to a contemporary discourse analysis of courses offered in 2007 by all Australian schools of architecture. This analysis was supported by curriculum mapping to reveal the power relations inherent in architectural curricula. Summarised ideological positions were then presented as ‘story-lines’ and organised in relation to ideological indicators for curricula, namely ethos (values), eidos (structure) and praxis (valid knowledge).

This research method was used to investigate the following questions.

1. Why would sustainable design education be marginalized?
2. What strategies are used to marginalize or promote particular ideals in architectural education?
3. Is sustainable design education marginalized in Australian architectural curricula?
    - If so, how?

The following sections summarise my answers to these questions by relating the influence of the ethos, eidos and praxis of architectural education both historically and contemporarily.

3. Why would sustainable design education be marginalized?

A history of ideas about architectural education shows that concern for nature, materials, comfort and durability have been omnipresent and have from time to time not only been performance parameters for architectural design, but also for the social causes for architecture. Sustainable design is a recent phrase which has come to be associated with concern for reducing the environmental impact of buildings as well as architectural engagement with sustainable development discourses. However, many of the issues associated with the sustainable design agenda, such as climate-responsive design, efficient use of materials and human comfort have been traditional issues for architectural design. In addition, there is widespread rhetorical support for engagement with ‘sustainability’ agendas amongst architecture’s professional organizations. The first question for my research was therefore why would sustainable design education be marginalized? The answer is that there are a number of key differences in ethos, eidos and praxis between traditional architectural concerns and the sustainability agenda.

3.1 Conflicts in Ethos

The sustainable development agenda is not a unified agenda. Contradictory views on development such as ‘no-growth’, ‘pro-growth’ and ‘ecological’ exist within discourses on ‘sustainability’. This has led to perspectives of ‘sustainable development’ as a failed concept (Adams, 2006). These contested ideals within sustainability discourses make it a difficult agenda to implement in the reform of curricula.

Advocates of sustainable development, such as the United Nations, promote a neo-liberal agenda which represents an entrenchment of growth-based economics regarded by many as ecologically unsustainable. Therefore the U.N. agenda of education *for* sustainable development (EfSD) can be hard to distinguish in intent from standard systems of education. This may contribute to the perception of some architectural educators that architectural education already *is* an education for sustainable development. After all, both the United Nations EfSD and 'professional' architectural education are premised on the sustenance of our current economic paradigm. The *change* agendas promoted by 'sustainability' or 'sustainable design' educators may be marginalized by their own lack of definition and therefore their lack of distinction from current practice.

Other grounds for marginalization can be found in the comparison of ideals of architectural education which are fundamental to the civic intentions of sustainable design education. The recurring intent of architectural education is reinforcing the definition of architecture as a discipline which is largely concerned with its spatial-aesthetic agency and of the architect as individual designer. The major problematic for architectural education appears to be learning how to design buildings with meaningful space, form and expression. This is ostensibly framed as vocational education.

The main problematic for sustainable design education on the other hand is to learn how architectural design can facilitate socio-ecological well-being. The main social agency of sustainable design is contributing to the sustenance of socio-ecological systems over time. This requires learning design in terms of civil action, rather than merely a vocation. Further, to this is more expansively engendering the idea that the vocation of education itself is a form of civil action. The emphasis of the sustainable design agenda is not on the individual designer or the embodiment of social ideals in an objectified building. Rather, the focus is on the collective or interdisciplinary *process* of enabling 'building' (both noun and verb) to sustain the natural and social systems with which it is interdependent. 'Sustainability' is therefore an emergent quality which is not immediately aesthetically experienced. The dominance of the ethical-aesthetic value orientation in relation to that of 'sustainability' in contemporary Australian architectural course descriptions is emblematic of these tensions.

Another tension arises because issues of ecological sustainability are also not necessarily immediate to the location of a building but range from local to global. Impacts may also be distant in time, indirectly related to the actual building, and more strongly associated with the supply chain that supported its creation, operation and eventual demolition or reuse. Architectural curricula on the other hand are focused on understanding the impact a building design might have on its immediate surroundings once it is built. The sustainable design agenda seeks to foster global-local '*glocal'* (AIJ, 2005)' life-cycle awareness whereas architectural education traditionally focuses on local impacts of the building once it is built. Students may well learn how to conduct a shadow analysis and to configure a building to its local climate, but rarely learn what sort of building design might contribute to the well-being of a bioregion or water catchment (which may be in other countries and may for example be affected by material manufacturing).

This difference in the physical and temporal scope of consideration is perhaps exacerbated by the shift away from science as the theoretical basis for architecture. This is evident in my analysis of Sydney Schools from 1977 to 2007. Social sciences and systems-sciences such as ecology were influential in non design subjects and prerequisite for design subjects in two of the three Sydney Schools until 1997. However between 1997 and 2007 these knowledges have become structurally disconnected from design subjects. A lack of scientific theory disables student's ability to develop qualities of mind such as ecological literacy which is argued to be fundamental to 'sustainability' education.

In contrast to the sustainable design agenda, the promotion of individualism is evident in the history of ideas that have shaped architectural education. Individualism also finds expression in contemporary architectural education with progression in design subjects almost exclusively culminating in the individual major design project. This is at odds with the perception of the need for interdisciplinary and collective cooperation when dealing with complex 'sustainability' issues. Professional ethics are intended to guide the social conduct of individual architects in these matters. However architectural curricula in Australia do not have a strong history of providing praxis for developing the ethical capabilities required for design collaboration.

There have been times in the past thirty years when design has been described more as a means of social change. However I have found that design education in Australia is predominantly positioned *for* architecture – as a means of reproducing the symbolic field, its precedent ideals and professional niches. Sustainable design education is also *for* architecture but only in so far as the influence of fields of knowledge such as ecology provides opportunities for innovating design methodologies. Sustainable design is more concerned with how architecture can change in order to be a *means of* influencing socio-ecological sustenance and wellbeing. Rather than being primarily *for* architecture this agenda considers design as positioned *for* 'sustainability'. While there is no doubt that sustainability discourses have infiltrated discourses on architectural education, the findings described above establish grounds for conflicts between the dominant ethos in architectural and sustainability agendas respectively. These are summarized in Table 2.

Architectural Education	Sustainable Design Education
The main *problems* for architectural education are creating meaningful space, form and expression and Vocational training;	The main *problems* for sustainable design education are of socio-ecological well-being and Civic action-competence;
The main social *agency* of architectural design is aesthetics;	The main social *agency* of sustainable design is innovation in socio-ecological systems;
Its impacts are considered locally;	Its impacts are considered 'Glocally' and temporally;
Its theory is increasingly based in arts rather than sciences;	Its theory is currently based in sciences rather than arts;
Its over-arching goal is *sustaining* the role of the profession	Its over-arching goal is *changing* the role of the profession

Table 1: Conflicting ethos in architectural and sustainable design education.

The 'ecological' paradigm calls to attention the need to accept change as our survival strategy. Adopting this perspective has the potential to be incredibly empowering for architectural design education because 'design' *is an intention to change.* What to change, for whom, when and how are the ethical questions that, if applied to the ethos of architectural education, would position design as being *for* social and ecological change. Learning to be an agent of change would therefore be *implicit* in design education. The main intention of architectural education is however, to sustain rather than to *change* the profession.

3.2 Conflicting Eidos

The organization of architectural education in Australia reflects its predominant ethos as an education *for* architecture rather than in architecture as a means of survival. Discourse analysis of course handbooks shows courses have overwhelmingly described their disciplinary focus and their professional accreditations. Advocates of sustainable design argue that interdisciplinary curriculum should be fundamental to an education *for* sustainability. However, despite many courses being offered within multi-disciplinary faculties, most design subjects are organized as discipline-specific studios.

Other differences in eidos exist. The sustainable design agenda favors education *as* sustainability, which requires learning through identifying and designing out 'unsustainable' conditions (Table 2 next page). This in turn requires a curriculum that engages with 'real-world' situations and takes advantage of 'service-learning' through community engagement. While it has been observed that structuring curricula around studio design problems provides the capacity for architectural education to be education *as* sustainability, it is evident that studios are neither the major vehicle for engagement with sustainability agendas nor do they provide '*as sustainability'* pedagogy. Instead 'sustainable' design objectives are most commonly taught as an education *about* sustainability i.e. removed from the problem context and delivered in lecture-based subjects. Other aspects of the '*as'* sustainability eidos which are not evident in course or subject descriptions are the use of university campuses and buildings, and their surroundings as '*sustainability*' learning sites, nor are the basis for core design studio projects the adaptive the reuse of buildings. Design studios currently almost always assume a new building.

Architectural Programs must decide that 'sustainability' is a core conviction and therefore, a principle reason *for* the education offered in order to align the eidos of their education with the sustainability education agenda. The commitment of all the staff and students to the exploration of the issues of sustainability in core streams of study is required so a curriculum model for sustainable education can be developed. It will be important to be mindful of both the *process* and *context* of learning and the need for continually evolving content.

3.3 Conflicting Praxis

Synergies exist between architectural and sustainable design in the small-group and progressive assessment within a studio environment. Architectural education and sustainability education share a concern for life-long learning. Discourses in architectural education often make reference to the perception of architecture as a life long pursuit. This perception has also been formalized by requirements for continuing professional development. However, there are differences in terms of transmissive versus transformative teaching styles. This area of conflict is associated with which types of knowledge are enabled by *praxis* (action-reflection-learning) cycles, and also the extent to which 'learner centered' approaches empower students in developing self-knowledge.

Education about sustainability typically introduces content and knowledge about sustainability issues. This approach allows sustainability to be taught through principles, rules, or laws in special courses within a program and does not require any change to standard curriculum models. ***Education for sustainability*** emphasises learning for change. This approach includes learning about social values, critical analysis to identify areas of contemporary practice that require reform, and developing capabilities to affect the reforms. This type of curriculum is predicated on the conviction that aspects of current practice are not sustainable and need changing. It focuses on how to facilitate change without requesting personal change toward sustainable practice from either students or the teaching program. ***Education as sustainability*** emphasises learning as change. In this model the process of actually trying to cease unsustainability and live sustainably becomes the learning activity, and as a result the class-room, the studio, the administration, the campus, the practice, the professional organisations etc should become contributors to sustainable development.

Table 2: Distinctions between EfS curriculum models. (Sterling, 2001)

International research has indeed recorded instances where such conflicts of interest have become manifest in a perceived marginalization of sustainable design curricula. However, the lack of investigation into how such marginalization actually occurs led me to the question, which strategies are used to marginalize or promote particular ideals in architectural education? My answers to this question are now presented.

4. What strategies are used to marginalize or promote particular ideals?

Curricula development is an ideological process involving hegemonic struggle. As such, various strategies are employed to promote and empower certain ideals and forms of knowledge, while diminishing and disempowering others. Through analysis of changes in the interrelated ethos, eidos and praxis of Sydney architecture schools over the last thirty years, and the curriculum mapping and content analysis of contemporary Australian architectural curriculum, I have identified six major hegemonic strategies (Table 3).

Ethos:	– Universalising traditional architectural strategies as ‘sustainable design’ strategies; – Framing ‘sustainability’ concerns in the context of architectural design;
Eidos	– Protecting core subjects by liberalising elective subjects; – Decoupling progression in design from progression in non-design subjects; – Preferential weighting of units of credit;
Praxis:	– Offering ‘stand alone’ subjects without praxis

Table 3: The major hegemonic strategies observed in Australian architectural education.

Over time, the analysis of Sydney architecture schools shows that these strategies have both promoted and discouraged sustainable design education. Identifying these strategies helps to explain changes in the power-relations of different elements of curricula, and provides criteria for investigating the hegemony of ideologies in curricula at a given time. The current position of sustainable design curricula in Australian architecture courses is thus a manifestation of the historic implementation of such strategies. But does this mean that sustainable design education is currently marginalised in Australian architectural curricula? This last research questions was addressed by critically analysing the ethos, eidos and praxis of architecture schools in Australia.

5. Is sustainable design curricula marginalized?

My historical discourse analysis of the fields of sustainability and architectural education has identified grounds for ideological conflict. The review of curriculum changes in Sydney Schools and the contemporary review of Australian architectural curriculum have identified strategies for promoting or subordinating particular ideals. With these insights I have analysed the position of sustainable design in contemporary Australian architectural curricula. I conclude that sustainable design education does indeed currently appear marginalised as a result of the persistence of conflicting ideologies whose dominance is supported by the presence of disempowering hegemonic strategies. I conclude that the sustainable design agenda is currently marginalised by the dominant ethos, eidos and praxis of Australian architectural curricula.

5.1 Marginalised by Ethos

The sustainable design agenda is marginalised by the dominant *ethos* of architectural curricula. Content analysis of handbooks, course descriptions and design subject descriptions shows their explicit and implicit values to be oriented towards ethical and aesthetic concerns rather than concern for sustainable design. The ethical concerns were associated mainly with professional responsibilities to clients, building occupants, the built environment, as well as reflecting social and cultural values. Aesthetic values were associated with such issues as the form, order, space, and tectonics.

Functional aspects of building design and its impact on built environments were also prevalent values. Sustainable design values were among the least prevalent value positions expressed in Program and Course documentation. Where sustainability values were expressed they were positioned as in service to architectural design, rather than as a cause for architectural design.

5.2 Marginalised by Eidos

The predominant structure and organisation of Australian architectural curricula also marginalises those of sustainable design. Sustainable design concerns represent on average, 12% of the total units of credit required for architectural studies. Of these 'sustainability credits', most are allocated to technology related subjects (22%) rather than design studios. Sustainable design also becomes less prevalent as a proportion of units of credit allocated in the last two years of most architectural courses. The average allocation is 14% for the first three years of study and 10% for the final two years of study. These final years are typically the 'professional degree' courses, which gives the impression that sustainable design diminishes in importance as design education becomes more professionally oriented.

By far the most common place for explicit engagement with sustainable design is in elective rather than core subjects (Figure 2). On average 51% of elective stream subjects dealt with aspects of sustainable design. Studio based teaching has been regarded as the main pedagogical vehicle for introducing students to the core values of architecture. The absence of sustainable design from design subjects, and from core subjects in general is therefore likely to contribute to a hidden curriculum which further diminishes the perceived architectural value of such knowledge.

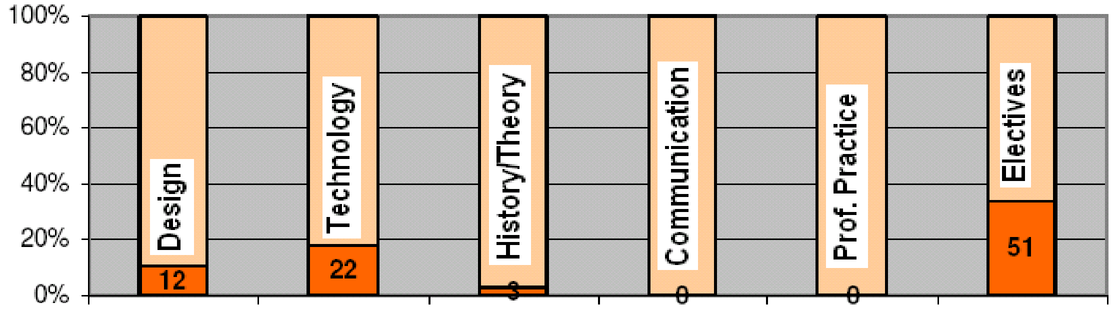

Figure Two: The average % of stream UOC engaged with aspects of sustainable design in Australian architecture programs in 2007.

Sustainable design knowledge is generally not a prerequisite for progression in design subjects. Fifteen of the sixteen architecture schools analysed did not require non-design subjects to have been passed in order to progress in design subjects. This marginalises sustainable design agendas because most of this content is currently presented in non-design subjects. In addition, most courses are not organised in ways that enable progressive reinforcement of sustainable design knowledge. Most courses provide stand alone 'sustainable design' subjects in either design or non-design streams. This represents an *'about* sustainability' approach, which is the least progressive mode of sustainability education.

5.3 Marginalised by Praxis

Praxis is related to pedagogy and the kind of knowledge that is promoted as valid in curricula. Proponents of sustainability education argue that responding to situations of unsustainability is primarily an ethical responsibility. Education should therefore develop ethics that accord with a sustainability agenda, and empower students as citizens who are able to apply their specialised knowledge for social and community benefit. Curricula that facilitate students developing self-knowledge and an image of self as a 'sustainable designer' are therefore necessary. The capacity for contemporary architectural curricula to enable this praxis is already marginalised by the dominant orientations of ethos, and structural limitations of eidos. However, it is further marginalised by the kind of knowledge presented in sustainable design subjects themselves.

A review of the learning objectives of sustainable design-related subjects shows that most subjects aim to impart instrumental knowledge rather than develop self-knowledge. Instrumental knowledge represented approximately 66%, while the development of self-knowledge represented only 34% of 'sustainable design' learning objectives respectively (Figure 3). This creates a bias toward transmissive rather than transformative forms of teaching and learning. Sustainable design learning is therefore not only marginalised by a lack of praxis across the total curriculum, but also from within subjects intended as its primary vehicles.

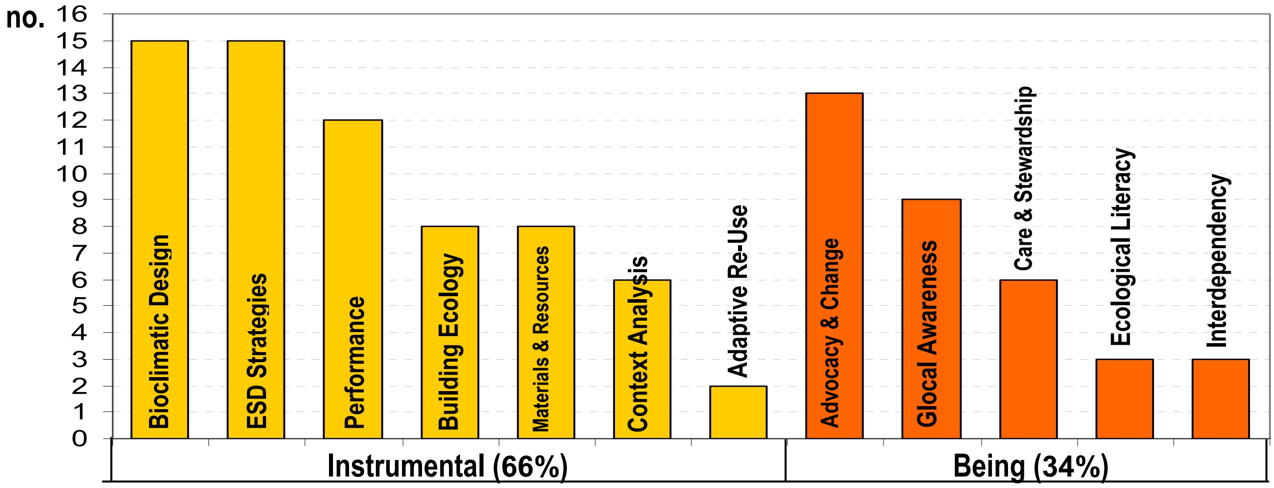

Figure Three: Proportion and incidence of knowledge types in 'sustainability' learning objectives.

Over the past thirty years, changes in curricula ethos, eidos and praxis indicate a drift away from science and towards arts as a fundamental epistemology of architecture in Sydney schools of architecture. Due to the scope of my historical analysis I can not be definitive about whether this drift is evident in other Australian architecture schools. However, I have observed an emphasis on 'design fundamentals' and less emphasis on architectural, environmental and social sciences in contemporary Australian architectural curricula. Because 'sustainable design' is predominantly framed in terms of science and technology, science based epistemologies are essential to theory building. The current bias toward arts based epistemologies therefore aids the marginalisation of sustainable design praxis as it is most commonly defined.

Some schools are beginning to broaden the definition of sustainable design as not only scientific and technical but also as cultural and historical. While these subjects provide new grounds for architectural engagement with sustainability issues, scientific methods are still the predominant ways in which western society analyses and understands our physical relationships with, and effects on the planet. Empowering students in architectural methodologies such as ecologically sustainable design therefore requires *at least* that they learn enough architectural science to be able to communicate with people whose disciplinary focus is scientific. Proponents of sustainable design would call this aspiration the need to develop basic ecological literacy. This learning objective is however, poorly supported by current architectural curricula.

6. Conclusions

These findings describe conflicts of ethos, eidos and praxis between architectural and sustainability education in Australia's schools of architecture. The current marginalisation of sustainable design curriculum is a manifestation of historical and on-going hegemonic struggle between the competing ideals of architecture and sustainability. Furthermore, the dominance of particular ideals is continually influenced by hegemonic strategies which manipulate course ethos, eidos and praxis. I therefore conclude that my hypothesis; *that dominant ideologies shaping architectural education in Australia prohibit, rather than support the sustainability agenda* – is a true interpretation of the current situation.

In the past thirty years awareness and concern for changes in the earth's biocapacity have increased, as have rates of urbanisation. Consequentially so has awareness of building as an influence on social and environmental change.

Despite this, Australian architectural education has remained remarkably unchanged in ethos, eidos and praxis. Emblematic of this stasis is the observation that even learning objectives for sustainable design subjects do not represent a progressive engagement with their own field. *Not only* are most learning objectives constructed instrumentally, but also many represent universalisations of traditional concerns in architectural science such as bio-climatic design, thermal performance and the efficient and appropriate use of materials. Traditional knowledge of how building designs might change in response to climate need to be coupled with for example, new knowledges of how building designs have contributed to climate change and how the human habitat can be designed to adapt to such change.

Even though sustainable development is a contested concept, its various discourses represent *the only major global socio-economic reform agenda.* Indeed, sustainable development is the only truly global conversation on ecological interdependency and social equity in human history. Yet our engagement with 'sustainability' in Australian architectural education continues to be marginalised by ideas which are in some cases at least 2000 years old. Sustainable design education is simply not a core conviction for the majority of our architecture schools.

7. Recommendations

Architectural educators have a responsibility to create curricula that fulfil both the civic and vocational roles of university education and have far more freedom than practitioners to choose their emphasis. History has shown that it is possible to develop curricula which intend to simultaneously be *for* architecture and *for* progressive social change. What is required of educators is *intent*.

A practical first step is to ensure that passing non-design subjects in which sustainable design is currently taught are prerequisite for progression in studio-design streams. A second practical step is to restructure curricula so as to offer '*as* sustainability' education in which sustainable design studios are the core vehicle for investigating and designing out 'unsustainabilities'. In the process students must demonstrate the instrumental knowledge taught in non-design subjects. Thirdly, studio projects should try to foster long term community engagement and implement a continual experiment in rethinking the physical settings for teaching and learning. Students should gain experience in eliminating unsutainabilities in existing buildings, not only the new. Assessment should be informed by monitoring and reflecting on potential and actual contributions to the health of the biosphere and the equity of society.

Taking these first steps would begin to align the *ethos*, *eidos* and *praxis* of architectural studies with the sustainability agenda. And also show students through the tacit experience of their learning, that '*being'* an architect involves being foremost an agent of social change, rather than only perpetuating a image of a design professional who has 'sustainability' as a skill set.

Educators should be mindful that instituting such change is not only a matter of planning integrated curricula. Reform is an ideological struggle. Therefore hegemonic strategies which have historically maringinalised sustainable design such as weighting credit-points, controlling pre-requisites for progression through design subjects, providing or denying reinforcement of certain knowledges, re-naming rather than reforming subjects to universalise or contextualise concepts as 'for' architecture, and protecting the biases of the 'core' course by liberalising elective streams, could also prove effective in its promotion.

The implication of architectural educators failing to engage effectively in the sustainability discourse is that their students will themselves eventually be marginalised. This is because other professions are becoming educated in ways which make useful, meaningful and influential contributions to the sustainability issues facing humanity. I hope that comprehending the limitations of ideology and hegemony in architectural education identified by this research will encourage and assist architectural academics to design appropriate curricula for change. After all, design is our best method of using change as a survival strategy.

Keywords: Environmental Issues, Transition and movement, Perception, Architectural community

Summary

Since the 1990's, environmental issues have been key issues. The general public and architectural community is increasingly concerned those issues year by year, so major movement of environmental strategies and developments have been conducted in the architectural community in Japan. An awareness and perception on environmental issues are expected to be changing in both architectural community and general public. But it is uncertain which direction we are moving to and how much progress we have achieved so far. It will be useful if there is some monitoring and guiding system that will suggest and show the direction and progress on environmental strategies in the building sector.

Reviewing the movement and transitions relating to environmental strategies, especially assessment tools in the architectural community are useful to consider a future trend and direction. It is also important to identify what is a character of the movement, what is being improved and what is a key driver of improvement.

The purpose of this study is to determine progress of building performance relating to assessment tools based on real data, key movements, opinion of key actors in the architectural community, and to provide primary information that supports to consider a future direction and strategies to the architectural community in Japan.

The real data survey covered specific events, environmental statistics data of buildings, leading edge buildings and those applied techniques. The human perception survey covered a series of questionnaires on environmental issues and building performance. The questionnaire surveys were implemented three times in the architectural community in Japan, in 2000, 2004 and 2007 to measure a change of human perception among several years interval.

1. Introduction and Methods

Several surveys have been conducted about real data and human perceptions on environmental issues in the architectural community in Japan. The questionnaire surveys were conducted three times to measure the change in human perception during a few year intervals. The first survey was conducted in 2000 and the second survey was conducted five years later in 2004, and third one in 2007 using the same questionnaire items. Respondents of these surveys were Japanese local governments, building design and engineering firms, construction companies and utilities companies. About 60 to 150 people responded to the questionnaires.

Some of questionnaires contained both current issues and future estimates in order to know future expectations on environmental and building issues.

2.Real data survey

2.1 The trends of specific events and energy consumption

2.1.1 General events and buildings

Fig.1 shows the transition of major events, policies and laws, current expressions, and key words that relate to environment and buildings in Japan from 1970 to the present day. It can be divided into four specific periods based on the social situation as follows:

1955 to 1973: General trend: rapid economical growth period
Building: pollution issues, smog, wind harm, sunlight shading
Large and tall buildings were designed and constructed. Most of them were designed to be mechanically controlled buildings for example; skyscrapers in Tokyo.

1974 to 1988: General trend: period of stable growth,
Building: limitation of resources and chasing improvement efficiency
Energy is one of the critical issues for building design, for example; super energy conservation buildings, passive solar houses.

1989 to 1994: General trend: bubble economy and the collapse of the bubble economy

Building: chasing technological limitation, realization of global environmental issues, for example; Hyper building projects which are over 1000m -3000m height were proposed and Environmental symbiosis houses.

1995- today: General trend: Collapse of the reliance on technological and social systems,
Building: practice and implement of environmental strategies, for example; Natural conditioned buildings, CASBEE assessed buildings.

It is difficult to draw a clear connection between the social situation and building design. However, some buildings indicate that social events influenced the building concept and design, such as energy conservation building around the period of the oil crisis, hyper building projects around the period of the bubble economy, and natural conditioning buildings after Kyoto summit.

2.1.2 Environmental strategies of the Government and Architecture Community

Since the late 1990s, a series of specific events have occurred in both policy and architectural strategies. Some important laws were launched by the government, and an agenda, proposal, and charter relating to the environment and buildings were established by the architectural community. There is a clear transition in both society and the architectural community toward environmental concern.

However, it is still not known whether environmental performance has improved along with strategies.

A more subjective analysis is needed in order to show the social transition and suggest a rough overall trend.

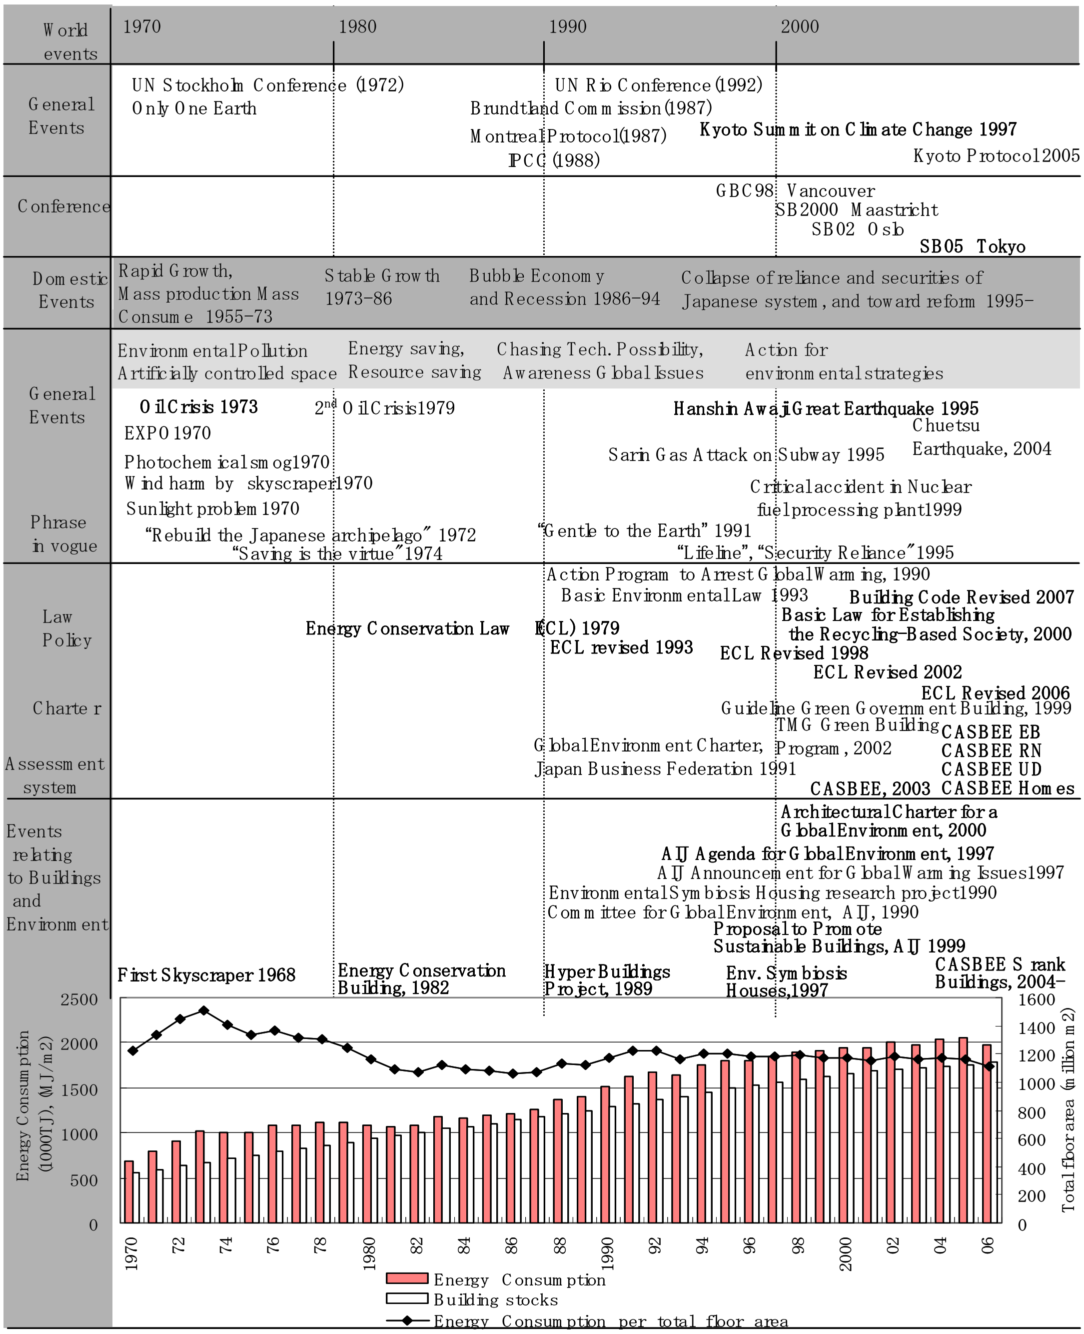

Fig.1.1 Trends of specific events relating to buildings and environment and energy consumption
Energy and building stock data , source: EDMC 2007

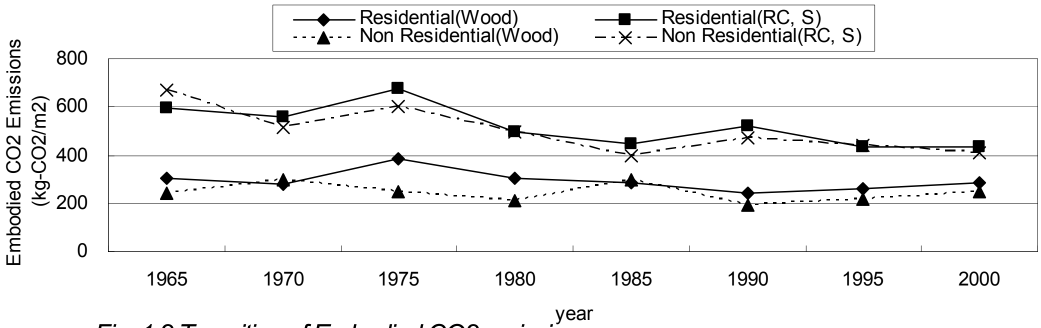

Fig. 1.2 Transition of Embodied CO2 emissions,
Source. Y.Kawazu, Ph.D Thesis, Utsunomiya University,.2008

2.1.3 Stock and energy consumptions

Fig. 1.1 shows the transition of building stocks and operating energy consumption of non-residential buildings, and energy consumption per total floor area. The peak of the energy consumptions was around 1973, and after the oil crisis it began to decrease year by year until it stabilized in the present day.

On the other hand, the trend of energy consumption of buildings as a whole has been increasing year by year and it suggests that energy consumption of buildings has started to decrease around 2006.

Several reasons are considered for this situation. Building stocks and building floor area per person have been increasing and building operating hours of each building have been becoming longer and longer. These trends suggest that there is a gap between the strategies of energy conservation in buildings and the real situation in society.

Fig.1.2 shows that the transition of embodied CO2 emissions of buildings and houses using Input and Output analysis based on I/O tables from 1965 to 2000 in Japan. It suggests that embodied energy and CO2 of RC and S structured buildings improved about 30 % during 35 years. Most of these improvements are brought by industrial sectors that improved efficiency of building material productions and building component productions.

A survey of several environmental data was required, and energy consumption and building stock data were selected to understand the progress in reality. Data availability was also considered. Other data related to environmental issues is difficult to collect or to use to survey the current situation.

2.2 A transition of design strategies and performance of cutting edge Buildings

Several cutting edge buildings were reviewed in order to understand the trend of environmental design strategies. These buildings were selected as case study buildings for the series of events of the Green Building Challenge in 1998, 2000, and 2002. Those were considered the cutting edge buildings in Japan in those days. The design concepts, environmental design strategies and environmental performance of these buildings were reviewed to understand the trend of environmental strategies and their environmental performance.

Table 1 Average performance and introduced design items of Japanese case study buildings

	98		2000		2002	
	Performance score	Desitng items	Performance score	Desitng items	Performance score	Desitng items
Resource Consumption	2.46	10	1.76	11	2.3	9
Environmental Loadings	2.23	3	1.90	3	2.3	2
Indoor Environmental Quality	3.43	4	2.57	4	2.0	3
Longevity,Quality of Service,Service Qu	2.56	2	2.70	3	2.7	2
	98		2000		2002	
actual annual operating energy consumption (GJ/m²/yr)	1.3		1.9		2.3	
actual annual emission related to consumption CO2 (kg/m²/yr)	53.4		93.5		111.2	

Table 1 show that the number of design items, environmental performance score based GBTool, and energy consumption of the case study buildings. The trend shows that energy consumption and CO2 emission per total floor area clearly increased year by year. According to design strategies and the average performance score of "Resource Consumption", energy performance of case study buildings should have improved compared to previous GBC projects.

Despite design strategies and better performance scores, energy consumption of case study buildings has not improved. There are several reasons to explain this situation. It is supposed that operating hours, occupancy and office equipments of office buildings has been changed year by year and these factors affect energy consumption and CO2 emissions trend/. This suggests that it is very important to establish benchmark value and reference building performance based on building types and its detailed conditions.

3. Human Perception Survey

3.1 Methods and questionnaires

The questionnaire survey was conducted to know the human perception on building environmental issues within the architectural community in Japan. The respondents were people in local government, design firms, construction companies, utility companies, etc. It was distributed to 250 people, and answers were obtained from a total of 149 people in 2004, and survey was implemented through Internet by using a web-based questionnaires in 2007. The respondent of the survey in 2007 were 75. This is smaller number of respondent than it was expected. There were technical issues that were accessibility of the system and user friendliness of inputting data on the web-site.

This questionnaire survey prepared several sets of questions that related to the current situation and the near future in order to measure the change and transition. There was also contained another set of questions that were part of questionnaire survey conducted in 2000 and in 2004 in order to measure a change and transition during a few years period from 2000 to 2004 and 2004 to 2007.

The questionnaire survey covered several questions shown in Table 2. Some of questions asked are about the present and future situation and it is expected that the same type of survey will be conducted five or ten years from now. It is expected that this survey would support to compare the differences of perception between past and present, and discuss the future trend.

3.2 Overall issues

3.2.1 Influential Events

Table 3 shows the ranking of most influential events for respondents which relating environmental issues. "Kyoto summit on Climate Change" was ranked first by respondents in 2004 and 2007. "Health issues" and some laws relating to environment were ranked second and third in 2004. "Earth summit", "Oil crisis in 70s" and "Building Code revised" were ranked in 2007. Other events varied based on the ages of the respondents.

Table2 Questionnaire items and respondents

	Question	Respondents
Overall	Priority of Issues Influential events	Local government
Buildings	Building name Negative factor to enhance Green buildings Trend of Energy consumption	Design Firm Construction Company
Design process	Effective tools Environmental design strategies Importance of design strategies Information source	Sub-construction Company Utility Company
Environmental Assessment tools	Awareness of assessment tools Purpose of assessment Environmental criteria weighting Cost and time for assessment Assessment tool user	Others
Env. strategies	Effective strategies: Law, policy and program Research and development	

Table 3. Most influential events based on ages of respondents

Ranking	2004	2007
1	Kyoto Summit on Climate Change	Kyoto Summit on Climate Change
2	Health issues	Earth summit / Oil crisis in 70s
3	Energy Law revised	Building Code revised

3.2.2 Priority of issues

Fig. 2 shows the priority of issues. "Environmental loads" and "Resource consumption" will become more important in the near future, compared to "Economics," which is considered most important today.

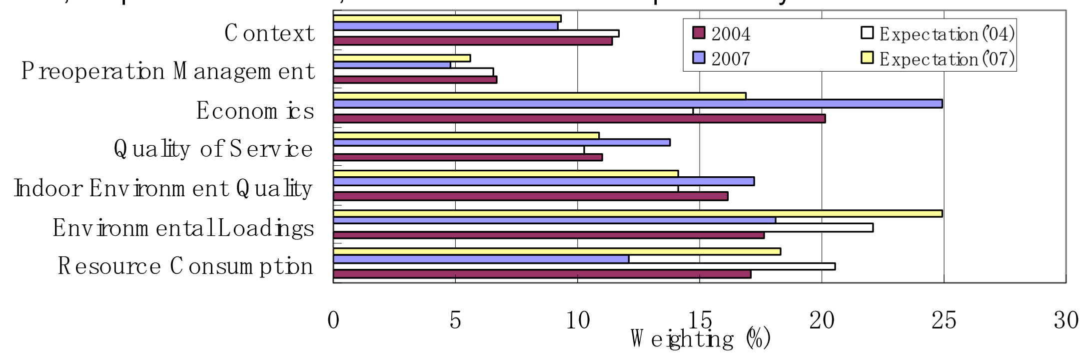

Fig.2 Which environmental criteria is important, today and ten years from now?

3.2.3 Information Source

Fig. 3 shows the popular information source. Professional books and magazines are a popular information source today but many people assess that the Internet will be the most popular source ten years from now.

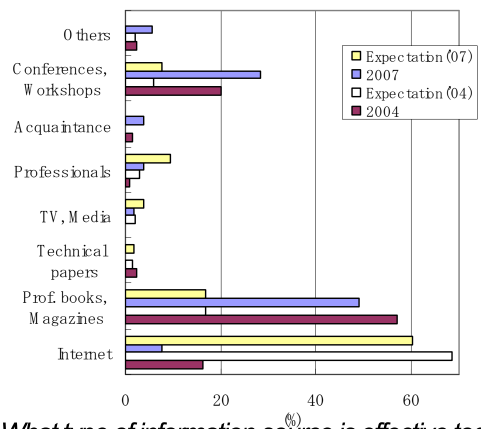

Fig.3 What type of information source is effective today and ten years from now?

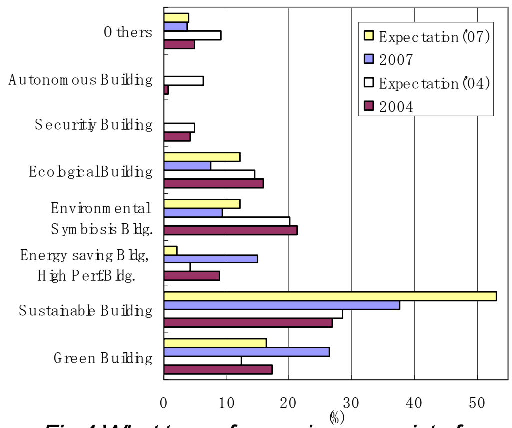

Fig.4 What type of name is appropriate for cutting edge buildings, today and ten years from now?

3.3 Buildings

3.3.1 Building name

Name of "Sustainable Buildings" is supported by many of respondents and expected as future cutting edge building's name. "Green Buildings", "Environmental Symbiosis Buildings" are also popular among the Arch. Community in Japan (Fig.4).

3.4 Design Process

3.4.1 Negative factors

Fig. 5 shows the negative factors in achieving green and sustainable buildings. Increasing initial cost is considered to be a key negative factor to achieving green and sustainable buildings in the present and ten years from now.

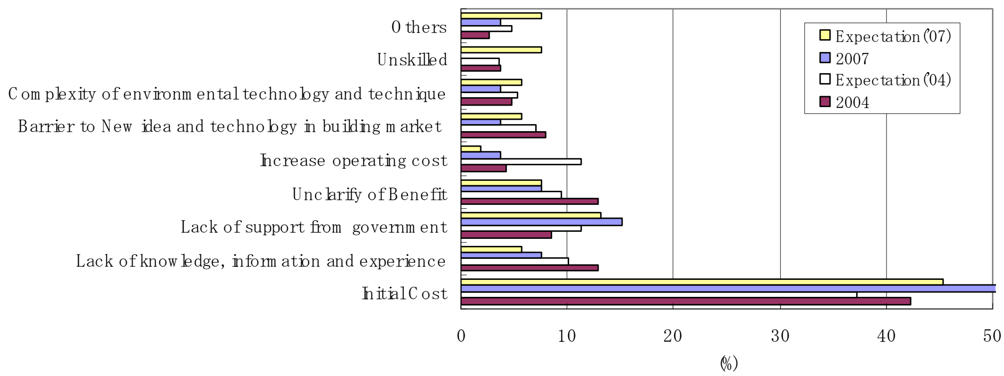

Fig.5 What is a negative factor achieving green, sustainable buildings, today and 10 years from now?

3.4.2 Effective tools for environmental design

Fig. 6 shows the effective tools to supporting environmental design. Energy simulators were thought to be the most effective tools today and environmental assessment tools were supposed to be the most effective as near future tools.

3.4.3 Popularity of environmental design strategies and methods

Fig.7 shows popularity of the environmental design strategies and methods. It shows the difference among 2000, 2004 and 2007. “Recycled material usage” and “Reduce wastes“ were popular in 2000 but their portion are decreased in 2004 and 2007. “The basic law for establishing recycle based society” was introduced in 2000 and many of strategies relating to recycle and reducing wastes were implemented and are achieving results today. Sun-shading, LCA and LCC strategies make up only a small portion in 2000 and 2004 but it is shown that there is an expectation of greater use today. PV and Thermal insulation were supported continually through 2000 to 2007.

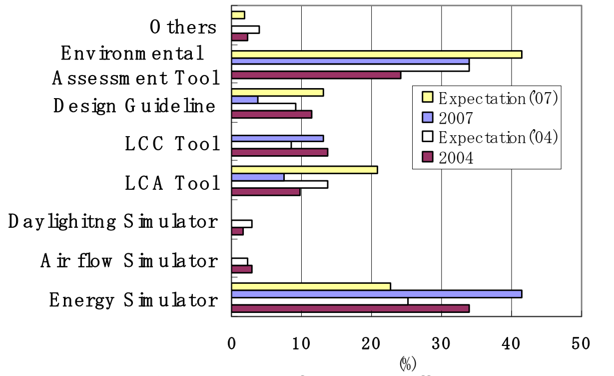

Fig.6 What type of tools are effective to design green buildings today and ten years from now?

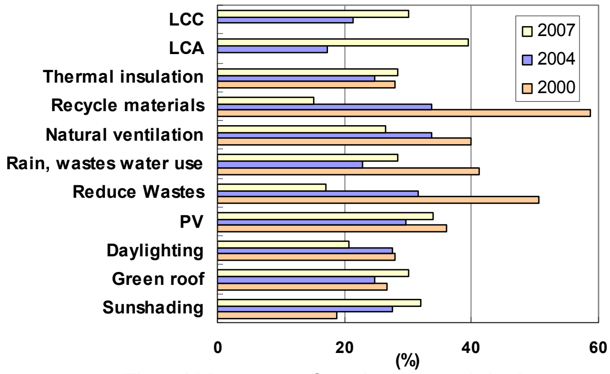

Fig. 7 What type of environmental design are you interested in?

3.5 Environment Assessment

3.5.1 Recognition of assessment tools and purpose of environmental assessment

Fig. 8 and Fig. 9 show the transition of recognition of assessment tools and the purpose of assessment between 2000 and 2004. Around 30 to 40% of respondents knew BREEAM and GBTool in 2000, and more than 50% of respondents knew CASBEE in 2004, and more than 80% knew LEED and CASBEE in 2007. Many of the respondents think the main purpose of environmental assessment is “reducing environmental loads” among 2000, 2004, and 2007, and its ratio increased compare to other purposes.

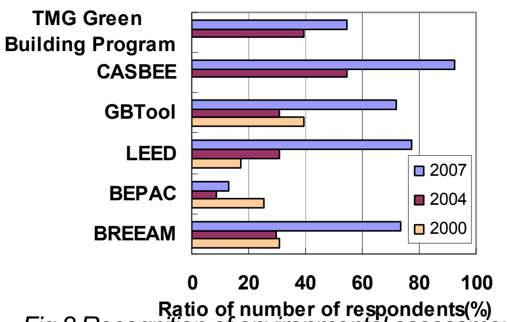

Fig.8 Recognition of environmental assessment tools?

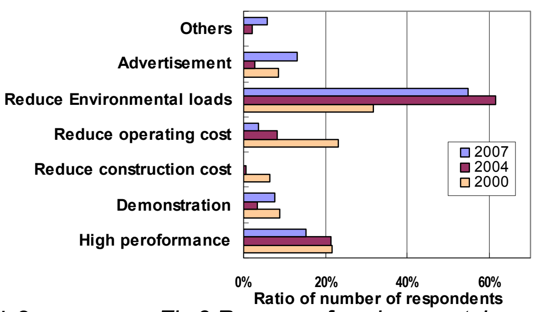

Fig.9 Purpose of environmental assessment?

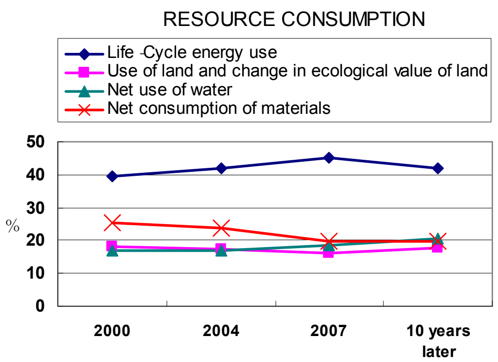
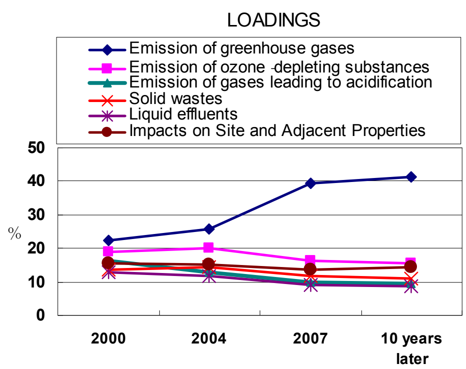
3.5.2 Weighting of Environment assessment criteria

Fig. 10 shows the transition weighting value about resource consumption, environmental loads, and indoor environment. The differences of weighting value between 2000 and 2004, and ten years from now are small changes. The assessment criteria relating to “Energy,” “GHG,”“Thermal comfort” were weighted higher than other criteria.





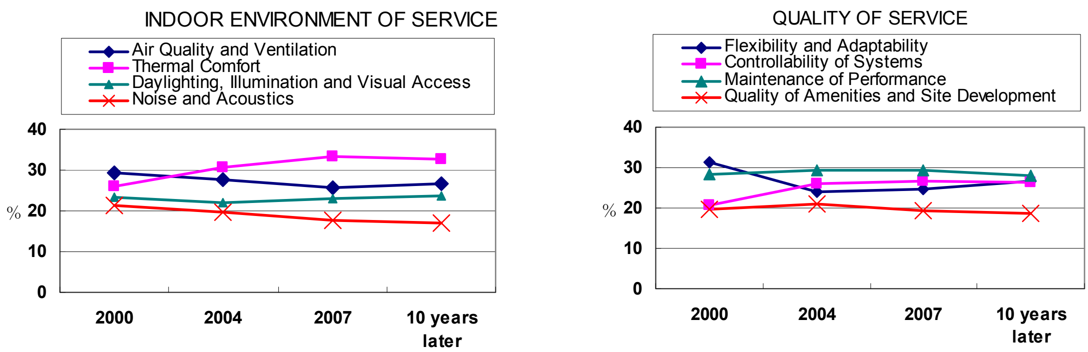


Fig.10 Weighting of environmental assessment criteria

3.6 Environmental strategies

3.6.1 Law, Policy, and R&D

Fig. 11 and Fig. 12 show the effective environmental strategies and R&D. Regulation and taxes are considered effective policies and many people support the R&D related to energy. Energy managements systems, especially, are expected to increase in the near future.

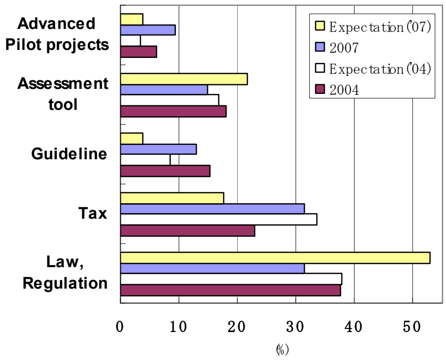

Fig.11 What are the most effective strategies to achieving sustainable buildings?

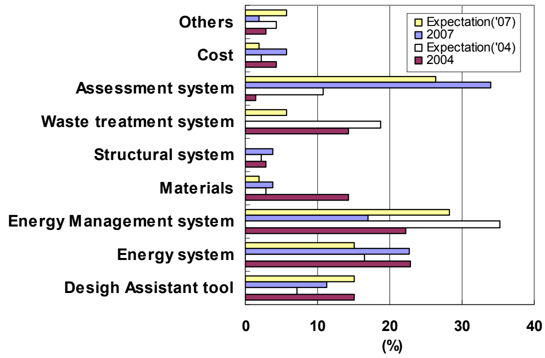

Fig.12 What kind of R&D should be focused on?

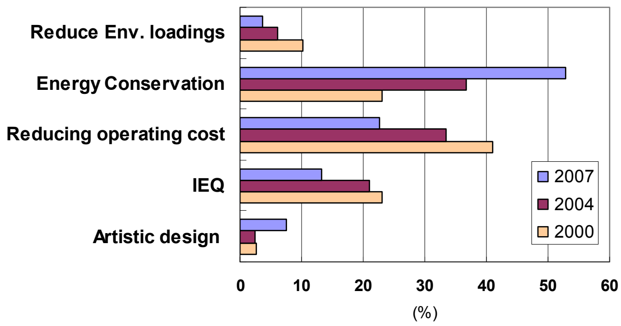

Fig.13 Which design strategies are most popular to invest ?

4. Results

The real data survey and analysis results show some progress and changes between the 1990's and 2004.The data suggests that the environmental performance of leading edge buildings has achieved some progress, and several advanced technologies and green design strategies have been applied year by year.

However, there is a gap between the strategies and reality of energy performance progress that affects the sustainability of society, as energy consumption of buildings stock increases year by year and its trends still continues.

The questionnaire survey results show that the priority of environmental issues and green design strategies have changed between 2000 and 2004. It is supposed that the reason for these changes is that information about environmental issues, experiences of green design strategies, and environmental assessment tools affected key actors in architectural community in Japan.

5. Conclusion and future research

The architectural community has a large responsibility to society through the designing and construction of buildings. It is important to assess the progress and the direction of strategies of the architectural community in order to achieve a sustainable society.

This paper describes an idea and demonstrates a framework to assess the progress and movement in the architectural community. The results suggest that it is possible to assess the movement and progress of environmental strategies by surveying several indicators, events, energy consumption and environmental performance of buildings, and human perception through a questionnaire survey.

It is expected that this framework will be revised and modified into an appropriate one to support the environmental strategies of the architectural community both locally and internationally.

This study is the pilot survey and we are planning to continue conducting this series of surveys both locally and internationally, and present them to the public periodically.

It would be useful if we could conduct the surveys in different countries and regions, and compare technological and cultural aspects to understand what is needed to realize different approaches and solutions while considering each area's climatic and historical backgrounds.

Table 4 show a framework and for future survey. Future works will be expected to describe technological and cultural change and progress, along with the gap between reality and human perception about environmental issues relating to buildings, and these will suggest progress and direction. To map technological change and cultural change, several representative indicators and questionnaire items will be selected to explain the situation appropriately.

Table 4 Framework for further survey

	Overall	Technological Change	Social and Cultural change
(Reality) Data surveys	1) Global issues progress 2) Building community progress	1) Building system progress 2) Energy consumption 3) Building stocks 4) Advance technologies 5) Performance score of cutting edge buildings 4) Design process and tools 5) Affect of assessment tools	1) Weighting on Tech vs Tradition 2) Weighting on Environment, Economy and Social 3) Green movement events 4) Building names 5) Green Design strategies 6) Cost premium 7) Engines and drivers of Change
(Perception) Questionnaire surveys

Keywords: workshop, sustainable building, integral design, permanent professional education

Summary

Within the present context of the Dutch Sustainable Building Practice it is hard for the different involved building design disciplines to give a good collective answer for a variety of questions from society especially sustainability. To change this situation a change is necessary: an Integral Approach is needed. This change can not only by 'prescription' of new ways of working by methods, but also by working in the changing situation and adapting / reflecting / learning to this situation.

As traditional methods did not work out adequately a new approach within the building industry is proposed. Integral Design; A "thinking in levels" approach improved the design and decision process by structuring them at different levels of abstraction. The newly developed methodology for structuring and documenting integral design processes enabled verification and reproduction of decisions made during designing. Morphological charts are used to write down the ideas and concepts.

The workshops for multidisciplinary professional design-teams, throughout 2004-2008, showed that integral design provides a suitable methodological foundation for improvement of integrating the activities of a building design team as well as integration of sustainable comfort systems in the conceptual phase of design process. Workshops form part of the permanent professional educational program for BNA (Royal institute of Dutch Architects) members since 2006.

1 Introduction

Preservation of energy resources, occupant comfort and environmental impact limitation are the key issues of modern and sustainable architecture. A major portion of primary energy consumption, about 40 %, is due to create thermal comfort in buildings by heating, cooling, ventilating and lighting. During the last decades, the main focus of research in Building Services was on reduction of energy consumption of buildings. The strong focus on the energy reduction led to situations in which health and comfort are endangered. By using sustainable energy the negative effects of energy use become less important and the focus could be turned to health and comfort again.

The application of sustainable energy systems and components is too complex for integration in the early stages of building design. As a result, sustainable design options are added to the final stages of the design. This results in sub-optimal designs and rejection of the proposals.

The HVAC-industry has identified a need to better integrate comfort and sustainable energy systems in buildings. In 2000, the Royal Institute of Netherlands Architects, BNA, the Dutch Society for Building Services, TVVL, and the Delft University of Technology, TUD participated in a research project called Integral Design. The focus within integral design is on all that is essential to completeness, from all design disciplines nothing essential should be lacking. Since year 2001 'integral approach' has been propagated within Dutch building design practice, through continuously developing 'learning by doing' workshops by the Royal Institute of Dutch Architects (BNA), the Dutch society of consulting engineers (ONRI) and the Technische Universiteit Eindhoven (TU/e). The workshops are a kind of practica or something very similar and are used to structure design actions from different design team members and to evaluate the proposed design method to improve sustainable design.

2 Methodology: Integral Design – Morphological Overviews

The frame for structuring actions of team members is found in 'Integral Design' model, a collection of design tools within a design process matrix. Integral Design is problem oriented and distinguishes, based on functional hierarchy, various abstractions and/or complexity levels during different stages and design activities. This model is used because it allows design to be explicitly approached on different abstraction levels. This aspect is important because of the focus on sustainable comfort systems; changes on the level of sustainable comfort systems automatically have effects on the level of a building as a whole, and vice versa.

In order to confront respective knowledge and viewpoints of design team disciplines morphological overviews, a specific design tool and one of the features of integral design, are used. The main aim of use of morphological overviews (Zwicky and Wilson 1967) is to explore 'field of possibilities', leading to more thoroughly considered solution proposals (Krick, 1967). This method uses a morphological chart where the main task is divided in functions and/or aspects, based on different abstraction levels. Following this initial interpretation of design task by design team, for each of these (sub) functions/aspects a variety of possible solutions can be generated.

By using the morphological overview all disciplines can look into the required completeness: if all necessary functions and aspects are listed. The construction of a morphological overview is like a kind of matrix. On the vertical axis of the matrix the required functions (or sub-functions) and main aspects are given. On the horizontal axis possible solutions for these functions or aspects are given. The purpose of the vertical list is to try to establish those essential aspects that must be incorporated in the product, or essential functions that the design has to fulfill. They should cover all the necessary functions and the main aspects to consider for the product/building to be designed.

3 Experiments: Workshops in 'practice'

To test and analyse what kind of aspects are of influence on knowledge exchange during design processes different workshops series with professionals where initiated. The setting chosen is that of Reflective Practice (Schön 1983). To use human subjects in laboratory experiments to study design theory provide some insight. However, extending results from laboratory experiment to conclusions for the engineering practice is a risk. The effect of Macrocognition describes the differences in cognitive functions performed in natural – versus artificial, laboratory – settings. The real-world setting requires activities in ways that artificial settings can rarely simulate. Schön (1987) has proposed a practicum as a means to 'test' design(ing). Where a practicum is" a virtual world, relatively free of the pressures, distractions, and risks of the real one, to which, nevertheless, it refers (Schön 1987, p.37)". In Schön's practicum a person or a team of persons has to carry out the design. A practicum can asses a design method and the degree to which it fits human cognitive and psychological attributes (Frey and Dym 2006). Crucial is the simulation of the 'typical' design situation. A workshop can be seen as a specific kind of practicum. It is a self-evident way of working for designers that occurs both in practice as during their education. As such a workshop provides a suitable environment for testing the approach. Besides full design team line-up there are a number of other advantages of workshops with regard to standard office situations, while at the same time retaining practice-like situation as much as possible. Workshops make it possible to gather a large number of professionals in a relatively short time, repetition of the same assignment and comparison of different design teams and their results. Never the less the workshops are a virtual world; "contexts for experiment within which practioners can suspend or control some of everyday impediments to rigorous reflection-in-action (Schön 1983 p. 162). Schön refers further to the dilemma of rigor and relevance in professional practice, there is a choice to stay on the high, hard ground ("A high, hard ground were practitioners can make effective use of research-based theory and technique") , or to descend to the swamp ("a swampy lowland where situations are confusing") and engage the most important and challenging problems? (Schön 1983 p. 42).

Together with the Dutch Royal society of architects (BNA) and the Dutch Association of Consulting Engineers (ONRI), since 2005 there were organized 5 series of workshops with experienced professionals from both organisations voluntarily applying to participate. The participants of each discipline were randomly assigned to design teams, which ideally would consist of one architect, one building physics consultant, one building services consultant and one structural engineer. The composition of the design teams is not mentioned for each specific team, but they always existed of at least 3 but mostly 4 different disciplines. Starting with a three day practice-like 'building team' concept, in which all disciplines are present within the design team from the start, the integral design method workshops have evolved to finally a two-day series.

3.1 Three different views (1st workshop series)

The first workshop series was organized in May/June 2005. The series took place during three weeks, consisting of three meetings taking place on the same weekdays.

On the first workshop day the traditional design process is simulated. During traditional design processes the architect is the first one that starts to work on a design assignment. His interpretation of design task is from then on leading during design process. Somewhere along the way other design disciplines are introduced in design process as additional advisers who are confronted with problems that initial client's and architect's ideas created. During the second day all disciplines start working on new design task from the very beginning of the first design session. During this session the disciplines are divided into separate mono disciplinary design teams, within which they individually work on the same design assignment. The reason that they work in teams is to encourage discipline-related cross-pollination in order to get approximately same contributions per discipline in all multidisciplinary design teams, which are to be formed at the start of the second design session. This way variation between different design teams concerning these aspects is kept low. During the second design session new multidisciplinary design teams, different from those of the first day, are again randomly formed. The only used criterion is that none of the participants should be twice put together in the same team. By configuring new design teams each day, the influence of the group forming effect is excluded. The third and final day is used for introduction of the methodical design tools, meaning that morphological overviews are applied during both interpretation and generation activities. The lay-out, the design sessions and formation of design teams are the same as during the second day. The design assignment is different, it is actually varied during all three days, but the type and the size of design tasks are similar. Morphological overviews are used during the third day to structure, as a consequence of the used setting accelerated design processes.

During each meeting two 60-minutes lasting design sessions were observed. The main research aim was to assess the usability of morphological overviews for different design activities of the same design team. The measurements were conducted in four different ways: through direct observations of design teams' activities, by taking photographs of design team's work, through analysis of design teams' produced material and by asking participants to fill in a number of questionnaires.

Table 1 Overview information workshop and analysis workshop series 1

31 May, 7 and 14 June 2005		Utrecht, Kropman	
Workshop series I		**BNA, ONRI, KCBS**	
Type of participants 4 disciplines: Architects (5), Building physics advisers (5), Building services advisers (8), Structural eng. (6)		Number 20 persons 5 teams av. Mark: 7,5 | response: 88%	Arrangement Same teams during whole series, design task the same during 2nd and 3rd day. Last day for 'decision making'.
Days | hours/day 3 | 4	Sessions/day | total 2 | 6	Time/session | total 60min | 6h	
Observations by TU/e students	Arrangement 3 per team (for different aspects)	Using predefined forms (3 types)	Additional photo, questionnaires
PROGRAM [in concept] Day 1: 1 lecture 'methodical design' 2 design session teams (60min) Pause 3 design session teams (60min) Day 2: 1 lecture 'sustainable comfort sys.' 2 design session teams (60min) Pause 3 design session teams (60min) Day 3: 1 lecture 'Kesselring method' 2 client feedback session (60min) Pause 3 design session teams (60min)		AIM Day 1: Introduction of morphological overviews, with the main aim to 'learn' how to use them. Day 2: Use of MO's for interpretation of task and generation of possibilities. Day 3: Use of MO's for selection, through feedback with the client, and for integration activity. Theoretical model of interpreting – generating – selecting – integrating is hereby utilised in order to explore possible use aspects of morphological overviews (MO's).	

Analysis
Positive results: Extensive observations by students provided large variety of data on design process, that can be used to properly evaluate workshops. Working in teams was experienced as positive by the participants, a majority thought that it even led to synergy. Very interesting was the development of participants' perspective towards proposed approach; at the beginning (1st day) almost 1/3 thought of it as not relevant for them, and at the end of 3rd day none of them had negative view on it. It shows the importance of the chosen 'several days' set-up, in which this workshop series can be seen as satisfactory course.
Negative results: Because same 'team interpretation' of design task couldn't be reached, the end results couldn't be compared. Attitude of participants towards workshops was influenced by the fact that researches from TU/e led the whole 3 days. ('course instructor from BNA, ONRI and/or TNO possible in the future?) Design teams changed to frequently during workshop series. 'Kesselring method' was still to much for the participants to comprehend, probably because of the combined feedback with the client. Structural engineers were 'structurally' passive during design process.
Conclusion [to take into account for next workshops]: - Instead of theoretical interpretation–generation–selection–integration activities, use observed interpretation/generation–generation/selection. - Selection as a separate activity has to be more explicitly brought in, in relation to client; combination for Kesselring is too much complicated
Remarks: Although observation by 3 students per group provided various data, there is no 'control measurement' and their presence is a bit overwhelming. The 'client' was not prepared for its role, this was partly the reason why planned feedback didn't work out.

3.2 Single double-checked view (2nd workshop series)

This workshop series was organized in October/November 2005. Based on evaluations from the 1st series, the observation forms were adjusted. Instead of three different, only one type was to be used. Besides, two instead of three students per design team were deployed. These two students had to observe the same team during all three workshop days. Furthermore, instead of TU/e Master students, Architectural Design Management Systems students (ADMS is a bi-annual postgraduate designers' programme at TU/e) were doing the observations. This way both need for decrease of number of observers as the need for control of acquired data was met.

The workshop series' setting concerning design sessions was largely unchanged. The most significant change occurred by itself: since we were dependant on the voluntary application of participants it happened that for this workshop series structural engineers did not apply. Two things were observed, design and communication, both in relation to use of morphological overviews. Besides, the main communication patterns were again registered in 10-minute intervals. Design wise, morphological overviews could be used either for discipline based introduction of new proposals, or for integration of already introduced object design knowledge. Communication wise, morphological overviews could be used either for explanation of design proposals or for archiving.

Table 2 Overview information workshop and analysis workshop series 2

24, 31 October and 7 November 2005		Delft, TNO Bouw	
Workshop series II		**BNA, ONRI, KCBS**	
Type of participants 5 disciplines: Architects (6), Building physics advisers (5), Building services advisers (6), Structural eng. (1), Manager (1)		Number 20 persons 5 teams av. mark: 7,0 / response: 96%	Arrangement Same teams during whole series, design task the same during 2nd and 3rd day. Last day for 'client' feedback.
Days | hours/day 3 | 4	Sessions/day | total 2 | 6	Time/session | total 60min | 6h	
Observations by ADMS students	Arrangement 2 per team	Using predefined form	Additional photo, questionnaires
PROGRAM [in concept] Day 1: 1 lecture 'methodical design' 2 design session teams (60min) Pause 3 design session teams (60min) Day 2: 1 lecture 'sustainable comfort sys.' 2 design session teams (60min) Pause 3 design session teams (60min) Day 3: 1 lecture 'relation with the client' 2 client feedback session (60min) Pause 3 design session teams (60min)		AIM Day 1: Teams were not obliged to work with morphological overviews, main aim was to learn how to use them. Day 2: Results from day 1 used to point out what the advantage is of integral approach. Emphasise also on use of MO's for feedback with the client. Day 3: 'Learning effect' was mainly expected to emerge from interaction with client; transparency of process and design decisions should show the added value.	

Analysis

Positive results:

Although only one manager was involved in workshop, it showed that their contribution within design team setting in conceptual design phase is not relevant (with respect to design content).

Morphological overviews were differently used within different-sized design teams. They were considered helpful in structuring the communication of design teams, especially in more complicated situations. Four-discipline teams used them more for communication purposes than 3-discipline teams. This statement is backed up by the results of the various questionnaires that all participants were given, regardless of discipline or the design team arrangement.

Negative results:

Use of ADMS students didn't produce better observations than last time, when TU/e students observed.

Big differences in experience between participants caused sometimes too big unbalance within design teams; as addition to the absence of structural engineers.

Feedback with client was a step too far, just as previous attempts to introduce 'Kesselring-method' for decision making processes. It seems that 'only' the use of 'morphological overviews', as a basic tool for structuring design process, is more than enough in this short amount of time.

Conclusion [to take into account for next workshops]:

- Introduce only use of morphological overviews, in relation with thinking in abstraction levels.
- Clients need to be 'real' in order to get more commitment from participants.

Remarks:

BNA / ONRI representatives acted as clients.

Workshops were led by TNO representative, this is preferred setting for conduct research because of unobtrusive presence of researches.

Some participants still complained about 'many' student-observers.

3.3 Workshop setting modification (3rd workshop series)

The third workshop series was held in June 2006. Observations during, as well as participants' reactions on the previous two workshop series showed that morphological overviews indeed were useful within the design team and the workshop setting; the next step was to determine the effects of morphological overviews. This meant that we had to move more towards an experimental setting, where quantitative measurements instead of qualitative assessments were possible.

The first consequence was that morphological overviews could not be introduced at the start of workshop series, since this would exclude the possibility of stimulating the traditional building design approach during the workshop series. In order to be able to separately measure the possible effects of morphological overviews, the phased introduction of two changes to traditional approach was needed: 1) design team setting from the very beginning of conceptual design phase, 2) use of morphological overviews.

The second consequence was the design team arrangement. To compare different design processes, not all design teams should work the same way (as was the case during previous workshops). The usual solution would be 'matched design teams', something we oppose because of no resemblance with the practice situation. The solution we came up with was not to observe the same design teams during the whole course of workshop series, but to compare the average results of each workshop day while changing the members of the design teams. This meant different design teams each day, which consisted out of same group of participating designers. The team formation was at random, the only rule was that two designers could be in the same team only once. During previous workshop series we had also compared average results of different workshop days, but at that time we were interested in different activities within same type of design process. This time the focus was on comparison of the same activities within different types of design processes.

This was also the first time that the participants were not satisfied with the workshop. Moreover, they were even disappointed about abrupt ending of the workshop series. They felt that ID-model and morphological overviews, as core of 'ID-methodology', were introduced too late. There was no possibility for a full learning cycle. Therefore, introduction of morphological overviews during the last day was clearly a step back in the workshop development; the participants needed time to adapt and demanded feedback, see table 3.

Table 3 Overview information workshop and analysis workshop series 3

12, 19 and 26 June 2006		Apeldoorn, CODA	
Workshop series III		**BNA, ONRI, KCBS**	
Type of participants 4 disciplines: Architects (7), Building physics advisers (6), Building services advisers (7), Structural eng. (3)		Number 22 persons 6 teams av. mark: 7,3 | response: 98%	Arrangement Random teams that changed each day; clear build-up of program – 1st day traditional, 2nd integral and 3rd incl. method
Days | hours/day 3 | 4	Sessions/day | total 2 | 6	Time/session | total 30-90min | 6h	
Observations by ADMS students	Arrangement 1 per team, (2 teams/day videotaped)	Using predefined forms (2 types, individual and team observat.)	Additional video, photo, questionnaires
PROGRAM [in concept] Day 1: 1 design session architects (60min) CODA building guide tour 2 lecture 'sustainable comfort sys.' 3 design session teams (60min) Day 2: 1 lecture STB 2 design session teams (30min) Pause 3 design session teams (90min) Day 3: 1 lecture 'methodical design' 2 design session teams (30min) Pause 3 design session teams (90min)		AIM Day 1: Traditional approach as reference, to compare with day 2 and 3; also to enhance 'learning effect' Day 2: Design team approach, starting together from 1st session. Different teams and task from day 1. Day 3 Introduction of methodical design 'tool'. (different teams/task). Initially, all disciplines were supposed to work individually during 1st session on day 2 and 3; in order to be able to compare all 3 days. Due to circumstances started with teams.	

Analysis

Positive results:
Set-up of workshop, mainly dictated by 'scientific requirements' is workable. It allows multiple comparison of different processes.
First time that the comments during the workshop from the participants themselves showed that 'learning by doing' indeed is effective.
Enthusiasm is clearly higher than during previous workshops, resulting also in less drop outs. 'By accident' found formula 30/90 minutes for duration of design sessions for one design task proved to be most pleasing.
Constantly changing teams adds to creation of good working atmosphere because people get to know each other better through 'forced contacts'.

Negative results:
Very difficult to observe 1st and 2nd day, because of individual (silent) work.
TNO lecture about 'sustainable comfort systems' was by participants seen as nothing new, no added value.
Usually the 3rd day of workshop is best rated, this time however not. The participants felt that workshop abruptly ended, without feedback on the main theme of the whole series – working with morphological overviews.
Method was actually not assessed, because participants were mainly busy understanding it – partly the same situation as during workshop no.01 (beforehand information does not help either).

Conclusion [to take into account for next workshops]:
- Introduction of 'methodical design' shouldn't happen during the last day: it is too new, participants need time to adapt and demand feedback.
- In current setting the additional sessions are needed.
- Quality of video cameras and preparation of rooms needs to be better.

Remarks:
Video cameras poor quality of sound; teams should also maybe be in separate rooms. Preferably videotape all teams, now only two out of 6 observations per day usable.

3.4 Final workshop setting (4th and 5th workshop series)

The development of the workshop setting was a learning-by-doing process. Instead of starting with a theoretically 'optimal' configuration, workshops were continuously adjusted and improved based on evaluations of participants and analysis of observation results, resulting in the final arrangement as shown in Figure 1. In the current configuration (Figure 1) stepwise changes to the traditional building design process type, in which the architects starts the process and the other designer join in later in the process, are introduced. Starting with the traditional sequential approach during the first two design sessions on day 1, which provide reference values for effectiveness of the method (amount of integral design concepts), the perceived "integral approach" is reached through phased introduction of two major changes: (1) all disciplines start working simultaneously within a design team setting from the very beginning of the conceptual design phase, (2) the integral design model / morphological overviews are applied. The second design setting allows simultaneous involvement of all design disciplines on a design task, aiming to influence the amount of considered design functions/aspects. Additional application of morphological overviews during the third setting demonstrates the effect of transparent structuring of design functions/aspects on the amount of generated (sub) solution proposals. Additionally, the third setting provides the possibility of one full learning cycle regarding the use of morphological overviews. It concerns an individual, rather than collective/team learning cycle, because in order to be able to effectively apply a new approach, one has to first understand it and make it his or her own (Jones, 1992).

Design team arrangement is the crucial element. To be able to compare different types of design processes, while at the same time excluding team development aspects (Tuckman, 1965), the same design teams are not observed during the two workshop days, instead the average results of each design setting of all participating teams are compared. For each setting the arrangement of design team members is changed (although all design teams are composed out of the same group of participating designers). The only rule is that no two designers can be in the same team twice. The focus is on the comparison of the same activities within different types of design processes. The sequence of used design settings is of utmost importance. Reverse or mixed order is not possible because learning effects would not allow for valid comparison of results (Herzog, 1996).

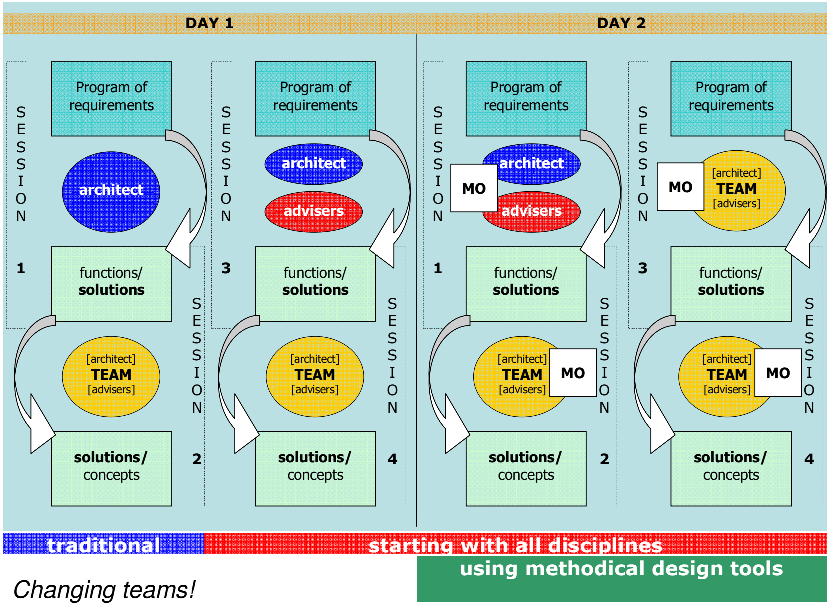

Figure 1 Four different design settings during the final set-up of the two-day 'learning-by-doing" workshop

Table 4 Overview information workshop and analysis workshop series 4

15 and 22 May 2007		Zeist, Buitenplaats Groenoord	
Workshop series IV		**BNA, ONRI, KCBS**	
Type of participants 6 disciplines: Architects (9), Building physics (6), Building services (8), Structural engineers (1), Project leaders (2), Managers (2), Developers (2)		Number 27 persons 7 teams (*) av. mark: 7,0 | response: 96%	Arrangement Two full days, teams and tasks change during noon break. Smooth transition from traditional to integral design.
Days | hours/day 2 | 8	Sessions/day | total 4 | 8	Time/session | total 30/90min | 8h	
Observations by ADMS students	Arrangement 1 per team + video	Using predefined form	Additional video, photo, questionnaires
PROGRAM [in concept] Day 1 1 design session architects (30min) 2 lecture 'sustainable comfort sys.' 3 design session teams (90min) Break 4 design session individual (30min) 5 design session teams (90 min) Day 2 1 lecture 'methodical design' 2 design session individual (30min) 3 design session teams (90min) Break 4 design session teams (30min) Pause 5 design session teams (90 min)		AIM Day 1 Traditional situation in the morning, with variation to it by letting all disciplines individually start working on new design task in afternoon. Day 2 Morning exercise using 'methodical design' approach; starting individually to let everybody 'learn' their own way. In afternoon start on again new task, but this time as a team. This allows comparison of individual/team initial start and interpretation of design task. Results of this set-up should lead to final conclusions for definitive workshop format.	

Analysis

Positive results:
The first major improvement is introduction of an extra experiment (1st during 2nd day). The possibility for an individual learning cycle in working with morphological overviews together with the feedback from organizers is created. With this intervention the main objections from previous workshop, lack of feedback and the abrupt ending of workshop, is removed.
The two-day instead of three-day workshop setting is the second major improvement. The participants get impression that more time is dedicated to the 'main issue' of the workshop, working with morphological overviews.
The transition from 'traditional' to 'integral' design setting proved indeed to be smooth. It also led to insight that working in teams is the main issue.

Negative results:
It remains very difficult to observe the first two experiments, since no structuring tools are given to design teams.
The last experiment / design setting was, even beforehand, seen as needless by the participants. The impossibility of always creating the optimal process during practice, as simulated during the third experiment, and therefore the need of mastering the situations as shown in the last design setting was not (made) obvious to the participants.
Large number of 'non design disciplines' (20%) was not stimulating during design process, partly because of their deviating notion of design concept.

Conclusion [to take into account for next workshops]:
- More emphasis on why the last design setting is so important
- Physical distance between design teams needs to be bigger (sound quality)
- Morphological overviews also as a tool for 'live' observation?

Remarks:
The participants had clear preference for the third design setting – starting individually with MO's, then moving on to team configuration.
Use of microphones satisfactory. However, teams should be further apart.

Table 5 Overview information workshop and analysis workshop series 5

5 and 12 February 2008		Utrecht, Forum 't Zand	
Workshop series V		**BNA, ONRI, KCBS**	
Type of participants 4 disciplines: Architects (5), Building physics advisers (4), Building services advisers (7), Structural engineers (3)		Number 18 persons 5 teams av. mark 7,4 / response 97%	Arrangement Two full days, teams and tasks change during noon break. Smooth transition from traditional to integral design.
Days | hours/day 2 | 8	Sessions/day | total 4 | 8	Time/session | total 30/90min | 8h	
Observations by Video cameras	Arrangement 1 per team	Using -	Additional video, photo, questionnaires
PROGRAM [in concept] Day 1 1 design session architects (30min) 2 lecture 'sustainable comfort sys.' 3 design session teams (90min) Break 4 design session individual (30min) 5 design session teams (90 min) Day 2 1 lecture 'methodical design' 2 design session individual (30min) 3 design session teams (90min) Break 4 design session teams (30min) Pause 5 design session teams (90 min)		AIM Day 1 Traditional situation in the morning, with variation to it by letting all disciplines individually start working on new design task in afternoon. Day 2 Morning exercise using 'methodical design' approach; starting individually to let everybody 'learn' their own way. In afternoon start on again new task, but this time as a team. This allows comparison of individual/team initial start and interpretation of design task. Results of this set-up should lead to final conclusions for definitive workshop format.	

Analysis

Positive results:

The workshop setting proved to be the right one. The overall ratings were never before as high, although the average mark for the workshop was 'only' 7,4. Interestingly, none of the participants mentioned the redundancy of the last experimental / design setting, which was a big issue during the previous workshop series. Seen in retrospective, this might have had to do with the influence of the other disciplines involved during the previous workshop series…

The absence of the (student) observers was not felt during the workshop, it certainly did not result in less good atmosphere. One might even say that the participants acted more freely, even though they were still videotaped.

Negative results:

The main negative result concerned the organisation of the workshop, especially on behalf of ONRI. Apart from TU/e, there were during both days also no other representatives present (from neither BNA, ONRI and TNO).

The ratings for the speakers were below average. However, this negative aspect highlights even more the high ratings for the workshop as a whole.

Because there were no 'live' observations, it s difficult to give a preliminary evaluation without doing the full analysis of data. Even though the results of student observations often proved to be contradictory when fully analysed, their first-hand evaluation did provide a globally accurate first impression.

Conclusion [to take into account for next workshops]:

- This workshop setting can be considered as the final one.
- Even though the quality of sound recordings is better when the teams work in separate rooms, it also creates an experimental atmosphere during the design sessions. This is the reason to use larger rooms where teams can work next to each other in a more informal setting.

Remarks:

Videotaping the sessions is research-wise preferable, even necessary, which makes the live use of morphological overviews for research purposes less important.

4 Results Workshops

During all workshops, following the assignment presentation the design process was observed and no further intervention took place. Observations were conducted in two different ways: (1) noting design teams' activities using observation forms (by students) and the last 2 series the workshop sessions were registered by video cameras because the participants found the student something disturbing their concentration, (2) by taking photographs of design team's work (by researchers, in 10min intervals), (3) the acquired data was analysed together with the material produced by the design teams. The additional resources of information were the questionnaires that participants had to complete after each day session and another questionnaire after a period of approximately six months.

Over the past four years 5 series of workshops have been conducted, these typically include around twenty participants and lasted for two or three days. A total of 107 designers participated in the five workshop series, in which 74% of the designers were present during all days. The average age of the participants, all members of eider BNA or ONRI was 42 and they had on average 12 years of professional experience. Direct at the end of the workshop the participants were asked to fill in a questionnaire in which questions were asked about the importance of the use of Morphological Overviews within the design process and about the concept of the workshops themselves, the results are given in table 6.

Table 6 Overview results questionnaires participants workshop series, rating from 1 to 10.

	series 1	***series 2***	***Series 3***	***series 4***	***series 5***	***Total***

5 Discussion and Conclusions

The theoretical basis of the workshops, Integral Design methodology with Morphological Overviews as important design tool for the conceptual phase of the design process was tested in "learning by doing" workshops approach developed throughout 2005-2008 in which professionals from BNA (architects) and ONRI (consultants) participated. The workshops were conducted by KCBS, Knowledge Centre Building and Systems (the cooperation between TNO Bouw Delft (Organization for Applied Scientific Research, Built Environment and Geosciences) and Technische Universiteit Eindhoven). The overview in this paper of the series of workshops prove the positive experiences of the workshops by multidisciplinary professional design-teams, throughout 2005-2008. Most important recommendations and conclusions;

- working on inter-disciplinary knowledge exchange by profession organizations (BNA, ONRI) in collaboration with knowledge / research / education institutions (TU/e, TNO) has to be organized and developed; permanent professional education is a core activity for the future

- workshops are an effective tool to couple practice / research / education; the 'learning by doing'-principle is an effective aspect; the adaptive characteristics have to be developed more extensively; feed-back and evaluation are important tools to use experiences from the past; workshops should be part of the permanent professional education

- design methodology and design tools, for multi-disciplinary design teams, help to structure and develop each others knowledge and are thus a necessary perquisite to develop / effectuate sustainable integral designs

Although the workshop experience of the participants is positive, they find it difficult to implement in practice. When participants were asked for the reason of the difficulties, they mention the already longer existing project setting in which they operate and in which they are the only ones with knowledge about this design tool. The workshops provide only a introduction and a few exercises to work with the design tool, most of the participants need more time to fully implement the basis into their own design process approach. Also the participants find it difficult after the short training sessions of the workshops to really change their traditional approach.

Acknowledgements

TVVL, BNA and TU Delft have supported the Integral Design project. KCBS, Kropman bv and the Foundation 'Stichting Promotie Installatietechniek' (PIT), support the new research.

Keywords: post occupancy evaluation, timber frame, catalytic projects, ecovillage, vested interests

Introduction and Summary

Context:

The Building Industry is inexorably driven by profit motive and Building as Usual (BAU) is very difficult to change, due to deeply entrenched vested interests which are stubbornly inimical to any reform, perceived to be a threat to those profits. The question is whether the global awareness of grave hazard to human habitat and reforming initiatives can in fact prevail over profit motive and short term-ism ?

The **rationale/significance** of this paper is to give an account of how this small professional practice, (in the context of the GAIA International network) over thirty years can make some progress across a wide spectrum in 'budging BAU' by:

1 . design of **catalytic building projects** ,

2 facilitating **post occupancy evaluation** of that completed work ,

3 collaboration in **eco village** development and **urban planning / zoning** initiatives

4 contributing to **institution building** to counteract the prevailing negative trend

5 activism to assist **governmental fiscal and other instruments** to be devised and applied

6 occasional **teaching**

7 international **think tank** activity in GAIA International.

The **objective** of the paper is to suggest that if these pluridisciplinary efforts are multiplied there is hope for step change in the future of a sustainable building and construction industry.

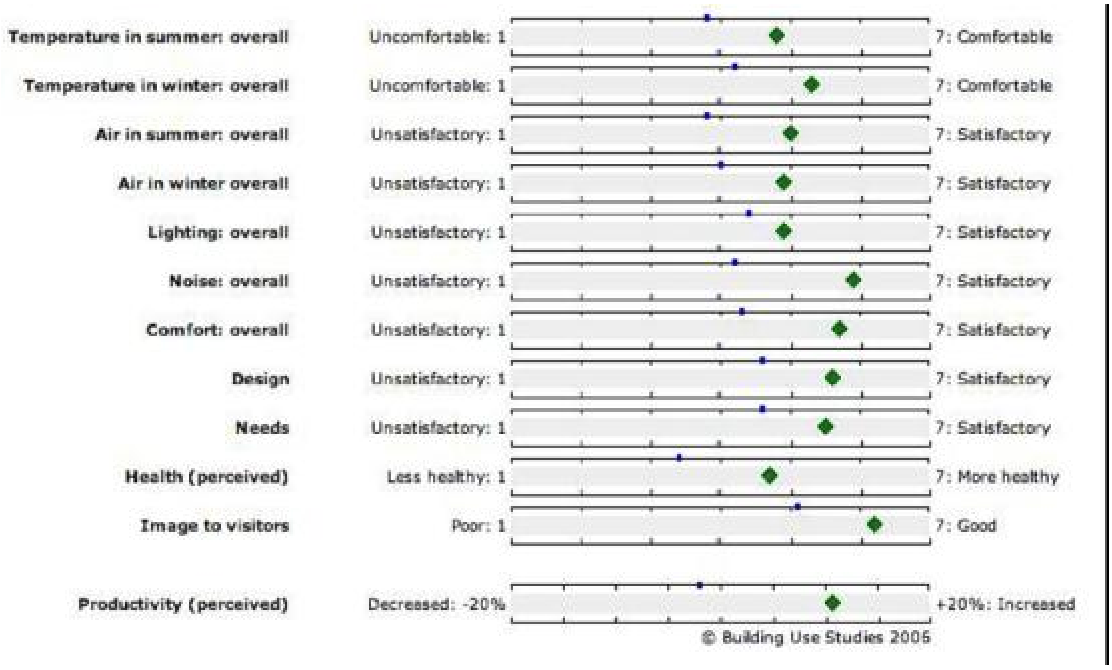
The paper is **organised** around an account of the 7 headings above , leading to **Concluding Comments** with **References** .

Catalytic Project 1 Navan Credit Union; Eco Offices (2005) [1,2,3,4,5]

OBJECTIVE : Post Occupancy Evaluation to learn lessons

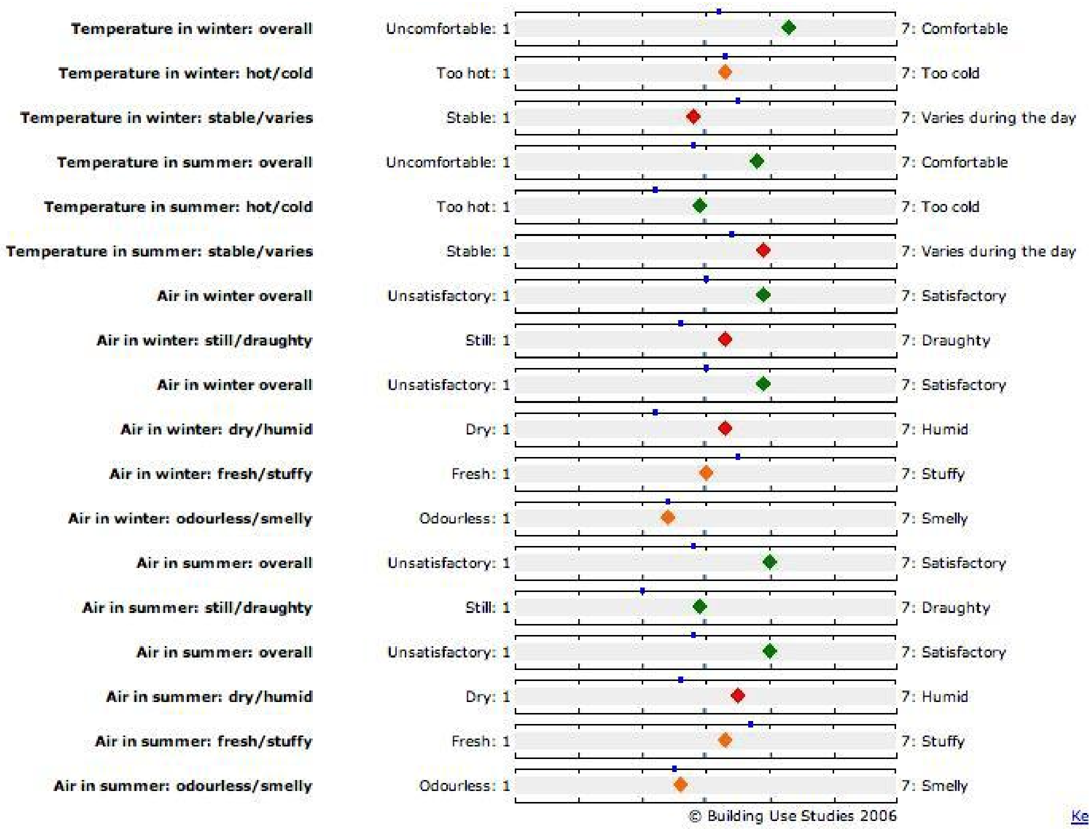
Detailed quantitative and graphic results from are shown below of several years of assessment, and iterative fine tuning, of a completed five storey eco office building, Navan Credit Union: See(www.constructireland.ie/artcles/navan.php) and SB05 proceedings with many passive and low energy design features including:

Blue marks are normative



These results based on independent interviews with the users of the building conducted by Prof George Baird and processed by Adrian Leamon are among the top 5% of all buildings surveyed by the **http://www.usablebuildings.co.uk**

His more detailed analysis indicated perceived shortcomings, again using traffic signal colour codes, as follows on a 'warts n' all basis' : again blue marks are normative:



Lessons learned from these user interviews have lead to fine-tuning and remediation with a view to a follow up interview where it is hoped even better results may be obtained.

ENERGY USE

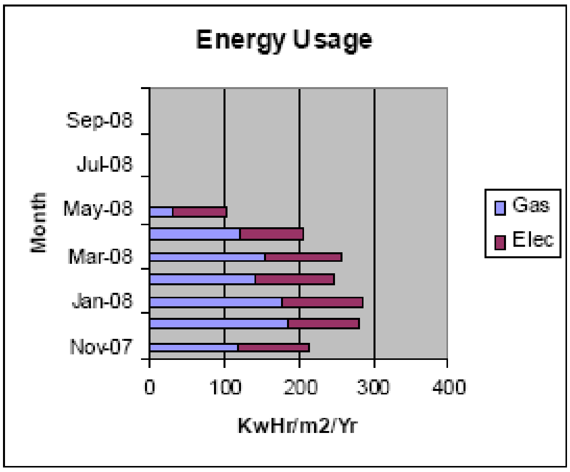


Fig 1. Overall energy monitoring results to Oct 2007 from Nov 2006 expressed as KwHrs / sqM /annum and not normalised: early anomalous results during commission and test phase are notable .

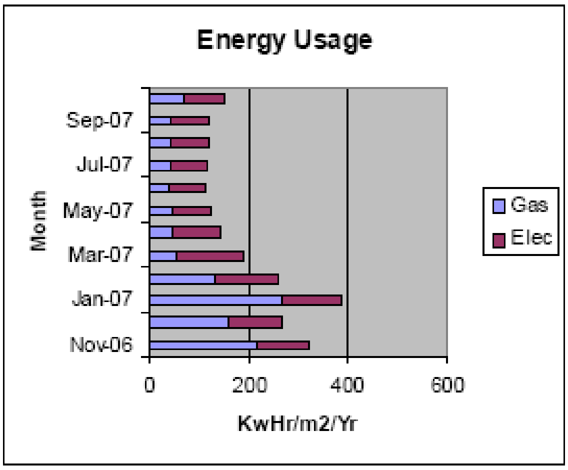

Fig 2) Results from Nov 07 to May 2008 show we are converging on 100 Kwhrs / sq m /annum , a realistic de facto target for best practice office buildings; Although the Winter 07/08 are badly skewed upward by boiler problems (for reasons noted in the text) the winter peak was much less than the previous year (to be updated Sept 2008 before presentation of the paper)

Through a process of elimination energy inefficiencies continue to be eliminated; these include elimination of an air curtain at the main and busy entrance with a generous draught lobby with automatic doors and user behaviour in relation to use of heating ventilation and cooling.

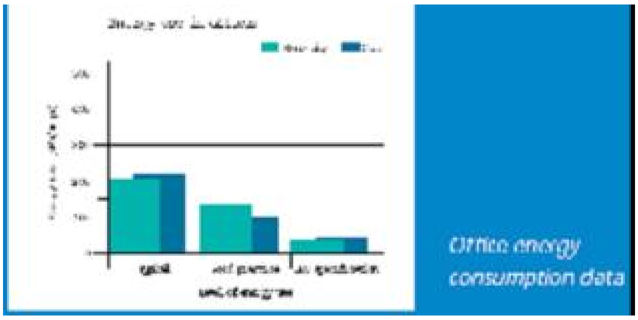

Fig 3 C Typical Good Best Practice

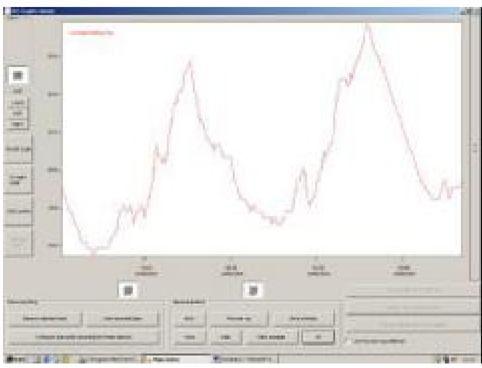
Reference (BRECSU)~ 400 to ~100

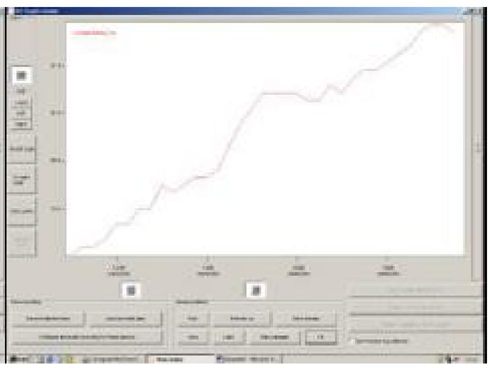
Kwhrs /sq m / annum

VENTILATION Solar Chimney

This simple device (seen centrally above right) at the top of the atrium has proved very successful, especially in fine tuning.
In deep Winter both the 'venturi' and solar chimney are closed down fully . In the shoulder seasons of Spring / Autumn this solar chimney is gradually utilised more or less as required and only in high Summer the Venturi ventilator (see below) is introduced.
From this figure may be seen that velocities of 1 metre per second of free ventilation are achieved in sunlight / naturally in phase with requirement for enhanced ventilation. The consulting engineers have been agreeably surprised by volumes moved.

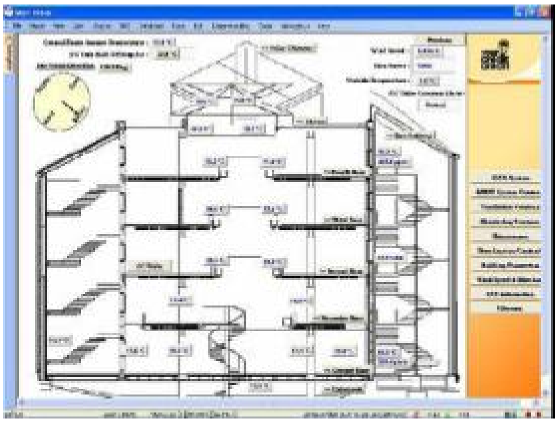
Temperature Control





The commonplace issue here is to control the afternoon 'spike' in office temperature; the left hand shows temperature over two Summer days and the right a daily detail ; it may be seen that auxiliary cooling (gas heat pump) is utilised to delay the natural spike of temperature at 21.25 Deg C until after office hours when it is allowed to climb (when natural ventilation is closed down for security). One of the key issues is staff culture/ behaviour - opening a window is better than turning up cooling.

Conclusion

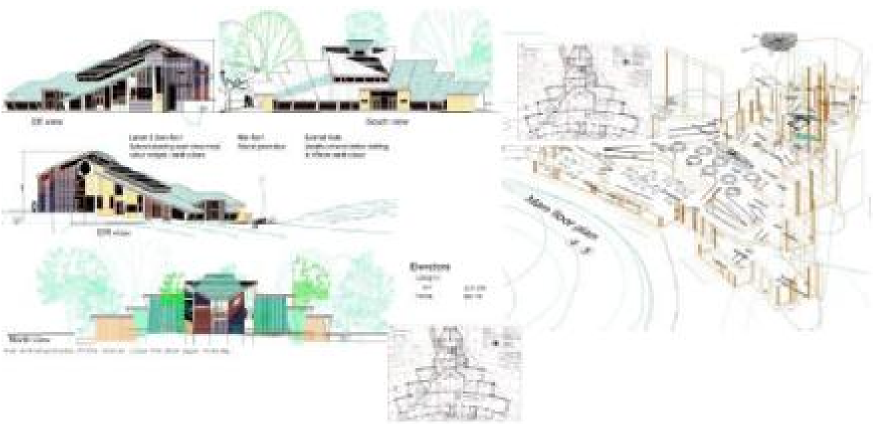


From these results and ongoing work it would appear that 100 KW hrs/Sq M /annum is an achievable target for an office building of this kind at this stage ; ie double the original target which is more appropriate to eco / quasi passive housing. Whereas the atrium design has genuine architectural benefits it contributes to stratification in the building leading to variations during the day ; cold at low level in winter mornings where sedentary workers start their working day . The 'cooling behaviour' of the occupants is cultured by their negative summer experiences of the high thermal mass original building; they are predisposed to the use of auxiliary cooling with inadequate resort to the passive features. The architect would prefer not to install auxiliary cooling at all in this temperate climate. The parallax between design intentions and experienced outcome informs continuing design development in this field.

Catalytic Project 2 Third Level Campus Creche; Dundalk Institute of Technology

OBJECTIVE : Roll forward, on the learning curve of lessons learned from Project No 1

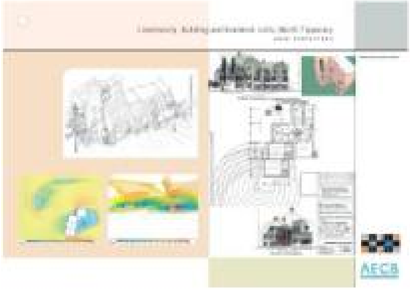
This new design is ready to build on site and awaits funding. Many of the features of the Navan project are reinterpreted here. An essential, point here is form language; an organic building which aims through form, scale, colour, texture, natural light, and ventilation to enhance the earliest years of education of preschool children; the facility itself has a high environmental pedagogical intent re flows of water light waste air etc. In many respectsit brings the thinking of High Scope, into the 21st century.



3 Collaboration in eco village development and urban planning zoning initiatives

OBJECTIVE : The projects are 'budging BAU' by becoming points of reference /precedent for development in Ireland, demonstrating application of principles on macro scale. Two examples will be discussed; The Village Project, Cloughjordan , Tipperary and Laytown Eco Residential Business Zoning.

3.1 The Village Cloughjordanwww.thevillage.ie



One of our principals is a member of the eco village and the Planning Group therein. Infrastructure is complete and roll out of clusters on site is commencing. See www.thevillage.ie We are also designing a community building and some live-work units at the core of the site along with a further Cluster 9 of the development. Infrastructure is now complete and the first roll out of the clusters is just beginning.

3.2 Laytown Eco Residential Business Zoning

This study was undertaken for the landowner of 75 Hectares on the main rail line in the country, on the Belfast /Dublin axis. It resulted in the formal adoption by the Planning Authority of an innovative "Eco Residential Business" zoning. The principles followed were of those of systems theory ; a tolerance of a certain degree of democratic free market 'chaos' while introducing attractors , being an urban civic space and balancing-lake ; one hard edged / urban, one soft-edged, natural.

As an essay in stochastic planning, the out-turn is, as yet, unclear as to how it will affect the market place;as in all 'budging bau' the impulse is sent into the system in the hope that good will come of it of but short of eco fascism one must wait and see how our free society is affected .Three dimensional mixed use live work development is envisaged.

4 /5 Counterculture institutions to BAU with access to Government at Highest Levels.

OBJECTIVE : To proliferate and mainstream eco building ,rather than BAU

In the centre of Dublin a multi faceted sustainability Institution has slowly grown due to the work of a committed team; see www.cultivate.ie . **éasca** has also been founded by the author and others to attempt to shift the sector toward sustainability; the word in Gaelic means 'easy' and the acronym is the Ecological and Sustainable Construction Association. We are subtly engaging vested interests; upstaging those who just 'greenwash' Building As Usual (BAU). See www.easca.ie. **éasca** is often hosted by Cultivate and the offices and staff of **éasca** are shared at Cultivate for synergy and efficiency, in Temple Bar, at the cultural heart of Dublin , the capital city. (Temple Bar itself as an urban quarter has an inspiring history as an urban renewal cell and much of what was learned there is being replicated throughout the city.) **éasca** now has a burgeoning membership with many partners from the sector signing up, to a subscription based on turnover, and assisting the organization to make a difference nationally . The Green Party after a dramatic walk out in negoatiations to form a coalition , managed to secure three Government Ministries: Environment, Heritage and Local Government: Energy and Communications: Food and Horticulture. The synergy between these Ministers and éasca / Cultivate is promising. An advisory committee to the Minister has been formed which sits in his office. A number of initiatives are in hand including a revision of the Building Regulations to effect a 40% improvement in primary energy usage compared with a conventional base case; an escalation to 60% improvement is scheduled to follow . It remains to be seen what possible effect is possible with a majority Government party still very committed overall to BAU, with ministries such as Finance still in the control of that centre right party. The Government have just started addressing the issues, as severe financial penalties are brought to bear under EU and Kyoto measures.

6 Teaching : OBJECTIVE : To communicate with Youth, as the future practitioners and policy makers.

Occasional teaching as guest lecturer allows one to budge BAU by facilitating the new generation of architects and allied professions; it is noticeable how Staff have now become interested; a recent lecture to second year students in Waterford School of Architecture attracted the attendance of the Director and ten staff from several years and a lively discussion followed; one has the sense that things are changing and perhaps a green 'chain reaction' is possible after all ?

7 International think-tank activity in GAIA International [6, 7, 8, 9, 10]

OBJECTIVE : To proliferate and synergise internationally

GAIA International was founded in 1990, standing for "the balance and integration of the built environment with ecosystems for the welfare of all species on the planet". It is a non corporate informal structure of disparate, but like-minded professionals in practice, research, teaching, writing and publishing who by contact from time to time enable and sustain and encourage each others work .It budges BAU in subtle and sometimes overt ways. Several members have contributed significantly to the literature REFS, whereas others teach and practice.

OPTIMIZED DESIGN OF CONCRETE STRUCTURES FROM THE ENVIRONMENTAL POINT OF VIEW

Petr STEPANEK, Prof., Dr.Eng.[1]
Jan PLSEK, Eng.[2]

[2] Department of Concrete and Masonry Structures, Brno University of Technology, Brno, Czech Republic, plsek.j@fce.vutbr.cz

Keywords: optimization, design, concrete, structure, environment, stochastic, programming

Summary

A basic formulation of the optimized design of concrete structures is presented. Deterministic and stochastic optimized design alternatives are shown. The proposed method enables the inclusion into the formulation not only of reliability design according to codes; it is also possible to use fully probabilistic design based on stochastic mechanics. The objective function can be a vector function, which has to be transformed into a scalar function. The environmental aspects of a designed structure such as emissions of CO_2, SO_x or embodied energy are included in the objective function. For transformation from vector to scalar objective function weighting and normalising methods are used. Methods for the solution have been discussed in some other publications (Stepanek, 2006; Stepanek, Plsek, 2007). Two solved design examples are presented.

1. Introduction

There is a current tendency to design new concrete structures and also reconstructions effectively from the viewpoint of minimising the initial cost while preserving serviceability parameters (i.e. Frangopol, 2001, Mróz, 1998). However, this trend in design specialises not only in the execution phase of the construction but also pays attention in recent years to the construction life cycle – MIT conference, 2003.

A key desire of engineers while designing structures has for a long time been to design a structure from such materials whose properties are fully utilised in the structure (conditions of load-bearing capacity) thus causing the structure to fulfil the conditions of applicability (especially in view of cracks and strain). This fact has recently resulted in the origin and construction of a number of composite structures. These structures are formed from different materials, usually combining concrete (utilised in compression areas - its properties may be modified by various additional components) with materials featuring very good properties in tension (steel. glass, carbon and aramid).

A new approach is also manifested in the design of structural materials with programmed physical properties in order to optimally fulfil the functional demands during the predicted activities within an individual structure over the course of its life cycle.

Optimisation of concrete structure design is generally based above all on the following principles (see Stepanek, 2006): optimisation of the technology used when manufacturing concrete components, optimisation of the composition of concrete mixture, optimisation of the shape and reinforcement of structural members, and optimisation of the cost and/or environmental impacts in relation to the life cycle of a concrete structure.

This paper is related to the optimisation of the shape and reinforcement of concrete members by taking into account cost and environmental aspects.

2. Optimised design of concrete structures

To make the design of a structure effective, it is necessary to adopt the method of optimised design. It isn’t really so useful to simply optimise the initial cost. Far more appropriate is to minimize the total cost, i.e. the cost over the life cycle of a construction, and maximize the stiffness of the designed structure at prescribed cross sections. Engineering optimization plays an increasingly important role in structural design. It was carried out at various quality levels from a design update based on a designers opinion to the application of exact mathematical optimisation models. These computational models are usually deterministic with respect to the complexity of the whole design (see IFIP conf., 2003). The optimisation methods and theories of design have significantly developed in the last thirty years.

To find the best possible design of structure or member without a negative effect on the reliability system as a whole, it is necessary to use an optimised method. However, it must be said that a significant amount of the existing optimised methods are specialized in the area of structural design that considers all parameters as being deterministic (DBSO – Deterministic Based Structure Optimisation). The general deficiency of DBSO is the omission of uncertainties while determining loads, material characteristics, responses and the stability of the structure. Elimination of that deficiency enables the combination of design methods based on comprehensive probabilistic accesses and optimised methods. This assessment is called Reliability Based Structure Optimisation (RBSO).

The crucial conceptual problem is, however, the question of how to make provision for stochastic variability, which especially concerns the properties of materials and general loading including environmental and technological effects. Methods of providing for stochastic variability have been well elaborated in simulation reliability models especially – Frangopol, 2001.

2.1 Reliability based optimization - consideration of the randomness of some input variables

The task is defined as follows

a) the target function reaches the extreme

$\{f(\{x\})\} =$ extreme, (1.a)

while keeping the restrictive conditions implicit from

b) the reliability requirements of the designed structure expressed in probabilities

$P_{fj}(\{x\}) \leq P_{fj}^{0}$ $\quad j = 1, ..., np$, (1.b)

and other conditions with the included further terms containing probabilities. These conditions can be expressed in the form of

c) the equalities $\{h(\{x\})\} = \{0_1\}$, (1.c)

d) the inequalities $\{g(\{x\})\} \leq \{0_2\}$, (1.d)

where $\{x\} = \{x_{s1},...,x_{snt}\}^T$ are the design variables, $\{f(\{x\})\} = \{f_1(\{x\}),...,f_t(\{x\})\}^T$ is the vector of the target functions, $f_i(\{x\})$ is the i-th target function, $\{h(\{x\})\}$ is the vector of the restrictive conditions in the form of equations, $\{g(\{x\})\}$ is the vector of the restrictive conditions in the form of inequalities, $P_{fj}(\{x\})$ is the probability of the structure's failure (the j-th condition of the reliability relating to some mode of failure or to applicability in a given locality), P_{fj}^{0} is the permissive probability of the failure determined for the j-th conditions of the reliability, and $\{0_1\}$ and $\{0_2\}$ are zero vectors of the relevant type.

For an established vector of the design variables, the conditions of equilibrium of the solved structure – with the application of discretion of the solved task via an FEM method – can be expressed in the form (1.c), where

$\{h(\{x\})\} = [K(\{x\})]\{\Delta\} - \{F\}$, (2)

$[K(\{x\})]$ is the stiffness matrix of the solved structure, $\{\Delta\}$ is a vector of the nodal parameter of deformation and $\{F\}$ is the loading vector of a structure.

2.2 Deterministic based optimization (DBSO)

The task is defined analogously to the RBSO but the conditions (1.b) are not used and in the relations (1.a), (1.c) and (1.d) the probabilities are not included. For the solution of this task it is possible to apply mathematical programming algorithms and algorithms based on evolution processes too.

3. Optimised design of a concrete cross section

Let's assume an RC cross-section of any shape and reinforcement, which is allowed to contain inner openings and whose perimeter is approximated by closed polygons, placed in a Cartesian ordinate system YxZ. The cross-section is stressed by a set of loading cases $\mathbf{L}_j = (N, M_y, M_z)_j^T$, $1 \leq j \leq N_L$, which represent inner forces (see Fig. 1.a). They are obtained from a previous static calculation on a studied structure in a specified critical cross-section on the axis of a particular bar element. The loading cases are vectors of random quantities with known probability distribution, of which statistical dependences are given by correlation matrix. Design of the cross-section has to minimize the selected objective function and meet all restrictive conditions (constraints), i.e. bear every loading case L_j safely. Cross-section reliability is expressed by the probability of failure $p_{f,j}$, which depends on L_j as well as on cross-section geometric and material parameters and uncertainties.

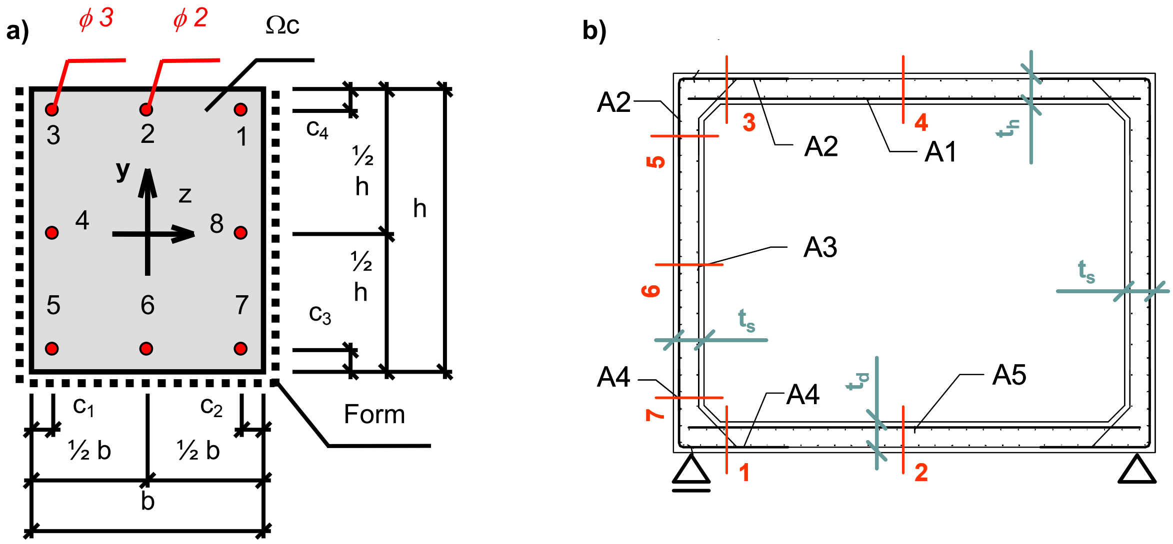

Figure 1 Schemas of solved structures: a) cross section optimization, b) a collector

The vector $\boldsymbol{x}$ of the considered design variables includes characteristic dimensions of a cross-section $\boldsymbol{r}$ (e.g. the width and height of a rectangular cross-section), as well as the set of reinforcement diameters ϕ and strength of concrete f_c and steel f_s, therefore $\boldsymbol{x} = (\boldsymbol{r}, \phi, f_c, f_s)^T$. For simplicity, all variables are taken as continuous.

3.1 Objective function for DBSO and RBSO

For the purpose of DBSO and RBSO comparison, probabilities are omitted in the RSBO objective function and a common simple objective function is defined. Economical and ecological aspects (acquisition costs and CO_2 and SO_2 emissions associated with concrete member formation, respectively) are taken into account. The problem is multicriterial and all the mentioned aspects should be minimised. The method of weighted sums was applied; the problem seems to be monocriterial with regards to the solving algorithm. However, the terms of the objective function have different units and thus can not be directly summed; for that reason they must first be normalized by the chosen reference values:

$$f(\mathbf{x}) = \alpha_p \frac{P(\mathbf{x})}{{}^{\circ}P} + \alpha_{co} \frac{CO_2(\mathbf{x})}{{}^{\circ}CO_2} + \alpha_{so} \frac{SO_2(\mathbf{x})}{{}^{\circ}SO_2}, \qquad (3)$$

$$P = V_c U_p^c + m_s U_p^s + S_f U_p^f, \qquad (4.a)$$

$$CO_2 = V_c U_{CO2}^c + m_s U_{CO2}^s, \qquad (4.b)$$

$$SO_2 = V_c U_{SO2}^c + m_s U_{SO2}^s, \qquad (4.c)$$

where the used symbols mean: P acquisition costs, CO_2 the amount of CO_2 emissions, SO_2 the amount of SO_2 emissions, ${}^0P$ (or ${}^0CO_2$, ${}^0SO_2$) the reference values set by the problem designer, α_P (or α_{CO}, α_{SO}) weights in the objective function for P (or CO_2 and SO_2, respectively), V_c concrete volume, m_s reinforcing steel weight, S_f the form area of a 1m-long beam fragment with a designed cross-section, U^c_P (or U^s_P, U^f_P) the costs of concrete (or steel and form, respectively), U^c_{CO2} the embodied unit amount of CO_2 emissions from concrete production, U^s_{CO2} the embodied unit amount of CO_2 emissions from steel production, U^c_{SO2} the embodied unit amount of SO_2 emissions from concrete, and U^s_{SO2} the embodied unit amount of SO_2 emissions from steel production.

3.2 Specification

Let a simply-supported beam with a constant RC rectangular cross-section be uniformly loaded all along its span l by its self weight *g* and imposed load *q*. The objective is to design all unknown cross-section parameters with the help of the proposed RBSO and DBSO algorithms and to compare the acquired results.

Some of the parameters are given: the strength classes of materials (f_c and f_s), the number of reinforcement bars N_ϕ and their positions in the cross-section (covers c_1 to c_4, see Fig. 5). Reinforcement bar diameters ϕ and cross-section dimensions b and h (width and height, respectively) are left for optimisation.
The calculations are carried out in 5 variants of weighting coefficients α_P, α_{co}, α_{so}, see (3) and 2 variants of cross-section dimensions, which are either optimised or given (fixed).

Given cross-section parameters: Concrete C25/30, steel B490(R), number of reinforcement bars $N_\phi = 8$ and axial covers $c_{1..4} = 40$ mm. Cross-section dimensions: optimised $b, h \in \langle 200, 600 \rangle$ mm or fixed $b = 300$ mm, $h = 500$ mm. Reinforcement bars: corner bars: $\phi_{1,3,5,7} \in \langle 10, 22 \rangle$ mm, inner bars: $\phi_{2,4,6,8} \in \langle 0, 22 \rangle$ mm.
Loading case specifications: Number of loading cases $N_L = 1$. A simply-supported beam is strained the most in the middle of the span by simple bending, so

$$\mathbf{L}_1(\xi) = (0,\ M_y(\xi),\ 0)^T, \tag{5}$$

$$M_y(\xi) = -\frac{1}{8}\left(g(\xi) + q(\xi)\right) l^2, \tag{6}$$

where l is the effective span (8 m), $g(\xi)$ and $q(\xi)$ are random variables with mean values $g^\bullet$ and $q^\bullet$, respectively, obtained from

$$g^\bullet = g_k = b^\bullet\, h^\bullet\, \gamma_{cncr}, \tag{7}$$

$$q^\bullet = q_k, \tag{8}$$

where $b^\bullet$, $h^\bullet$ are design variables b and h, respectively, γ_{cncr} is reinforced concrete unit weight (25 kN/m^3) and q_k the given characteristic value of imposed load (14 kN/m).

Stochastic model parameters are shown in Tab. 1. Each of the random quantities is assumed to be normally distributed without mutual correlations. The mean value of $q(\xi)$ is determined in such a way that the value q_k is its 95% fractile. Multipliers γ_g and γ_q are relevant partial factors for permanent and variable loads in accordance with code EC2 *Design of Concrete Structures,* 1991 [1] ($\gamma_g = 1{,}35$, $\gamma_q = 1{,}5$).

Table 1 Random quantities and their parameters

$\boldsymbol{H}(\xi)$	Random variable	Mean value	Units	γ or σ Type	Value
$\boldsymbol{L}_1(\xi)$	$g(\xi)$	$g^\bullet$	kN/m	γ	0,213
	$q(\xi)$	9,333	kN/m	γ	0,304
$\boldsymbol{D}(\xi)$	$b(\xi), h(\xi)$	$b^\bullet$, $h^\bullet$	mm	γ	0,02
	$f_c(\xi)$	25	MPa	γ	0,12
	$f_{s,1}(\xi)\ldots f_{s,8}(\xi)$	490	MPa	γ	0,06
	$c_1(\xi)\ldots c_4(\xi)$	40	mm	σ	5
	$\phi_1(\xi)\ldots\phi_8(\xi)$	$\phi_1^\bullet \ldots \phi_8^\bullet$	mm	γ	0,05

Objective function parameters: Reference values were derived from a 300 x 500 mm^2 rectangular cross-section reinforced by 8 bars of diameter 22 (maximal allowable reinforcement) ^0P = 1246 CZK (Czech Crowns), $^0CO_2$ = 63.3 kg, $^0SO_2$ = 0.239 kg. Other input parameters for optimization: costs U^c_P = 2343 CZK/m^3, U^s_P ´19 CZK/kg, U^f_P = 400 CZK/m^2 and embodied values U^c_{CO2} = 321kg/m^3, U^s_{CO2} = 767 kg/m^3, U^c_{SO2} = 1.11 kg/m^3, U^s_{SO2} = 3.67 kg/m^3.

Five alternatives of weighting in the objective function were calculated: alt.1: α_P = 1; α_{CO} = 0; α_{SO} =0; alt.2: α_P = 0.75; α_{CO} = 0.125; α_{SO} =0.125; alt.3: α_P = 0.5; α_{CO} = 0,25; α_{SO} =0.25; alt.4: α_P = 0.25; α_{CO} = 0.325; α_{SO} =0325; alt.5: α_P = 0; α_{CO} = 0.5; α_{SO} =0.5.
Other parameters and specifications for concrete section design are taken from standard EC2. Required cross-section reliability is given by minimal Cornell safety index β_{min} = 3.8, which corresponds to the maximal failure probability p_f^{max} =7.2 . 10^{-5}. The number of simulations for p_f estimation is set to $N_S = 100$. $Z(\xi)$ is assumed to be normally distributed.

3.3 Results

Numerical results are listed in Tables 2 and 3. The variant with fixed cross-section dimensions resulted for both DBSO and RBSO in the same results without regard to summation weight changes.

Table 2 Results of DBSO; all variants "b, h = const" always led to the same results shown in the first column; the reliability indexes for DBSO were calculated additionally after termination of the optimisation process

Weights Dimensions		Weights 1-5 Fixed	Weights 1 Optimised	Weights 2 Optimised	Weights 3 Optimised	Weights 4 Optimised	Weights 5 Optimised

Reliability Index	[-]	3,8	3,8	3,8	3,8	3,8	3,8

The DBSO amount of steel is always greater than that obtained by RBSO; the amounts of concrete are almost equal in all cases. Modifications of summation weights caused only small changes in the results for

CO_2 and SO_2 emissions. There are substantial differences in the reliability indexes (on average 17% for “optimised dimensions” cases) and total costs (on average 22% for “optimised dimensions” cases).

4. Optimisation of a concrete collector

An optimization of the load bearing concrete structure of a collector was made – Fig. 2. It was required that the structure be designed with normal steel reinforcement, stainless steel reinforcement and GFRP (Glass Fiber Reinforced Polymer) reinforcement. Because of the different mechanical characteristics of reinforcing materials and their costs it was necessary to use optimized design.

The cross section was modeled as a frame structure – in fig. 1.b. The load stages taken into account for design were: dead load (own weight, earth pressure), and traffic live load. Static solution of the structure covers the following load combinations: fully covered up structure, structure covered up on one side, and fully covered up structure with the influence of ground water. The design was created according to code EC2.

From the mathematical point of view a task is a continuous deterministic or stochastic non linear problem of mathematic programming. The solution was carried out using the GAMS system with the Conopt solver according to described theory – Stepanek, 2007. Because of the limited range of this contribution only the DBSO task will be described.

Design parameters were: t_h thickness of top plate, t_d thickness of bottom plate, t_s thickness of walls and amount of reinforcement A_i at designed cross sections of the framed structure – see Fig. 1.b. Design variables are considered as continuous quantities; constraints for thicknesses of plates and walls are t_d, t_h, $t_s \in$ <100, 600> mm, constraints for the diameter of reinforcing bars are <6, 30> mm and the distance between rebars is equal to 100 mm.

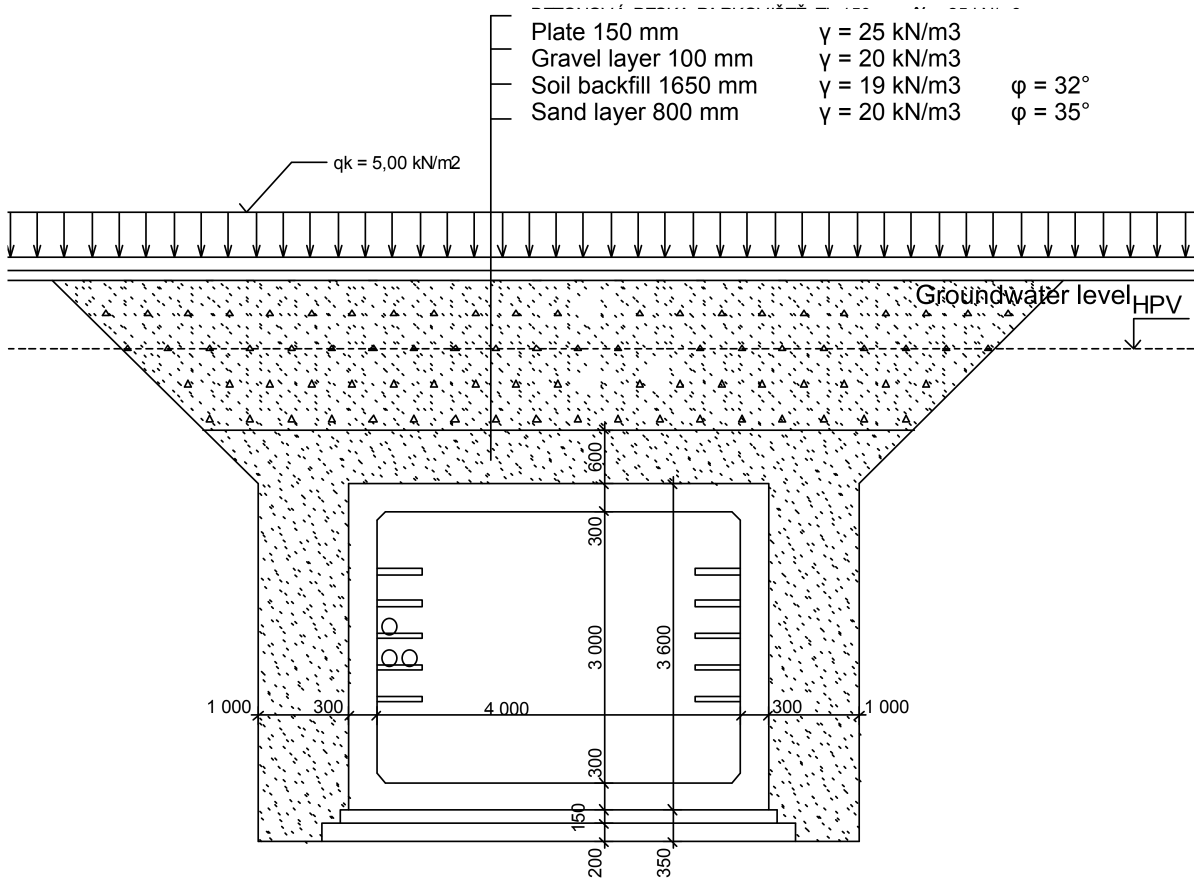

Figure 2 Schematic of the solved load bearing structure of the collector

4.1 Objective function

The target function describes the costs of the execution of a 1 m length structure, the environmental impact expressed in terms of CO_2 and SO_x emissions, embodied energy E and the bending stiffness of some cross sections

$$f(X) = \alpha_P \frac{P(x)}{{}^0P} + \alpha_{CO} \frac{CO_2(x)}{{}^0CO_2} + \alpha_{SO} \frac{SO_2}{{}^0SO_2} + \alpha_E \frac{E}{{}^0E} + \alpha_B \sum_i^7 \beta_i \frac{{}^0B_i}{B_i} \tag{9}$$

where the newly-used symbols mean E energy consumption for 1m length of structure, B_i the bending stiffness of cross section i (i = 1, .., 7 according to Fig. 1.b), ${}^0E$ (or ${}^0B_i$) being reference values for energy (or stiffness) set by the problem designer, and the realization of α_E or α_{Bi} weights in the objective function for energy or bending stiffness, respectively.
Objective function parameters: Reference values were derived for a structure of 1m length with maximal cross section dimensions and a complete structure reinforced with the maximal allowable reinforcement. Input values for those calculations were calculated from tab. 4.

Table 4 Unit costs and environmental impacts

Material	Energy [MJ/kg]	CO_2 [kg CO_2 / kg]	SO_x [g SO_x / kg]	Unit cost	
Concrete C35/45	0,8	0,13	0,5	2385	CZK/m3
Steel rebar	49	3,2	14,6	23,7	CZK/kg
Stainless steel	113	6,7	303,6	200	CZK/kg
GFRP rebar	41,6	1,92	14,66	acc. to diameter	CZK/m'

Constraints: in addition to such defined constraints as intervals of the allowable range of design parameters it is necessary to fulfill reliability constraints according to the ultimate limit states at cross section i defined by EC2 for all described load combinations.

We optimized the collector cross section design using 2 alternatives. The 1st alternative specified as "costs vs. stiffness" was calculated with weighting coefficients $\alpha_B \in$ <0,1>, $\alpha_C = 1 - \alpha_B$, $\alpha_{CO} = \alpha_{SOX} = \alpha_E = 0$. The 2nd alternative "eco-impact vs. stiffness" was calculated with weighting coefficients $\alpha_B \in$ <0,1>, $\alpha_C = 0$ and $\alpha_{CO2} = \alpha_{SOX} = \alpha_E = (1 - \alpha_B)/3$.

4.2 Results

Both alternatives ("costs vs. stiffness" and "eco-impact vs. stiffness") give corresponding (but not identical) results. For this reason and because of limited range of this text only the results of the 1st alternative will be discussed.

From Fig. 3 it follows that the most expensive collector structure design is with stainless steel reinforcement. The costs for a structure with GFRP reinforcement are much lower (about 50% of the stainless steel variant) and the best design from the standpoint of cost optimization is with normal steel reinforcement.

Fig. 3 illustrates the results of parametric optimization studies for some types of weighting (transformation from vector objective function to scalar function). If α_B decreases and other weighting factors increase the change of optimal solution goes through four phases. The difference is with transitional values α_B only – see fig. 3. From $\alpha_B = 1$ to value $\alpha_B = \alpha_{B,Xmax}$ the design variables reach their maximal prescribed values (1st phase). If $\alpha_B \in (\alpha_{B,reinf}\ ;\ \alpha_{B,Xmax})$ decreased, the reinforcing area also decreased and the height of the cross section was maximal and equal to the upper limit of the constraints – 2nd phase. In the 3rd phase for $\alpha_B \in (\alpha_{B,t+reinf}\ ,\ \alpha_{B,reinf})$ the optimization results did not change. If $\alpha_B \leq \alpha_{B,t+reinf}$, the optimization procedure changes the height of the cross section and reinforcement.

From the environmental point of view the worst result is from stainless steel reinforcement, steel reinforcement is better and the best results are obtained from GFRP reinforcement. The difference between steel and GFRP reinforcement from the environmental point of view was approximately 3-5% of the optimal values for stainless steel. Embodied energy and CO_2 emissions for steel (or GFRP) reinforcement are about 50% (or 45%) of those from a stainless steel reinforcement solution. For SOx emissions greater differences were obtained because of the fundamental variance in the embodied emissions.

5. Conclusion

1) It is possible to use the proposed DBSO and RBSO approach in the design of structures. It is possible to include not only reliability criteria according to design codes but also environmental aspects.

2) Materially-optimised structures seem to be environmentally friendly without attempting any explicitly prescribed task to take into account ecological aspects, because material savings cause less pollution.

3) Including the maintenance and repair costs into the objective function will make it possible to use lifetime assessment during the environmental design of structures.

4) From the results of the numerical example, it follows that DBSO, in comparison to RBSO, results in an over-designed cross-section.

5) With the help of RBSO, it is possible to achieve a structural design with a well-proportioned level of failure probability with respect to various failure modes, which is economically advantageous.

6) The objective function has a significant influence on the obtained optimal results. In case of a vector objective function we have to transform this function into a scalar function. Therefore it is necessary to discuss its form and type of weighting. Sometimes it is very useful to do a parametric study for weighting values.

Keywords: living skins, green façades, living wall, green wall, opportunities, critique, appropriateness, framework

Summary

This research argues the current practice of green façades in terms of the accomplishment of a broader range of opportunities they might realize. It analyses existing green façades according to different types, construction systems, and relationships with the immediate context. This reveals there are two major categories of green façades: opaque green façades, and transparent green façades. The research identifies a series of opportunities related to six areas: human comfort; expressive capacity; air & water quality; indoor-outdoor relationship; urban biodiversity; and carbon neutral architecture.

It combines the classification of green façades and the identification of opportunities they offer to develop the Green Façades Framework. This framework enables the critique and evaluation of existing green façades in terms the extent to which they accomplish such opportunities, hence facilitating a determination of their appropriateness to different conditions, solar orientations, and user needs.

The proposed Green Façades Framework is applied to five existing examples of green façades to evaluate their appropriateness to their particular conditions. This application detects the deficiencies of these green façades, enables a deeper critique of their design and reveals the usefulness and limitations of the Framework to improve the current practice of green façades by assisting designers to define more appropriate green façades.

1. Introduction

Architecture today is experiencing an emerging practice in and increasing application of green façades. More architects are experimenting with diverse ways of incorporating greenery into building façades, developing a wide spectrum of systems. Recent examples from Madrid, Spain and Vancouver, Canada reflect the international uptake of this technology [Fig1].

Figure 1 Architecture today is experiencing a boom in green façades around the world. House in Madrid [Spain, 2003]; Aquarium in Vancouver [Canada, 2006]; Prada store basement [Tokyo, 2005].

In this context, leading architects such as Jean Nouvel and Herzog & de Meuron, are utilizing green façades as a natural response to both the current accelerated information society, one which demands a changeable architecture, as well as to carbon neutrality, one which demands an environmentally concious architecture.

Architects are exploring the changeable and expressive capacity of vegetation in the façade, fascinated by its faculty to naturally introduce the notion of time, providing an ephemeral dimension:

"*The ephemeral dimension infers a rapport between architecture and ephemeral elements. Vegetation is one of these and is of course very fleeting, very sensitive and very changeable*" (Nouvel, 2007).

Recent buildings illustrate this statement. The green façade of Nouvel's Quai Branly Museum in Paris [2006], achieves a spectacular explosion of different plant species, emphasizing the thickness and heaviness of 'living walls'. In Tokyo, the green façade of the basement of Herzog & de Meuron's Prada store [2005] uses the same moss-type plant creating different inclinations.

Figure 2 The Green Façades of the Quai Branly Museum in Paris [Nouvel] and the basement of Prada store in Tokyo [Herzog and de Meuron] explore the expressive capacity of green façades.

But, do these green façades realize the full range of opportunities they embody? Although the expression of changeability that occurs naturally through the passing of time is a key aspect of current practice of green façades, this research considers there are many other qualities of green façades that are ignored or underestimated. Looking at these two examples, it seems striking, for instance, to find both green façades respond in such a similar way – attached to opaque walls – to the very different conditions they face: Quai Branly Museum's faces north-west to a main street and the Seine river, while Prada's basement facade faces south-east and north-east to the entrance of the store..

Instead, green façades could and should respond in different manners to different orientations as a means of emphasizing the variability of their surroundings. Green façades could and should show different faces according to the movement of the sun. The opacity or transparency of the walls that they are attached to should play a key role in this sense. Using green facades in this way could significantly reduce the energy demand of buildings, refreshing the façade in summer, allowing for solar energy gain in winter through transparent green façades, or insulating from the cold through opaque green walls. Green façades could also incorporate flexibility and movement in the building envelope, through rotating or sliding systems, allowing users to create their desired relationship with the outdoor space.

Green façades can also act as water storage, reducing runoff, and can even purify grey water generated wtihin the building. In a similar manner, they can purify the air of their surroundings by trapping pollutants such as CO_2. In this sense, green façades can be considered a building material with great potential to contribute to carbon neutral architecture over its life-cycle. Green facades can significantly improve urban biodiversity, especially when situated within the wider green network, enhancing the activity of living organisms. They can even provide space for urban agriculture, acting as cultivated green surfaces, where vegetables can grow.

This research argues that at present green façades are in a rather preliminary stage, given that their design is relatively intuitive and based more on exploring their expressive capacity than on maximizing the breadth of opportunities they can provide. Consequently, designers are often unaware of the larger range of opportunities in green façades. To further this discussion, this research develops and proposes a Green Façades Framework to provide a set of attributes that will assist designers in defining green façades that appropriately satisfy a project's needs.

2. Methodology

The research begins with a preliminary analysis of the current practices of green facades. It classifies them into two major categories: opaque green façades - those attached to an opaque wall, and transparent green façades - those associated to a transparent wall. Within these two categories, five distinct construction types have been identified [Table 1]. The research provides a preliminarily critique of the current practice of green façades by illustrating deficiencies and missed opportunities in their designing and construction process.

The research then, based on related studies, identifies a broader set of opportunities for green façades. These have been condensed into six areas: human comfort, expressive capacity, water & air quality, indoor-outdoor relationship, urban biodiversity, and carbon neutral architecture.

The combination of the two previous findings – the types of green façades on the one hand, and a broader range of opportunities on the other – lays the foundation for development of the Green Façades Framework. This framework enables the critique and evaluation of different types of green façades in terms of the extent to which they accomplish the identified opportunities and helps to determine their appropriateness for different conditions in an effort to improve current practice.

The Green Façades Framework is applied to existing examples of green façades to evaluate their appropriateness to their particular conditions. Five case studies are analysed, corresponding to the previously identified five main types of green façades. The application of the framework reveals its usefulness and limitations in assessing how designers select and define more appropriate types of green façades for specific projects. The research concludes with designs for an opaque and a transparent green façade seeking to fulfill the identified opportunities. Built prototypes of these designs will be monitored in a test room to compare achieved data with related research.

3. Current practice of living skins

The current practice of living skins is situated within the context of a contemporary type of façade that reacts to the stimuli of its immediate environment – in other words, a responsive façade. Green façades represent a natural alternative within this type of façade, they are living skins, changing and reacting naturally to surrounding stimuli.

Within current practice, living skins belong to one of two major categories: those attached to an opaque wall – opaque green façades; and those associated to a transparent wall – transparent green façades. These, in turn, split into five subcategories: greenery climbing through an opaque wall, greenery attached to an opaque wall as a green tapestry, greenery composed of green vertical panels, greenery between two transparent layers and greenery in the external layer and a transparent wall as the internal layer.

Table 1 Types of green façades

	Types of Green Façade	
1 OPAQUE		Greenery climbing through an opaque wall
		Greenery attached to an opaque wall as a green tapestry
		Greenery composed of green vertical panels
2 TRANSPARENT		Greenery between two transparent layers
		Greenery in the external layer and a transparent wall as the internal layer

This analysis detects some preliminary missed opportunitites in green façades, suggesting the need for a deeper study on the opportunities behind green façades.

4. Green Façades Framework

The research identifies six areas of opportunity for green façades: the improvement in *Human Comfort*; the exploration of their *Expressive Capacity;* the influence in *Air & Water Quality;* the enrichment of the *Indoor-Outdoor Relationship*; and the contributions to *Urban Biodiversity* and *Carbon Neutral Architecture*. The combination of the previous analysis – the types of green façades and a broader range of opportunities – lays the foundation for development of the Green Façades Framework.

In order to evaluate the appropriateness of different types of green façades, the framework builds on the available literature on the benefits of greenery to the built environment. Due to the limited literature specifically on green façades, the contribution of green façades to their surrounding environment is assumed to be similar to that of other green surfaces such as trees, grass, parks, or green roofs. Therefore, in analysing the influence of green façades to human comfort conditions, for example, the framework assumes green façades contribute significantly to the reduction of indoor air temperature in the summer by reducing the external air temperature of a west-facing orientation up to 4ºC on a clear August day in Japan; (Hoyano, 1988) and by 5ºC in South Africa (Holm, 1989). This cooling effect could reduce annual cooling energy use by 31%, while windbreak plantings around unprotected homes can reduce annual heating energy use by 15% (McPherson, Nowak et. al., 1993). According to computer simulations, in a warm climate such as Madrid, cooling energy use reduction could reach up to 45% and heating reduction up to 23% (Laurenz, 2005). According to research studies on green roofs, the energy required for space conditioning due to the heat flow through the roof would be reduced by more than 75% (Liu and Baskaran, 2003).

Studies on urban parks suggest that for every 100m2 of vegetation, air temperature is reduced by 1ºC, and that by increasing the ratio of green area to built area by 10% a 0.8ºC reduction is achieved (Dimoudi and Nicolopoulou, 2003). Similarly, Central Park in New York reduces its nearby temperature by 2-5ºC (Rosenzweig, Solecki & Slosberg, 2006), and Shinjuku Gyoen park in Tokyo reduces the urban heat island effect by 2ºC and decreases the temperature in adjacent areas within the range of 80-90m from the boundary. (Honjo, Narita, et. al., 2002). Vegetated courtyards reduce air temperature approximately 4-5ºC (Reynolds, 2002), and vegetated roofs reduce air temperature between 0.5-2ºC (The City of Toronto and Ryerson University, 2005).

The Green Facades Framework, based on these studies, extrapolates data as a series of charts to facilitate the understanding of green facades in relation to identified opportunities. In measuring existing types of green façades, the framework develops an evaluation process which consists of measuring the contribution of each type of green façade based on a scale of values that ranges from the lowest to highest contribution (0-1). This evaluation process proposes different point-scale values depending on the opportunity the framework is evaluating. In addition, some opportunities are more complex to evaluate than others, and requires including more factors in the evaluation process, such as the green façade orientation. This means, for instance, that when evaluating the potential of green façades to influence the comfort temperature and energy demand reduction, the framework proposes a five-point scale of values or percentages, which depends on the orientation of the façade. In this sense, an opaque green façade, where greenery is attached to an opaque wall, performs best with a northern orientation (1) due to the thermal insulation capacity required by north façades. However it does not perform too well for a south-east or western orientation (0.2), since it does not allow solar energy gains. On the contrary, transparent green facades perform best with a south east or western orientation (0.8-1) since they allow solar energy gain, while they perform poorly for a northern orientation, due to their weak insulation capacity. The evaluation of other aspects, such as the influence on acoustics, is much simpler. The framework, based on related studies, measures the green façades attached to opaque walls as contributing to outdoor noise reduction, while the transparent green façades do not contribute at all to this effect. The following Table 2 summarizes one of the charts developed by the framework which shows this evaluation process.

Table 2. Green Façades Framework measuring the contribution of different types of green façades to improve human comfort conditions

	Contribution of green façades to improve human comfort				
Greenery climbing on an opaque wall 	Comfort temperature & reduction in energy d. 	Acoustic Insulation	LOW 0 — HIGH 1	Humidity	LOW 0 — 0.5 — HIGH 1
		Visual Comfort		Psychological benefits	LOW 0 — 0.5 — HIGH 1

		Visual Comfort	LOW 0 — HIGH 1	Psychological benefits	LOW 0 — 0.5 — HIGH 1
Greenery external transparent internal 	[illegible]re & [illegible] d. 	Acoustic Insulation		Humidity	LOW 0 — 0.5 — HIGH 1
		Visual Comfort	LOW 0 — HIGH 1	Psychological benefits	LOW 0 — 0.5 — HIGH 1

The evaluation of green facades against the six areas of opportunity reflects crucial differences between the two main categories of green façades –opaque and transparent. For example, transparent green façades are visible from both the outside and the inside, creating opportunities for green façades to enhance the indoor space. They perform much better than the opaque green façades in terms of indoor temperature, reduction in energy demand, indoor visual comfort and psychological benefits. On the contrary, opaque green façades can only partially achieve many of these opportunities, but they provide greater thermal insulation capacity. In addition, some of the attributes are only evaluated for opaque green walls, such as the acoustic influence, and others are only evaluated for transparent green façades, such as the influence on indoor visual comfort.

This framework enables the critique and evaluation of different types of green façades in terms of the extent to which they fulfil identified opportunities, which helps to determine their appropriateness to different conditions in an effort to improve the current practices for building green façades.

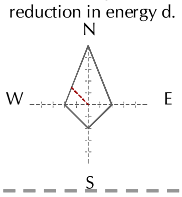
5. Application of the framework

The research applies the green façades framework to existing examples of green façades to evaluate their appropriateness to their particular conditions. Five case studies are selected, corresponding to the previously identified five main types of green façades. The case study selected for a green façade where greenery climbs through an opaque wall is the Rue des Suisses apartment complex designed by Herzog & de Meuron in Paris in 2000. The example selected for the greenery attached to an opaque wall is the Quai Branly Museum designed by Jean Nouvel in Paris in 2006. For a green façade composed of green vertical panels the selected case study is Seedorf House, designed by Manuel Perez in Madrid in 2004. For a green façade between two transparent layers the selected example is the Arts and Human Sciences building by Lacaton & Vassal in Grenoble, France, 1995-2001. Finally, the selected example for a green façade where the external layer is the greenery and the internal layer is the transparent wall is the Gymnastic Pavilion designed by Abalos and Herreros in Madrid in 2002.

By applying the framework to these existing examples, each can be evaluated and critiqued for their suitability within their given context. Table 3 shows an example of how each of the case studies has been evaluated by the framework.

Table 3. Evaluation of the Quai Branly Museum, greenery attached to an opaque wall

Project information	Quai Branly Museum, Paris	Greenery attached to an opaque wall as a green tapestry
Project Quai Branly Museum	**1. Human Comfort**	
Location Quai Branly Street, Paris	Comfort temperature & reduction in energy d. (compass diagram)	
Year 2006	Acoustic ...ation: LOW 0 – HIGH 1	Humidity: LOW 0 – 0.5 – HIGH 1
Architect Jean Nouvel	...l ...ort	Psychological benefits: LOW 0 – 0.5 – HIGH 1
Green Façade orientation North-west	**2. Expressive Capacity**	LOW 0 – HIGH 1
	3. Air and Water Quality	LOW 0 – 0.15 – 0.3 – 0.5 – 0.75 – HIGH 1
	4. Indoor-Outdoor Relationship	LOW 0 – 0.25 – 0.5 – 0.75 – HIGH 1
	5. Urban Biodiversity	LOW 0 – 0.25 – 0.5 – 0.75 – HIGH 1
	6. Carbon Neutral Architecture	LOW 0 – 0.5 – HIGH 1



These evaluations bring together the overall performance of the green façades based on each opportunity. The application of the framework reveals its usefulness and limitations in assessing how designers select and define more appropriate types of green façades for specific projects.

6. Living wall proposal

Subsequent to the case study evaluations, the research proposes two new living wall systems, constructed in collaboration with a local company, MUBI [www.mubi.ca] in order to find local materials to be included in the prototypes. Both an opaque living wall and a transparent living wall are presented.

The first prototype, an opaque living wall, is currently built and installed for monitoring purposes. In order to make it as thin, light, and simple as possible the opaque living wall panel is composed of the following four main layers:

- Moisture and root barrier layer
- Mineral wall which is a rock wool layer
- Felt layer
- Plants which will be inserted in previous layer

These layers form a sandwich in which an irrigation system is embedded. Plants are introduced into the panel through holes in the felt layer, which act as pockets for the vegetation. This provides freedom to select diverse plant species to create an exuberant green wall [Fig 3]. The panel is attached to opaque walls through metallic fasteners.

Figure 3 The design of the two opaque Living wals recently built in Vancouverl

The opaque living wall prototype is based on hydroponics plants, where the nutrients required by plants are introduced within the water of the irrigation system. The prototype living wall will be installed in a test room and monitored in order to achieve more accurate data on its environmental behaviour.

7. Conclusion / Discussion

This research attempts to clarify the definition of appropriate living skins in response to an identified absence of design criteria for the increasing applications of green facades around the world. It presents a larger range of opportunities than those typically considered by designers and forwards the following conclusions:

- **Types of green façades**. The research provides a relevant classification of living skins based on two main categories: opaque and transparent living skins. This classification has been developed by analysing the current practices for building living skins, studying a series of existing examples, and identifying their construction systems.
- **Decisive attributes in green façades**. The research provides a larger spectrum of opportunities to be considered when determining living wall systems. From the all opportunities analyzed, the research focuses on the opportunity to enhance human comfort, specifically in terms of temperature and reduction in energy demand. This is mainly because this opportunity's relationship to passive architecture, in terms of different façade orientations and options for taking advantage of solar energy. At present, the greatest amount of available research and data relates to the influence of vegetation on human comfort conditions.

The research proposes a framework which combines these two findings, one extracted from the current practices of green façades and the other extracted from related research. This enables the evaluation of each type of green façade for particular projects. This is indeed the most relevant contribution of this research: to provide an understanding of why a particular type of living skin, such as opaque, performs better in a north orientation, while other types of living skins, such as transparent façades, function better for south, east and west orientations.

The framework also reveals clear differences between the behaviour of the two main categories: opaque and transparent green façades. It shows that opaque green façades can only partially meet many of the identified attributes. This is mainly due to the fact that opaque green façades only affect one side of the façade, the outside; while transparent green façades affect both the inside and the outside. It also reflects the deficiencies in current practice, namely the enrichment of the indoor and outdoor relationship and the contribution to air and water quality. None of the existing green façades has incorporated any flexible systems nor has the option of retaining rain water or treating grey water been considered.

The research combines the current practice of green façades with current research on green façades, two fields that appear to be limited in their interactions. Current practice seems to be more concerned with exploring the expressive capacity while research seems to be more concerned on exploring the influence on human comfort. This project, by combining both and evaluating them, intends to provide a deeper study of green façades in order to improve their present status. The research proposes living wall systems for each of the two major categories, opaque and transparent. Ongoing will monitor these proposed systems in order to test their behaviour, contrast them with related research, and discover whether the identified opportunities are fulfilled.

Keywords: Unfired industrial produced loam bricks; Passive House Standard; Pilot building projects

Summary

The target of the Austrian research project LEHM.konkret was to develop a sustainable building solution that takes all three dimensions of sustainability into account. Besides environmental aspects such as the recyclability, energy efficiency in production and use phase of the building, aspects of social sustainability like health and comfort as well as the achievability of the building solution have been considered. By joining forces, partners of industry, science and building practice developed a solution for the Passive House Standard based on unfired, industrially produced and ecologically optimized loam bricks.

Within the research project, two building prototypes were realized with unfired loam bricks: two-storey family houses with the Passive House Standard. One of the challenging steps was to implement a sufficient load bearing use of the unfired loam bricks, which would allow a realization of passive houses with nearly 100 % unfired loam brick walls. The projects were completed in summer 2006. The evaluation results regarding the practicability of the scientific solutions were documented and first experiences of the house owners were collected.

The current challenge is the realization of building projects of a larger scale like the residential house “Orasteig” with 170 apartments, where parts of the project will be constructed with the newly developed building solution.

1 Introduction

The urgent demand for energy efficiency in the building sector is realized by a constantly growing group of stakeholders and policies. Consequently, this energy efficiency includes the improvement of the energy use during the production of the building products as well as the energy use of the building during its use phase. The Passive House Standard is one answer to this requirement regarding the energy efficiency of the building sector.

The traditional and natural building material, unfired loam, with its positive influence on health and comfort, as well as its ecological properties has been rediscovered by many stakeholders. Its excellent life cycle performance due to the low energy consumption during production also has a very positive influence on the life cycle assessment of the concerned building elements. The interest is increasing constantly. Unfortunately, loam constructions in general have been driven out of the industrial building sector and at the moment there are no building systems for industrial loam constructions available on the market. The market is restricted to some small providers of loam products, primarily loam plaster.

The main idea within the project LEHM.konkret was to combine the advantages of the passive house solution with the advantages of the traditional building material, unfired loam. The industrialized production of the traditional building material, unfired loam brick, served the purpose to provide the comfort and safety-guarantee of an industrially produced product.

Within the research project, an unfired and industrial produced loam brick was developed and improved to a satisfying level of quality.

Based on the performance of the newly developed unfired industrially produced loam brick, necessary construction details were developed in order to reach the Passive House Standard as well as consider the special properties of the unfired loam brick.

The most important step was the demonstration of the research results within two building projects. The realization of two building prototypes offered an excellent opportunity to evaluate the practicability of the newly developed construction details and building solutions. The results of the two projects partly confirmed the theoretically developed solutions but also answered some open questions.

2 The Research Project

2.1 Previous Scientific Steps before Realization of the Pilot Building Projects

In order to reach the final target of the research project several new technical solutions had to be found; starting with the optimized performance of the unfired loam brick, and ending with the solutions for the execution procedures and the construction details for the building.

2.1.1 Optimization of the Building Product "Unfired Industrial Loam Brick"

The first step was the improvement of the unfired, industrially produced loam brick that can be used for load bearing masonry in two storey houses, under consideration of some static parameters. Based on an analysis of a conventional unfired loam brick, the main target here was the revision of the material mixture, the brick geometries and the format. The development has been executed with focus on the advanced development of the following properties:

- Compressive strength
- Bending tensile strength
- Thermal capability
- Sound insulation
- Drying properties
- Processing performance
- Ecology, health and hygiene of material mixture

Figure 1: Several tests regarding the strength properties of the unfired loam brick walls have been done

2.1.2 Solutions for Building Execution, Construction Details

Essential for a successful execution of unfired loam constructions is the durable protection against water and intense, long-term moisture during the construction and the use of the building. Different parts of the unfired loam brick walls need a particular treatment during the execution. The research focused on simple solutions that are achievable, effective and allow an efficient integration within the framework of a construction site's conventional operation routine.

The limits, special properties and necessities of the unfired loam brick, which have to be considered, were identified by test results. Of course, the requirements for Passive House Standard, including air tightness, heavy windows and doors, as well as excellent heat insulation and particular HVAC equipment were taken into consideration by the project group. The most challenging and important part of the research activities was the creation of construction details that met, and are meeting the requirements for Passive House Standard under consideration of the limits and special necessities of the unfired loam bricks.

As the intention was to construct buildings with an excellent performance regarding health and comfort, another research target was to define wall systems and indoor materials which respond to the high level of the purely natural building, material unfired loam.

2.1.3 Static Calculations

In its current evolution the unfired loam brick does not have the same strength as fired brick. With static calculations, the limits and possibilities of the load-bearing, unfired loam brick walls were appointed. Recommendations for the building structure have been set and considered during the planning and realization of the pilot building projects.

3 The Pilot Building Projects

3.1 Function and Basic Data of the Pilot Building Projects

The following two pilot building projects that have been realized within the research project are:

3.1.1 Detached Family Home

The two storey house with 118,79 m² living space and 13 kWh/(m²a) was realized with 20 cm load bearing, unfired loam brick walls, 30 cm of mineral wool for the outer walls and 12 cm inner walls of unfired loam bricks. The outer walls have a U value of 0,12 W/m²K.

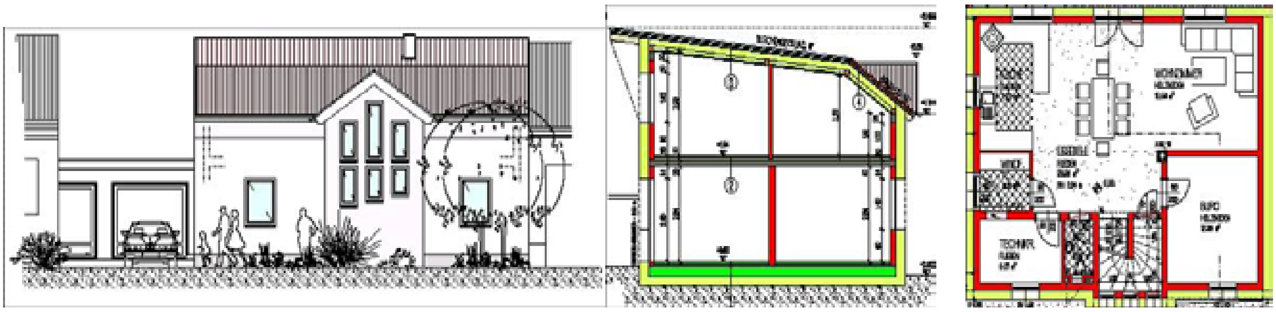

Figure 2: Construction plans for the detached family home. All red marked walls are unfired loam brick walls.

3.1.2 Organic Farm with Integrated Guest Rooms

The house for a farmer and his family with a 290 m² living space is also divided into two stories. The family wanted to provide guests with the opportunity to experience the excellent indoor air quality in rooms which are built only with natural building products. For this reason, two additional guest rooms available for renting are integrated into the project.

4 Construction and Experience

Within both projects many different trial experiences have been collected. In the following section the main conclusions are summarized.

4.1 Protection against Water and Long-Term Moisture

Currently, the unfired loam bricks do not have the same water resistance as fired bricks. They must receive a durable protection against water and long-term moisture during the construction as well as use phase of the building. The unfired bricks were delivered on conventional palettes, which were properly covered to avoid water inside the packages.

4.1.1 The Basis / First layers

During the construction period, the floors can become flooded by melting snow or rain. During the use phase of the building the flooding can occur due to an overflowing bath tub or faulty washing machine. Any contact between the base of the unfired loam brick walls and water on the indoor floors has to be avoided. To guarantee the protection of the wall base, the first one to two layers of the walls have been constructed with fired (water resistant) bricks. Furthermore, the water was lead off in a controlled way, which was ensured within the slope in the floors and water pipes at the lowest point.

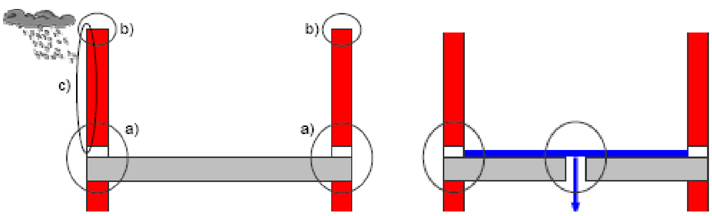

Figure 3: Certain parts of the unfired loam brick walls need durable protection against water and long-term moisture during the construction as well as use phase of the building.

4.1.2 The Top / Final Layer

As the unfired loam bricks have a perforation for technical reasons, it is important to make sure that no rain or snow gets inside the perforation during the construction of the walls. For this reason, during the construction phase, the top layers were covered with a waterproof material that was easily removable.

The supports of the concrete floors got a waterproof leveling course (bituminized felt on a leveling concrete course) which prevents great amounts of water, affected by the concrete flooring, inside the perforation of the top layers.

During the construction phase of the walls, the layer for the sills was covered.

4.1.3 The Wall Surface

During a long lasting rain period, the side of the unfired loam brick walls that were most affected by weather was protected with a waterproof cover. Limited contact of the wall surface with water by rain- or snowfall during the construction period or by water splashed by the user during any other time does not have any significant negative influence on the walls.

4.1.4 Inside the Walls

For the wall parts with water pipes inside, it is recommended to construct those areas with fired bricks or to furnish them with a waterproof sealing coat.

Figure 4: The first two layers were constructed with fired loam bricks. The last layer under the sills and top layers of the walls have been covered with a waterproof material to prevent water inside the brick perforation.

4.2 Attachment of Heavy Doors and Windows with Passive House Standard

The windows and doors with Passive House Standard usually are heavier than conventional windows and doors. An airtight fixing of those kinds of windows and doors was achieved by a leveling concrete course around the wall opening. The heavy windows and doors were only fixed at the fired lintel element (top) and at the concreted sill (bottom). The bearing length of the lintels always had a minimum length of 25 cm inside the wall. The side parts only have been attached with spacer screws (7,5 x 152 mm, each 80 cm). One third of the window frame was positioned to the inside part the insulation level.

Tests with a certain glue and insulation foil confirmed that the insulation foil for airtight connections has the same adhesion quality on unfired loam bricks as on conventional fired bricks.

Figure 5: Fired lintel element, leveling concrete course around wall opening and airtight connection of windows and doors for Passive House Standard.

4.3 Static Strengths and Limits

The specific properties of the unfired loam brick wall regarding strength (f_k = 2,0 N/mm²) and mechanical resistance require for some considerations during the planning and construction phase of the building. For both pilot projects, static calculations have been done to appoint the peak loads and to guarantee the structural resistance of the buildings.

4.3.1 Point Loads

In general, point loads should be avoided. If this is not possible, additional support for point loads could be, for example, integrated columns inside the unfired loam bricks.

4.3.2 Support of Ceilings

Experience regarding peak loads in ceiling supports showed that the particular ceiling, constructed from prefabricated element, affects a high linear distributed load on the inner side of the top brick layer. An optimized load distribution was reached due to a levelling course of concrete on top of walls, which provides an even surface and a solid connection between walls and ceiling. Ecological concrete solutions are already possible with new concrete products without cement. The consideration of the maximum span between the load bearing walls is very important.

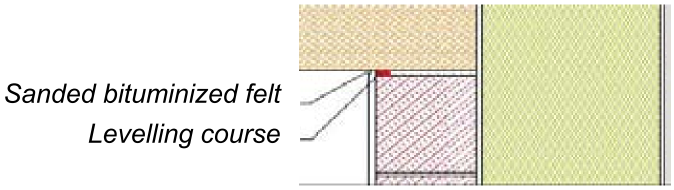

Figure 6: Optimized distribution of the high linear distributed load, affected by the ceiling.

4.3.3 Installation Lines in the Walls

Regarding electrical installations and other works on the wall, horizontal electrical installation lines have been avoided. Exceptions have a maximum depth of 10 % of the wall thickness. Water pipes are mainly led into the floor.

Figure 7: Water pipes are mainly led into the floor. Installation lines in the unfired loam brick walls are not a problem.

4.4 Indoor Air Quality

The inner surface of the walls has the highest influence on the indoor air quality and thereby on the health and comfort of the inhabitants. To make sure that the positive influence of the unfired loam brick walls on the indoor air quality is continued with a plaster material that has the same properties, loam plaster was used for the inner sides of the walls.

It is recommended to do the plasterwork during the months where there is a minimum of 5 °C outside temperature to guarantee conditions for fast drying of the loam plaster. Due to a very tight time schedule on one of the building projects the plasterwork of the family house was done during winter time. Resulting from the low temperature on the outer walls as a result of the very low temperature outside and the air tightness of the building, the ventilation system was used during the drying process to avoid cracks in the loam plaster. When the drying process was finished, and before the inhabitants moved into the house, the filter of the ventilation system was changed.

Figure 8: The loam plaster was executed with two layers and a reinforcement fleece in the first layer to ensure a good adhesion on fired as well as unfired loam bricks. The sorption capacity of the loam has a positive influence on the humidity of the rooms.

4.5 User Experience

Figure 9: Regarding operation costs, indoor temperature, indoor air humidity, the feed-back of the house owners was very positive. A challenging experience was to affix heavy weight onto the walls.

4.5.1 Operation Costs

In general the feedback of the house owners was very positive. The energy consumption responds to the expectations on a Passive House Standard (€ 200, - per year for heating and warm water). During the winter period the house owners of the detached family home had a usage of 15 kg of wood-pellets per week.

4.5.2 Indoor Temperature

The buildings are cold during the summer and warm during the winter season. During the first year the detached family home had no window coverings as protection against the sun. Even considering this circumstance, a slow increase in indoor-temperature was realizable, which started with an outside-temperature of 29 °C.

4.5.3 Indoor air humidity

Regarding the balance of the indoor air humidity, the inhabitants confirmed an observation, which is mentioned very often in connection with unfired loam constructions: due to the excellent sorption ability of the unfired loam, the mirror in the bathroom does not steam up, even after a long hot shower.

The inhabitants also made an interesting observation during winter: the influence of the sorption capacity and, by this, the balance of the indoor air humidity is, of course, limited by available humidity in general, inside or around the building. During the cold season, outside air becomes very dry, having a big impact also on the quality of the indoor air. Another very desirable aspect of the unfired loam is that it can keep a balance in terms of indoor-air humidity, which is providing a very pleasant indoor climate. But of course the unfired loam cannot “create” humidity when there is no moisture available.

4.5.4 Resistance of walls

Up until now, nearly two years after the finalization of the building projects, no cracks have been found in the unfired loam brick walls.

One criticism was the low resistance regarding dowel extraction. This problem was solved with injection dowels at certain spots bearing high loads on the walls. Lower loads were hung using long screws.

5 Current Challenge

Within the next months a large residential project incorporating 170 apartments will be built in Vienna. The cost efficient and government subsidised project won first place in the housing competition and foresees a big variability in floor plans and sizes. Within the project, sustainability in construction works goes hand in hand with high level architectural urban planning.

The building demonstrates excellent technical and ecological performance with an advanced energy standard, and the use of ecological building materials like, for example, unfired loam bricks. The upper two of the four stories will be constructed with unfired loam brick walls. Several feasibility studies have been conducted, and a static calculation has approved the intention.

Figure 10: The results of the research project LEHM.konkret and the experiences due to the pilot building projects will be important for the realization of a large-scale project like “Orasteig” with its requirements regarding the operation routine.

6 Conclusion

The traditional building material, unfired loam, in combination with the well developed and highly sophisticated technology of the Passive House Standard, provides a perfect example for sustainability in construction works.

The unfired loam shows an excellent performance regarding:

- Minimised CO2-emission and minimised emissions of SOx, NOx, OrgC, HF
- Low energy consumption in production
- Recyclability
- Thermal capability due to high mass
- Acoustic protection due to high mass
- Indoor air quality by humidity sorption
- Protection against electromagnetic fields
- Fire safety

During the execution of the walls with unfired loam bricks, the main experiences have been that the processing is very similar to fired bricks. For this reason the efficient training of building labourers is no problem at all. A fast execution was realised with a mortar carriage and the tongue and groove system was experienced as very practicable due to the similarity with conventional brick constructions.

In general, the current result is very satisfying, but for the successful planning and execution of an unfired loam brick building with Passive House Standard, the consideration of certain requirements are needed.

Each unfired loam material mixture has a different properties; some have necessary properties for being a construction material, others not. Nevertheless, there is still a real need for further research activities, especially regarding the compressive strength and the water resistance of the unfired loam brick. Due to the special sorption ability, the air humidity has a very big influence on the strength performance of the unfired loam brick. Also the significant shrinking and swelling of certain loam material mixtures has to be reduced. An improvement regarding those properties is absolutely necessary, and potential for improvement is foreseen.

Standardisation criteria still do not exist apart from some German recommendations of the last century. A harmonised standard will be important for the marketability of this building system.

Also specific training tools for architects and labourers would be very important to maximise the marketability of the building solution.

THERMAL BEHAVIOUR OF A WALL-LINING CONTAINING PHASE CHANGE MATERIALS

Kenneth IP MSc PhD CEng MCSIBE[1]
Dianne DYBALL BSc, MSc[2]
Andrew MILLER BSc, PhD, CEng MCIBSE[1]

[1]Centre for Sustainability of the Built Environment, School of Environment and Technology, University of Brighton, Brighton, UK, k.ip@brighton.ac.uk, a.miller@brighton.ac.uk
[2]John Packer Associates Ltd, Uckfield, UK, dianne.dyball@jpa.uk.com

Keywords: micro-encapsulated phase change materials, wall-lining, latent thermal storage

Summary

In temperate climates like UK, buildings constructed with high thermal mass materials have the intrinsic capacity to alleviate the effect of overheating in the summer. Phase change materials (PCMs), which have a high latent heat capacity to volume ratio is a potential effective means to improve the thermal capacity of light-weight or existing buildings. The feasibility of applying PCMs in buildings was investigated through a research and development collaboration between University of Brighton and OMNOVA Wallcoverings (UK) Ltd. The aim was to develop a PCM wall-lining which can reduce energy consumption of buildings, by minimising the use of air-conditioning, and improve the thermal comfort during periods of extreme climate conditions.

This paper reports on the measured experimental findings of the thermal performance of a prototype phase change wall-lining developed and manufactured. Samples of the prototypes were tested using Differential Scanning Calorimeter (DSC) in the laboratory which provided evidence of the projected and actual sensible-latent heat transfer behaviour of the micro-encapsulated PCM. In order to evaluate the thermal performance in actual installed conditions, the prototype wall-linings were subject to a regime of cyclic environmental conditions in a 13.8m^3 chamber. The results were compared with a control chamber that was subject to the same conditions but without the phase change wall-lining. The experiments provided measured data on the effect of different supply air conditions to the charging and discharging behaviour of the wall-lining, the amount of energy stored and the moderation of peak temperatures. These experimental results enabled the evaluation of the effectiveness of the latent heat storage by the PCMs within the wall-lining and are analysed and discussed.

1. Introduction

Research collaboration between University of Brighton and OMNOVA Wallcoverings (UK) Ltd has resulted in a project to develop a thermally interactive wall-lining, utilising OMNOVA's manufacturing technology, that can improve the thermal storage capacity of buildings, reduce overheating and reduce demand for conventional cooling systems. This has been realised by the inclusion of phase change materials in wall-linings.

Phase Change Materials (PCMs) are materials that not only absorb sensible heat as the temperature increases but also absorb latent heat when melting and release the stored heat when freezing, both at an almost constant temperature. PCMs can be used in buildings to significantly improve the thermal mass as they have a much greater ability to store heat than conventional building materials such as concrete. Concrete has a sensible heat storage capacity of 1.0 kJ/kgK, whereas an inorganic phase change material such as calcium chloride hexahydrate can store up to 193 kJ/kg during phase transition. PCMs are able to reduce peak temperatures in buildings by absorbing excess heat during the day and releasing the heat at night when the surrounding temperature is cooler. The storage and release of excess heat results in a narrower temperature band over a diurnal period therefore improves thermal comfort for the occupants.

A significant development in phase change technology is the ability to microencapsulate PCMs. Microencapsulation is the packaging of micron-sized materials (both liquids and solids) in the form of capsules, ranging from less than 1μm to more than 300μm. Microencapsulated PCMs can be used to introduce high thermal storage capacity into conventional building materials. Examples of research developments using microencapsulated PCMs include gypsum plaster (Schossig et al., 2004), concrete (Cabeza et al., 2004), and wallboard (Hummel, 2004); (Khudhair et al., 2003).

An advantage of using a wall-lining containing phase change materials is its direct exposure to heat exchange within the room. Other PCM materials are located deep within the construction of a wall or ceiling and would have less effective heat transfer.

2. Phase Change Wall-lining Development

Initial investigations to incorporate microencapsulated phase change materials into a vinyl wall-lining were successful using microencapsulated phase change materials supplied by BASF. This preliminary phase change wall-lining was tested and the results showed it successfully slowed the temperature rise and reduced peak room temperatures, as reported at SB05 (Dyball, 2005).

To progress the development of a phase change wall-lining to a prototype stage it was desirable to increase the thermal storage capacity of the wall-lining. Outlast Technologies Inc, specialists in the research of phase change materials, was approached to develop microencapsulated phase change materials specially formulated for inclusion in a vinyl wall-lining.

Outlast supplied a range of their microencapsulated PCMs, known as Thermocules®, with different particle sizes for joint development work. Analysis of the Thermocules® determined the larger the particle size the larger the heat storage capacity. Extensive experiments were undertaken to develop a plastisol formulation containing the highest possible loading of the largest Outlast Thermocules, referred to as XXL(2). The resulting formulation was coated out and cured and a vinyl wall-lining containing 46% by weight of microencapsulated phase change materials was produced.

Differential Scanning Calorimeter (DSC) analysis of the lab prepared phase change wall-lining revealed the phase transition temperature has shifted from 24°C phase change temperature of XXL(2) Thermocules) to 23°C. This raised concern that the shell of the Thermocules may have ruptured during processing and the wax core contaminated. If the wax core was contaminated it is likely that after thermal cycling (repeated heat then cool cycles) each phase transition would show a different profile in the DSC graph as the phase change material would be unable to perform in the same manner as the wax composition would have changed. The results, illustrated in Figure 1 showed that repeated heating and cooling of the phase change wall-lining did not affect the phase transition temperatures. The shape of all the peaks remained the same after 22 cycles confirming the Thermocules performance had not been compromised and they were robust enough to withstand the manufacturing process.

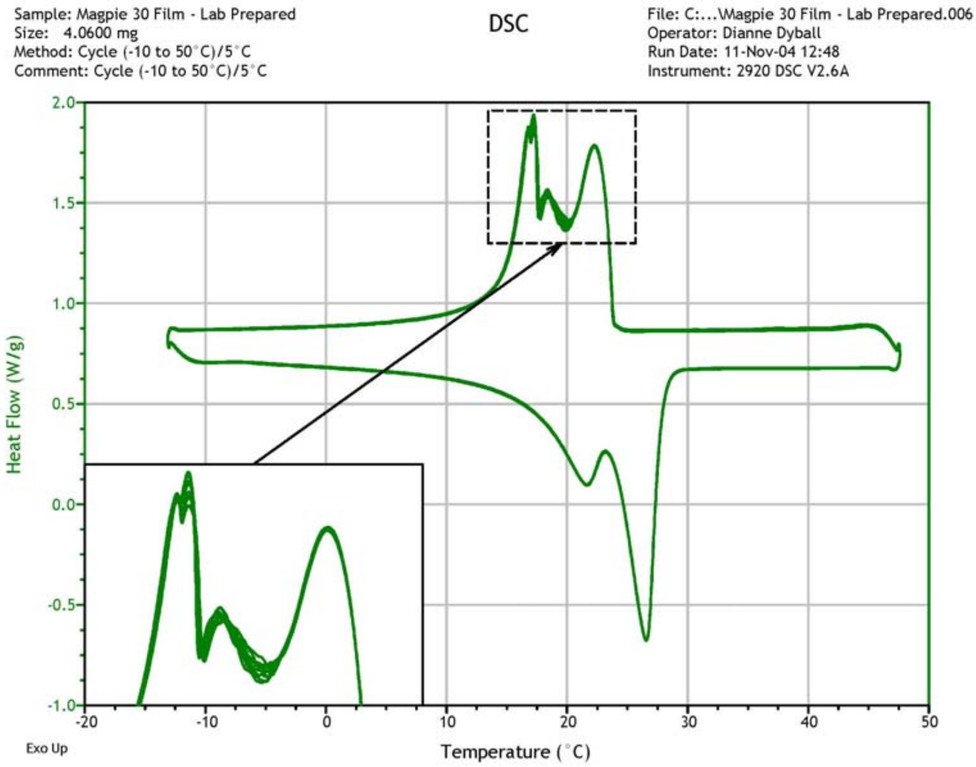

Figure 1 Results of thermal cycling lab prepared phase change wall-lining

A successful pilot scale trial was undertaken and manufactured 50m of 700mm wide, 6mm thick phase change wall-lining. The wall-lining contained 45% by weight of Outlast XXL(2) Thermocules. The thermal performance of the trialled manufactured phase change wall-lining was thermally analysed and the results are shown in figure 2. The DSC results of the manufactured phase change wall-lining show the phase transition temperature is 23°C and the latent heat storage capacity is 87 J/g. This latent heat capacity equates to 503 kJ/m^2.

The graph also includes the DSC results of the Outlast XXL(2) Thermocules used in the phase change wall-lining. This makes it easy to identify any change in the peak profiles and highlight any problems that may have occurred to the microcapsules during manufacture. From the graph in Figure 2 it is clear the melt point has shifted from 24°C to 23°C as occurred in the lab prepared sample. As this is consistent with the inclusion of XXL(2) into vinyl wall-linings there is no need for concern. There is no other significant change to the profiling of the Thermocules within the phase change wall-lining therefore the inclusion was a success.

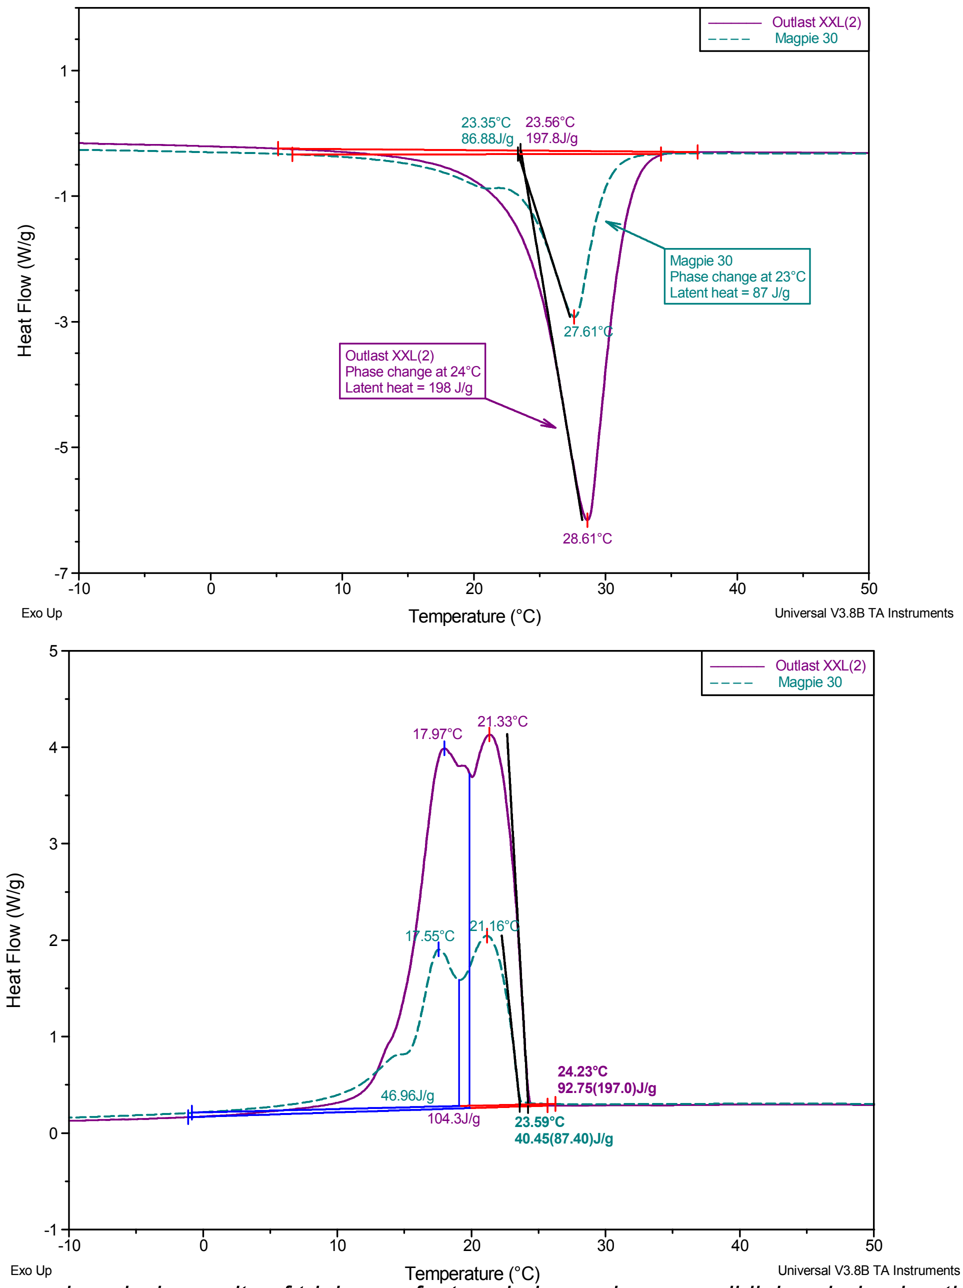

Figure 2 Thermal analysis results of trial manufactured phase change wall-lining during heating cycle (upper) and cooling cycle (lower)

The prototype phase change wall-lining was tested by Gearing Scientific Ltd to determine the conductivity value. The thermal conductivity value of a material is important as it is a measure of the rate at which heat can pass through a material.

The phase change wall-lining was tested using a LaserComp Fox 200 thermal conductivity instrument which conforms to ISO 8301. The tests were conducted at temperature intervals from 20°C to 30°C to ensure before, during and after phase changes were included. The results showed the thermal conductivity value of the prototype phase change wall-lining is 0.12 W/mK.

3.0 Experimental Setup and Measurements

To evaluate the thermal performance of the phase change wall-lining using realistic room conditions two environmental test chambers were proposed. To determine the variables that need to be considered a mathematical model was first developed. A one dimensional finite element heat transfer network through a chamber wall with phase change wall-lining and timber board was then established and simulated to predict the performance. The different elements to be considered for the heat transfer in a chamber with air supply and exhaust are illustrated in Figure 3. The proposed environmental chambers would be used to evaluate the thermal performance of the phase change wall-lining when subjected to different supply air conditions.

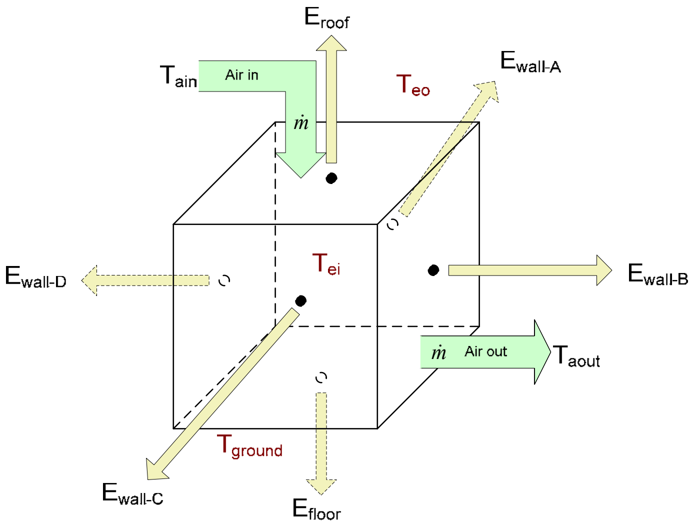

Figure 3 Heat transfer of Environmental Chamber

Two highly insulated, identical chambers, 13.8m^3, were constructed in an open laboratory space that has relatively stable thermal conditions at the University of Brighton, see Figure 4.

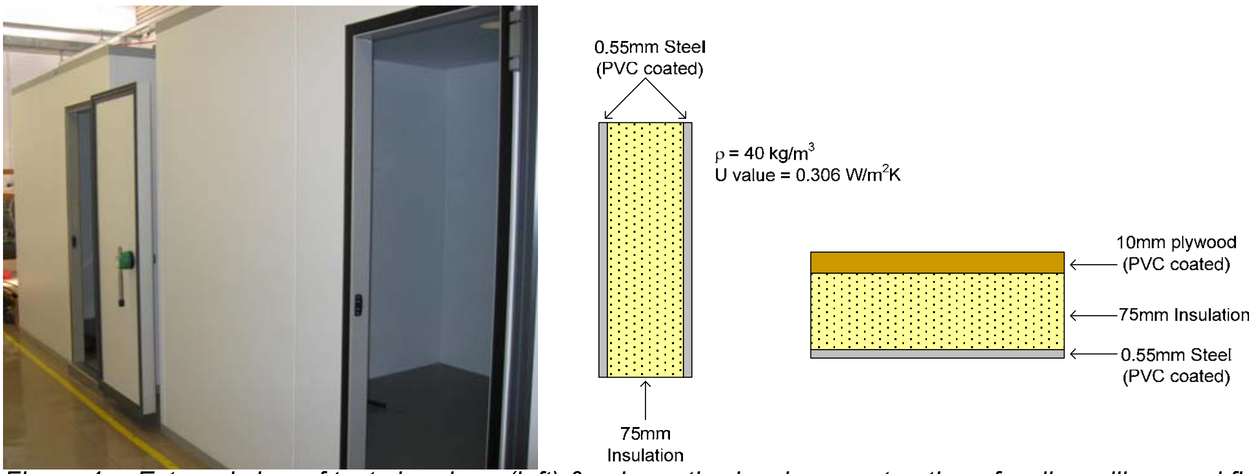

Figure 4 External view of test chambers (left) & schematic showing construction of walls, ceilings and floor (right)

The temperature and air flow inputs to the chambers are set by an Excel programme that operates the air-conditioning system via a programmable logic controller (PLC) in a control panel. The system can operate to provide supply air temperature between 15 - 30°C and air flow of 1.5 – 10 air changes per hour (ach).

The supply temperature is monitored by two air temperature probes, both located in the ductwork prior to air inlet as shown in Figure 5, which feeds back to the PLC and enables the program to adjust the amount of heating or cooling necessary to maintain the temperature set-point.

The test chambers were fitted with extensive surface, air and room temperature sensors which were all connected to a data logger for data acquisition at timed intervals.

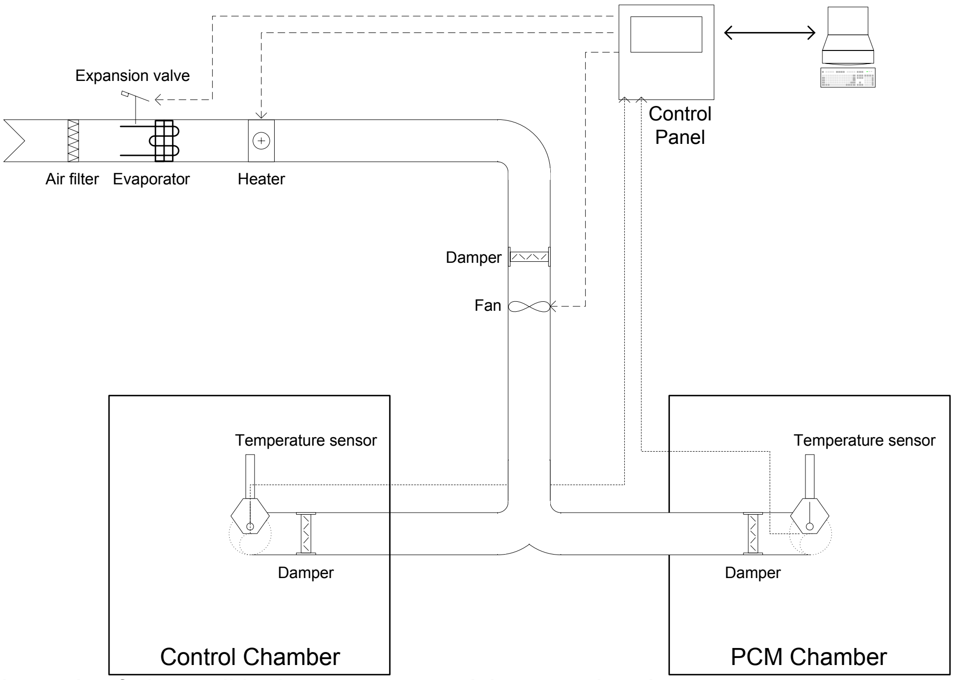

Figure 5 Schematic of air-conditioning system supplying test chambers

The test chambers were heated and subsequently cooled to a fixed temperature. Each experiment used a different air supply rate, which remained constant throughout the duration of the experiment. The experiment continued until steady state conditions were reached.

4.0 Results and Discussion

The aim of the experiments was to evaluate the effect of supply air conditions to the thermal behaviour and storage capability of the phase change wall-lining. Two sets of results are illustrated to demonstrate the charging and discharging behaviour. Figures 6 and 7 show the PCM charging process when air at 30°C was supplied whereas Figures 8 and 9 show the PCM discharging process when the air supply temperature was set at 15°C.

4.1 Heating cycle

The graphs have been divided into 'zones' to represent different stages of the heat transfer process. Figure 6 showing the heating cycle in the Control Chamber has been divided into Zones A, B and S. Zone A is the initial stage when warm air begins entering the chamber. The curve in Zone B shows the effect of sensible heat storage of the chamber walls, which is proportional to the rate of change of temperature. The steady state heat transfer occurs in Zone S where heat contributing to thermal storage gradually diminishes. The charging time (Zone B) is affected by the air change rates; the use of 9 ach reduced the charging time by nearly 50% in comparison with the 3 ach air flow rate.

In Figure 7, heating results for the PCM Chamber, an additional zone has been created. For the PCM Chamber Zone B exhibits the phase change characteristics of the wall-lining where the rate of air temperature increase is reduced in comparison with Figure 6. As the microencapsulated PCM is evenly distributed within the wall-lining, the thermal behaviour is similar to a wall with high thermal capacity that slows the change in temperature, in particular more evidently in the temperature region where phase change occurs. The phase change processes appear to occur mainly between the first 6 to 9 hours. A comparison of the time for the air temperatures to reach a reference temperature of 24°C for the experiments in each test chamber show significant difference from 100, 250 and 880 minutes to 230, 540 and 1740 minutes. Zone C exhibits the sensible heat transfer characteristics similar to Zone B of the Control Chamber (Figure 6) whilst Zone D shows the more gradual temperature rise, due to the additional thermal capacity of the phase change wall-lining, until steady state conditions are reached in Zone S.

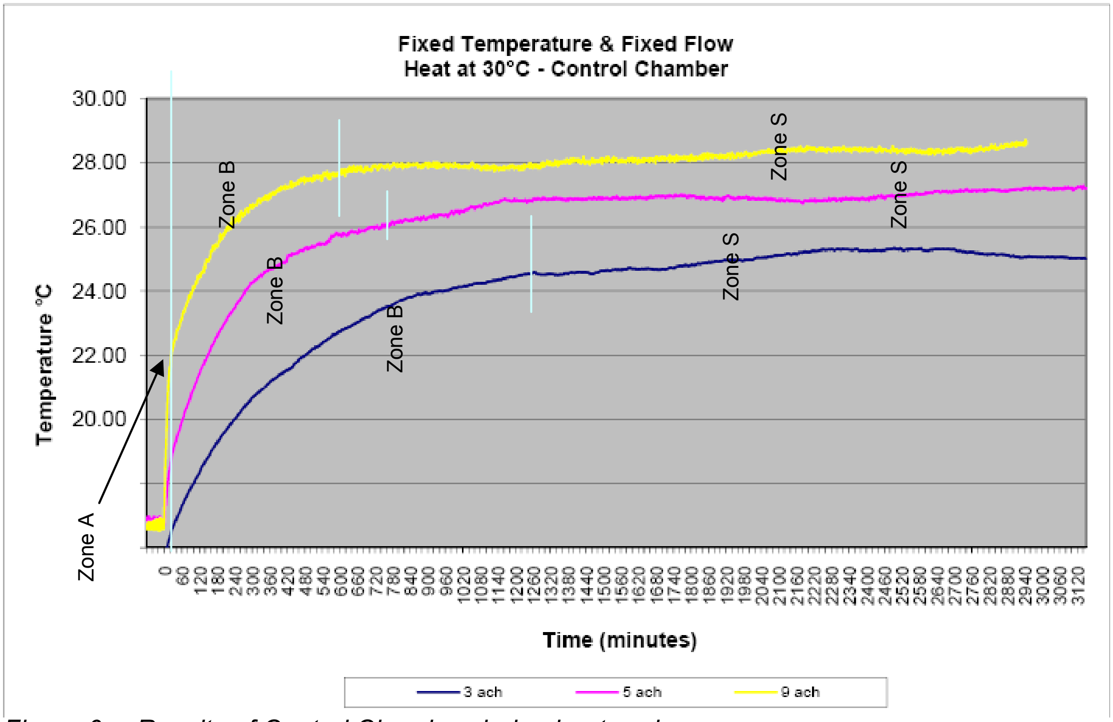

Figure 6 Results of Control Chamber during heat cycle

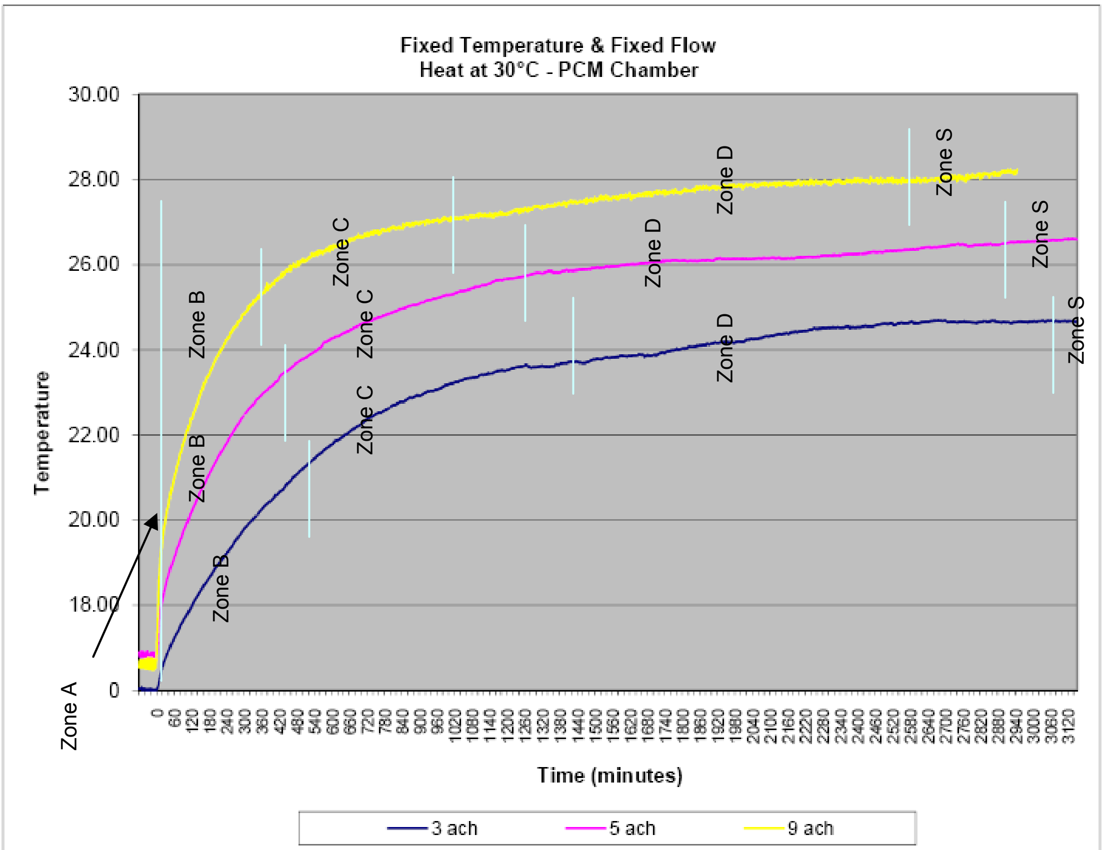

Figure 7 Results of PCM Chamber during heat cycle

4.2 Cooling cycle

For the cooling cycle where the supply air was maintained at 15°C for the three different air change rates in the test chambers the results have also been zoned using the same format as for the heating cycle results.

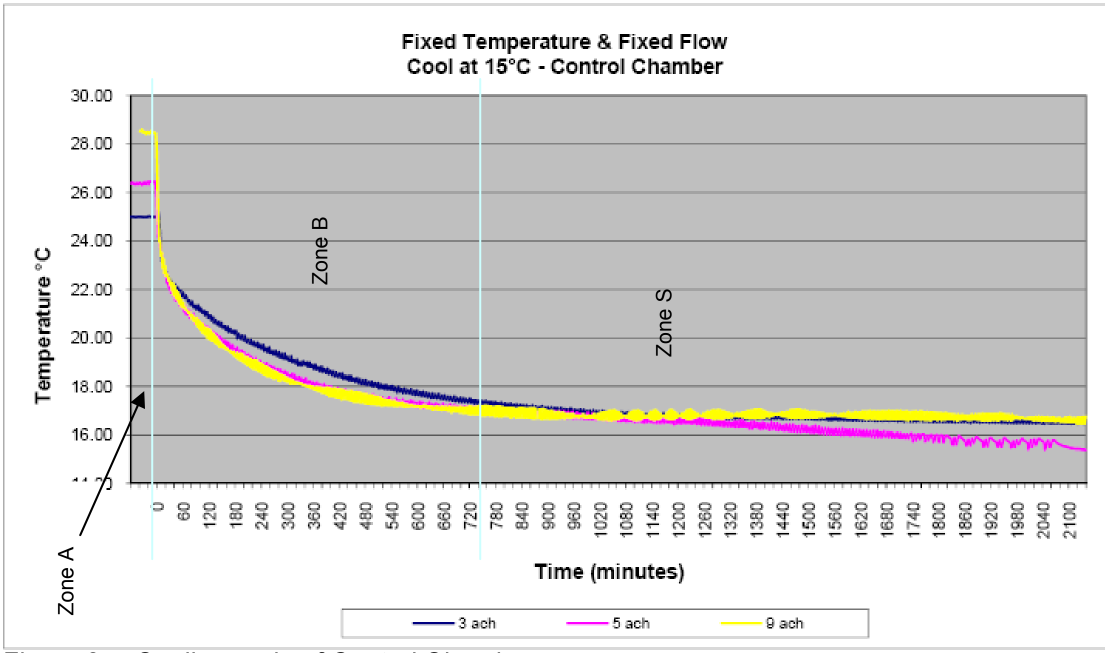

Figure 8 Cooling cycle of Control Chamber

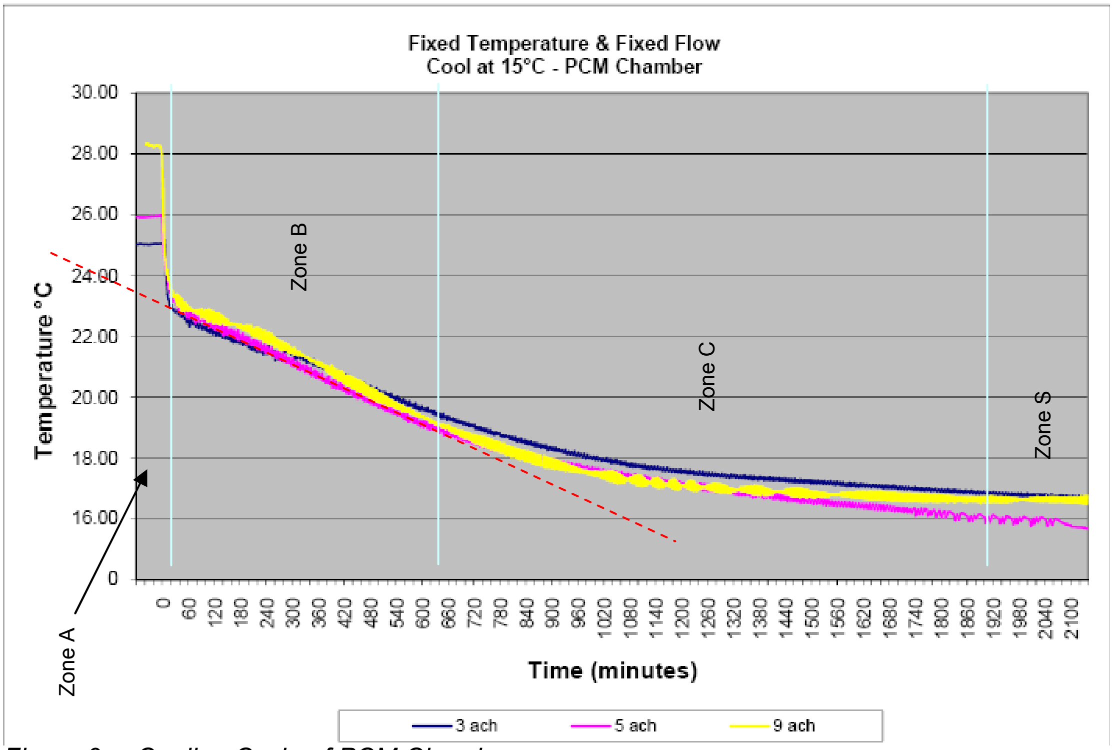

Figure 9 Cooling Cycle of PCM Chamber

The graphs for the cooling cycle in Figures 8 and 9 show the temperature variations are less distinctly separated than those in the heating cycle. This can be attributed not only to the relatively smaller temperature differences between supply air and the external air but also the supply air and the phase change temperatures when the experiments were performed.

Zone A in Figures 8 and 9 show the warm air of the chamber being replaced by the 15°C supply air. The temperature drops quickly as the thermal capacity of air is low. Zone B in the Control Chamber (Figure 8) exhibits the non-linear characteristics of the sensible heat transfer process, therefore illustrating the heat being removed by the chamber wall as the temperature drops. It took about 12 hours to reach steady state.

Zone B in Figure 9 exhibits a linear temperature profile of a constant rate of change of temperature. Such characteristic is in contrast to the results for Zone B of the Control Chamber. It illustrates the rate of change of temperature is maintained by the latent heat released from the PCM in the wall-lining. Zone C shows a non-linear reduction in temperature when most of the PCM in the phase change wall-lining has solidified and the sensible heat transfer process dominates. Zone S again represents the steady state conditions in the chambers.

As the supply air temperature is only 7°C below the phase change temperature, the air change rates do not appear to have significant effects on the temperature during the cooling cycles. This suggests the lower flow rate may be used to save fan energy.

5. Conclusions

This research investigates the potential of applying phase change materials contained within wall-linings to enhance the thermal capacity of buildings. The research has successfully developed and manufactured wall-lining prototypes containing micro-encapsulated phase change materials. The laboratory tests showed the PCM wall-lining has a latent heat capacity of 503 kJ/m^2 with a phase change temperature of 23°C. The dynamic thermal behaviour of the wall-lining as installed in a room has been evaluated using two identical environmental test chambers. Analysis of results for this part of the research is still on-going. Initial comparison of results between the PCM and Control Chambers provided information on the cyclic charging and discharging behaviour of the phase change wall-lining. Future work will focus on establishing the energy stored and detailed performance data to enable the prediction of the daily and seasonal thermal performance with the UK climate.

Keywords: energy efficiency, Ecobuildings, retrofit, innovation, EU project, high performance, design guidelines, information tool

Summary

The building sector is at present responsible for more than 40 % of the EU energy consumption. The EU 6FP Ecobuildings concept is expected to be the meeting point of short-term development and demonstration in order to support legislative and regulatory measures for energy efficiency and enhanced use of renewable energy solutions within the building sector, which go beyond the Directive on the Energy Performance of Buildings. The projects aim at a new approach for the design, construction and operation of new and/or refurbished buildings, which is based on the best combination of the double approach: to reduce substantially and, if possible, to avoid the demand for heating, cooling and lighting and to supply the necessary heating, cooling and lighting in the most efficient way and based as much as possible on renewable energy sources and polygeneration.

The results of the four Ecobuildings projects BRITA in PuBs, SARA, DEMOHOUSE and ECO-CULTURE are presented in this paper and shall be discussed during the conference presentation. The main focus is on the BRITA in PuBs project with 8 demonstration buildings and additional project results such as retrofit design guidelines, an electronic database on retrofitting knowledge, a quality control toolbox and many more.

Figure 1 The Berlaymont Building in Brussels; head office of the European Commission. The building was energy retrofitted beyond national requirements – an Ecobuilding.

1. Introduction

Ecobuildings (European Commission, 2004) is an energy demonstration initiative of the European Commission (DG TREN) within the sixth Framework Programme. The definition of the Ecobuildings concept according to the Commission is given in the first paragraph of the abstract. The Ecobuildings projects focus mainly on demonstration but do include also minor parts on research and technical development and on training and dissemination.

Since Ecobuildings deal in comparison with Concerto, another EU Commission initiative, (European Commission, 2005) with single buildings, the concept can be applied at any building and in any country.

Concerto aims to demonstrate the high potential for energy efficiency and high share of renewables which can be achieved through a fully integrated approach in high performing communities. In order to achieve this aim, the Concerto projects will apply highly efficient energy saving measures, to significantly increase the percentage of renewable energy supplies and integrate the self supply of renewable energies and polygeneration into ecobuildings. That means that Concerto might be translated to a combination of Ecobuildings with a common and energy efficient supply system. The concept is therefore mainly applied to new settlements.

Ecobuildings as buildings with an energy performance better than required by the national implementation of the Energy Performance of Buildings Directive (EPBD), include different types of energy efficient buildings such as zero heating energy houses, zero energy houses, passive houses, 3-litre houses, ultra-low energy houses, etc. All those names describe different levels of energy consumption, partly with integrated renewables and partly with defined types of technologies. For example a passive house in the original German definition uses the mechanical ventilation system for space heating as well. Therefore it can abandon an additional hot water heating system, however it relates on a hot air heating system, mostly combined with a heat pump. The 3-litre-house concept on the other hand can be realised with many energy-efficient technologies, yet the primary energy demand for heating, ventilation and domestic hot water (plus cooling if necessary) is limited to the equivalence of 3 litre of heating oil per m² floor area. Figure 2 illustrates the relations between the different terms for energy efficient buildings.

Figure 2 Illustration of the some of the many terms used in the area of energy efficient buildings.

What makes Ecobuildings as concept especially interesting is that it can be applied to all type of buildings: new buildings, existing buildings, single buildings or combined in Concerto projects. Various energy saving technologies at the building envelope and the installation systems can be used and combined with renewable energies. Particularly the application at existing buildings is of importance. Today the heating energy consumption of buildings in Germany is shaped by the existing building stock. 95 % of the heating energy is used for buildings that were erected before 1982, see Figure 3. Other EU Member States have similar figures. Therefore new buildings even with a very low energy demand can influence the total consumption only marginally. The focus has to be on the challenge to reduce the energy consumption of existing buildings.

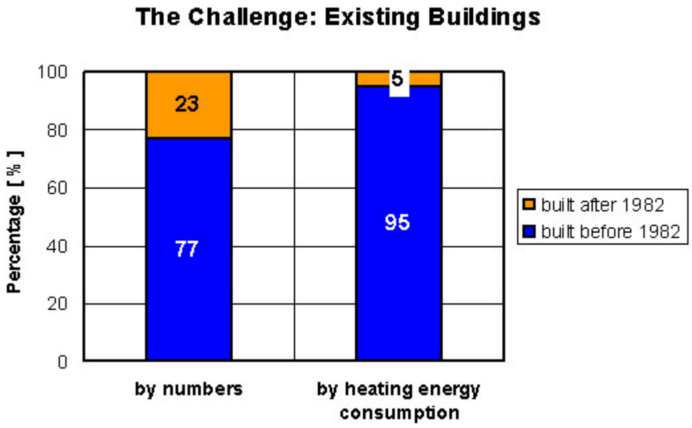

Figure 3 Heating energy consumption in Germany by buildings of different age groups.

2. The 4 Ecobuildings Projects of the 6th Framework Programme

2.1 Similarities and Cooperation

The 4 Ecobuildings projects within the 6FP started under the same call and therefore also roughly at the same time. Their project phase runs from 2004 to 2008. The demonstration projects concentrate on different building types, from new buildings to existing buildings, from large cultural buildings to social housings or public buildings. Also the research work is quite diverse. However besides a general information exchange (mainly via the coordinators) the work plan in all projects foresaw a common dissemination task. Main parts of this task are a website portal for all 4 projects (www.ecobuildings.info), common posters, an Ecobuildings newsletter and a high quality brochure including all demonstration projects. Additionally the project BRITA in PuBs has organised two Common Ecobuildings Symposia in Berlin in November 2005 and Stuttgart in April 2008 with presentations from all projects and many interesting discussions (Kratz, Erhorn, 2005 and Goerres et ali, 2008). Figure 4 shows the actual Ecobuildings poster.

Figure 4 Common poster of all 4 Ecobuildings projects.

2.2 Demohouse

The aim of the project is to develop minimum standards and recommendations in connection to healthy, cost effective, energy efficient and sustainable rehabilitation and to facilitate implementation through the development of a "Decision Support Tool". In 6 participating countries, a pilot project and a reference project was defined. The pilot project is the actual demonstration project, where the recommendations of the investigations and research are implemented. The reference project is a housing complex that has recently been renovated (or which is in the process of renovation) according to the usual local (national) standards. The pilot projects and reference projects are compared in terms of improvement of:

- energy consumption,
- sustainability in general and
- socio-economic aspects.

The demonstration buildings are new or renovated (partly social) housing complexes:

- old urban building in the centre of Bilbao (Spain)
- social housing complex in Budapest (Hungary)
- a development of residential buildings in Attica (Greece)
- suburb housing projects in Copenhagen (Denmark)
- high-rise multi-dwelling houses in Graz (Austria)
- low-rise multi-dwelling houses in Warsaw (Poland)

Besides the demonstration buildings, the project will produce the following results: A common evaluation protocol and a state-of-the-art-in-renovation report.

2.3 ECO-Culture

The ECO-Culture project addresses demonstration of energy efficient technologies integrated into three high-performing cultural ecobuildings:

- the Danish Royal Theatre, Copenhagen (Denmark)
- the Amsterdam Library, Amsterdam (The Netherlands), see figure 5
- the New Opera House, Oslo (Norway).

Figure 5 Photo of the newly erected Ecobuilding Amsterdam Library.

Focus is on investigations, demonstration and testing of the following technologies which have been selected out of the integrated ECO-concepts as being especially innovative and contributing to further development:

- energy storage ("climate belt" with thermoactive slabs, double aquifer)
- heat pump (sea water, ground water)
- advanced demand controlled hybrid ventilation
- building integrated PV systems
- advanced Building Energy Management Systems (BEMS) and benchmarking
- use of environmental friendly concrete for thermal storage in thermoactive slabs.

2.4 SARA

SARA aims to construct sustainable, cost effective, high energy performance, public-access ecobuildings that are immediately replicable at large scale in many locations. The ecobuildings are equipped with advanced sustainable energy technologies integrated by an innovative architectural approach and combined monitoring and building management systems (BMS). SARA involves the demonstration of 7 highly sustainable and replicable public-access buildings in 6 EU Member States and 1 additional country. The key aspects of the project are public-access, innovative yet cost effective and replicable results, consideration of end users and an interdisciplinary team working on various RTD activities. These aspects, applied across various climatic regions produce large scale social, urban and environmental benefits. The project will therefore contribute to future development of European energy policy and legislation that will accelerate market penetration of innovative sustainable technologies. The project includes the following demonstration buildings:

- office and exhibition hall, Sinabelkirchen (Austria)
- primary School, La Tour de Salvagny, (France)
- community centre (refurbishment), Naples, (Italy)
- health centre, Barcelona (Spain)
- supermarket, Ljubljana (Slovenia)

- student service building, Southampton (UK)
- community centre, (refurbishment) Bukara, (Uzbekistan)

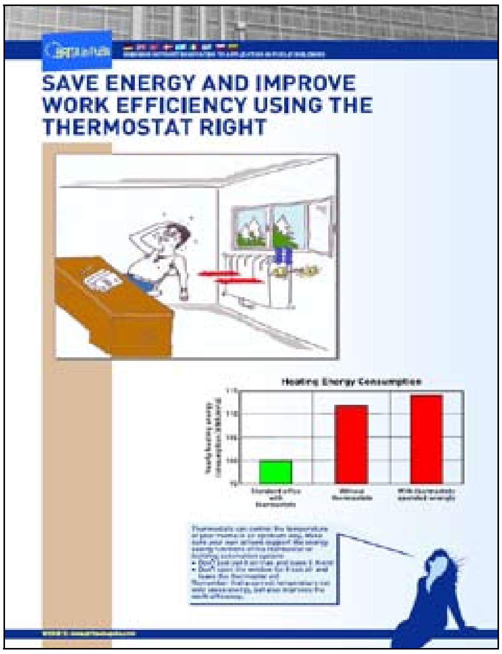
In combination with the demonstration buildings the project works on an instant replicability potential, an integrated BMS and monitoring, shared solutions and interests and technical advice and support.

2.5 BRITA in PuBs

The BRITA in PuBs project (Bringing Retrofit Innovation To Application in Public Buildings) aimed at increasing the market penetration of innovative and effective retrofit solutions to improve energy efficiency and implement renewables, with moderate additional costs.

In the first place, this was realised by the exemplary retrofit of 8 demonstration public buildings in the four participating European regions (North, Central, South, East). By choosing public buildings of different types such as colleges, cultural centres, nursing homes, churches etc. for implementing the measures it is easier to reach groups of differing age and social origin. Public buildings are used as engines to heighten awareness and sensitise society on energy conservation.

Secondly, the research work packages included socio-economic research such as the identification of real project-planning needs and financing strategies, the development of design guidelines, of an internet-based knowledge tool on retrofit measures and case studies and a quality control-tool box to secure a good long-term performance of the building and the systems. The training and dissemination work contains blackboard information sheets, see Figure 6, an Ecobuildings E-learning module, architectural student courses and a facility managers training based on the results of the demonstration projects.



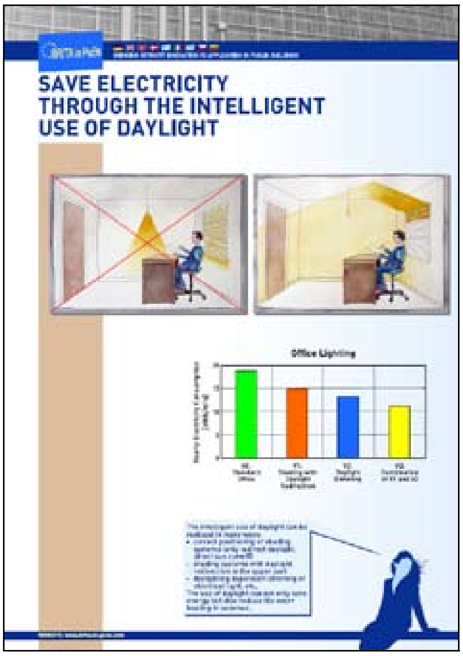


Figure 6 Examples of blackboard information sheets for training energy efficient user behaviour.

The demonstration buildings are listed in the following:

- nursing home Filderhof, Stuttgart (Germany)
- city college Plymouth (UK)
- community centre Borgen (Norway)
- church Hol (Norway)
- cultural centre Proevehallen, Copenhagen (Denmark)
- Evonymos ecological library, Athens (Greece)
- students centre “Brewery”, Brno (Czech Republic)
- main building of the Vilnius Gediminas University (Lithuania)

The project website (www.brita-in-pubs.eu) contains a building diary with updated information on the status of the demonstration projects. Figure 7 presents an overview of the buildings.

Figure 7 The demonstration buildings in the BRITA in PuBs project after the retrofits.

The general aim of the retrofits at the demonstration buildings was to reduce the primary energy demand for heating, ventilation, cooling and domestic hot water by factor 2 and at the same time to improve the user satisfaction by also factor 2. The latter was analysed by user comfort questionnaires. All buildings were monitored for at least one year. The diagram below compares the primary energy consumption before and after the retrofit for each building. The reduction factors of the buildings range between 1.2 and 4.1 and the average is 2.2 and therefore meets the goal (Citterio et al, 2008).

	Filderhof	Borgen	Hol	Prøvehallen	BUT	VGTU
Before retrofit	397	280	257	302	515	284
After Retrofit Foreseen	177	111	184	197	271	183
After Retrofit Measured	97	102	141	243	257	186

Figure 8 Comparison of the total primary energy consumption before, calculated after and measured after the building retrofits. The results of the Evonymos building are not yet available.

A Life Cycle Assessment of the retrofits has also been made within the project. The analysis showed significant energy and environmental convenience of the accomplished retrofits. In particular the energy and environmental payback times that resulted were very low, with values varying from 0.3 to 2 years. This means that in a relatively small time period the global energy and environmental investments are fully repaid by the obtained benefits. The relatively long useful time of the retrofits therefore produces large energy consumption savings and avoidance of emissions of large quantities of pollutants. It is interesting to note that the largest benefits are generally related to the insulation of the buildings: high efficiency windows, mineral wool and glass wool sheets, in fact, insulation allows great energy savings over a long period with a relatively short life-cycle impact. Even renovation of heating plants and lighting systems produces large benefits. In contracts, the use of renewable energy had lower benefits due to the low productivity of the plants with outputs sometimes lower than expected at the design stage.

The demonstration projects have their own national and international dissemination results, for example the community centre in Borgen had Chinese visitors and the wind generators in Plymouth have been presented in tv footages by both, the BBC and the local commercial television (see project website for the videos).

The project has performed socio-economic research such as an overview report on financial strategies in the different participating countries for the improvement of the energy quality in the existing building stock (Triantis et al., 2006). A detailed analysis of barriers for the energy efficient retrofit of public buildings was also made (Thunshelle et al., 2006).

The partners of BRITA in PuBs have written 14 retrofit design guidelines (see figure 9) with about 4-8 pages each, focusing on specific technologies like innovative insulation, advanced windows, passive solar heating, reduction of overheating, hybrid ventilation, improved daylighting, solar thermal systems, solar heating and cooling, photovoltaic integration and heat pumps or on more general items. The latter deal with the interdisciplinary design approach, energy simulation tools, life cycle assessment and long-term monitoring. The guidelines contain information on why to use the technology, requirements in regulations, current practice, different innovative solutions with their advantages and disadvantages, energy savings and costs, as well as information on maintenance and best practice examples. They are available for download at the project website.

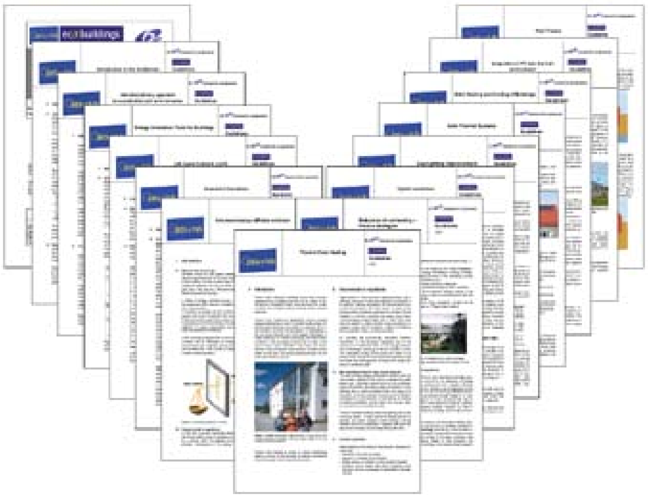

Figure 9 Cover pages of the available retrofit design guidelines (Thunshelle et al., 2008).

An electronic database offers many different types of information for decision-makers of public renovation projects. The BRITA in PuBs information tool BIT (Erhorn-Kluttig et al., 2008) presents in a clearly structured and simple to use way all demonstration buildings from the project plus additional more than 30 educational case study buildings from a just finished IEA project (Erhorn et al., 2003). In a matrix the buildings are opposed to different retrofit strategies starting with the building envelope, over heating and ventilation systems, solar control and cooling systems, lighting systems to renewables and management methods. Figure 10 presents the title page of the BIT tool. The retrofit technologies and the case studies are described in detail in so-called viewers, see Figure 10. For both, the case studies and the retrofit measures, more detailed information is offered as pdf-downloads including the final reports from the demonstration buildings and the retrofit design guidelines.

Figure 10 Title page of the BRITA in PuBs information tool BIT (left) and Retrofit Measure Viewer (here: Lighting Innovations) within the BIT tool.

An additional feature of the information tool is the performance rating tool. Here the user can visually compare the electricity, heating and water consumption of a specific building with the national average for in total 19 different building types.

Another project result is the quality control toolbox. The energy efficiency of buildings should be confirmed in all major stages of a renovation project: planning and design, implementation, use, operating and maintenance. The energy and facility management costs can be optimized by using *BEMS* (Building Energy Management Systems). All major stages of a renovation project are described in the toolbox and put into practice by using new auditing tools e.g. review lists. The review lists are introduced in appendixes.

The demonstration projects and the other project results are documented and illustrated in the BRITA in PuBs brochure. The brochure, with the title page shown in figure 10, can be downloaded from the project website.

Figure 10 Title page of the BRITA in PuBs brochure containing information on the demonstration buidings and all other project results.

3. Conclusions

All four described Ecobuildings projects offer various interesting project results which are now available for use and/or download at the websites. The combination and close link between demonstration projects, socio-economic research and training plus dissemination resulted in a very good transfer of the lessons learned from the demonstration buildings and the combined knowledge of the participating experts to the target audience reaching from public authority decision makers to facility managers, students, building users to the general public. The main conclusion however is that the Ecobuildings concept by the European Commission is a key solution for the major challenge in building energy efficiency: the existing building stock.

Keywords: energy consumption, single household, energy saving, energy conservation behavior, house, appliance, lifestyle

Summary

Based on the fact that single households have occupied the largest portion of Japanese households since 2007, and because it was reported that a decrease in the number of household members leads to an increase in energy consumption per individual based on a national scale questionnaire survey, we investigated the energy saving potential of single households in Japan by both measurements and a questionnaire survey. First, measurements on energy consumption of six apartment houses located in the northern part of Japan were conducted in 2005 and 2007. The occupants of these six houses were three university students and three office workers. An energy conservation lifestyle menu was assigned to each house occupant for each season and the energy saving effect of this menu was analyzed. Secondly, a questionnaire survey on the energy conservation behavior of university students was conducted in 2007. From the measurements, it was found that the energy consumptions of the single households varied with different house occupants of students and office workers even though they were single households, as well as with energy sources. The results of the experiments on the energy conservation lifestyle showed that the annual energy consumption and CO_2 emission rate of a house decreased by 2.8 GJ/year and 0.4 t/year, respectively. From the questionnaire survey, the tendency of single households to show preference with regard to energy conservation behavior varied with family types. One approach to address this problem is to provide energy-efficient measures suitable for each family type.

1. Introduction

The first commitment period under the Kyoto Protocol started at last this year (2008). CO_2 emissions still show a tendency to increase in the residential sector of Japan, and efforts should be exerted to reduce such emissions as quickly as possible. According to household projections for Japan, single households are estimated to be the family types sharing the largest part of Japanese households after 2007. It is reported that a decrease in the number of household members leads to an increase in energy consumption per individual based on the national scale questionnaire survey (Inoue et al., 2004). However, detailed surveys on energy consumption focusing on single households have not yet been undertaken. Thus, it is important to clarify the energy characteristics of single households to provide suitable measures for effectively reducing CO_2 emissions. Therefore, the purpose of this study was to determine the energy saving potential of single households in Japan by conducting both measurements and a questionnaire survey. First, measurements on the energy consumption of six apartment houses in Akita Prefecture were conducted in 2005 and 2007. The six occupants of these houses consisted of three university students and three office workers. An energy conservation lifestyle menu was assigned to each house occupant for each season and the energy saving effect of this menu was analyzed and compared with the proposed "CO_2 diet of 1 kg/day per head" from the Japanese Ministry of the Environment. Secondly, a questionnaire survey on energy conservation behavior of university students was conducted in 2007.

2. Measurement of Residential Energy Consumption for Single Households

2.1 Description of Investigated Houses

Table 1 shows a summary description of seven apartment houses. The occupants of the six houses (A01-A06) were single households and those of one reference house (A07) were a family household. All houses were located in the northern part of Honshu Island in Japan (i.e., Tohoku area). The six single occupants consisted of three university students (A01-A03) and three office workers (A04-A06); the measurements on energy consumption of the former and latter occupants were conducted in 2005 and 2007, respectively. The measurement for the occupants of the reference house was performed in the periods 2002-2005 (Genjo et al., 2005). Thermal performances of all investigated houses conformed to the current Japanese residential standard for energy conservation. The total floor areas of four houses varied from 25 to 78 m^2. In addition, the four investigated houses (A01-A04) used only electricity, and the other three houses (A05-A07) used electricity, city gas and kerosene. The occupants of A01-A03 were university students as mentioned above. They do not usually stay at home and lead an irregular lifestyle whether on weekdays or on weekends. The various activities in the houses of these students usually occurred from evening to night. Also, these students tended to dine out and rarely cooked in their house. On the other hand, the occupants of A04-A06 were office workers. They lead a regular lifestyle on weekdays compared with the student single households, although they were not usually at home from 8:00 a.m. to 20:00 p.m. because of work, and they often stayed out at weekends. The occupant of A04 usually stayed with his parents at weekends, and washing and cooking activities were usually done at the family home. In A07 as a reference for a family household, the housewife was usually at home except when she was out for a part-time job three days a week.

2.2 Items and Method of Measurement

The measurement items are shown in Table 2. The consumptions of electricity, gas and kerosene were measured. The consumption of gas was classified into two end-uses (i.e., hot water supply and cooking) using records on gas usage by the occupant. Energy data not measured were compensated by referring to energy bills. Temperature and humidity level in the living room and another room, and outdoors at 1.1 m above the floor surface were also measured. In addition to these measurements, an interview on the usage of appliances and occupants' lifestyle was also conducted.

2.3 Result of Daily Energy Consumption by End-Use

The profiles of daily energy consumption per head by end-use and daily mean temperature of the seven houses for a one-year period are shown in Figure 1. The daily energy consumptions per head of student houses A01-A03 from March 2005 to February 2006 and the office worker houses A04-A06 from March 2007 to February 2008 were compared with that of the family house A07 from March 2004 to February 2005. Energy consumptions were classified into the following seven categories: space heating/cooling, hot water supply, cooking, refrigerator, audio visual/information, housework/sanitation, lighting and others. Calorie conversion was performed for each energy source, that is, 3.6 MJ/kWh for electricity (secondary conversion value), 45.9 MJ/Nm^3 for city gas and 37.3 MJ/L for kerosene.

As seen in Figure 1, daily energy consumption of A01-A06 ranged from 20 to 130 MJ/day and showed large seasonal fluctuations the same as that of the reference family household (A07); in particular, those for A03 and A05 in winter were equal to three times as much as that for other seasons. The daily average indoor temperature of these two houses in winter was about 20ºC and was higher than those of the other houses. The space heating systems for A03 are electric storage heaters with operation at night and those for A05 are a vented kerosene stove and other electric heaters. Not only the type of space heating system but also the area and time of using the space heating system were found to have an effect on the variation of energy consumption. On the other hand, the annual energy consumptions per head of the single households of A02, A03 and A05 were larger than that of the family reference A07, with the exception of A01 and A04 in which the occupants were rarely at home, and that of A06 was the same that of A07.

The energy consumption by end-use of single households revealed two significant characteristics. First, the energy consumption for audio visual/information was much higher in family households. In particular, that of A02 was 16 times as high as that of A07, and those of the other five houses were from two to five times as high as that of A07. Most occupants of the investigated single households in the measurements frequently used TV and PC, making energy consumption for audio visual/information of single households high. Second, that for cooking is said to be much lower in single households than in family households, except for A05 and A06 where the occupants cook for themselves.

Table 1 Description of Investigated Houses

House	Completion	Total floor area[m^2]	Structure	Heat loss coefficient [$W/m^2 \cdot K$]	Normalized leakage area[cm^2/m^2]	Energy sources by end-use				Family member
						Space heating	Space cooling	Hot water supply	Cooking	
A01	2002	26.5	Wooden	1.9	1.7	Electricity	Electricity	Electricity*	Electricity	1
A02	2001	29.0	Wooden	2.2	1.3	Electricity	Electricity	Electricity*	Electricity	1

3. Questionnaire Survey of Residential Energy Consumption for Student Single Households

3.1 Items and Method of Survey

A questionnaire survey on lifestyle, energy conservation behavior, residential energy consumption in addition to possession of housing equipment and appliances intended for university students of two universities located in the northern part of Honshu Island, Japan (i.e., Tohoku area) was conducted in the summer of 2007. In this survey, both 105 single households and 38 family households of all 143 respondents were investigated. Family numbers ranged from two to seven for the family households. The investigated items are shown in Table 3. A liquid crystal thermometer with a questionnaire sheet was distributed to each student. The students were then requested to set the thermometer in their living rooms and measure the temperature three times a day (i.e., when rising, going home, and going to bed) for one week. Monthly energy consumption from August 2006 to July 2007 was also investigated using utility bills, such as electricity, gas, kerosene and water bills, besides the annual energy consumption was investigated using the questions selected from some choices.

3.2 Result of Monthly Energy Consumption by Energy Source

The profiles of average monthly energy consumption by energy source of 38 single households for a one-year period are shown in Figure 2. These profiles were classified according to three types of energy source: 5 all-electrified houses, 29 houses using electricity and gas, and 4 houses using electricity, gas and kerosene as energy sources. Electricity was used for space heating/cooling, lighting and various electric appliances; on the other hand, gas was used for hot water supply and cooking in all houses except the all-electrified houses. Calorie conversion was performed for each energy source using the questionnaire for the monthly amounts in utility bills, that is, 3.6 MJ/kWh for electricity (secondary conversion value), 45.9 MJ/Nm^3 for city gas, 100.5 MJ/Nm^3 for LPG and 37.3 MJ/L for kerosene. It is noted that there is in fact somewhat a discrepancy between the values of electricity and gas for each month which were based on the utility bills shown in Figure 2 and the actual monthly consumption. In addition, the value of kerosene for each month shown in Figure 2 is different from the actual monthly consumption because of the estimation, which was based on the purchase amount.

As shown in Figure 2, it was found that the profile of monthly energy consumption showed a seasonal fluctuation, and the monthly energy consumption ranged from 0.5 to 1.8 GJ/month. The profile of the houses using electricity and gas showed that the maximum and the minimum of the monthly energy consumption appeared in February and in September, respectively. In fact, the minimum value would appear in August, causing the above-mentioned discrepancy. Thus, it could be said that one of the characteristics of residential energy consumption of student single households is a decrease in monthly

Table 3 Investigated Items of Questionnaire Survey

Building characteristic	House type (detached, apartment), Structure, Story, Completion, Gross floor area
Cooling system	Possession, Cooling period, Cooling time, Set point temperature
Heating system	Type of heating system, Heating period, Heating time, Set point temperature
Ventilation system	Window opening in living room, Type of ventilation system
Hot-water supply system	Energy source, Set point temperature of hot water, Frequency of bath and shower
Cooking system	Energy source, Frequency of cooking
Appliance	Possession and frequency of using appliances, Size and set point temperature of refrigerator, Size and type of TV
Consciousness of environmental problems	Degree of concern about environmental problems, Consideration for energy conservation in daily life, Behavior on resource conservation and reuse
Energy conservation behavior	Degree of action on residential energy conservation behavior
Energy consumption	Energy sources, Annual amount used for electricity, gas and water, Annual purchase amount of kerosene, Monthly amount or rate of electricity, gas and kerosene in utility bills

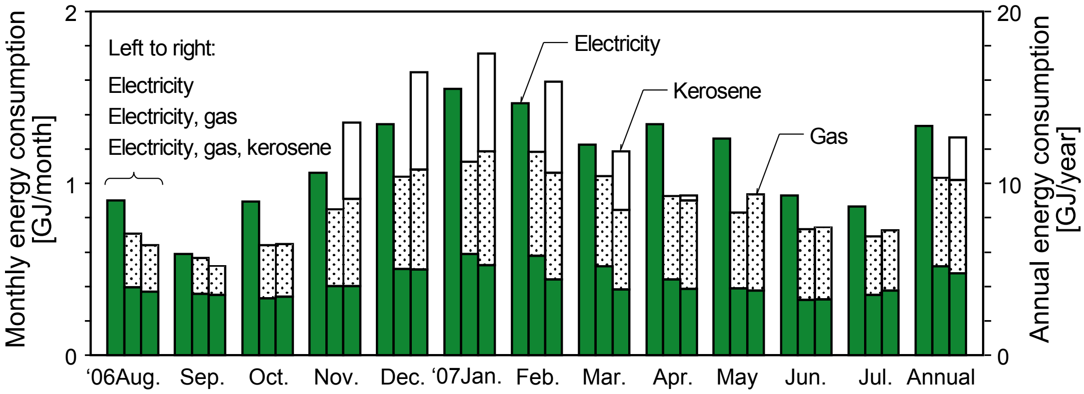

Figure 2 *One-year profile of monthly energy consumption by energy source classified according to the three types of energy source for student single households.*

energy consumption during the summer vacation. The increase in monthly energy consumption during winter is similar to the profiles obtained by the measurement shown in Figure 1.

3.3 Results of Possession and Frequency of Using Appliances

The frequency of using 13 appliances by family type is shown in Figure 3. The frequency of using each appliance was selected from the choices of five levels. The rest of the percentages except for that of "Do not have" in Figure 3 can be defined as the possession rate in this paper. It was found that the appliances of which the possession rate varied from 105 single households to 38 family households were an electric water heater, a video for playing games, a desktop computer, a laptop computer, CD/MD, DVD, an electric toilet seat and a dehumidifier. The possession rates of all these appliances mentioned for family households were found to be higher than those for single households, and those of an electric water heater, a desktop computer, DVD and a dehumidifier were quite particularly higher than those of the other appliances. There was a large difference between single and family households in the percentage of "Used everyday" of a rice cooker, a microwave, a washing machine, and an electric toilet seat, although there was a small difference for a gas water heater, TV, a video for playing games, a desktop computer, a laptop computer, and CD/MD. Based on the results, it can be inferred that single households tend to spend less time for cooking and housework activities than family households.

3.4 Result of Energy Conservation Behavior

Figures 4(a)-(AA) show the degree of action on residential energy conservation behaviors by family type. Whether or not an occupant shows several residential energy conservation behaviors for each appliance was evaluated using five levels. The tendency of preference on energy conservation behaviors varied from 105 single households to 38 family households for several appliances, as well as from contents to contents even if the behaviors were displayed for the same appliance. From a general overview of the results, the behaviors of which the degrees of actions were relatively high (i.e., > 50%) and common for both family type were as follows: 'use water for washing the face, hands and dishes for hot water supply' (washing the face or hand, and cooking) (Figures 4(h)-(j)); 'plug off not in use for a rice cooker' (Figure 4(n)); 'switch off not in use' for TV (Figure 4(q)); 'stop keeping warm', 'lower the set point' and 'close a cover not in use' for an electric toilet seat (Figures 4(x)-(z), and 'turn waste lights off' for lighting (Figure 4(z)). The behaviors of which the degrees of actions were relatively low (i.e., < 20%) and common for both family type were as follows: 'clean an air filter' for space heating/cooling (Figure 4(b)); 'use a microwave for preparation' for induction heating in a cooker/gas kitchen range (Figure 4(l)); 'defrost frozen food by itself' for microwave (Figure 4(o)); and 'plug

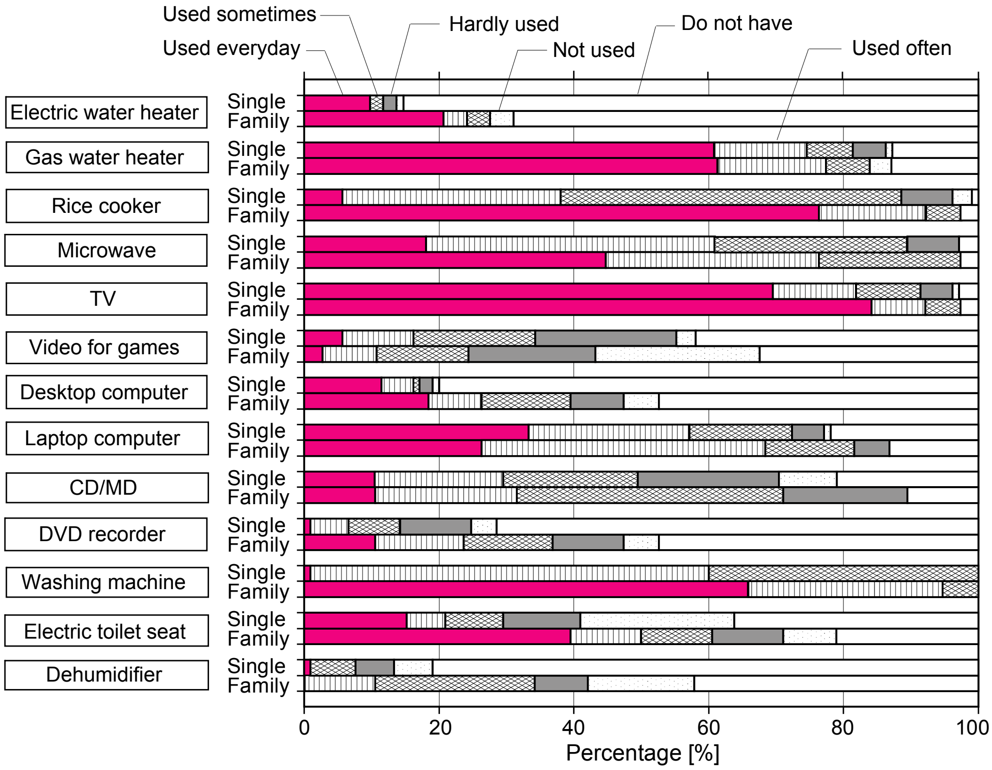

Figure 3 Frequency of using 13 appliances by family type.

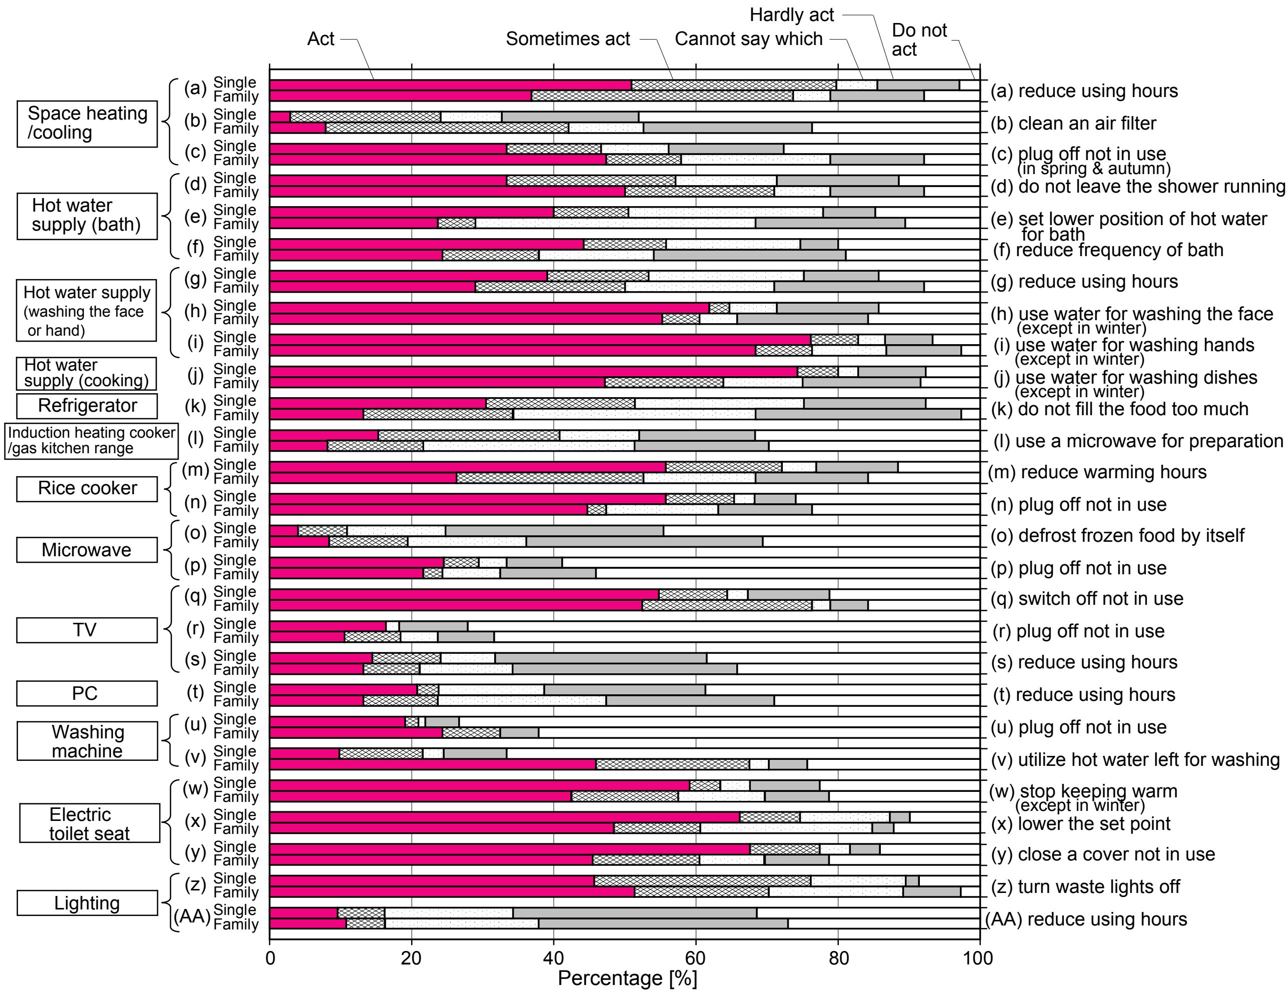

Figure 4 Degree of action on residential energy conservation behaviors by family type.

off not in use' for microwave, TV and washing machine (Figures 4(p), (r) and (u)), 'reduce using hours' for TV, PC and lighting (Figures 4(s), (t) and (AA)). One possible explanation for this result is that the troublesome energy conservation behaviors and the need to reduce using hours of appliances are difficult to act on for both family type. Furthermore, the behaviors of which the degrees of actions were different in each family type were as follows: 'reduce using hours' and 'plug off not in use (in spring & autumn)' for space heating/cooling (Figures 4 (a) and (c)); 'do not leave the shower running', 'set lower position of hot water for bath' and 'reduce frequency of bath' for hot water supply (bath) (Figures 4(d)-(f)); 'reduce using hours' for hot water supply (washing the face or hand) (Figure 4(g)); 'use water in washing dishes (except in winter)' for hot water supply (cooking) (Figure 4(j)); 'do not fill the food too much' for refrigerator (Figure 4(k)); 'reduce warming hours for rice cooker' (Figure 4(m)); 'utilize hot water left for washing' for a washing machine (Figure 4(v)); 'stop keeping warm (except in winter)', 'lower the set point' and 'close a cover not in use' for an electric toilet seat (Figures 4(w)-(y)). Most of the degrees of actions on the energy conservation behaviors mentioned above were found to be higher in single households than in family households, with the exceptions of the behaviors such as 'plug off not in use (in spring & autumn)' for space heating/cooling (Figure 4(c)), 'do not leave the shower running' for hot water supply (bath) (Figure 4(d)) and 'utilize hot water left for washing' for a washing machine (Figure 4(v)). Based on the above-mentioned results, it can be said that the energy-efficient measures to be provided must be suitable for each family type.

4. Comparison of the Annual Energy Consumption of Single Households for the Present Study with the Previous Study

Figure 5 summarizes the annual energy consumption of single households for a previous study and the present study. The figure shows the average annual energy consumption of 129 single households in the Kanto area in Japan based on a national scale questionnaire survey (Inoue et al., 2004). The average annual energy consumptions of six single households (three university students and three office workers) from the measurement and 38 single student households selected as the valid answer from the questionnaire survey on energy consumption are shown in Figure 5. As shown in Figure 5, the annual energy consumption of single households ranged from 10 to 23 GJ/year, probably because of the different house occupants of students and office workers even though they were single households, and the various types of energy sources.

5. Experiment on Energy Conservation Lifestyle

5.1 Contents of Experiment

Experiments on energy conservation lifestyle were conducted for three university students (A01-A03) in two seasons (autumn of 2005 and winter of 2005-2006) and three office workers (A04-A06) in four seasons (spring, summer, autumn, and winter of 2007). An energy conservation lifestyle menu for each season was assigned to each occupant. Energy consumption was analyzed for one week when energy conservation behavior in accordance with the menu was shown. In addition to this experiment, a questionnaire survey regarding the energy conservation lifestyle menu was conducted. The answers of each occupant indicating the degree of action for each energy conservation behavior were any of the following five levels: 1, do not act; 2, slightly act; 3, sometimes act; 4, considerably act; 5: completely act.

5.2 Results of Questionnaire Survey on Energy Conservation Lifestyle Menu and Daily Energy Consumption by End-Use in Winter

The degree of action for each energy conservation lifestyle menu and energy consumption averaged for one week under the energy conservation lifestyle were compared with those averaged for one week (one week before the week for observing the energy conservation lifestyle) under the usual lifestyle for each house. The results of the case on energy consumption for space heating will be discussed here. Table 4 shows the

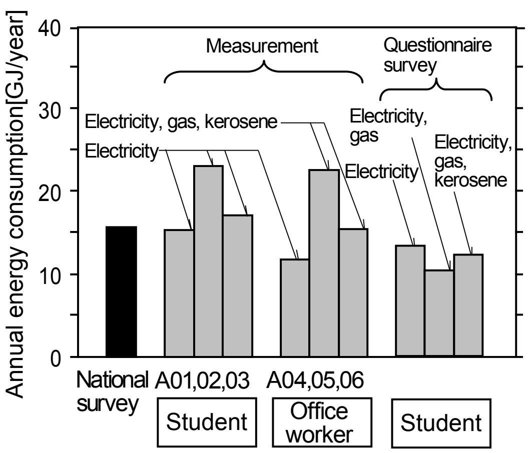

Figure 5 Comparison of annual energy consumption of single households for the present study with the previous study.

degree of action for space heating as part of the results of the questionnaire survey on the energy conservation lifestyle menu in winter. The degree of action for ‘Lower the set point temperature for a main heater’ increased in A01, A03 and A04, and that for ‘Reduction in using hours’ increased in A01, A04 and A05. In addition, that for ‘Control the amount of heat storage for a storage heater’ increased in A03. As shown in Figure 6, the daily average energy consumption for space heating during the energy conservation week of the houses except for A02 and A06 decreased compared with the case during the usual lifestyle week, and that of A03 drastically decreased by 31 MJ/day. Thus, all the houses in which the occupants set the menus for change of set point temperature and use hours showed a reduction in the energy consumption for space heating. On the other hand, the daily energy consumption of A02 under the energy conservation lifestyle increased by 19 MJ/day compared with that under the usual lifestyle, probably because the occupant did not change his lifestyle at all. In addition, two houses (A03 and A05) achieved the target “CO_2 diet of 1 kg/day per head” as proposed by the Japanese Ministry of the Environment from Figure 6.

5.3 Effects of Energy Conservation Lifestyle on Annual Energy Consumption and CO_2 Emission Rate

The annual energy consumptions and CO_2 emission rates of the six houses under the energy conservation lifestyle were estimated from the results of the energy saving effect obtained from the experiment on energy conservation lifestyle in each season. In the estimation of the days for each season, spring, summer, autumn and winter were assigned to May and June, July and August, September and October, and the rest of months, respectively. As mentioned above, the experiments under the energy conservation lifestyle were conducted for three university students (A01-A03) in only two seasons, and the saving effect estimated for each house was not necessarily correct. Note that the data for estimating the energy saving effect of A02 was not the data shown in Figure 6, but that for one week after the energy conservation lifestyle week. Therefore, we concentrated on the annual energy saving effect for three office workers (A04-A06) estimated from the results of the four seasons. As shown in Figure 7, the result of the experiments on energy conservation

Table 4 Degree of Action* for Space Heating from the Results of the Questionnaire Survey on Energy Conservation Lifestyle Menu in Winter

Energy conservation lifestyle menu	A01		A02		A03		A04		A05		A06	
	(a)	(b)	(a)	(b)	(a)	(b)	(a)	(b)	(a)	(b)	(a)	(b)
Lower the set point temperature for a main heater	1	5	N.A.	N.A.	3 25℃	5 20℃	1 23℃	2 22℃	5 20℃	5 20℃	4 19℃	4 19℃
Reduce using hours	3	4	N.A.	N.A.	1	1	3	4	2	3	5	5
Clean an air filter	5	5	4	4	1	1	5	5	1	2	1	1

(a) Usual lifestyle, (b) Energy conservation lifestyle

*Degree of action: 1, do not act; 2, slightly act; 3, sometimes act; 4, considerably act; 5, completely act

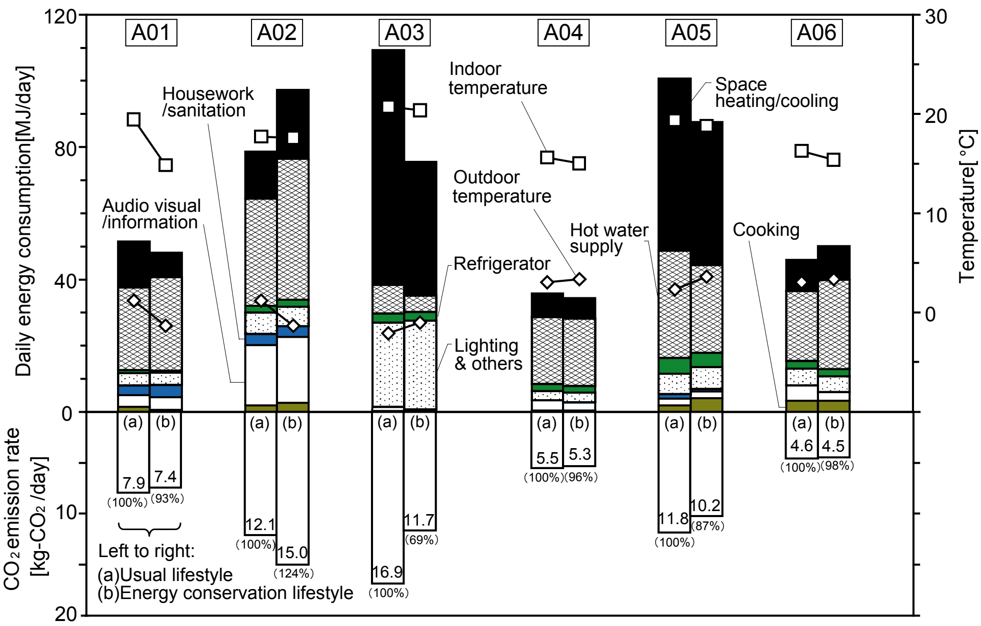

Figure 6 *Daily energy consumption by end-use, CO_2 emission rate and daily average temperature in experiment on energy conservation lifestyle in winter (CO_2 conversion values for estimating CO_2 emission rates are 0.555 kg/kWh for electricity, 2.49 kg/L for kerosene and 2.08 kg/m^3 for city gas).*

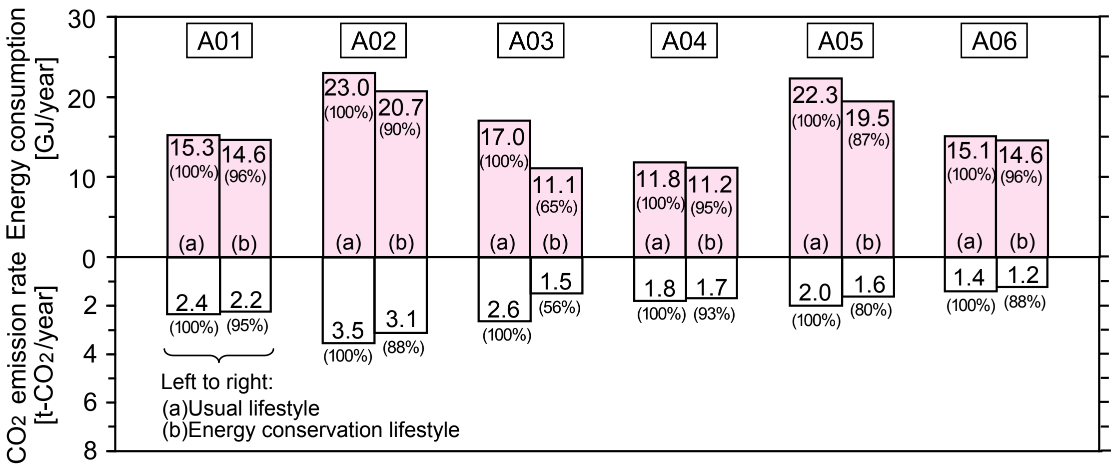

Figure 7 Estimated annual energy consumptions and CO_2 emission rates under the energy conservation lifestyle.

lifestyle proved that the annual energy consumption and CO_2 emission rate of A05 decreased by 2.8 GJ/year and 0.4 t/year, respectively. However, it was also found that the energy conservation lifestyle for one year in the case of the other two houses (A04 and A06) failed to achieve the target “CO_2 diet of 1 kg/day per head” as proposed by the Japanese Ministry of the Environment.

6. Conclusions

From the measurements and questionnaire survey on the residential energy consumption for single households, the following conclusions were drawn:

1) From the measurements, the daily energy consumption of six single households ranged from 20 to 130 MJ/day and showed large seasonal fluctuations the same as that of the reference family household. The differences in energy consumption among the houses were brought about by the winter season.

2) From the measurements, two characteristics of energy consumption of six single households were revealed as follows: Energy consumption for audio visual/information was much higher and that for cooking was much lower than that of the reference family household.

3) From the questionnaire survey, the profile of monthly energy consumption of student single households showed a seasonal fluctuation, and the monthly energy consumption ranged from 0.5 to 1.8 GJ/month. There was a decrease in monthly energy consumption during the summer vacation.

4) From the questionnaire survey on the possession and frequency of using appliances, single households tended to spend less time for cooking and housework activities than family households.

5) The tendency of single households to show preference on energy conservation behavior varied from that of family households. One approach to address this problem is to provide energy-efficient measures suitable for each family type.

6) The annual energy consumption of single households varied from 10 to 23 GJ/year from the results of both measurements and the questionnaire survey. This variation was caused by the different house occupants such as university students and office workers even though all of them were single households, as well as the different energy sources.

7) From the experiment on the energy conservation lifestyle, the annual energy consumption and CO_2 emission rate of a house proved to decrease by 2.8 GJ/year and 0.4 t/year, respectively.

The results of this study highlight the importance of energy-efficient measures suitable for each family type. This information has statistical significance due to the single households that was examined for the purpose of clarifying energy characteristics.

A GLOBAL REVIEW OF OUTSIDE AIR IN BUILDINGS

Derek POWELL B.Eng.[1]

Keywords: outside air, regulations, building, economizer, ventilation, indoor air quality

Summary

A common trade-off in sustainable buildings is between higher outside air rates for improved indoor air quality, and lower outside air rates for improved energy performance. The tension between these two desirable goals is likely to strengthen because on the one hand companies are seeking to attract high-quality employees and provide more productive working environments, and on the other hand the cost of energy is set to increase due to climate change response measures and dwindling resources. This paper presents a global review with the aim of identifying and explaining trends in regulated and desired outside air rates around the world and how building designers have been managing the trade-off between indoor air quality and energy conservation. Based on this review, the paper makes some suggestions about what the future trends might be in Australia.

1. Introduction

Outside air is required in buildings to improve the indoor air quality, and to replace any air that is exhausted from the building. Increased levels of outside air can lead to better occupant comfort and performance, and improved concentration within high intensity work areas. Poor air quality creates discomfort and can be attributable to higher levels of absenteeism. Acceptable levels are regulated around the world, and specified as a legal requirement for any building design. Additionally, there are more and more green building ratings that are incorporating higher levels of outside air in their requirements for a rating. However, with the increasing energy costs and subsequent awareness of sustainability, there is a trade-off in achieving these higher levels of outside air, and the associated increased HVAC energy costs.

This paper presents a number of initiatives available to address the pressure between higher outside air rates and lower energy costs. The goal is to achieve all the benefits from increased outside air, while minimizing the energy costs required doing so. There are additional design tips or 'watch it's' that should be considered within HVAC design, to ensure the effective control and supply of outside air.

2. Background to outside air in buildings

2.1 Historical perspective

Buildings were originally built to incorporate natural ventilation, but with the advent of greater population densities, dust and noise pollution; filtered mechanical ventilation gained in popularity. The removal of natural ventilation as the norm meant that the amount of outside air now had to be regulated, to ensure the air quality within enclosed buildings.

In Australia, originally local state building regulations governed the quantities of outside air, but this was replaced with an Australian standard; AS 1668.2, which was published in 1976, 1980, 1991 and 2002. This Australian Standard sets the minimum outside air requirements for different types of occupancy, and through the Building Code of Australia (BCA) is a legal requirement for any building design.

2.2 Why we need a minimum amount of outside air

Outside air provides for a healthy and comfortable environment. It is not only required for its oxygen content, but also to prevent the build up of contaminants such as CO_2, volatile organic compounds (VOC's) from solvents, paint and synthetic building materials, allergens, micro-organisms and dust. Building occupants may be exposed to a mixture of hundreds or thousands of airborne contaminants, originating from numerous sources, both inside and external to the building (Wargocki et al., 2000).

Different areas within a building require different minimum outside air rates. The same person when in a meeting room requires more outside air than when in a general office space. Historically, this distinction for confined spaces with greater occupancy density is due to body odour, and the close proximity of people. Concentrations of individual contaminants are frequently in the order of one one-thousandth of published occupational exposure limits, but may still be above odour detection thresholds.

During the 1970's energy crisis, the regulations for outside air were decreased due to the energy savings that this created. However, an increased use of synthetics in buildings and a rise in reporting's of 'Sick Building Syndrome' led to the regulations being increased again.

2.3 Why we might want higher levels of outside air

Higher levels of outside air assist in better occupancy comfort and health, provided the source of outside air is not contaminated. Higher outside air rates enable people to be more alert and think more clearly, and are required in areas such as air traffic control booths where concentration levels are critical. Lower levels of outside air can lead to increased discomfort, absenteeism and a decrease in productivity.

There is often a misconception that a reduction in the amount of outside air will lead to increased savings due to the reduced load on the HVAC system to treat the air. However, Milton, et al. (2000) showed by reducing the level of outside air to below comfort levels, the occupant absenteeism rate is more likely to increase, and any savings in energy from the reduced outside air will be overcome by the increased costs for the absent workers. It is important to note that higher outside air rates alone are not the final solution, but are a vital part of Indoor Air Quality (IAQ).

3 Outside air rates around the world

Regulations and building codes have been established around the world to specify the minimum requirements for provision of outside air supply to various building types. The table below shows a selection of these for Australia, UK, USA and Europe, relevant to general office areas. These requirements are dependent upon the room type, climate and application of the specific building, and are all rated in terms of occupancy.

Also shown in the table are the various international requirements for 'Green Building Ratings'. Credits achieved through rating systems like Green Star in Australia, and LEED in USA are becoming a major goal for building designers. Their requirements are more complex than the regulations, ensuring the quality of the indoor air and level of contaminants, rather than just a requirement based on occupancy.

Table 1: Outside air rates around the world

	Regulation / Building Code (*)		Green Building rating	
Australia	BCA / AS1668.2	10 L/s/person	Green Star	Building Air Change Effectiveness must be greater than 95%
UK	BSRIA CIBSE BCO	8-12 L/s/person 10 L/s/person 12-16 L/s/person	BREEAM	12 L/s/person
USA	ASHRAE (STD 62.1)	2001: 10L/s/person 2004: 8.5L/s/person	LEED	1.3 x the ASHRAE requirement

		2007: 8.5L/s/person (**)	(13L/s/person)
Europe	DIN EN 13997	8.5 L/s/person	

* All outside air rates stated are for general office areas.
** Based on an occupancy density of 5 people/100m2.

3.1 Why the rates are different

Internationally, the rates for outside air provision differ slightly as shown in table 1. There are differing views around the world on energy conservation and indoor air quality, and in some climates, hygiene and increased body odour can become more important.

Due to the improved performance of supply systems, filters and maintenance and the increased costs of energy, there is a general movement in the regulations to allow for lower levels of outside air. Building's striving to achieve green building ratings and higher occupant comfort and performance are demanding higher levels of outside air, reflected in the rising green building rating requirements.

4 The implications of higher outside air rates

4.1 Heating/cooling

The schematic of figure 1 shows a typical HVAC circulation system. As exhaust is drawn out of the building, outside air enters the Air Handling Unit (AHU) via a filter, and is mixed with the building's return air to be re-supplied.

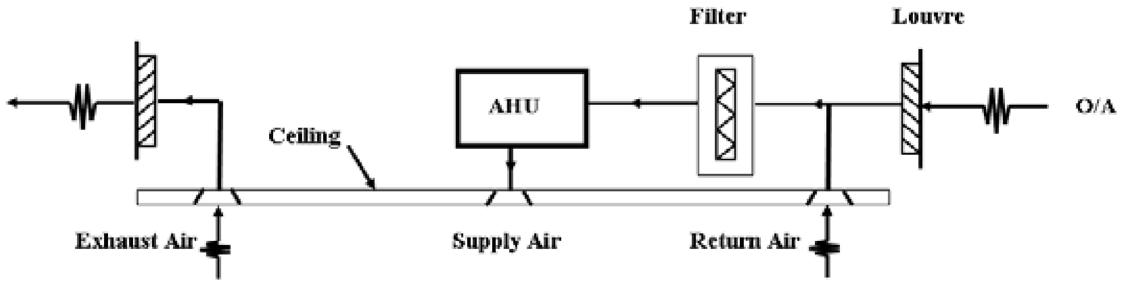

Figure 1 Introduction of Outside air increases the work to Air Handling Unit.

The outside air must be treated before it can enter the building as supply air, and as such requires work from the AHU to match the required conditions of the internal space. In temperate climates where the ambient temperature is close to the room temperature, high outside air rates can be used without penalizing the operating costs too severely. Alternatively, in very hot or very cold climates, higher outside air rates will increase the cooling or heating loads, and hence the energy costs.

4.2 Humidity

In a humid climate, higher outside air rates can significantly increase the latent cooling loads as the increased moisture content within the outside air must be removed by the AHU system. In high humidity regions, outside air should never enter an air-conditioned space un-treated, as it can result in condensation forming on supply diffusers.

4.3 CO_2 Emissions

Without appropriate solutions, increasing the amount of outside air can indirectly create increased CO_2 emissions. The additional load on the HVAC system for the conditioning of outside air requires an increase in energy for the building's plant. This increase in energy use will have a negative impact on the building's level of CO_2 emissions, which needs to be limited.

5 Managing the trade-offs between energy and outside air

Higher outside air rates are beneficial to building comfort, occupant performance and productivity, decreased absenteeism, and overall IAQ. However, the pressures against obtaining these greater rates are the increased load on the HVAC system, and the subsequent increase in energy costs and CO_2 emissions.

There are systems that can be applied to the HVAC system with the potential to reduce these pressures while being able to maintain or increase higher levels of outside air. The following five options detail how the HVAC system can be optimized to gain the benefits of higher outside air, while reducing the costs and emissions.

5.1 Demand-controlled ventilation

HVAC systems are traditionally designed to meet the maximum occupancy levels and loads that a building may experience within its lifetime. To achieve higher outside air rates to meet this criterion would be unnecessary for much of the time. By allowing for air balancing (in accordance with ASHRAE standard 62.1-2004), a building with fluctuating occupancy levels can employ a system that only introduces the amount of outside air required at any time, therefore reducing the pressures on the HVAC system.

Demand-controlled ventilation monitors the amount of CO_2 within the building, and adjusts the amount of outside air entering the system accordingly (Braun et al., 2001). The CO_2 level within the return air stream or conditioned space is monitored before it is recirculated back into the supply, and a signal sent to a controller to adjust the variable intake for outside air. With demand controlled ventilation in place, Brandemuehl and Braun (1999) showed that there is potential to save up to 20% in electrical energy for cooling, while maintaining outside air levels.

For the ventilation to be most effective, it should be installed in conjunction with an economizer system as described in section 5.3.

5.2 Energy recovery technologies

The energy costs for the HVAC system can be reduced if the level of conditioning (temperature and moisture content) required for the outside air is minimised prior to it entering the AHU. There are a number of technologies available to offset the temperature and humidity difference between the outside air and supply air, which take advantage of the conditioned exhaust air leaving the building. To offset the difference, energy may be transferred from the supply air to the exhaust air (cooling), or vice versa (heating).

This energy transfer can be achieved using the following systems.

1. Thermal wheels use an air permeable medium that rotates through the supply and exhaust air streams, facilitating an energy exchange. They can transfer both sensible and latent heat between the streams, by the use of a silica compound within the air permeable layer that also absorbs excess moisture within one stream, and transfers it to the other (Braun et al., 2001). Due to the direct contact between both air streams and the permeable layer, trace amounts of exhaust air can come into contact with supply air, and result in minor contamination. However, a ‘purge’ section can be designed within the wheel which allows excess pollutants to be removed. According to Hamilton (1986), thermal wheels have relatively high heat transfer efficiency, and low energy consumption.

2. An alternative to a thermal wheel is a sensible heat wheel. In climates where high humidity is not as prevalent, a sensible heat wheel can be used to simply transfer the sensible energy (excluding moisture content) from one air stream to another. These systems are identical to thermal wheels, but the air permeable layer will not contain any silica gel or other compound capable of absorbing moisture.

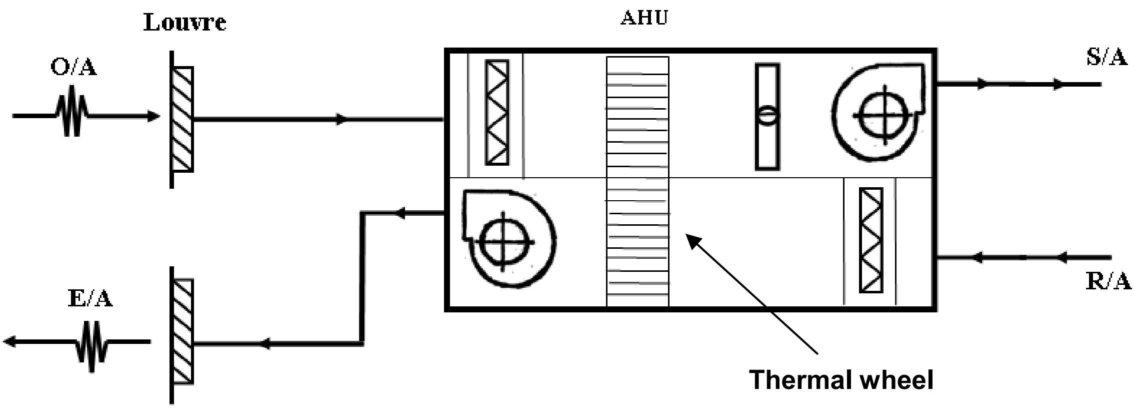

Figure 2 Schematic of thermal/sensible wheel used for heat exchange.

3. A Run-around coil system facilitates the heat transfer from exhaust to supply (and vice versa) by utilising coils with heat transfer fluid, stretching between the outside air intake and exhaust air streams. As there is no direct contact with the heat transfer fluid, this system is only capable of transferring sensible heat and has no possibility of cross contamination. This system has a relatively low heat transfer efficiency compared to thermal wheels (Hamilton, 1986).

5.3 Economizer

Economizer systems take advantage of the changing ambient conditions throughout the day. They are very beneficial in cold and temperate climates, where the ambient outside air temperature can be close to the supply temperature during cooling. In this occurrence, it can be more efficient to increase the supply of outside air to the system, exhausting the warmer return air, and subsequently reducing the HVAC energy costs when it is economic to do so. An economizer circuit monitors the external ambient conditions, and regulates the amount of outside air intake.

How it works:

- As the outside air decreases below the return air temperature, the economizer circuit will direct 100% outside air into the system.
- If the temperature reaches that of the supply air, therefore not requiring any chiller load, then ‘free cooling’ can occur, where 100% unconditioned outside air will enter the supply system.
- When the outside air temperature is below the supply air, the economizer will only direct the amount of outside air into the system, which is required to cool the return air to the correct supply temperature.

Economizer circuits are becoming increasingly popular, with some regulations – eg. those in California, specifying them as mandatory. Brandemuehl & Braun (1991) also distinguish the use of two different types of circuits; ‘Dry bulb’ economizers monitor the ambient dry bulb temperature and fluctuate the outside air intake accordingly, while ‘Enthalpy economizers’ monitor the ambient wet bulb temperature, and increase the outside air supply when lower than the return air.

5.4 Air-change effectiveness

Air change effectiveness (ACE) compares the age of air within the building (time since air molecules have entered), to the age of air that would occur if the air was perfectly mixed (ASHRAE 1997). The greater the level of ACE, the cleaner the air is for occupants to breathe.

Monitoring the air change effectiveness (ACE) will ensure that the supplied outside air is delivered to the building occupants in the most effective way, offsetting the age of internal air.

The ACE within a building is dependent upon the degree of short circuiting that occurs between the supply and return air, and the amount of outside air that enters a system. However, Fisk et al. (1995) showed that simply increasing the amount of outside air to the system will not greatly improve the ACE, due to the lack of mixing between the supply air and internal 'aged' air.

In order to achieve greater ACE within a building, the following options are available to ensure adequate mixing of air:

1. Efficient placement of air diffusers can limit the amount of short circuiting, and ensure that the throw of supply air creates sufficient mixing of internal air. In Australia, Green Star recommends that a well designed ceiling air diffusion system can achieve an ACE of near unity (08-1.2) at design flow rates.

2. Upward displacement systems with high level return air provision can eliminate direct short circuiting, and as such can be more efficient than perfect mixing (Fisk et al., 1995). These systems can ensure adequate movement of internal air, and the removal of 'aged' exhaust air. According to Green Star, displacement ventilation systems typically achieve an ACE greater than 1.2.

5.5 Source control of contaminants

Within a building, air can become contaminated with pollutants that are harmful to the indoor air quality. These contaminants must be exhausted from the internal air and their concentrations reduced to an acceptable level as specified by ASHRAE 129-2004. Outside air is then required to balance out the internal air supply, which may be at levels higher than required to achieve the benefits mentioned previously.

Limiting the amount of contaminated air exhausted from a building will reduce the amount of additional outside air required, and therefore could potentially reduce energy costs for the HVAC system. The exhaust system can be optimised in the following ways:

1. Minimising the direct contaminant sources can be achieved by selecting low emitting products and materials where usually high levels of contamination would occur (eg. paints, adhesives, carpet, furniture). Maintenance of appliances and regular duct cleaning can also minimise these levels.

2. Increased efficiency of exhaust systems, and maximising pollutant removal is possible by localising exhaust points above direct sources of contamination. Kitchen sinks, kettles, stove tops, photocopiers/printers and bathrooms should contain localised exhaust points that can directly remove the contaminants before they can spread around the building. Increasing the pollutant removal efficiency of the exhaust system will assist in achieving a greater ACE (Fisk et al., 1995).

6 Outside air Watch-its

6.1 Outside air intake location

Careful consideration must be given to the location of outside air intakes. Do not locate intakes close to building exhausts, car park discharges, cooling towers, boiler flues or generator flues. Analysis of the contaminant concentrations within the proximity of the intake location should be conducted, along with standard ambient conditions of wind speed and direction that can potentially affect the fan power required to draw in the air.

6.2 Outside air temperature sensors

The ambient conditions of outside air need to be highly accurate to supply information for economizer circuits, and heat recovery systems. Avoid locations of outside air temperature sensors, where the sun or other heat sources may influence the reading.

6.3 Effective control of outside air

Ensure outside air sensors are correctly calibrated and the systems commissioned. Avoid oversized dampers, which may restrict fine adjustments of the outside air intake. Use minimum flow dampers in addition to variable flow opposed blade dampers, with centralised controls to include any economizers or heat recovery systems.

In the case of variable air volume (VAV) systems, it is better to use variable speed outside air fans complete with accurate flow measurement to prevent the outside air reducing as the supply air reduces. By directly controlling the outside air intake as a separate system, the level within the building can be effectively monitored and provided with most efficiency.

7 Conclusions

Increased outside air rates can improve occupant concentration, performance and productivity, and decrease the amount of absenteeism within the workplace. If un-assisted, higher levels of outside air will increase the energy costs associated with the HVAC system. By utilizing the solutions presented in this paper, and by incorporating the effectiveness of air intake and exhaust systems a building can maintain a balance between the higher levels of outside air, and a reduction in HVAC energy costs.

Within Australia, the increased pressure to obtain a Green Star rating by offering increased outside air and air change effectiveness, while minimizing the energy costs is steering building design to include the heat recovery technologies shown in this paper, and to provide better filtration of the outside air to improve its quality.

Keywords:• Laboratory, Ventilation, Energy saving, Safety, On-going-commissioning, Fault detection

Summary

•

Most of laboratories are highly energy consuming buildings, which contain much exhaust to ensure safety of human body from toxic substances. Air change rate of fresh air intake caused by exhaust for lab facility comes up to 20• 60 air-change/h, compared to office building of only 1• 2 air-change/h to control density of CO_2 . Conventionally, because safety takes precedence, it was allowed that great volume of ventilation consumes much energy, however, recent demand for sustainability strongly requires coping with both proper safety and energy saving. A primary cause, which makes lab exhaust greater, is installation of many spot exhaust devices such as fume hood to prevent human body from suffering chemical exposure. However, codes and regulations require that constant and adequate face velocity to be maintained at sash opening of fume hood for prevention of exposure to toxic substances, it would be a problem if exhaust amount were simply reduced. In recent years, VAV system is introduced for fume hoods which operates together with sash, still, to take diversity factor into system design for energy saving becomes more important. On this paper, we introduce a case where 55% reduction of energy consumption was achieved by introducing VAV and design optimization, compared with conventional system. Furthermore, we propose a methodology targeted to detect fault and optimization by on-going-commissioning. And we also propose the visualizations about fault detection system for end users. The visualizations are friendly tool that end users are able to recognize the trends of possibility of fault before the experts of building energy management analyze the data of energy consumption. This methodology would contribute to energy saving, reduction of CO_2, and improvement of sustainability.

•

1. Features of Laboratories: Coexistence of "Safety for human body" with "Energy saving"

When experiments are performed in the laboratories or research facilities, materials are used which are harmful to human body, represented by chemical substances. Therefore, it is necessary to secure the human body against toxic substances. To ensure safety, at the laboratories, mass machine ventilation is performed. That is why laboratories are the buildings where the energy consumption is higher than that of general office buildings. In other words, seeing from a sustainable point of view, coexistence of "Safety for the human body" with "Energy saving" should be important themes. Consequently, both safety at laboratories and energy consumption are mentioned as follows at first.•

••• Safety for the Human body in Laboratories

When experiments are performed in laboratories, there might be many occasions where harmful materials breathed into the body or stuck to the skin or the mucous membrane. Accordingly, to control air quality of places around people in experimental area, special mechanical ventilation devices such as fume hood are introduced in laboratories. Safety for the human body is improved by these systems. About the ventilation by the fume hood, Laws, Codes or Regulations prescribe passage air velocity for the opening area of the sash of fume hood (Face velocity (Figure 1)). The above is a reason why ventilated air volume could not be reduced simply. Table 1 lists Codes and Regulations for face velocity.

•

• • • • • • (National Fire Protection Association)	Ave. • • • • • • • • • • •

• •• • Energy Consumption in Laboratories

Such as the above-mentioned fume hood, local exhaust facilities and spot ventilation devises perform the forced ventilation, making air flow around people in experimental area. Because a lot of fume hoods are installed in laboratory, there is much amount of energy consumption by air conditioning and ventilation facilities. About air change rate by fresh air intake, laboratories and general office buildings are compared to grasp aspect of energy consumption briefly. Figure 2 shows that fresh air change rate in general office building is around 1• 2AC/h for CO_2 Control, and around 5• 10AC/h for Temperature Control. On the other hands, in laboratories, it amounts to 20• 60AC/h by fume hood In addition, almost all air from Air-Handling-Unit (AHU) is taken form the outdoors, because it is necessary to make up for exhausted air. When the flesh air is taken from outside, it is important to remove the heat load from the air. Therefore energy consumption is huge in laboratories.

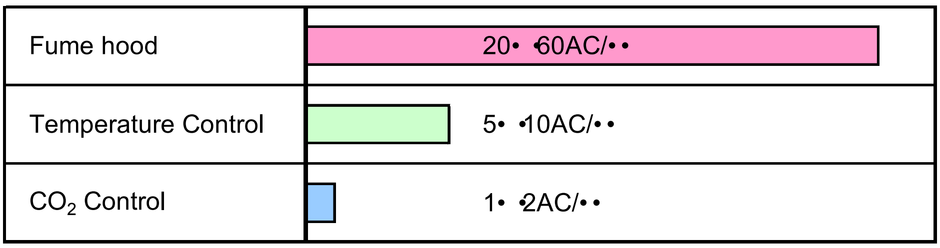

Figure 2• Comparison of Air Change Rate by the difference of the control

•• • Proposed System for Coexistence of the Safety with the Energy Saving from points of sustainability

A fact, that energy is wasted by much quantities of mechanical ventilation, have been accepted, that is to say, safety is made have top priority conventionally. However, recently, it is strongly demanded socially in view of sustainability, that energy saving is necessary to be balanced more while safety is secured fairly In addition, under the circumstance where complexity, advancement and accuracy are required depending on contents of research in recent laboratories, numbers of fume hood installed is increasing, and the operating time becomes irregular. Accordingly, by the operation of the more number of fume hoods, the more outside fresh air to be treated by air conditioning system. As the first step solution, VAV system (Variable Air Volume System) comes to be adopted. The system regulates the air volume matched to the opening area of the sash part of fume hood In the laboratories where a large number of spot ventilation equipments are installed, it is important to design the automatic control systems which function based on "Probability of simultaneous use" for the reduction of building energy consumption. Consequently, in our study, it was examined that design and operation of ventilated air volume does not become superabundant and wasteful. Fume hood is not examined as one piece of article, but it is examined as a part of the whole air conditioning system in the building. Not only the achievement of the energy saving, but also the maximization of the energy consumption efficiency is aimed at.

• •• • **Optimum Design and Operation based on Probability of Simultaneous Use•**

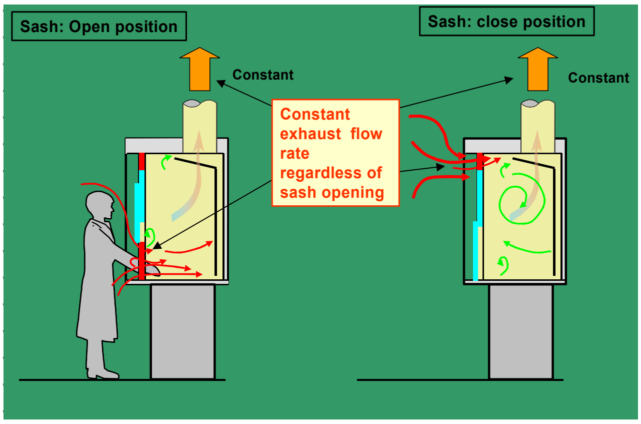
•

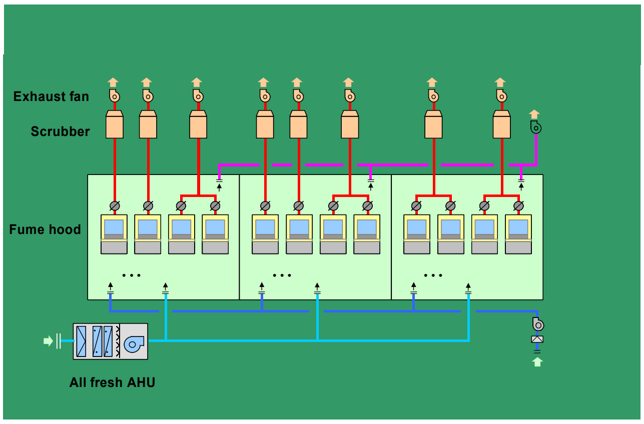
•

• •• •• Conventional Independent Exhaust System without Probability of Simultaneous Use•

In Conventional independent exhaust system, constant air volume is exhausted regardless of the opening area of the sash of fume hood. (Figure3) When Fume hood is not in use, indoor air is exhausted from the opening provided at the upper part of the sash. In addition, the exhaust from fume hood is connected to an exhaust fan in a duct system i.e. one-on-one system. (Figure4)

•





• *Figure 3• Conventional type Fume hood*

Figure 4• Conventional independent exhaust system

•

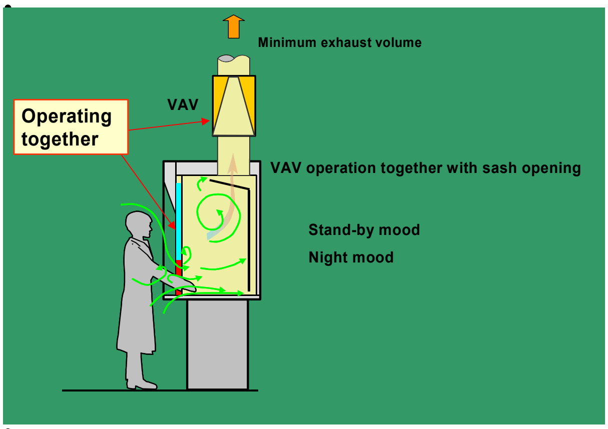
•

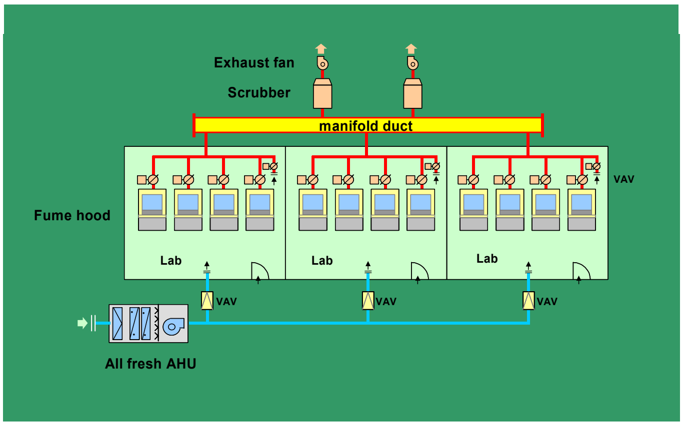
•

• •• • • Manifold duct + VAV exhaust & supply system•

Because exhaust air volume is regulated by VAV system, controlled based on the opening area of the fume hood's sash, necessary exhaust air volume is set to be properly. (Figure5) In addition, during Standby Mode and Night Mode, exhaust air volume can be changed to perform minimum ventilation. Furthermore, an exhaust fan is not found every fume hood one-on-one, besides manifold duct, which gathers branch air ducts, is installed. As a result, the number of exhaust fans (or, scrubber) is reduced. (Figure6) Because fresh air intake to the laboratories is controlled by VAV system, make-up air volume is minimized.

•





• *Figure 5• VAV exhaust system*
• • • • • • • *Operating with sash*

Figure 6• Manifold duct
• •*VAV exhaust* • •*supply system*

•

•

• •• • • Introduction of demand factor•

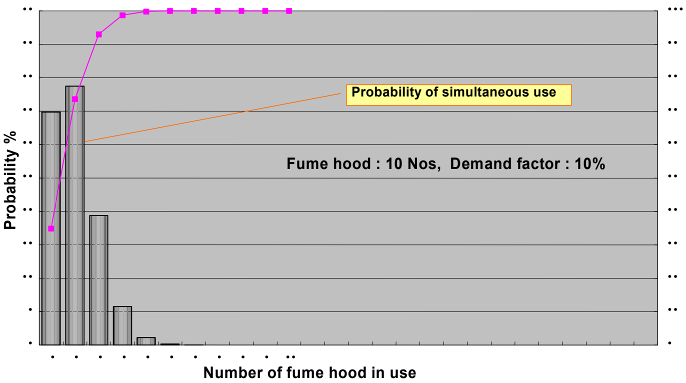
Figure7 shows the graph about probability of simultaneous use of fume hoods in lab. Statistical approach for ten Fume hoods was adopted, and demand factor (probability of simultaneous use) was calculated. Concretely, it is binomial distribution that was assumed that parameter (fume hood number) is 10 and demand factor is 10%. In this case, probability that only one of them is used is less than 40%. The simultaneous use more than six of them is not recognized. Accordingly, it is not necessary to make allowances for ability of full ventilation air volume for 100% of fume hoods.•

•

•

• •• • System Tuning compounded Statistical Method and On-Going-Comissioning (On-Going-Cx) for Accomplishment of the Optimization•

• •• • In case exhaust air volume of laboratory increases, chemical safety improves. On the other hand, energy saving factor deteriorates. Therefore, seeing from the point of view of sustainability, it is important that the most suitable point is found for the both (Chemical Safety and Energy Saving). Figure8 shows this point by a graph. The horizontal axis is Exhaust air volume, and the vertical axis is Performance. The circumstance of the change of Chemical Safety and Energy Saving is made in this graph. In this figure, the point of intersection of each curve is considered to be Optimum Point between Chemical Safety and Energy Saving. The examination result how this Optimum Point is achieved by Commissioning is described in the next clause.



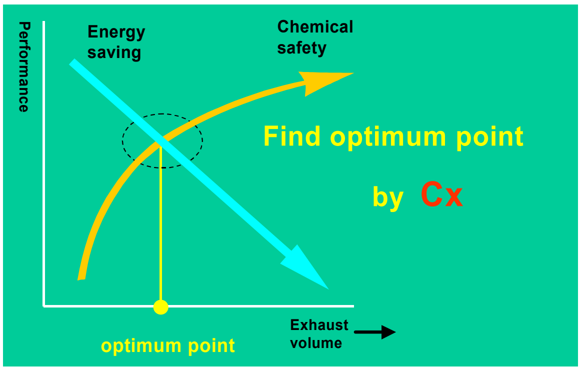


Figure 7• Probability of simultaneous use

Figure 8• • • • • •• • •• •

• •• • A large number of fume hoods are installed in the laboratories. The actual using situation of fume hood was grasped by actual survey. It was aimed that fusion with the system tuning about the air conditioning ventilation facilities of the building. Figure9 shows the plan of the building where actual survey was performed. Figure10 shows monitoring system. Monitoring system was installed in each fume hood, and actual in use situation of fume hoods was recorded. In addition the exhaust air volume by the VAV control system and the fresh air volume to balance the exhaust were also recorded by monitoring system. By this monitoring system, demand factor was found out. Figure11 shows usage of each fume hood. One base exhaust and 17 spot ventilation equipments (Fume hood, Spot Exhaust for Smell) are installed. The simultaneous use of spot ventilation is seven of them at the maximum. A ratio of the number is around 40% of the whole. About fume hood – h, in this graph, it is found that the sash of fume hood was kept in open position.

•

• •• Proposal of the methodology that aimed at the Fault Detection and the Optimization by On-Going-Cx

•

• •• • • Fault Detection System•

For the further improvement of the air conditioning system that leads energy saving, Fault detection systems are studied. The systems make it possible that the coexistence of the energy saving and safety by fault detection system where Building Management System and Building Energy Management System (BEMS) are put into use. About the item to be managed and the method of fault detection, they are divided into two approaches. First one is from indoor environment, second one is from operational condition of the devices (fume hoods).

(1) Approach from indoor environment

This is a fault detection approach where fault is detected by process values of indoor environment. Temperature(degree), relative humidity(• • RH), air pressure deference between rooms(Pa), cleanliness(number of particles/m^3) are nominated items to be monitored. Alert level (upper level / lower level) is settled in building management system. When a process values of the items deviate from alert level, warning is made in real time. Sensors installed for automatic control purpose are utilized for the monitoring purpose mentioned above. It is necessary that the validity of the located place of the sensors to be properly considered. Depending on a case, it is important define method of calculation to obtain a mean value when plural monitoring points are used. About the alarm of the air pressure deference between the rooms, it may arise in two cases. One is air conditioning system trouble, the other is caused by ventilation system for chemical safety. First one to be counter checked by air conditioning system monitoring device. And if the alarm is not arose by air conditioning system, it may considered arose by ventilation system. Second one occurs by ventilation system problem, and also improper user operation. Such as leaving room door open or leaving many fume hood sash open to be considered as example of improper operation.

•

(2) Approach from ventilation system itself and operational conditions

Air volume passing in a duct, is monitored by sensors. If it is considered too mach compared with design value, which is based on demand factor, alarm to be made. Besides above, each fume hood has sash opening sensor, then number of fume hoods in operation and opening height of each sash to be monitored for fault detection. This problem is caused by both mechanically and human error. Human error means careless mistake or user's offending against rule, S.O.P (Standard Operating Procedure). For example, in case S.O.P. requests user close a sash of fume hood every time after experimental activities, and if it was not done properly, exhaust air volume would be greater than designed set value. That means excess air is exhausted and energy is wasted, either.

•
•

• •• • • Visualization of Faults for User's easy recognition

With "fault detection" to say here, it means not only finding trouble of the air conditioning and ventilation device, but also finding trouble of the energy consumption (waste of energy). Since behavior of users affect energy consumption directly and seriously, it is thought important to have a user friendly tool complete with visualization that helps researchers in laboratory who use fume hoods realize extraordinary condition immediately by themselves, as well as the operation managers of the building. "Recognizing immediately" leads fast correction of improper usage, and to establish revised S.O.P. Energy saving and chemical safety are not attained until hard ware and soft ware are settled properly. In view of sustainability, especially large

energy consuming facilities such as laboratories, how to improve activities of end user is one of the key issue to be solved.
About visualization, following two categories are listed.
•••The category which identify the condition of the device
- ON or OFF of devise
- Alarms by trouble of devise
- Alarms by unusual number of operating equipments at the same time

•••The category which identify the energy consumption status
- Alarms by monitoring of current energy consumption
  (Alarms when the actual value exceeds the evaluated value)
- Energy consumption of every day, every week, every month
  (Visualization of the data of last year as the comparison value)

Figure15• 17 show the idea of visualization. Figure15 shows the current situation of fume hoods usage. Facility manager is able to be aware of the user's name who causes unusual energy consumption condition. It is necessary to inform user in each occasions, that many number of equipments to operate at the same time, or extraordinary outstanding zone in facility or time of the day. Therefore, to make user pay attention to status of usage and energy saving, visualization is made effectively with the colorful list (ex. orange or red color). Demand factor and number of fume hoods in operation is calculated, on the basis of actual survey value. Time zones with many fume hoods in use are displayed with the calculation results that made use of binominal distribution. Accordingly, prediction warnings are made based on data which were surveyed. If some openings of sash were left open, warning would be made to rectify the situation. These systems are useful for education and prepare guideline or S.O.P for end users. Figure16 shows plan of the building to check the current situation of fume hoods in use. Figure17 shows the list that make people recognize the using situation of fume hoods of the day before. By the accumulation of these data, SOP of management methods will be renewed. And it is possible to change the energy consumption of the building into more effectively

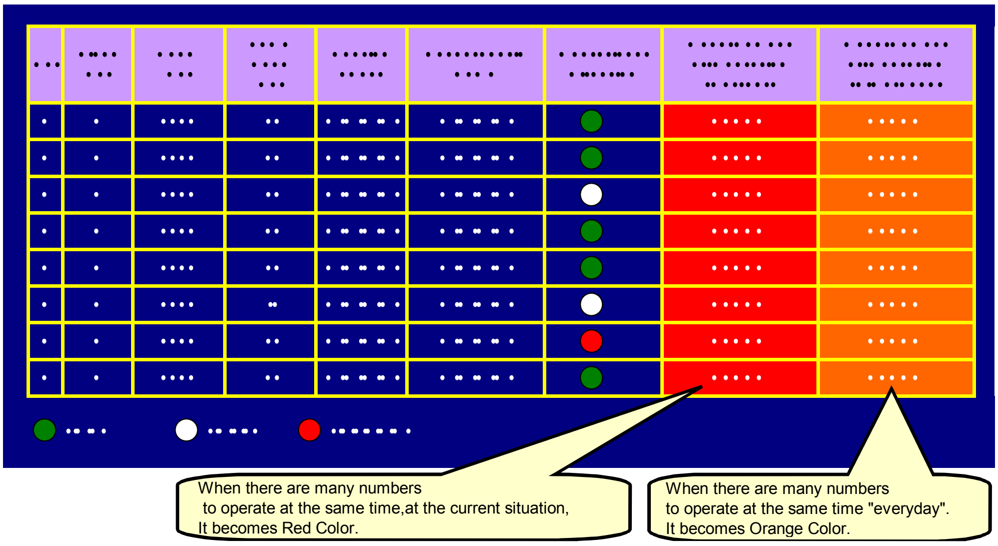

Figure 15• Example of Visualization• 1•

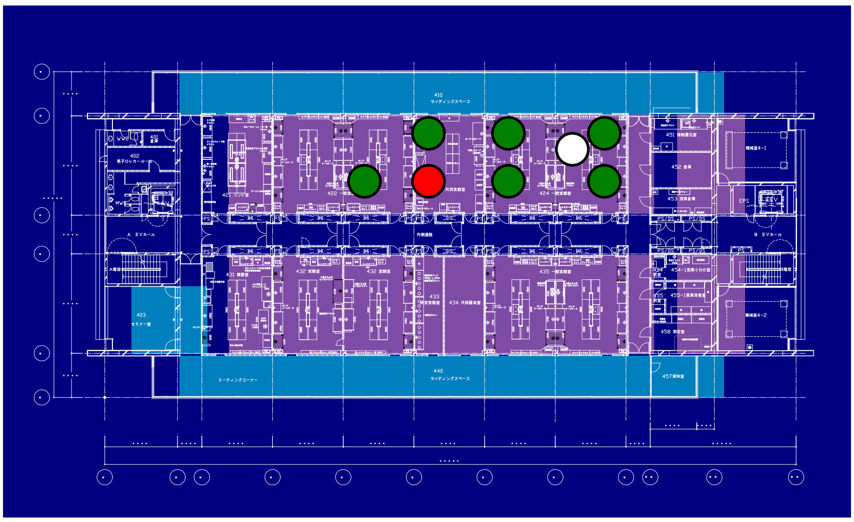

Figure 16• Example of Visualization• 2•

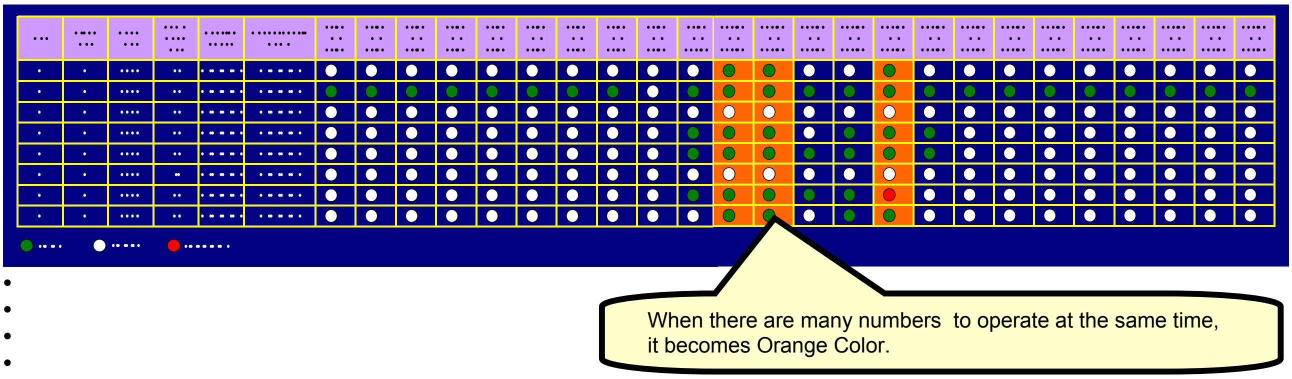

Figure 17• Example of Visualization• 3•

• •• • Conclusion•

On this paper, how to attain coexistence of safety for the human body with energy saving of laboratory for future sustainability was mentioned. Especially, in case of highly energy consuming facilities, it is important to make a careful consideration for both hard ware and soft ware such as users S.O.P. To obtain proper S.O.P., On-Going-Cx is significant. And it is also very important to make facility users prime movers who accomplish energy saving. Visualization tool as a fault detection system that helps user to recognize trouble of energy consumption, was proposed. This system and methodologies are useful for not only laboratories but also factories that require highly energy consuming environment for high productive performance (ex. electric devise, pharmaceutical, food factories). The proposed systems and methodologies may be utilized not only in the large facilities but also small in the others where no facility manager is controlling energy consumption. To make gross energy consumption improvement effective, small facilities improvement is a key issue. In view of the above, it is expected that proposed methodology may contribute to reduction of energy consumption and proper operation.

Keywords: Double skin envelope, Cavity temperature, Air velocity, Natural ventilation, Energy savings

Summary

The objective of this study is to evaluate the contribution of a double skin envelop for energy saving by natural ventilation in office buildings. A double skin envelop was installed to the east and west façade of the 1st floor in a building which is used as an office facility. Field measurements were conducted to test the performance of the double skin envelope in the winter season. The test was performed on two days that represented a typical clear day and cloudy day respectively.

On the clear sky day, the pattern of temperature variation in the cavity was similar to the intensity of vertical solar irradiance however the temperature variation was not affected by vertical irradiance significantly on the overcast day. The heating load from ventilation could be reduced by heating outdoor air in the cavity. Utilizing the western cavity, the heating load caused by ventilation was reduced by 33.69% on the clear sky day.

1. Introduction

Curtain wall structures covered with glazing are widely used for high-rise buildings since they have some advantage for visual satisfaction and provide an aesthetic exterior. To improve the performance of a glazing curtain wall, double skin envelopes are installed in many buildings. Double skin envelopes provide better thermal insulation and soundproofing than single glazing and they protect the blinds which are installed outdoors to reduce heating load. Energy to preheat outdoor air for ventilation can be reduced. Induced air from outdoors is heated in the cavity of the double skin envelope. In this study, the variation of air temperature in the cavity and air velocity at the inlet and outlet of the cavity were measured to evaluate the performance of double skin envelope for reducing heating load caused by ventilation.

2. Methods

The field measurements were conducted in the building located in Ansan, Korea (Latitude : 37˚ 17', Longitude : 126˚ 49'). The building has three floors and the first and second floors are used for experimental facilities. The third floor is used for offices for researchers and staff. The external appearance of the building and plot plan are shown in Figure 1. The long axis of the building was tilted by 26˚ counterclockwise from the north-south axis as shown in Figure 2.

Figure 1 View of tested building

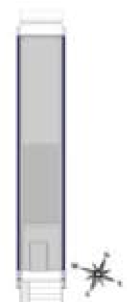

Figure 2 Plot plan

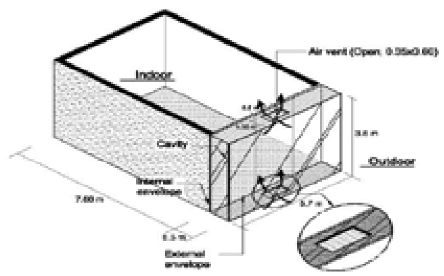

Figure 3 Conceptual description of double skin

Double skin envelopes were installed on the eastern and western façade of the first floor in the building. Glazing is installed both internal and external skins and both sides of the envelope were also covered with glazing to separate them from the adjacent double skin envelope so that the cavity was compartmentalized. The dimension of the double skin envelope is 5.7m (width) by 0.5m (depth) by 3.6m (height) and the conceptual performance of the double skin envelope is shown in Figure 2. Venetian blinds were installed on the outside of the internal skin in the cavity. The blind was set without a tilt angle and its depth was 2.54cm.

The top and bottom of the cavity were covered by transparent plastic panels except for the openings for air inlet and outlet. The dimension of the openings was 0.6m (width) by 0.35m (depth). The air inlet was parted from the ground by 0.3m. Figure 3 shows conceptual description of double skin.

The measurement was conducted in January to evaluate the performance of the double skin envelope for the winter season. Outdoor horizontal and indoor vertical solar irradiance, temperature at the air inlet, outlet and center of the cavity and air velocity at the air inlet and outlet were monitored every one minute.

3. Results

3.1 Solar Irradiance

In this paper, Jan 16th and 17th were selected because they could represent a typical clear sky day and overcast day respectively, and the solar altitude and azimuth of the two days were very similar. On Jan 16th, the maximum solar altitude was 31.72˚ and the solar azimuth varied from -62.88˚ to 62.88˚. On Jan 17th, the maximum altitude was 31.89˚ and the azimuth varied from -63.17˚ to 63.17˚.The variation of solar altitude, horizontal and vertical irradiance on Jan 16th and 17th are shown in Figure 4 and Figure 5 respectively.

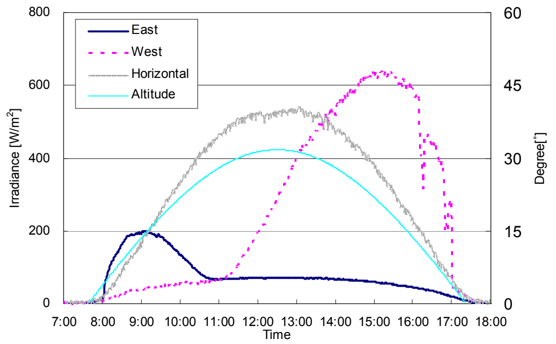

Figure 4 Solar irradiance and altitude on Jan.16th

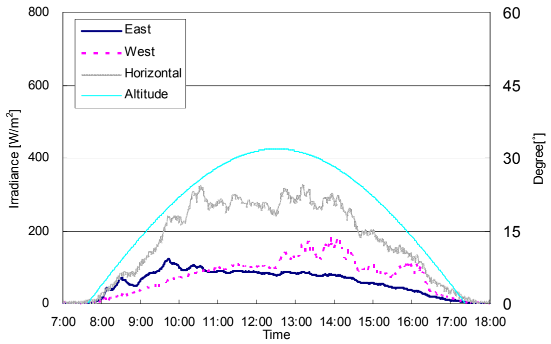

Figure 5 Solar irradiance and altitude on Jan.17th

On the clear sky day, the pattern of outdoor horizontal irradiance was very similar to that of solar altitude and the maximum value of irradiance was 540.12W/m^2 at 13:04 pm. After the sun rose, the vertical irradiance on the eastern envelope increased until 09:06 am up to 199.38 W/m^2. On the western envelope, the vertical irradiance increased radically after 11:00am and its maximum value was 640.84 W/m^2 at 15:17 pm. Since the building was tilted by 26˚ and the azimuth of the sun was -26˚ at 10:50 am

On the overcast day, the outdoor horizontal irradiance increased as the altitude of the sun increased but it was not as intensive as that of the clear sky day. The maximum value was 325.59 W/m^2. Solar altitude was not significant for indoor vertical irradiance. The maximum values of eastern and western irradiance were 122.66 W/m^2 and 184.59 W/m^2 respectively.

3.2 Variation of Temperature and Air Velocity on the Clear Sky Day

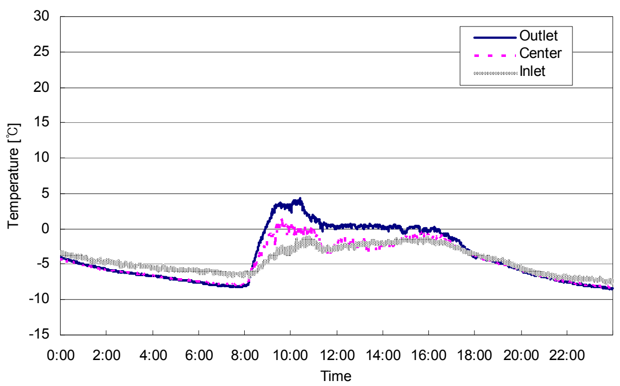

Figure 6 Cavity temperature (East)

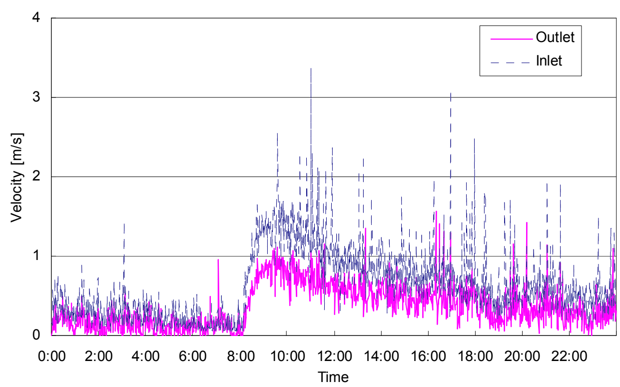

Figure 7 Air velocity at air inlet and outlet (East)

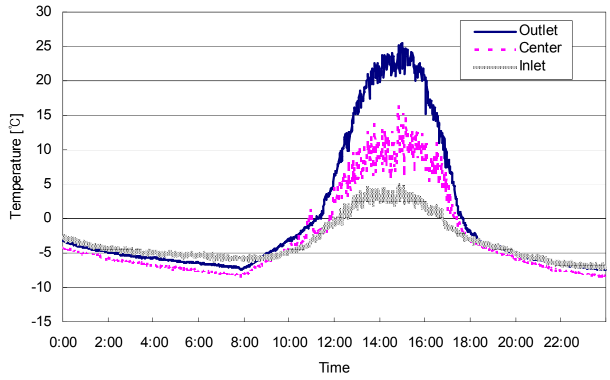

Figure 8 Cavity temperature (West)

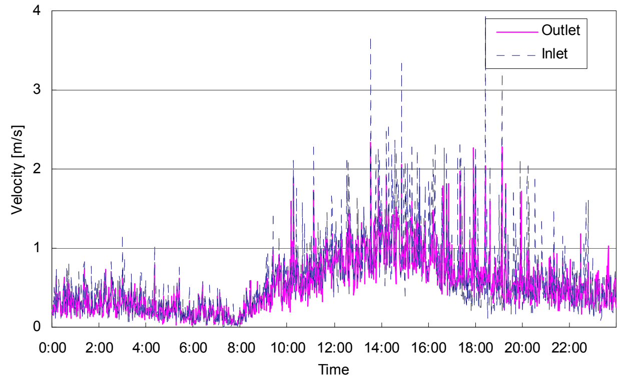

Figure 9 Air velocity at air inlet and outlet (West)

The temperature and air velocity variations on the clear sky day are shown in figure 5 ~ 8. The maximum difference between the air inlet and outlet was 7.61℃ and 22.0℃ in the eastern and western cavity respectively. The pattern of air velocity was similar to that of air temperature in the cavity. Since the temperature difference between the air inlet and outlet generate buoyancy, the greater temperature difference caused the faster air movement. The average air velocity from 09:00 to 18:00 was 0.46 m/s in the eastern cavity and 0.82 m/s in the western cavity.

3.3 Variation of Temperature and Air Velocity on the Overcast Day

Figure 9 ~ 12 show temperature and air velocity on the overcast day. The temperature differences between the air inlet and outlet were not as great as those on the clear sky day. The maximum temperature difference was 5.64℃ in the eastern cavity and 7.23℃ in the western cavity.

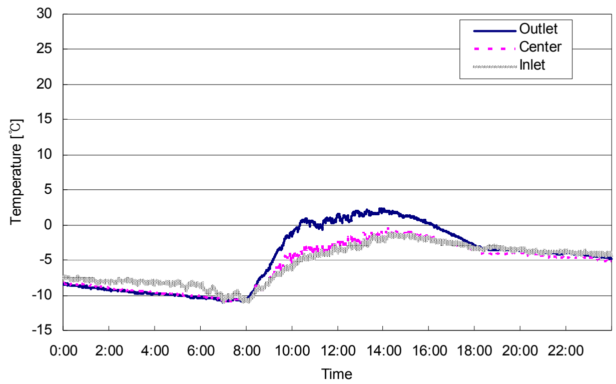

Figure 10 Cavity temperature (East)

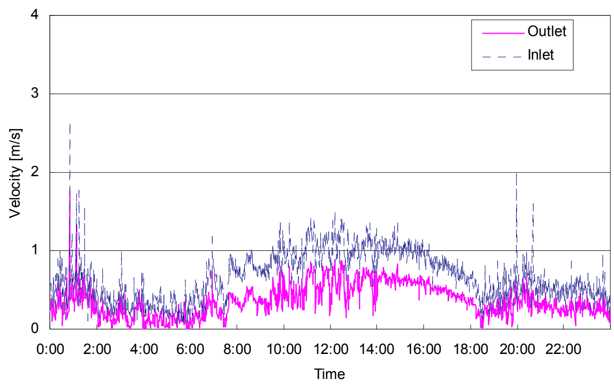

Figure 11 Air velocity at air inlet and outlet (East)

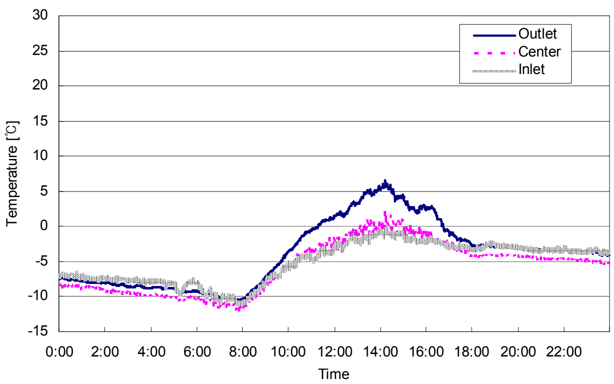

Figure 12 Cavity temperature (West)

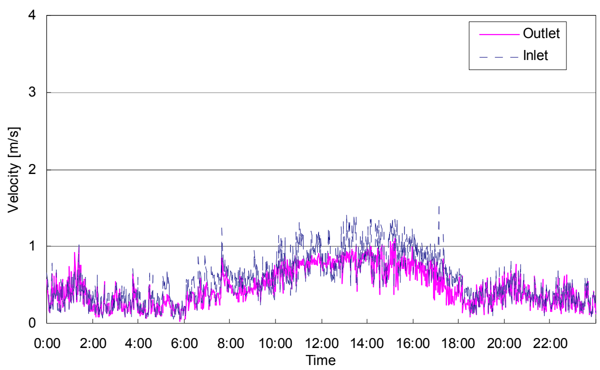

Figure 13 Air velocity at air inlet and outlet (West)

3.4 Reduction of Heating Load

The width and height of the office was the same as those of the double skin envelope and the depth was 7.68 m. The required amount of ventilation was 6,304m^3/h since the ventilation rate for office buildings is regulated at 4 air change rate per hour (ACH) in Korea.

Table 1 Ventilation rate and heating load reduction

	Jan. 16th		Jan. 17th	
	East	West	East	West
Effective amount of ventilation by double skin	4,178m^3	5,198m^3	3,822m^3	4,888m^3
Percent of natural ventilation by double skin	66.28%	82.46%	60.64%	77.55%
Heating load for 4ACH under single skin	203,138KJ	188,237KJ	209,083KJ	207,106KJ
Energy saving by induced ventilation from the cavity	15,025KJ	63,425KJ	14,763KJ	23,451KJ
Heating load reduction under double skin	7.4%	33.69%	7.06%	11.32%

The preheated air in the cavity was considered to be provided to the office. Effective ventilation rate was calculated from the air velocity at the outlet of the cavity. The heating load reduction for ventilation when the double skin envelop was installed was compared with the heating load when the single skin envelope was installed. The reduction of the heating load which was produced by ventilation was shown in Table 1. On the clear sky day, outdoor air of 5,398m^3 was provided to the office by the western cavity and it was 82.46% of required ventilation. In other cases, more than 60% of required ventilation could be provided by the cavity. However, the reduction of the heating load was feeble. In the case of the eastern cavity, the performance on the clear sky day was not definitely distinguished from the performance on the overcast day. It is considered that the cavity was affected by the office since the influence of solar irradiance was relatively weaker than that of the office.

If only sufficiently heated air (warmer than 20℃) was induced to the office to prevent cold draft, the amount of ventilation and heating load reduction would be 1,483m^3 and 34,423KJ when the western cavity was utilized on the clear sky day. In other cases, air temperature in the cavity did not reach 20℃. It is considered that the performance of the double skin envelope for reducing the heating load would be effective when it is applied to a hybrid ventilation system.

4. Conclusions

In this study, field measurements were conducted to evaluate the performance of a double skin envelope in order to reduce the heating load. It appears that the air temperature in the cavity was significantly influenced by vertical irradiance on a clear sky day but on an overcast sky day, the air temperature did not increase as much as that of the clear sky day. The cavity was naturally ventilated because the difference of temperature between the air inlet and outlet generated buoyancy. By utilizing the double skin envelope, the heating load could be reduced. On the clear sky day, 63,425KJ of the heating load was reduced in a day by western cavity and 1,483m^3 of outdoor air which is heated at a temperature warmer than 20℃ could be provided to the office. The performance of the eastern double skin for reducing heating was not significantly influenced by the amount of cloud. A double skin envelope could be effective, therefore, in reducing the heating load when it is applied to hybrid ventilation systems.

Keywords: active house, passive house, sustainable building envelope

Summary

The present trend in energy efficient sustainable dwellings is the passive house concept. Within the passive house concept every effort is made to minimize the energy use. Substantial savings can be achieved by passive energy systems, especially natural ventilation, summer shading and winter solar heat gain. The development of sustainable buildings is driven by the need to preserve the balance of nature. The ventilation capacity of many of these passive houses is critical. During a three week period different measurements in three of the first passive houses projects in Netherlands were undertaken to define indoor air quality and thermal comfort. Results showed that in some cases ventilation was completely insufficient. Energy saving and sustainability is very important but not at the risk of endangering health of the occupants. This was the starting point for a new approach, which led to an active house concept. By using ground air collectors, labyrinth foundation, muro-causter and hypo-causter, the whole building envelope and construction is thermally activated by natural pre-cooled air in the summer and natural pre-heated air in winter. A first design is presented to illustrate the concept.

1. Introduction

Over the last years average global temperatures have risen. Global warming, caused largely by carbondioxide emissions as a result of energy consumption, shows an increasing effect. Climate change is becoming a major problem. As results of Global Warming [Alley R. et.al. 2007] become more and more prominent, it is necessary to look for new possibilities to save energy and to generate sustainable energy to be used for comfort in the built environment. It is generally recognized that as the existing housing stock is responsible for a large share of the total energy consumption energy savings have to implied to new (re)construction activities. The European Commission reports that the energy demand in households accounts for 25% of the final energy needs in the European Unity. The latest trend on low energy housing is the Passive House. In Germany and Austria more than 5.000 Passive houses have been built and a lot experience was gained. Also in other European countries the passive house concept is promoted, still only a few houses in the other countries have been built. Designing and building of passive houses in a country is not a matter of straight forward following the experience of the already built examples from Germany or Austria. Each country has its own building tradition, architecture, building technologies, climate and culture. Architect and builders are familiar with local construction materials and detailed solutions which were developed to meet the specific building codes and standards of a country (Kaan en de Boer 2006). In France as an example only a few passive houses have been built (Thiers and Peuportier 2008), mainly for experimental purposes and the first attempt to reach the Passive House standard in France has failed (CEPHEUS project in Rennes (Feist et al., 2005)).

The Passive House concept is a relatively low cost method to achieve these energy savings (Storm et.al. 2005). The general definition of a Passive House is that the energy consumption is limited to around maximum 15 kWh/m² for space heating and around maximum total of 120 kWh primary energy/m² for heating, domestic hot water and electrical consumption by electrical equipment and lighting. To meet these criteria, the Passive House concept focuses first and foremost on reducing the energy demand of the building. Analysis of Passive House solutions shows high priority with regard to the performance of the thermal envelope: high insulation of walls, roofs, floors and windows/doors, thermal bridge-free construction and air tightness (Storm et.al 2006). At present in the Netherlands there is the PEP (Promotion of European Passive houses) project, in which ECN (the Energy research Centre Netherlands) and DHV, a Dutch consulting engineering firm, participate. In the Netherlands architect Erik Franke has built the first Passive Houses in the Netherlands according to the 'Passivhaus Projectierungs Paket'(PhPP) (Franke 2005). The

PhPP is a package of tools for architects to help them with the design of passive houses and was developed by the German 'Passivehaus Instituut' in Darmstad. In Germany, the Passiv Haus Institut took the traditional concept of passive solar building as a starting point and developed concepts for very low energy buildings by combining the principles with a very well insulated and air thight building envelope (Kaan & de Boer 2005).

1.1 The Dutch present situation

Though in the Netherlands a number of houses have been built according to PhPP, the actual performance of these houses was not yet thoroughly investigated. The aim of a study at the Technische Universiteit Eindhoven was to investigate if the ventilation levels reached by the installed mechanical ventilation systems in these Dutch passiv houses are sufficient (Balvers et.al. 2008). For the study three project of the Duth architect Erik Franke, a pionier on Passive Houses in the Netherlands, were chosen. Case 1 existed of one of the 12 houses that were built against the inener slope of a river dike. One of the main objectives of this original solar project was to prove that solar houses, designed and based on passive house technology, can compete in the housing market in the Netherlands on price, quality and comfort (IEA 2003). Case 2 and 3 were villas in which the used technology was also based on passive house technology. The study consisted of three methods for collecting data:

- a questionnaire to filled in by the main resident to gather information regarding use and maintenance of the ventilation system
- measurements during a period of 14 to 21 days of air flow, temperature, relative humidity and indicators of air pollution such as carbon dioxide, carbon monoxide and formaldehyde
- a logbook in which the residents kept a logbook to note specific events and changes in behaviour that might have influenced indoor air quality

The results of the measurements are given in table 1. Average airflow in use was in all cases lower than recommended by the Dutch Building Code while the capacity installed is proficient. Some high levels of carbon dioxide were recorded. CO levels in case 2 showed daily peaks around late afternoon and case showed only peaks when there were guest smoking inside the house. For the concentration of formaldehyde both cases and 2 showed distinct almost daily peaks in indoor formaldehyde concentration.

Table 1 Information on Dutch passive houses and measurement results (Balvers et al. 2008)

	Case 1	Case 2	case 3
Town	Sliedrecht	Dalem	Duiven
Type of house	Terraced house	Villa	Villa
Total gross volume m²	512	544	720
Total gross floor area m²	145	155	185
Year of completion	2004	2000	2004
Number of residents	3	3	4
Average U-value construction W/m²K	0,116	0,115	0,122-0,124
Ventilation rate in m³/h ± 2			
Bedroom 1 (2 persons)	18	blocked	13
Bedroom 2	15	23	6,5
Bedroom 3	n/a	n/a	5,5
Bathroom	30/62	20	8
Total air flow	63/110	96	62
Average night time CO2 level(ppm)			
Bedroom 1 (2 persons)	800	750	950
Bedroom 2	800	700	1650
Bedroom 3	n/a	n/a	900

The use and application of mechanical ventilation systems in such low-energy house is the critical aspect for creating an acceptable level of IAQ. The installed mechanical ventilation systems have three different setting of operation;

- level 1, used when no one is home
- level 2, standard operation when there are people at home
- level 3, designed for times of high levels of pollution

The mechanical ventilation system of all houses was by default on setting 1, even when people were at home. The residents of Duiven even turned their ventilation completely down to further reduce energy consumption. This while the functioning of the mechanical ventilation system is essential for maintaining a good IAQ. From this information it is concluded that the residents played an important role in the reached level of IAQ in their own houses.

The building needs to be passive to the external climate change and by good insulation minimize energy exchange with the outside. To reduce the energy use of buildings for heating, besides good insulation, a high level of building air tightness is necessary. Natural ventilation is strongly reduced by these measures and this has to be compensated by additional mechanical ventilation. Due to the required air tightness special attention should be paid to indoor air quality through adequate ventilation. Good ventilation is necessary for a good indoor air quality and to prevent moisture problems.

For good insulated low energy houses the needed heating energy for the ventilation air is around 50 to 65% of the total heat demand (Pottler et.al. 1999). This is the reason that often the ventilation are strongly reduced, some mention valuesas low as a ventilation rate of 0,4(de Boer et.al 2005). There is a competition between energy saving on the one hand and a good indoor air quality on the other hand. Storm et.al (20060 state; "However, since Passive Houses have air tightness, sufficient ventilation must be paid to the actual realization in practice of the required ventilation rate."

As stated by Kenda (2006), modern buildings do not breathe: the quality of air in contemporary architecture has negative consequences for the inhabitant's physical and mental state. Her study focuses on the beneficial integration of architecture and medicine in Renaissance Italy: Sixteenth century pneumatic architecture, especially the examples of hygienico-pneumatic villas. The villas are connected underground by labyrinth caves and wind channels to provide a unique natural ventilation system. The study of Renaissance pneumatic architecture suggests a critique of modern architectural models (Kenda 2006);" *Despite the rhetoric of "functionalism," the most iconic examples of modernist architecture often emphasize the individualistic expression of the architect rather than to promote the actual well-being of the inhabitants. With the recent revival of interest in traditional and environmentally sustainable architectural styles, there is now an opportunity to revive the therapeutic aspects of building well, so fundamental for the art of living well.*" These principles are taken as a basis and translated to modern demands.

2. Methodology; The use of accumulative capacity to save energy

2.1 Active versus passive

As the present passive house concept has some critical aspect related to adequate ventilation, we started to look at other ways for building to utilize the available on-site energy resources in a way that minimizes the need for purchased energy and still maintaining a satisfactory indoor environment.
Besides passive systems with their direct interaction between the building fabric and the environment, which do not produce power and do not need any mechanical devices or significant mechanical energy in order to operate, there are also active systems.
Active systems are designed to utilize the environment to either produce power, or to operate in conjunction with some mechanical devices to utilize renewable energy to provide heating and cooling (Wachenfeldt and Bell 2003). The direct inter-action between the building fabric and the environment in offers many possibilities to reduce the need for additional energy for conditioning in order to achieve the desired comfort and cover the residual demand. It is difficult to categorize the various active systems from true passive systems because they often combine strategies for power generation, passive cooling, passive heating as well as heat storage, heat recovery or avoidance of the various external and internal heat gains (Wachenfeldt and Bell 2003).
A modern variant is the use of the accumulative capacity of concrete constructions to flatten and damp the effect of fast changing outdoor temperatures. One of the first applications of a 'thermolabyrinth' was the 1977 Royal Academy of Music complex in London existing of theatres and music studios by Bill Holdsworth (Holdsworth 2005). Also in Germany there are several project with so called 'Thermo labyrinth' systems built, par example Stadttheater Heilbron and Terminal 1 Hamburg Airport. Recently in Australia there is built Federation Square in Melborne. In this project the outside air is led in a labyrinth under the square and blown into the atrium of the main building (Bellew 2004, AIRAH 2003). By doing this a significant cooling effect was realized.
An interesting modern technology related to the principles of 'thermo labyrinth'systems are earth-air heat exchangers, or ground tubes, or ground-coupled air heat exchangers (De Paepe and Janssens 2003). In the Netherlands only a few of these systems were applied, e.g. the firebrigade stations of Deventer and Soest by the architect Jòn Kristinsson (Kristinsson 2002). In Germany this principle is far more popular and applied in many buildings and passive houses (Pfafferot 1998), mostly with concrete or HDPE tubes as ground collectors.

2.2 Thermal capacitive active ventilation systems

There are ventilation systems which supply air through the concrete ceiling and so use the thermal capacity of the concrete. Of these systems there are different types, such as the ThermoDeck system Barton et al. 2001), or the Energon system (Piggins 1990). Termodeck, developed by two Swedish engineers Mr.Loa

Andersson and Mr E.Isfalt in the 1970s, uses the slab as a means of ducting ventilation through the building through oval or round shaped ducts (hollow-cores) within the concrete structure (Wachenfeldt and Bell 2003). In summer supply air fans at night bring in the cool air into the hollow slabs to cool the building and the warm outside air is cooled in the daytime. It utilizes the hollow cores within pre-cast concrete floor slabs as ventilation ducts to produce an environment which is thermally stable (Barton et al., 2002)
The TermoDeck system relies on heat being exchanged between the air in the core to the concrete of the slab, through the interface which is the surface of the core. Heat is conducted radially through the concrete from this interface until it reaches the surface (top and bottom of the slab) or to where the temperature gradient becomes small—in the horizontal direction between cores. As the temperature difference between the cores is relatively low, the high heat capacity of the concrete means that it is possible to neglect the influence of adjacent cores (Barton et al. 2002), see figure 1.

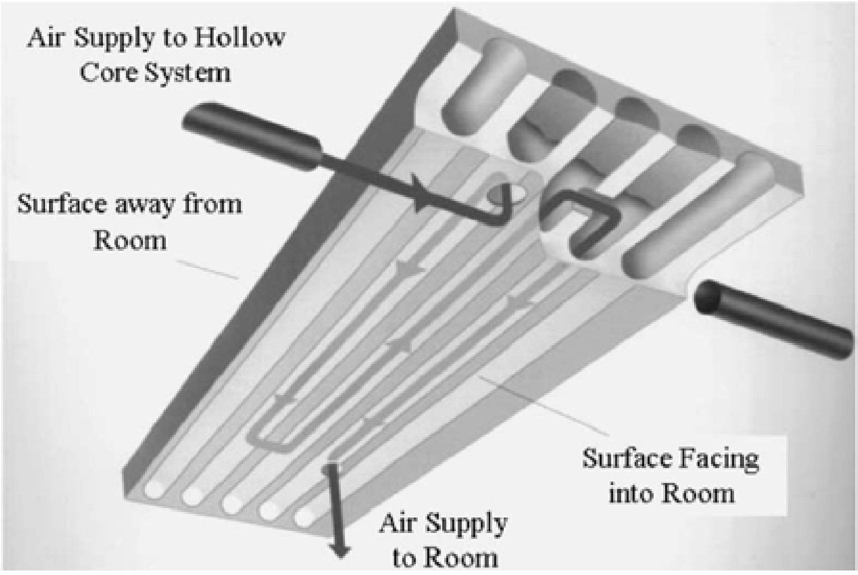

Figure 1 The ThermoDeck system (Barton et al. 2002)

The TermoDeck system employs low air velocities (i.e. approximately 1 m/s) with the result that buildings using this system tend to consume little energy (Barton et al. 2002). For example, the Elizabeth Fry Building consumes very little energy; its average electrical energy consumption for 1997 was only 61 kWh/m2 and its gas consumption was 37 kWh/m2 (Standeven et.al1998), figures which are less than half of the targets values for good practice air conditioned office buildings in the UK (DETR 1998). Typical energy consumption for heating and ventilation for the UK is around 200 kWh/m2./y (Wachenfeldt and Bell 2003). The Elizabeth Fry Building (John Miller and Partners) uses mechanical ventilation with heating and no mechanical cooling at all. Mixed flow ventilation is used throughout the building except the Lecture Theatre where displacement ventilation is used (Wachenfeldt and Bell 2003). The building was monitored for energy consumption and occupant satisfaction by the Professional Organization of Building Examiners (PROBE) team: it was perceived by its occupants to be a particularly comfortable building (Bordass et al. 1999).The PROBE team conclude that of 12 recently constructed buildings in the UK the Elisabeth Fry building had the highest occupant comfort scores and are also recorded the highest comfort scores recorded by the independent survey specialists Building Use Studies (Wachenfeldt and Bell 2003).

In Norway, the TermoDeck system was installed in some buildings in the early 80's. The thermal performance was reported to be good. However, various problems were identified (Wachenfeldt and Bell 2003).:
- Smell and dust from the un-treated concrete ducts.
- The connections between the ducts were not tight, resulting airflow at unwanted places and reduced performance.
- The ventilation systems were often under-sized, resulting in insufficient ventilation airflow to maintain comfort.

Due to these above mentioned problems, since the 1990s , there have been installed few, if any, ThermoDeck systems in Norway (Wachenfeldt and Bell 2003). Most of the TermoDeck systems delivered before this period have been rebuilt in order to increase the airflow rates and avoid especially the problem with concrete dust. The ducts within the concrete structure have therefore been abandoned, and were replaced by regular HVAC duct systems.

A concept to use the accumulation capacity of a building in combination with its envelope is the Lega beam Building System (Toft 1993). Hereby between the outer and inner building walls a concrete core is placed, see figure 2 A and B. In the space between the walls and the concrete core air flows which can also be cooled of heated with a ground-air collector.

In the early nineties the Fraunhofer Institute für Bauphysik studied a similar concept for a hybrid hollow-corefloor-slab-wall-air-collector system with passive discharge to the rooms above and below the slab (Becker 1995, Becker 1997). Figure 2 C presents a scheme of the system, that includes a horizontal hollow-core slab and vertical collectors. The basic repetitious module has a width of twice the core distance. The warmed air enters the slab from the collector through the southern end of one core, is pulled in and pushed through by means of a ventilator, and after discharging heat into the slab's concrete mass it returns to the collector through the southern end of the other core, with a lower temperature than at the collector's outlet (Becker 1995).

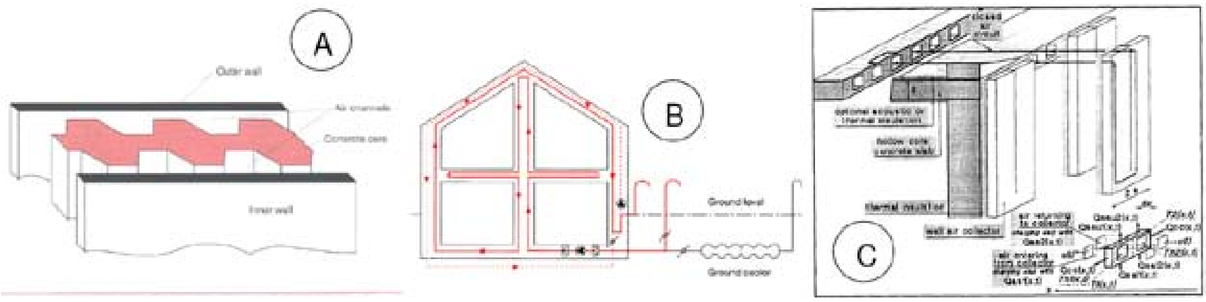

Figure 2 A & B. Legabeam Building Systeem (Toft 1993), 2 C. Scheme of hybrid slab-collector system, basic repetitious module, and basic slab slice (Becker 1995).

In the air ducts in the ground of the ground-air collectors and also in the labyrinth foundation by cooling of supply air, high relative humidity can occur. Often because of this effect air out these air-ground collectors is some what steel and not that suited to supply directly to the rooms. Especially at humid days there is condensation (Koene & Lightart 2001) When there is a long period of high relative humidity of condensation there is no way to avoid bacteria growth.

By these systems there is contact between the fresh outside air and the concrete, something which we think is not optimal, as dust and participles from the concrete can easily absorbed by the air. A system which does not have that drawback is the ConcreteCool system: concrete core cooling with supply air utilizes the high storage capacity of the concrete ceiling with aluminum ducts within the concrete. The supply air flows through the cooling tubes consisting of aluminum with high thermal conductivity.. To improve the heat transfer from the tube to the air, the inner surface was tripled. This system is already used in several German projects (Schröder 2002, Kiefer 2003), see figure 3.

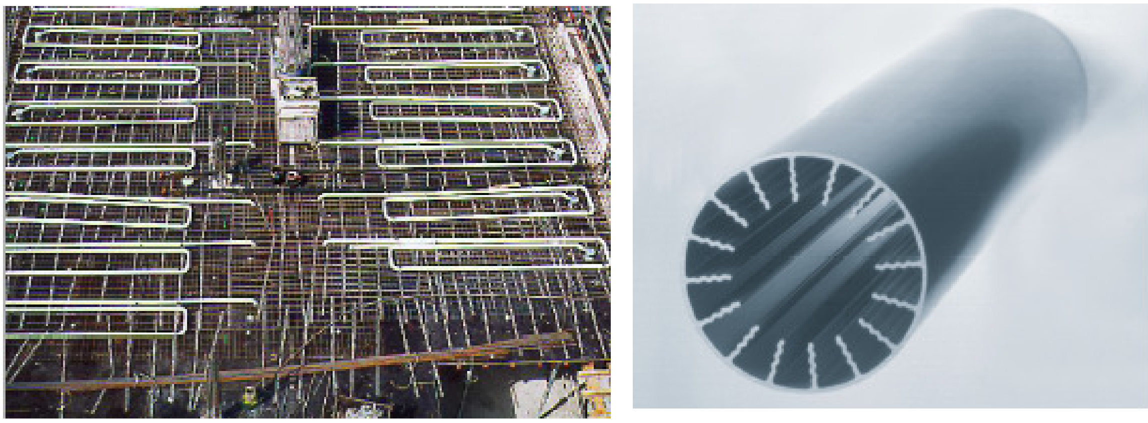

Figure 3 The concrete core activating system ConcreteCool

These systems, in which only air is used to condition the rooms, are based on ideas which can be traced to the Romans, see figure .Sometimes it is good to go back all the way to the beginning, the basis. The basis of conditioning buildings lays with the Greek and Romans. The Greek historian Xenophon mentioned the teaching of the Greek philosopher Socrates (470-399 BC) about the correct orientation of dwellings to have them cool in summer and warm in winter. The Romans pioneered with heating using double hollow floors through whose core the hot fumes of a fire were passed (Florides et.al 2002). They used with their 'hypocaust' and 'murocaust' the materials of the build construction to condition the building with hot air, see figure 4.

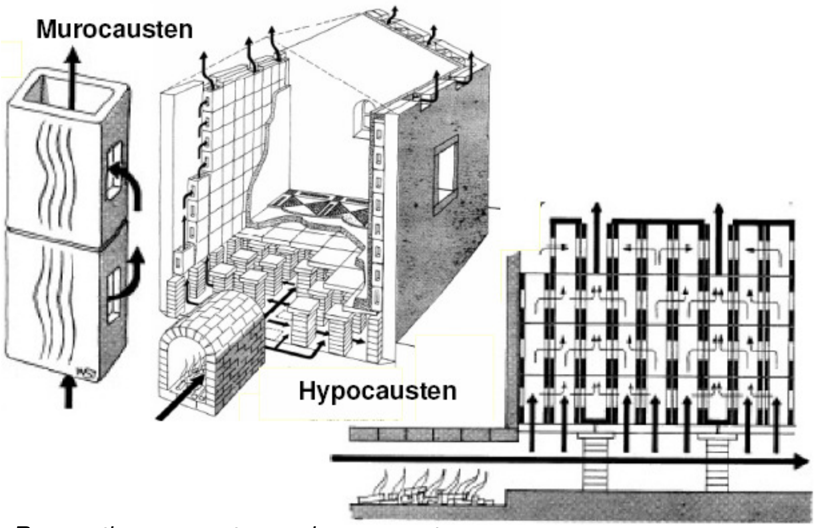

Figure 4 The Roman thermocausten and murocausten system

Since two thousand ears B.C. Mediterrian area has been a place where different architectonic cultures spread. People ruled by Romans assimilated their building techniques and technologies that became one thing with the local ones (Sansone 1999). The basic principles of orientation were known by Romans and they applied them to optimal valuing the effects. The planimetric distribution of the domus and its placing of the rooms was to optimize the influence of the sun rays according to the sun heights and the termic gap between morning and evening temperature. The *domus* often had a complex technological system to carry out what is like a modern centralized heating system. The system is generally called 'hypocaust', that means underground conditioning, in which a particular structure allows hot air to circulate under the floor (Sansone 1999).

BINE Informationsdienst, a service of the Fachinformationszentrum (FIZ) Karlsruhe GmbH and subsidized by the Bundesministerium für Wirtschaft und Technologie (BINE 2006) gives a overview of a few modern principles, of which some already have been applied in projects: Lutzstrassen Apartments in Berlin (Hastings and Mørk 1999) and Gardstens Bostäder aparmentscomplex in Gothenburg (SHINE 2006). These are systems which supply the heat of a thermal suncollector to the floors or walls, see figure 5.

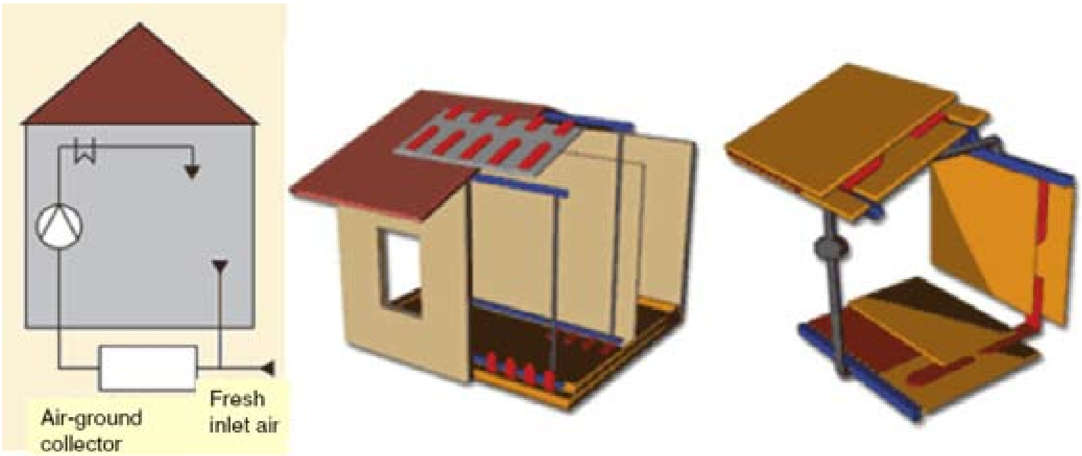

Figure 5 Modern principles of hypocausten and muro cuasten (BINE 2006).

Heat from air collectors can be transferred to mass using the room air, or, as in the Lutzstrassed Apartments in Berlin, warmed air can be blown, using fans, through hollow cores in a massive floor, called a *hypocaust* (Hastings, 1999, pp. 92-95), see figure 6 A.. Architects from the Institute for Building, Environment, and Solar Research designed the building with a closed loop from collectors in the south facade through tubes embedded in the concrete floor, and back to the collector. Discharge is by radiant transfer through the slab. This has the advantage of keeping the indoor air temperature from rising rapidly when the collector is heated by the sun.

In the apartment Block in Gothenburg, Sweden, by Christer Nordstrom ((Hastings and Mørk 1999)) air warmed from rooftop collectors is ducted by mechanical ventilation to a *murocaust* cavity in the external walls, formed by adding an insulated layer outside the existing not insulated masonry wall, see figure 6 B and C.

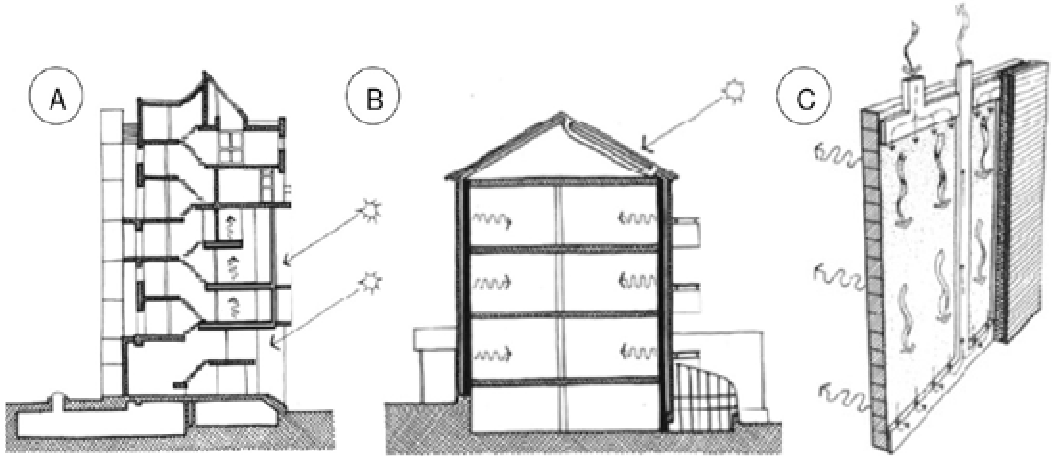

Figure 6 A Hypocaust in the Lutzstrassed Berlin: 6 B and 6 C Murocaust apartment Block in Gothenburg (Hastings and Mørk 1999)

3. Proposed active envelope solution; Active House

To avoid the negative effects of this possible bacteria growth the choice is been made for a separate system with strict moisture barriers by aluminum ducts in the buildings constructions, which carries the air through floors and walls. With a heat exchanger energy is exchanged between supply air and exhaust air, so there is no direct contact between the air directly blown into the rooms and air which went through the air-ground collector and the labyrint foundation. In our proposed system the outside air is let through a ground-air collector and through a labyrinth foundation into the building. There is a separation of the air into one straim used for ventilation and one stream for conditioning. The air for ventilation is supplied into the rooms through a separate floorcooling system. The air for the conditioning is used to cool or heat the total building envelope. The ground with its nearly constant temperature is used as source for cooling or heating for the floors, walls and ceilings. Activating of the buildings'enveloppe by air supplied concrete core can be done with the ConcreteCool systems of e.g. Kiefer in combination of hypocausten and murocausten, see the schematic in figure 7 .

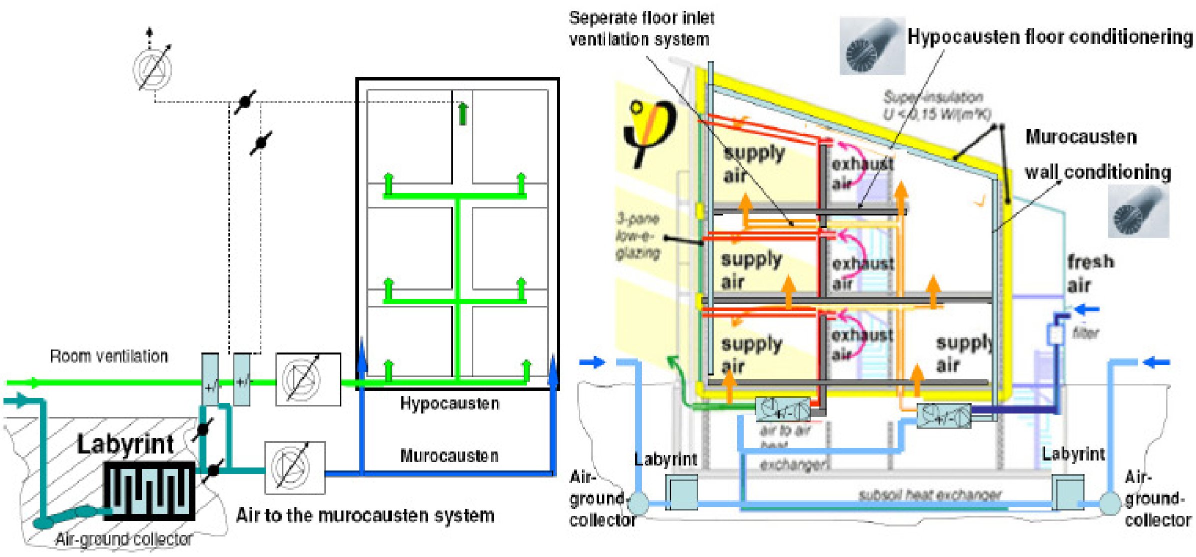

Figure 7 Principe schematic of the hypocausten /murocausten system in combination with air-ground collector and labyrinth foundation collector.

Keywords: roof-integrated PV Thermal collector model, performance comparison, thermal performance, electrical performance, radiant aluminum fin

Summary

The integration of PV modules into building facades or roofs can raise their temperature and thus decrease the power generation of the PV system. The hot air can be extracted from the space between PV modules and the building envelope and can be used as a heat source in buildings. The release of hot air from this space will enhance the performance of the BIPV system as it lowers the temperature of the PV modules. The type of solar collector that utilizes these two factors is known as a PVT (photovoltaic/thermal) solar collector. This paper compares the experimental performance of two different types of air-type PVT collectors that can be integrated into a roof structure: a base case with a 10cm gap for forced ventilation and another type with aluminum fins attached to a PV module to enhance the thermal performance of the module. The experimental results showed that the base case had an overall efficiency rating of 41.9% and the improved unit with aluminum fins showed 49.5% efficiency. For these types of air-type PVT collectors, forced ventilation of the air space improves the electrical performance as well as the thermal performance, and the fins help to improve the overall performance as they work as a radiating plate.

1. Introduction

The high temperature of PV modules reduces the efficiency of a PV system. In particular, BIPV systems appear to be more vulnerable to the PV module temperature, as they are attached to building surfaces. The extraction of heat from the space between building envelope and PV modules will increase the efficiency of the PV systems as it lowers the PV module temperature. It is also possible to utilize the extracted heat as a heat source for buildings. In addition to the improvement of the electrical performance of BIPV systems by the removal of the heat, the thermal collection through heating mediums such as air and water can be achieved with the device known as a photovoltaic-thermal (PVT) combined collector. To enhance the performance of the PVT collectors, it is important to collect higher thermal energy. Several works have sought to increase the air temperature from PVT collectors[1 2 3].

Thus, this study compares the experimental performance of roof-integrated PVT collectors that collect hot air from the space between the roofing surface and PV modules. There are two types of PVT collectors in this study: a prototype of a PVT collector on a sloped roof using PV modules and an improved model with aluminum fins attached to PV modules. Their thermal and electrical performances were analyzed to determine how efficiency is affected by the aluminum fins when these fins are attached to PV modules as a radiant plate.

2. Roof-Integrated PVT

2.1 Experiment Model Design

The roof-integrated, air-type PVT system was designed and built, as shown in Fig. 1. The PV arrays placed on the roof had a 1kWp capacity using eight 125Wp poly-crystalline PV modules. The specifications of the PV modules are shown in Table 1. The system consisted of four arrays, and each array was serially connected 2 modules with a maximum current of 7.04A and a maximum voltage of 34.8V

As shown in Fig. 1, the PV modules were integrated into the roof as building roofing materials while providing an air channel for the collection of solar air. The PV modules were attached onto aluminum profiles into rectangular timber that maintained an open air channel depth of 10cm between the PV modules and the roof surface. Exhaust air pipes that were 10cm in diameter were installed to extract heated air from the space in an effort to cool the PV modules. Fans were installed into each of four air extraction pipes for forced ventilation. The roof maintained a slope of 30°. This roof structure was built according to the required U-value of a building envelope based on Korean building codes.

Table 1 PV module specifications

SUBJECT	SPECIFICATIONS
Maximum power	125W
Maximum voltage	17.8V
Maximum current	7.04A
Shot current	7.66A
Open voltage	21.1V
Module size	670*1505*38mm
Weight	10.5kg
Cell type	6' poly-crystalline silicon

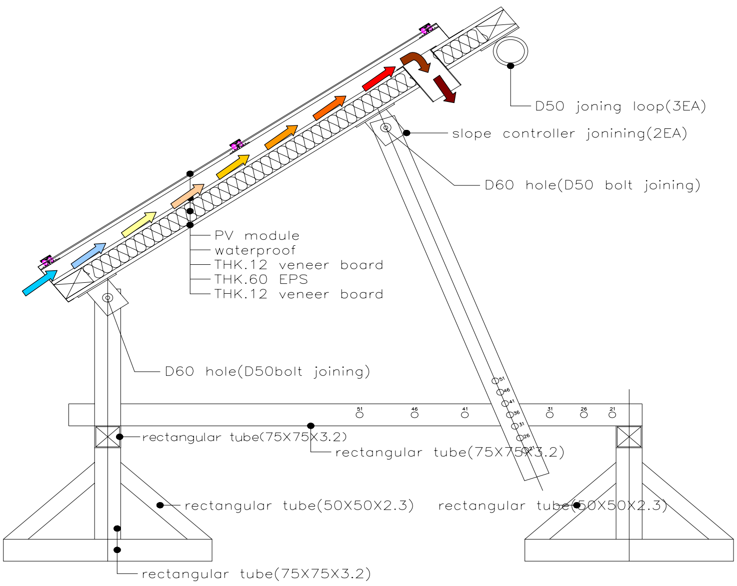

Figure 1 A cross-section of the roof-integrated PVT model

The basic configuration of air-based PVT system maintains an air gap between the building envelope and the PV modules. It uses heated air by fanning without any other special mechanism. However, this air that has been heated to a high temperature is useful in winter as a heat source in buildings. In this study, a new PVT model was proposed to improve the heat transfer through aluminum fins attached to PV modules. The attached fins transfer the heat from the PV modules and radiate it into the surfaces to raise the air temperature. They also raise the air temperature through a convection process in the space. As the attached aluminium fins increase the radiating surface of the PV module, the heat of the PV module releases more thermal energy actively at the achieved air flow. This, however, increases the electrical efficiency of PV systems by lowering the temperature of the PV modules. Cross-sectional views of the models investigated in this study are shown in Fig. 2. The schematic diagrams display a section of the base-type (a) collector, which inserts an air gap of 10 ㎝ between the PV module and the roof surface. Also shown is an improved type (b) that has aluminium fins attached to the back of the PV module. An aluminum plate with a thickness of 0.5mm was used for the fins, and they were attached to the back of a poly-crystalline silicon PV module with thermally conductive adhesive. The height of the fins was 5cm, and they were placed at intervals of 8cm.

Figure 2 Schematic diagram of roof-integrated air-type PVT collectors

2.2 Experiment Equipment and Methods

The PVT roof model used in the experiment was installed onto the rooftop of the Engineering Building at Kongju National University in Kongju (latitude 36.27N˚, longitude 127.07E˚). Fig. 3 shows photos of the model. Here, the slope of the model roof was 30˚ and it was orientated toward the south.

Several experimental devices were installed to measure the temperature of the PV modules and of the air in the space between the PV modules and the roof surface. Measurements were taken of the electrical power generation of the PV system, and the weather conditions were monitored. Solar radiation on the sloped roof surface and the outdoor air temperature were also measured. For the electrical measurement of the PV systems, electrical load resistors and a power meter were installed. A data acquisition instrument was also connected to record all of the data related to the thermal and electrical performance of the system and the outdoor conditions automatically.

Two different air-type PVT models were tested. The experiment with the base model was carried out during May and June of 2007, whereas that of the improved model was carried out during October and November of 2007. This paper analyzes the performance of the systems for one day in each case on a day with similar solar radiation. A T-type thermocouple was used to measure the temperature of the surface of the PV module and to measure the air temperature of the space. For the measurement of the air flow rate flow, meters were installed in the exhaust pipes. Temperature sensors were also installed to measure the temperature of the exhausted air. The air flow volume can be controlled in the range of 0~1500m^3/h.

Figure 3 Views of the roof-integrated PVT collector

3. Analysis of Experimental Results

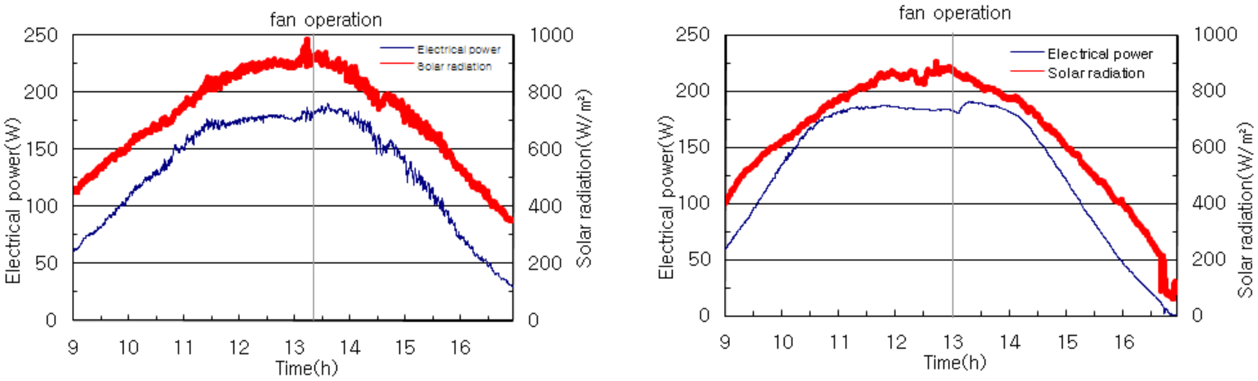
With the results of the outdoor testing of the roof-integrated PVT collectors, the variation of the electrical performance and that of the temperature of the PV module were analyzed. The collection of thermal energy by the PVT collectors via air circulation was also analyzed. The experimental results for the two different types of PVT devices were compared with a focus on the aluminum fins that were attached to the PV modules.

3.1 Electrical Performance

The electrical power generation of both PVT models appeared to be dependent on the amount of solar radiation. The variation in the electrical power generation of the PV system was analyzed to determine the cooling effect of forced ventilation. In order to compare the cooling effects of forced ventilation for both PVT models, the fan installed in the experimental model started at 1: 10 pm. Fig. 4 shows that forced air extraction increased the electricity generation of the PV system in spite of the decrease in the amount of solar radiation. This was clear during the period from 1:10 pm to 2:00 pm for both models.

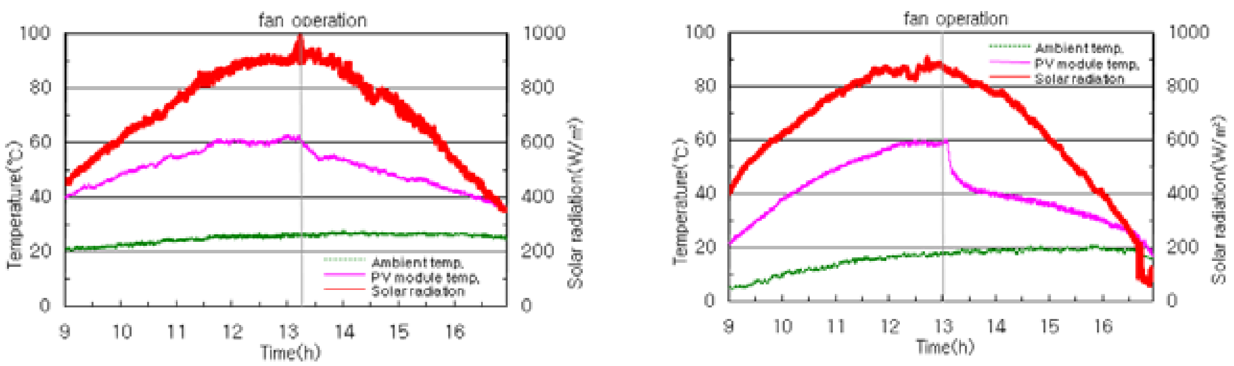
The improved model appeared to perform better than the base model. The electrical efficiency of the improved model changed from 10.3% to 11.4% due to the operation of the fan, whereas the electrical efficiency of the base model increased from 10.1% to 10.6%. These results indicate that the electrical efficiency of air-type PVT models can be improved by forced ventilation in the space between the PV module and the building surfaces. It also shows that the attachment of aluminum fins as a radiating plate contributes to further improvements. The fresh air intake into the air space by the fans decreases the PV module temperature, which helps improve the electrical efficiency.

As shown in Fig. 5, the variation of the PV module temperature indicates that forced ventilation lowered the PV module temperature of the base model and the improved model from 60℃ to 53℃ and from 59℃ to 41℃, respectively, under similar amounts of solar radiation. These temperature changes are related to the variation of the efficiency of the PV system. It was also found that the attachment of radiating fins onto the PV module contributes to a further reduction in the temperature.



a. Base Model b. Improved Model

Figure 4 Electrical power generation of the system in relation to solar radiation



a. Base Model b. Improved Model

Figure 5 Temperature variation of the PV module in relation to solar radiation

3.2 Thermal Performance

The thermal efficiency of the roof-integrated PVT collectors according to the amount of solar radiation is shown in Fig. 6 as calculated with Eq. (1). To calculate the thermal efficiency of the collectors, the measured air temperature of the inlet and outlet and the values for the solar radiation were used with an air flow volume of $150\mathrm{m}^3/\mathrm{h}$.

$Q_1 = A_{pvt}\, G$

$Q_2 = \dot{m}\, C_p\, (T_o - T_i)$

$$\eta_{th} = Q_2/Q_1 = \dot{m}\, C_p\, (T_o - T_i)/\, A_{pvt}\, G \qquad (1)$$

η_{th} : thermal efficiency

A_{pvt} : collector area (㎡)

T_o : collector outlet temperature (℃)

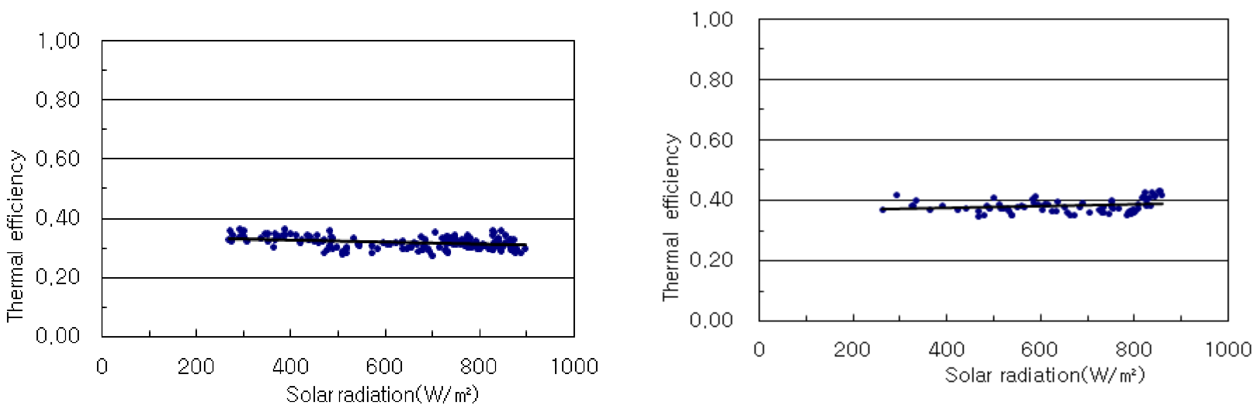
T_i : collector inlet(ambient)temperature (℃)

$\dot{m}$: mass follow rate(㎥/hr)

C_p : specific heat (kJ/㎏℃)

G : solar radiation (W/㎡)

The variation of the thermal efficiency of the roof-integrated PVT collectors is shown in Figs. 6. The average thermal efficiency of the base model was 31.6%, whereas that of the improved model was 38.1%. The thermal efficiency does not change according to variations in the amount of solar radiation, but the thermal efficiency of the improved model is approximately 7% higher than that of the base model. It is believed that the fins that were attached to the improved model contribute to enhance the collection of the thermal energy from the air-type PVT collector and that this is also related to the electrical performance of the PVT collectors: more heat from the PV module with radiating fins is released by aluminum fins that increase the air temperature of the space and lower the temperature of the PV module.



a. Base Model b. Improved Model

Figure 6 Thermal efficiency of the system in relation to solar radiation

4. Conclusions

This study analyzed the thermal and electrical performance of roof-integrated PVT collectors that are able to produce heat and electricity simultaneously. The experimental performance was analyzed for two different models: a base model with an air gap between the PV module and the roof surface and an improved model with aluminum fins attached to the PV module.

The experimental results shows that the electrical efficiency of the base model was improved by 5% as the fans had a cooling effect on the PV module; for the improved model, the efficiency increase was 10 %. The higher improvement is believed to have resulted from the radiating fins, which lowered the PV module temperature. The same pattern of an increase in efficiency applies to the thermal energy from the PVT models: the thermal efficiency of the improved model was 7% higher compared to that of the base model.

The overall efficiencies of air-type roof-integrated PVT collectors investigated in this study were 42.4% for the base model and 49.5% for the improved model due to the operation of the fan. Thus, it can be concluded that additional thermal energy generation of 30 ~ 40% was collected from the PVT collectors compared to a PV system that produces only electricity at an efficiency level of approximately 10%.

In this study, it was confirmed that the thermal and electrical performance of roof-integrated PVT collectors was increased by the attachment of radiating fins to the PV module.

Further studies are required to define a theoretical model for these models and to understand the effect of other factors on their thermal and electrical performances. Various configurations of the air channel when connected to the PV modules could also be studied to improve the thermal performance as well as the electrical performance. Furthermore, the contribution of this type of PVT collector connected to a building heating system could be studied in relation to a decrease of the building energy load.

Keywords: aged office building, refurbishment, integration, decision support, raised floor systems.

Summary

Traditionally, decision making on aged buildings is typically economically driven. This leads to the tendency to either delay refitting for as long as possible, thus causing building conditions to deteriorate, or simply demolish and rebuild with unjust financial burden. For traditional refurbishment, the technologies were typically limited to strip-clean and repartition. Changing operational patterns of business and the demand for better efficiency of office space and improved workplace environment will need more innovative and intelligent approaches to refurbishing office buildings. This paper introduces examples of Australian research projects which provided a more holistic approach to the decision making of refurbishing office space, using appropriate building technologies and products, assessment of residual service life, floor space optimisation and project procurement in order to bring about sustainable outcomes in response to social, environmental and financial implications. Innovative building technologies such as integrated raised floor systems will maximise the utility while promoting productivity improvement. Specific construction procedures including process map, procurement methods, are major issues explored. The paper also discusses the case studies on critical factors that influence some of these building components and key issues for integrated decision support when contemplating the refitting of old office buildings.

1. Introduction

The Australian construction industry has seen a booming market for retrofitting office buildings. The number of office buildings over 30 years of age has reached over 30% on average in Australian capital cities. This increasing stock of aging buildings requires their owners to decide if and when to refit them. It is believed that refitting of office buildings will occupy an increasing proportion of all capital works in the next 20 years. While refurbishment may cost much less than demolition and new construction (Caccavelli and Gugerli 2002), owners and other building stakeholders may have to deal with far more complicated and challenging retrofitting requirements than the traditional approach (Cox 2004).

Retrofitting of office buildings used to be done on ad-hoc basis. Owners, designers and contractors alike were often troubled by the poor building documentation and lack of reference to successful examples. As a result, designers may not foresee all of the potential problems, while the contractors apply huge mark-up for having to deal with the risks. As these professionals begin to get more volume of work, the characteristics of these refurbishment projects and strategies to maximise the opportunities for technological, sustainable and economic solutions become important issues.

Previous research identified the needs for the total consideration of buildings structural assessment and modelling of operating and maintenance costs (Reyers 2001), architectural and engineering designs that may maximise the utility of the existing structure, the need for productivity improvement, reduction of project risks and mitigation (Gray, 1999; Skorupka 2001), and innovative construction management approaches such as new procurement methods, work flow and scheduling and occupational health and safety (Cox 2004). Recycling potential and conformance to codes may be other major issues (Faniran, 1998 and Nigel et al 2001).

This paper introduces examples of Australian research projects which provided a more holistic approach to the decision making of refurbishing office space, using appropriate building technologies and products, assessment of residual service life, floor space optimisation and project procurement in order to bring about sustainable outcomes in response to social, environmental and financial implications. Innovative building technologies such as integrated raised floor systems will maximise the utility while promoting productivity improvement. Specific construction procedures including procurement methods, work flow and scheduling, decanting, and recycling are major issues explored. The paper also discusses the case studies on critical factors that influence some of these building components and key issues for integrated decision support when relifing office buildings.

2. Review of Related Research and Existing Methods

Over the recent years, research efforts have been made to explore the advantages of retrofitting of aged buildings (Allehaux and Tessier 2002; Anderson and Mills 2002; Jones Lang LaSalle 2005). The recent foci and commitment to sustainability encourages retrofitting options. In Europe for example, the retrofitting market has experienced considerable growth over the past 6 years (Caccavelli and Gugerli, 2002), which might be mainly due to the ever changing user requirements, lower cost of retrofitting, and massive energy consumption of old office buildings. In Australia, refurbishment of buildings is expected to form an increasing proportion of the annual capital budget with some estimates being as high as 50% by 2020. This has important implications for sustainability. If the Koyoto targets were to be reached, it is the existing building stock and their efficiencies which must be improved. Waste minimisation and recycling can also form a significant part of the equation, accounting for an estimated 0.5% of GDP.

While the pressure to retrofit existing building is mounting, there remain some major challenges on the refurbishment option as opposed to new build. They include:

- Decisions on political, social, environmental and financial implications of re-life compared to new build (Balaras 2004);
- Feasibility studies assessing the condition of the existing building, the residual service life, and estimating construction costs, modelling of operating & maintenance costs, and the utility and productivity expected from the refurbished building (Reyers 2001; ECI 2003)
- Architectural and engineering design to maximise the utility of the existing structure (Thomas et al 1996).
- Coordinated work scheduling for clients, consultants and contractors in terms of forward capacity and production planning linked with design, procurement and decanting schedules.
- Additional challenges for demolition and waste handling and disposal, potential recycling, occupational health and safety, condition surveys and identification of services etc (Nigel et al 2001).

Availability of historical data and tools for the modelling of different scenarios to allow comparison of the alternatives are other potential barriers. Largely due to the lack of as-built on old buildings, information on the modelling of operating and maintenance costs, the utility and productivity expected from the refurbished building, and the monitoring of building energy performance depending on the alternatives is particularly hard to come by.

Despite these concerns and challenges, the new refitting market is developing due to the sheer volume of work to be done. This phenomenon not only requires immediate attention but also application tools that can help stakeholders making decisions such as:

- Sustainability issues including indoor air quality, energy saving, waste handling, disposal, potential recycling and Occupational Health and Safety (OH&S);
- Conditions of existing buildings and the residual service life;
- Waste management issues and recycling potential;
- Associated risks, costs, time and project delivery patterns and project management processes.

Some earlier research has been conducted in the European countries and America to investigate methodologies and software tools for the assessment of a building's existing structural conditions, energy usage and estimation of costs. For example, TOBUS is an evaluation tool for the assessment of retrofitting needs of office buildings in European countries and for estimating the costs to meet these needs in compliance with sustainability issues such as energy performance and indoor environment (Caccavelli and Gugerli 2002). Office Scorer is a tool developed by the Building Research Establishment (BRE) in the UK in 2002 to systematically compare and test the environmental and economic impacts of different building design concepts for offices. BRE has modelled a number of buildings over a 60 year life and evaluated the economic and environmental impacts of a range of factors including building elements degradation, ventilation and cooling system energy saving (BRE and DTI 2002). EPIQR and MEDIC are software which can provide diagnosis of degradation of existing residential buildings, energy performance and indoor air quality (Flourentzou 2000).

A Facility Energy Decision System was developed by the Pacific Northwest National Laboratory in the US to inform decisions on energy-saving retrofit projects (FEDS 2004). In Australia, the Building Division of the Queensland Department of Public Works developed the Ecologically Sustainable Office-Fitout Guideline as a strategic asset management framework. It covers key aspects of community, energy, material and water in relation to office building fitout works (Queensland Government 2004).

These methodologies and tools provide the global view and focus shift to building's renovation and refurbishment processes. Some enable users make informed decisions in targeted specialty areas. However, most of the tools approached the building refurbishment issue on an ad hoc basis and tend to deal with specific issues within a region. The evaluation results of these tools can be very subjective depending on input and will require substantial as-built information, which is often lacking. Over reliance on computers may render these tools to become inflexible, unadaptable and non-updatable. Therefore, there is an urgent need to develop a more integrated and holistic system that operates in a scientific and procedural manner. In particular, knowledge gaps need to be covered in residual service life, waste management, floor space optimisation, project risk assessment, contractual issues and procurement patterns.

3. Sustainable Refurbishment with Integrated Technologies

To respond to the above challenges and provide a guide for the booming market of office building refurbishment, research projects in applying raised floor technologies and the integrated approach to "re-life" aged office buildings were recently undertaken in Australia. These research projects considered the design and implementation issues of using raised floor systems (RFS) for office space as well as constructability and specific contracting strategies to share risks as well as benefits between building owners, contractors and users. Characteristics of refurbishing projects that impact upon the effective management of the construction process, such as the identification and mitigation of risks, issues of decanting and existing tenants, identification of existing structure and services, work scheduling, occupational health and safety issues for construction personnel and tenants, demolition, waste and recycling, issues of quality and workmanship, cost planning and cost modelling methodologies. The research further explored holistic approaches to dealing with these issues and developed a decision-making support mechanism for assessing the condition of the existing building structure, residual service life and floor space optimisation. A combination of research methodologies were used in these projects, such as Delphi study, Process Integration, Case study and Industry interviews. Extracted information from these processes was presented as decision support tools to guide stakeholders in problem solving and decision making.

A Delphi study was conducted with the assistance of a panel of industry experts to determine the most relevant and important issues of consideration of refitting commercial office buildings. A unique aspect of the Delphi Questionnaire is that the industry experts consider the issues individually, without discussion with other experts (Chan 2001). A total of 48 issues identified by the comprehensive literature study and discussion with industrial partners were incorporated into the Delphi questionnaire. Through four rounds of electronically mailed questionnaire surveys, these experts evaluated, considered and reconsidered the relative importance of these issues presented particularly taking onboard feedback from peer reviews. A total number of 36 critical issues with commonly agreed high ranking were revealed. The six top ranked critical issues are Structural appraisal prior to refurbishment, Purpose of refurbishment, Energy saving potential, Cost analysis for sustainability and building efficiency, Project cost risks, and Building condition assessment.

The 36 critical issues identified were mapped against six major phases of project development for holistic consideration and problem solving. As a result, an integrated project map was developed and linked these critical issues with logic, order of execution, cross-reference, and quality control in mind, along the continuum of project development phases. Based on these issues, a Best Practice Guide was developed to encapsulate relevant problem solving logic and knowledge for decision making. The knowledge and information required for decision making is organised according to (1) the potential causes for this issue, (2) the problems it will bring about, (3) the possible actions that can be taken, and (4) the results from such actions. The top part of the module presents graphical linkage between these elements, depicting the inherent relationships. The bottom part further elaborates "what-to-do" actions of these elements according to the related project development phase. An application example of the Best Practice Guidelines is shown in Figure 5 as a way of dealing with Space Volume Limitation in the Case Study of research on the use of raised floor systems.

In addition to the Best Practice Guide for systematic and consistent approach to guide to building owners, developers and contractors through decision making on potential refitting projects, specific building technologies and systems are also needed to offer alternative fit-out methods, and respond to new office spatial and environmental issues. This concern was addressed in the raised floor project as below.

4. Integrated Office Refurbishment Using Raised Floor System

In addition to structural strengthening, office fitout is another most important task in office building refurbishment. Due to their inherent limitations such as rigid ceiling based HVAC system and wall mounted power, voice and data (PVD) distribution system, traditional office fitout methods cannot support the economical use of resources and provide a sustainable workplace environment on a cost-effective basis (Zhang 2005). Deployment of appropriate construction technologies, innovative building design and flexible facility management patterns needs to be done. As an alternative fitout method and product, Raised Floor System (RFS) has been seen as an integrated pool of technologies to meet the sustainable retrofitting of office buildings. A range of potential benefits of RFS based refit of office space has been identified, using underfloor HVAC system and PVD distribution system (Yang and Zhang 2005). This can be summarized in Figure 1.

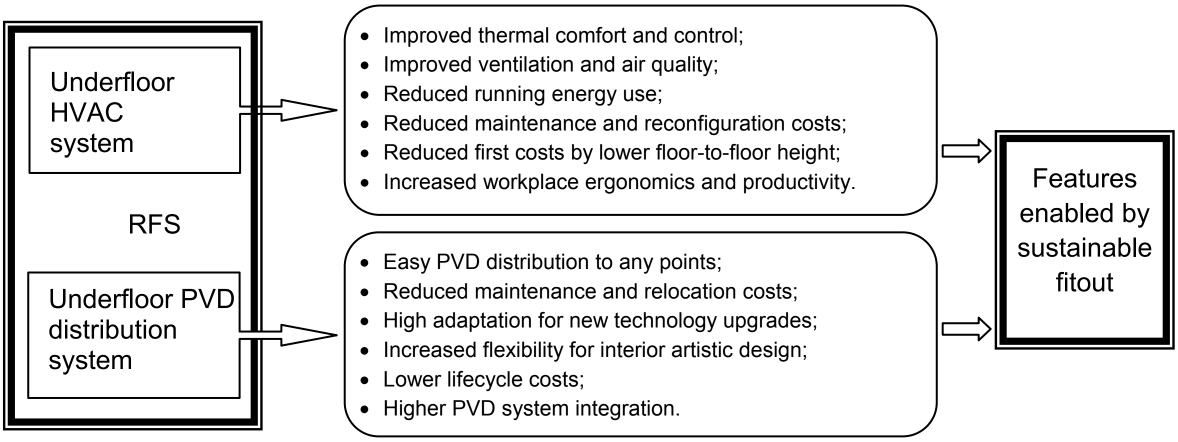

Figure 1 Potential benefits of RFS for office building fitout

A typical RFS consists of structural units, accessories and service units. The structural units, including panels and understructures, provide the basic platform of RFS, supporting loads above. The panels will form the raised floor surface on which office activities are carried out. Understructures supporting these panels create a plenum between the sub-floor and the panels that allows the distribution of building service systems and provides easy access to maintenance. The accessories, such as floor coverings, cable carriers and ramps, are indispensable to many flexible RFS functions, structural integrity, and improvement of workplace environment. The service systems include underfloor HVAC and underfloor Power Voice and Data (PVD) systems, both of which can enhance the versatility of RFS products for office buildings.

5. Case Study – Best Practice Guide for Using RFS

The RFS technology has been explored by many industry practitioners and applied to the refurbishment of a number of green and smart building projects (Zhang 2005). While many merits and potentials have been identified, as with the introduction of many new technologies, some of the earlier applications have experienced problems and encountered barriers preventing more effective implementation. The process maps and best practice guide developed in the re-life of office building project has been adopted to integrate RFS in office building retrofitting.

5.1 Factors Influencing and Problems Associated with the Refurbishment using RFS

Significant influence factors (SIFs) associated with RFS planning has been identified (Zhang 2005). If these factors were not accommodated appropriately, problems in the operation of RFS services might occur. The list of SIFs and Problems are presented in Table 1.

Table 1 SIFs and Problems Associated with RFS Uses in Office Refurbishment

SIFs	Abridged Name (Code)	Problems	Abridged Names (Code)
Structural constraints: *(5SIFs)*	Structural irregularity Space volume limitation Transition difficulties Overhead HVAC influence Structural beam restriction	Major: *(6)*	Uneven air distribution Hot spots Cool air leaking Draught Additional hole drilling Dust
RFS service integration: *(2SIFs)*	Fire safety system accommodation Cables and wires incompatibility	Minor: *(9)*	Uneven raised floor surface Poor panel & wall connectivity Poor floor connectivity Inconvenient underfloor access Noise Breakdown due to holes Panel moving Panel distortion Trip hazards
Industry practitioners' knowledge: *(8SIFs)*	Architects & engineers' incompetency Poor design influence on construction UAD influence on productivity Clients' low familiarity with UAD Contractors' incompetency QS' incompetency Low awareness of RFS Ignorance of RFS implementation		
Cost concerns: *(5SIFs)*	Capital cost obstacle Underestimate of LCC Poor design influence on cost Suspicion of RFS payback ability Ambiguity of fitout responsibility		

Further analysis on the impact of the 20 SIFs on RFS design, construction, operation and maintenance processes highlighted 36 project level critical factors (PLCFs), as shown in Figure 2.

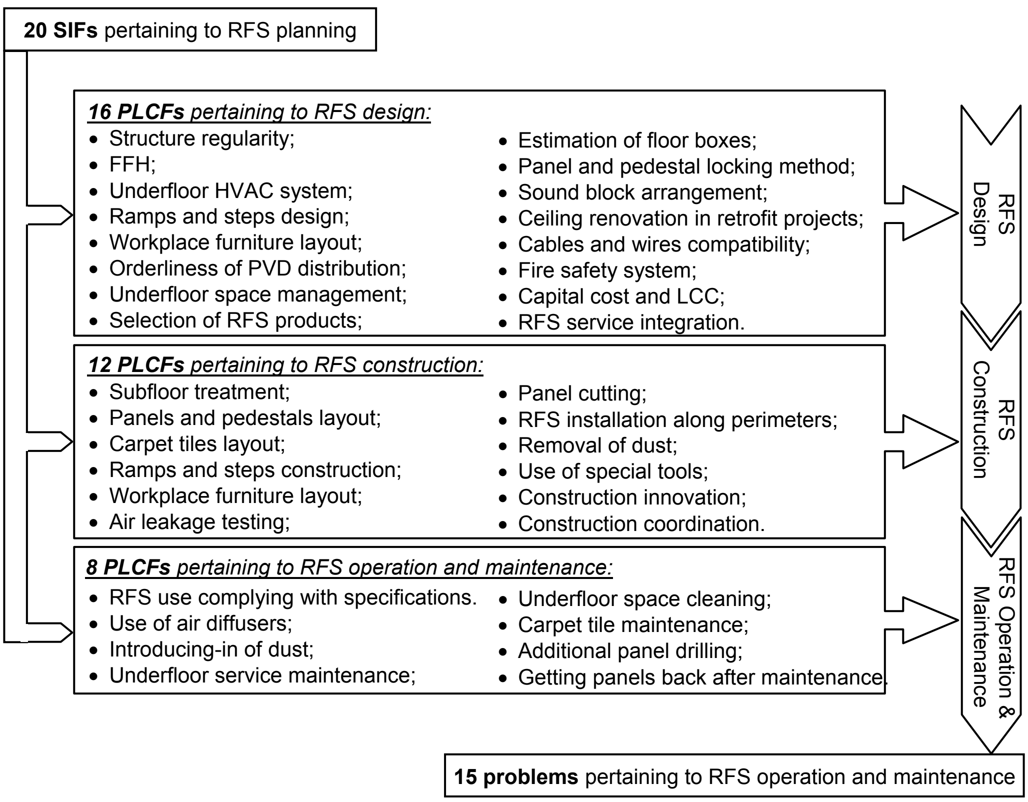

Figure 2 Causality among SIFs, problems and PLCFs in RFS project delivery

5.2 Process Map

With reference to the process map developed by the re-life project, an integrated process map was developed to improve the constructability of RFS in office building refurbishment, as shown in Figure 3. The process map presents a series of interrelated activities for each project stage. The map is hierarchical in nature, in which the lower-level diagrams are sub-elements of the upper-level ones immediately preceding them. Three levels of decomposition are applicable. The first shows the integration of RFS technology in the five stages of the RFS fitout project delivery. The second reflects major RFS constructability functions under each major project stage. Seven constructability functions are also presented at this level. The final level represents specific activities under each constructability function. A total of 37 constructability activities are identified at this level. The evaluation of 20 SIFs and 36 PLCFs is integrated into the process map through 7 activities, as highlighted by the boxes with thick rims.

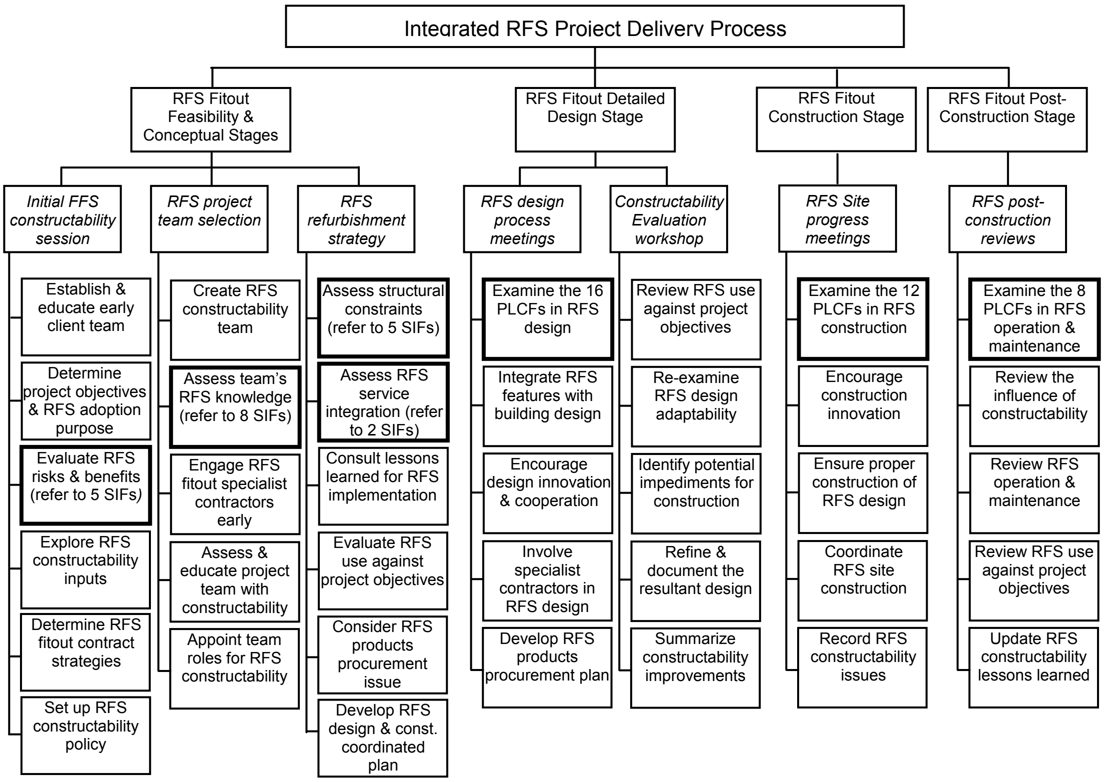

Figure 3 A process map for integrated RFS fitout project delivery process

5.3 Procurement Strategy

As the knowledge contribution of RFS specialist contractor is vital for the refurbishment plan and design, it is important to engage the specialist contractors as early as possible, preferably in the conceptual stage. *Nominated Specialist Contractors*, *Design-Build by Specialist Contractors* and *Design Assistants* are three typical methods allowing early involvement of specialist contractors. However, involvement as design assistants reduces specialist contractors' willingness for knowledge contribution as they have no guarantee to be awarded with the contract. Meanwhile, most specialist contractors have sufficient RFS fitout experience but little design skills, suggesting that they should pass on the construction knowledge to the design team rather than attempting for design. Therefore, *Nominated Specialist Contractors* is often chosen for the fitout work in the refurbishment. Under this scheme, the cooperation and communication in the project team demonstrates that the designers carries out the whole design including RFS fitout with knowledge input from specialist contractors in order to accommodate the SIFs and PLCFs appropriately. As to the contract of the whole refurbishment project, *Construction Management/General Contractor* (CM/GC) is chosen although design and build may also suffice. In comparison, CM/GC can support a non-adversarial relationship between the management contractor and the client, which is essential for improving team cooperation and communication and working for the common project objectives. Accordingly, the *Nominated Specialist Contractors under CM/GC* is believed to be the most preferable procurement strategy for the RFS fitout within the refurbishment of an office building, as shown in Figure 4.

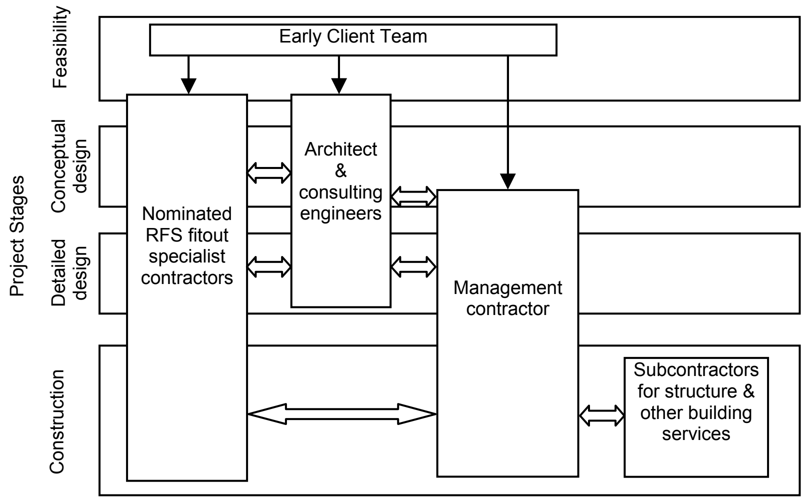

Figure 4 Nominated specialist contractors under CM/GC for RFS fitout project

5.4 Best Practice for Solving Typical Refurbishment Issues

Best practice guide was used to develop problem solving module for solving key issues associated with RFS use in refurbishment projects. A typical problem associated with RFS use in refurbishment project is the limited space volume in old office buildings. Figure 5 presents a problem solving module for space volume limitation. It demonstrates the possible reasons leading to concerns of limited space volume, the possible impacts and the actions to be undertake to accommodate the problem in the whole refurbishment delivery process.

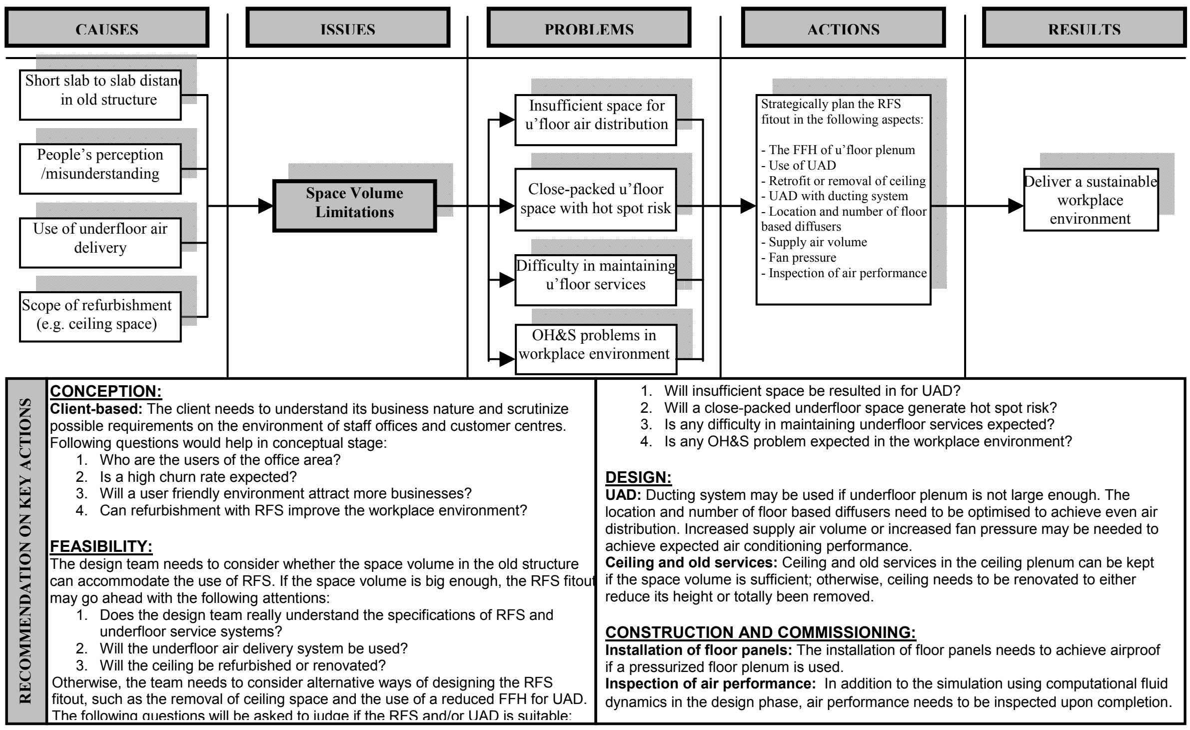

Figure 5 Problem solving module for space volume limitation

6. Conclusions

Construction industry in Australia is experiencing a booming market for office building refurbishment. Integrated methods and technologies can improve the effectiveness of retrofitting and achieve purposes of sustainable building practices. Developing informative guidelines will provide stakeholders of office buildings a valuable tool to make holistic decisions in dealing with complicated issues for refurbish works. Research projects had been undertaken in Australia to develop the decision making guidelines and integrated fit-out systems in order to respond to sustainability challenges.

Critical factors associated with the refurbishment of office buildings were identified through Delphi Studies, which led to the use of project maps and best practice guides to provide problem solving template for issues encountered in office refurbishment process. This was demonstrated through the decision making example of space Volume Limitation. Raise floor systems were used to demonstrate the potential of integrated technologies as part of office building refit. Barriers associated with the implementation of RFS were discussed and then integrated into the consideration of the fitout process. Nominated specialist contractor under construction management was recommended as an appropriate procurement strategy.

Keywords: bioclimatic design, design map, passive heating/cooling, weather data, cluster analysis

Summary

A kind of bioclimatic map gives useful information on design of climate-responsible buildings generally. In Japan, as passive heating/cooling design techniques have attracted the interest more and more to prevent the global warming problems, the authors are developing illustration maps giving good information on passive building design based on the newest and the finest meteorological data of Japan.

In this paper, at the first, indices to indicate natural heating/cooling potentials of local climate are discussed. After calculating values of the indices for all the weather stations over 800, color maps of several indices are illustrated to give passive design information.

Application of passive heating/cooling design techniques should be decided using not only these potential indices but the other indicators which represent heating/cooling requirements for a focused location. Therefore, the other five indices proposed by Watson and Labs (1991) after Givoni (1976) are also considered and an original computer program to calculate these five indices is developed.

Two kinds of indices mentioned above are combined and new indices are proposed. The calculated results of the new indices are shown as illustration maps to give design information from another point of view. Finally, a computer analysis of the proposed indices is conducted to classify regions from a point of view of the passive design techniques. As conclusive design information, a classified map and its brief description are presented.

The authors' methodologies or procedures of climatic analysis may be informative for the other countries or regions excluding Japan.

1. Introduction

1.1 Scope of Development of Bioclimatic Maps of Japan

In order to advance energy conservation and global warming prevention, the residential building code of Japan gives a map divided into seven zones which were classified by an analysis of heating degree-days calculated with the Expanded AMeDAS Weather Data (Architectural Institute of Japan, 2003 and 2005), which are mentioned amply in Subsec.1.2. A “Q-value” which is the heat loss coefficient per a unit floor area of a whole building is clearly defined for each zone in the code. Japanese house builders and architects are familiar with such mapped design information which helps them to plan thermal insulation performance.

All the authors have believed that a climate-responsible housing design, which includes not only the thermal insulation design but design of passive heating/cooling strategies, should be advanced for the sake of energy and global environment conservation. From this point of view, the authors had get an idea that some kinds of bioclimatic maps may be helpful to design the strategies and shared studies related to the development of the bioclimatic maps for application of passive heating/cooling design techniques, alias “passive design maps”. Well-arranged passive design maps are expected to be accepted as important design tools for sustainable buildings.

1.2 Description of AMeDAS and Expanded AMeDAS Weather Data

The most popular dense array system for weather data acquisition in Japan is known as "AMeDAS", which is the abbreviation for the Automated Meteorological Data Acquisition System. The observatories are located in about 840 points all around Japan as shown in Figure 1. This works out to be one observatory every 21 km^2 area on the average. The detail hourly data obtained by and estimated from the AMeDAS were compiled as a DVD named "The Expanded AMeDAS Weather Data DVD", alias "The EA Data DVD". The newest DVD including the data for 20 years since 1981 is published by the Architectural Institute of Japan (2005). One of the authors had worked for the publication during the last decade. The papers by Akasaka et al. (2000) and Matsumoto et al. (2005) are available for getting more information on the EA Data. Table 1 shows all the weather parameters recorded in the EA Data DVD. It can be said that the EA Data have enough quality and quantity to be used as a data source for our study.

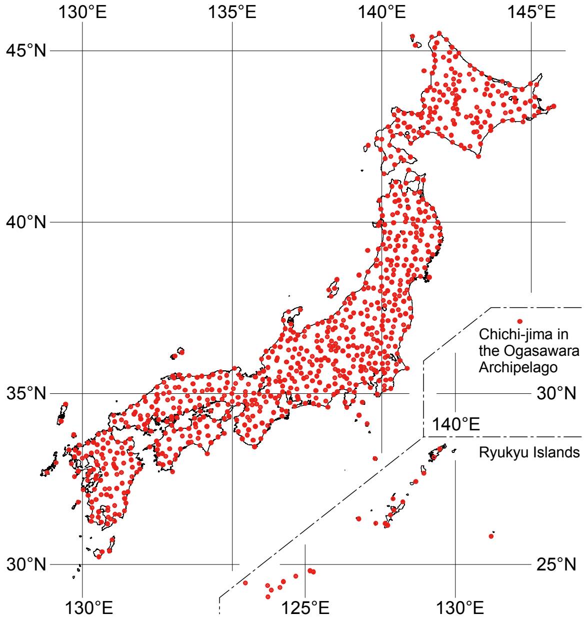

Figure 1 Distribution of the AMeDAS observatories

Table 1 Weather parameters recorded in the Expanded AMeDAS Weather Data DVD

Weather Parameter	Hourly Value Precision / Unit	Additional Statistical Value	Stat. Value Precision / Unit
Air Temperature	0.1 [°C]	Daily Average	0.1 [°C]
Humidity Ratio	0.1 [h/kg']	Daily Average	0.1 [h/kg']
Horizontal Global solar irradiation	0.01 [MJ/(m^2·h)]	Daily Integrated Value	0.1 [MJ/(m^2·d)]
Downward Long-wave Irradiation	0.01 [MJ/(m^2·h)]	Daily Average	0.01 [MJ/(m^2·h)]
Wind Direction	16 directions' index*	*The index when maximum wind speed was recorded for the day*	
Wind Speed	0.1 [m/s]	daily average	0.1 [m/s]
Precipitation Amount	1 [mm]	Daily Integrated Value	1 [mm]
Sunshine Duration	0.1 [h]	Daily Integrated Value	0.1 [h]

* 1: NNE, 2: NE, ... , 16: N, 0: Calm

1.3 Procedure Outline of the Development

In order to obtain several design maps which are comprehensible and useful for general house builders and logically acceptable for the related researchers and specialists, the following steps are taken in this study:

1) Development of suitable indices to explain natural potentials for passive heating/cooling and have clear physical meanings. Two series of indices are considered: The one series is designated as "potential indices"; the other one is "dimensionless indices". After calculating every index for each observatory, a series of color-contour maps of the dimensionless indices is illustrated to obtain passive design information and discussions on utilization capability of the indices;

2) Literature survey and consideration of other indices proposed previously to give different viewpoints. As discussed later, indices by Watson and Labs (1992) after Givoni (1976), which are designated as "strategy requirement indices", are adopted. A computer program to calculate these indices based on the EA Data is also developed.

3) Determination of the final indices named "passive design indices". Each passive design index is multiplied by the related strategy requirement index in order to generate one of the passive design indices. After calculating them, the another maps are illustrated to obtain passive design information which is different from the information obtained by maps of the dimensionless potential indices; and

4) Proposal of a "regional passive design concept map" for the sake to obtain more comprehensive design information as a conclusion. A cluster analysis is applied for the passive design indices to classify regions in which concepts of bioclimatic design strategies are different each other.

Following four sections are described in order of these steps. All the illustration maps shown later are drawn by original software named "ColorMap", which was enclosed with the EA Data DVD and introduced in the paper by Matsumoto et al. (2005).

2. Potential Indices

The indices to indicate several natural potentials which affect to reduce heating and/or cooling energy when they are utilized well by suitable passive design strategies are considered in this section. The Indices are designated as "potential indices" for a brief description.

2.1 Determination of Heating and Cooling Season and Degree-Days

At the beginning, heating and cooling seasons should be defined, because passive techniques can be generally classified into two types: of course, one is techniques for heating season; and the other is those for cooling season. As mentioned below with Figure 2, the authors defined the two seasons for every AMeDAS location by annual daily air temperature profile at the location for each year between 1981 and 2000.

2.1.1 Cooling Season

The day when daily air temperature reaches 22°C at first during a year is considered as the start of cooling season of the year, and the last day when the temperature reaches 22°C is considered as the end of cooling season of the year. The nomenclatures of m_c and n_c are representations of the start day's serial day number and the last day's serial day number, respectively counted from January 1.

2.1.2 Heating Season

The last day before the cooling season for a year when daily air temperature falls 18°C is considered as the end of heating season of the year and represented by n_h. The first day after the cooling season when the air temperature falls 18°C is considered as the start of heating season of the year and represented by m_h. Generally in Japan, the following relation is proved: $1 < n_h < m_c \leq n_c < m_h < 365$ (or 366).

2.1.3 Cooling and Heating Degree-Days

The degree-days indices are used to determine the dimensionless potential indices. The cooling degree-days CDD_{22-22} [K·d] and the heating degree-days HDD_{18-18} [K·d] can be expressed in Equations (1) and (2), respectively. The equations are applied for each AMeDAS location's daily air temperature for every year.

$$\mathrm{CDD}_{22-22} = \sum_{i=m_c}^{n_c} (\theta_{d,i} - 22)\,, \quad (1)$$

$$\mathrm{HDD}_{18-18} = \sum_{i=1}^{n_h} (18 - \theta_{d,i}) + \sum_{i=m_h}^{365\,(\text{or } 366)} (18 - \theta_{d,i}), \quad (2)$$

where $\theta_{d,i}$: Daily average air temperature on i-th day (serial day number through a year), [°C].

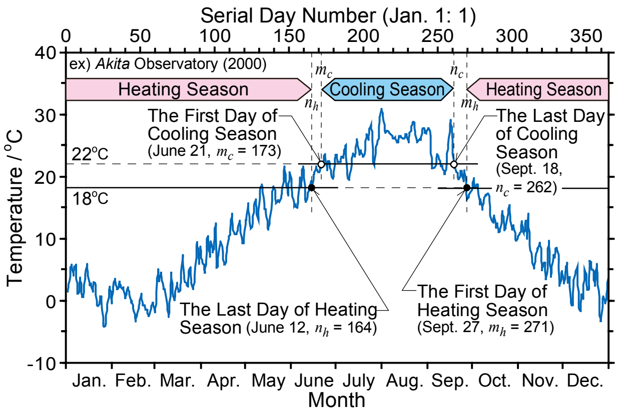

Figure 2 Definitions of heating and cooling seasons for a year

2.2 Considered Natural Potentials and their Indices

Six kinds of potentials are chosen on the bases of a literature survey of related studies and feasibility studies on utilization techniques of natural energy. The related dimensionless indices are also determined as well as basic indices indicating the potentials intermediately. Because every basic potential index has some kind of quantity which is fundamentally quite different each other, it is impossible for them to be compared directly. This is a reason why the dimensionless indices are additionally considered. A key term for eliminating dimensions is the Q-value (Q [W/(m^2·d)]) mentioned in Subsec.1.1, representing the heat loss coefficient per a unit floor area for a whole building.

2.2.1 Passive Solar Heating Potential: $\mathbf{PSP}$ and $\mathbf{PSP'}$

Kodama and Takemasa (1992) introduced the concept of passive solar heating potential, PSP [Wh/(m^2·K·d)], which is expressed in Equation (3). In order to eliminate this complicated dimension, Equation (4) is applied to define a new index $\mathrm{PSP'}$ [-] which is a simple modification of the PSP index. The index $\mathrm{PSP'}$ shows that an effective rate of passive heating by solar gain through south-facing window having a unit area to total space heating loads per a unit floor area. The prime sign is constantly added to show the index has no dimension in this paper.

$$\mathrm{PSP} = \left(\sum_{i=1}^{n_h} I_{s,i} + \sum_{i=m_h}^{365\,(\text{or } 366)} I_{s,i} \right) \Big/ \mathrm{HDD}_{18-18}\,, \quad (3) \qquad \mathrm{PSP}' = \mathrm{PSP}/(24 \cdot 3600 \cdot Q)\,, \quad (4)$$

where $I_{s,i}$: Daily integrated solar irradiation on the south-facing vertical surface for i-th day [J/(m^2·d)].

Because components of the beam and diffuse solar irradiations are not included in the EA Data DVD, Perez et al.'s decomposition method of hourly horizontal global solar irradiation (1992) is applied to calculate $I_{s,i}$.

2.2.2 Cross Ventilation Cooling Potential: $\mathbf{VCP}$ and $\mathbf{VCP'}$

A modified index after Akabayashi et al. (2003) is considered. We assume a typical human body, of which weight and surface area are 70 kg and 1.8 m^2 respectively, wearing clothes thermally equivalent to 0.5 clo and having a metabolic rate of 58.2 W/m^2. A room where the human body is surrounded is also assumed to have the following properties: the room air and mean radiant temperatures are equal to that of the outdoor air; the room air humidity is also the same as that of the outdoor air; the room air is calm and wind speed is

0.3 m/s. This is an image of a room condition without any space cooling and ventilation. We can calculate SET* by using the EA Data for j o'clock of i-th day data and these assumptions. The calculated value is represented as $\theta^*_{r,i,j}$ [°C].

When windows are opened for cross ventilation, thermal comfort may be improved due to indoor air speed increase. We assume that the cross ventilation can be operated in case of $\theta^*_{r,i,j} > 26$°C. Because the wind speed parameter ($v_{6.5}$ [m/s]) in the EA Data DVD is standardized as to indicate values at a height of 6.5 m from the grade line (G.L.) for each observatory, the wind speed is reduced to have value at a height of G.L.+1.5 m by using Equation (4), the reduced wind speed ($v_{1.5}$ [m/s]) can be considered as to be equal to that in the ventilated room. The SET* for this wind speed can be also calculated at j o'clock of i-th day like $\theta^*_{i,j}$ [°C]. It may be happened that $\theta^*_{i,j}$ falls 23°C due to higher wind speed. However, because window opening area is usually adjusted to be suitable for thermal comfort, $\theta^*_{i,j}$ is limited never to fall 23°C. On contrast, it may be also happened that $\theta^*_{i,j}$ exceeds 26°C due to higher outdoor air temperature and/or lack of wind speed. In such case, we assume that the cross ventilation is not operated. Figure 3 illustrates this approach concisely, instead of a little bit complicated description in the above. The indices are expressed in Equations (6)-(9).

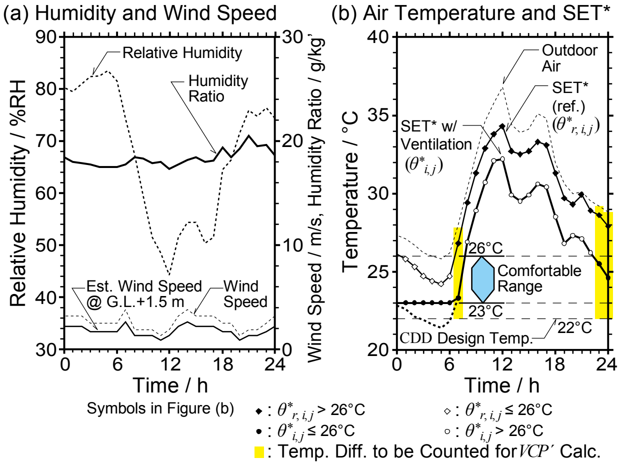

Figure 3 Illustrated explanation of space cooling effect of cross ventilation by the bases on SET calculation*

$$v_{1.5} = (1.5/6.5)^{0.25} v_{6.5}, \tag{5}$$

$$\delta_{c,i} = \begin{cases} 1; \; for\ \theta_{d,i} > 22, \\ 0; \; for\ the\ other\ cases, \end{cases} \tag{6}$$

$$\delta_{v,i,j} = \begin{cases} 1; \; for\ \theta^*_{r,i,j} > 26\ and\ \theta^*_{i,j} \le 26, \\ 0; \; for\ the\ other\ cases, \end{cases} \tag{7}$$

$$\mathrm{VCP} = \sum_{i=m_c}^{n_c} \delta_{c,i} \left\{ \sum_{j=1}^{24} (\theta_{i,j} - 22)\delta_{v,i,j} \right\}, \tag{8}$$

$$\mathrm{VCP}' = \mathrm{VCP}/(24 \cdot \mathrm{CDD}_{22-22}), \tag{9}$$

where $\theta_{i,j}$: hourly air temperature at j o'clock of i-th day, [°C].

2.2.3 Nocturnal Chilled Air Cooling Potential (Night Purge Potential): NCP and NCP′

We assume that the outdoor air temperature not exceeding 28°C can be injected at night time during the cooling season via a mechanical ventilation system performing air exchange of 0.5 ACH and temperature set point during the night time can be setback to be 28°C. When the volumetric heat capacity and ventilation air volume rate per a unit floor are represented as C_a (= 1,206.0)[J/(m^3·K)] and q [m^3/(m^2·h)], respectively, extracted energy at j o'clock of i-th day can be estimated by a term of $C_a q(28 - \theta_{i,j})$ [J/m^2]. Thus, the dimensionless index expressed in Equation (12) can indicate reduction rate of space cooling loads. The term of q is assumed to be 1.2 m^3/(m^2·h) because the average ceiling height of Japanese houses is about 2.4 m.

$$\delta_{n,i,j} = \begin{cases} 1; \; for\ \theta_{i,j} \le 28\ and\ I_{i,j} = 0, \\ 0; \; for\ the\ other\ cases, \end{cases} \tag{10}$$

$$\mathrm{NCP} = \sum_{i=m_c}^{n_c} \delta_{c,i} \left[\sum_{j=1}^{24} (28 - \theta_{i,j})\delta_{n,i,j} \right], \tag{11}$$

$$\mathrm{NCP}' = \frac{C_a \cdot q \cdot \mathrm{NCP}}{(\hat{Q} \cdot \mathrm{CDD}_{22-22})}, \tag{12}$$

where $I_{i,j}$ is horizontal global solar irradiation at j o'clock of i-th day, [J/(m^2·h)], used just for check whether the j o'clock belongs to night time or not, and $\hat{Q}$ is a unit-converted Q-value (= 24·3600·Q), [J/(m^2·K·d)].

2.2.4 Evaporative Cooling Potential: ECP and ECP′

The water to spray building envelops is available naturally due to rich precipitations and groundwater. Thus, evaporative cooling techniques must be useful. We assume that the evaporation occurs due to the humidity ratio difference between a typical envelop surface and the outdoor air and the moisture convection coefficient expressed by Lewis' analogy law. Equations (13) and (14) are expressions of the indices to indicate the potential. The index ECP′ shows an effective reduction rate of space cooling loads as well as the index NCP′.

$$\mathrm{ECP} = \sum_{i=m_c}^{n_c} \delta_{c,i} \left[\sum_{j=1}^{24} \frac{\alpha_c(v_{1.5}) \cdot r(\theta_{i,j})}{C_p(x_{i,j})} \{ \overline{x}(\theta_{i,j}) - x_{i,j} \} \right], \tag{13}$$

$$\mathrm{ECP}' = \mathrm{ECP}/(\hat{Q} \cdot \mathrm{CDD}_{22-22}), \tag{14}$$

where $x_{i,j}$: Humidity ratio of the outdoor air at j o'clock of i-th day, [g/kg'];
$\overline{x}(\theta_{i,j})$: Saturated humidity ratio on the typical envelope with a temperature assumed to be $\theta_{i,j}$, [g/kg'];
$C_p(x_{i,j})$: Isobaric specific heat of the humid outdoor air with $x_{i,j}$ (=1,004.6+1.846·$x_{i,j}$), [J/(kg'·K)]];
$r(\theta_{i,j})$: Specific latent heat of water at a temperature of $\theta_{i,j}$ (=1,996.1+1.846[$\theta_{i,j}$+273.15]), [J/g]; and

$\alpha_c(v_{1.5})$: Convective heat transfer coefficient depended to the neighbor air's speed of $v_{1.5}$, [W/(m^2·K)]. The well-known Jürges' formulae are applied to calculate this value.

2.2.5 Dimensionless Radiant Cooling Potential: **RCP** and **RCP′**

This potential is represented as RCP or RCP′ defined in Equations (15) and (16), respectively. The latter shows an effective reduction rate of space cooling loads.

$$\mathrm{RCP} = \sum_{i=m_c}^{n_c} \delta_{c,i} \sum_{j=1}^{24} \left\{ \left(\sigma_b \left(\theta_{i,j} + 273.15\right)^4 - L_{i,j}^{\downarrow}\right\} \delta_{n,i,j} \right., \quad (15) \qquad \mathrm{RCP}' = \mathrm{RCP}/(24 \cdot Q \cdot \mathrm{CDD}_{22-22}), \quad (16)$$

where σ_b : Stefan-Bolzmann constant (=5.67×10^{-8}), [W/(m^2·K^4)]; and
$L_{i,j}^{\downarrow}$: Downward long-wave (atmospheric) irradiation, [W/m^2].

2.2.6 Dimensionless Geothermal Cooling Potential: **GCP** and **GCP′**

We assume an earth-tube system installed at a depth of 2 m from the grade line and the outdoor air is pre-chilled and ventilated by the system. In order to indicate the performance and an effective reduction rate of cooling loads, the following indices are defined:

$$\mathrm{GCP} = \sum_{i=m_c}^{n_c} \left(\theta_{d,i} - \theta_{g,i}\right) \delta_{c,i}, \quad (17) \qquad \mathrm{GCP}' = 24 \cdot C_a \cdot q \cdot \mathrm{GCP}/\left(\hat{Q} \cdot \mathrm{CDD}_{22-22}\right), \quad (18)$$

where $\theta_{g,i}$ is daily averaged ground temperature for i-th day, [°C].

The ground temperature profile is estimated by finite element analysis program for one-dimensional heat transfer developed by Matsumoto et al. (1999).

2.3 Maps of the Dimensionless Potential Indices

The indices discussed in Subsec.2.2 were calculated for each AMeDAS location and for each year during the period from 1981 to 2000. The same indices for all the 20 years were averaged to get statistically stable information. For samples, the drawn maps of dimensionless potential indices are illustrated in Figure 4.

It is obvious that estimated potentials at a certain location are quite different from those in the other locations and give a lot of information on passive design. Additionally, these maps are nice educational materials for

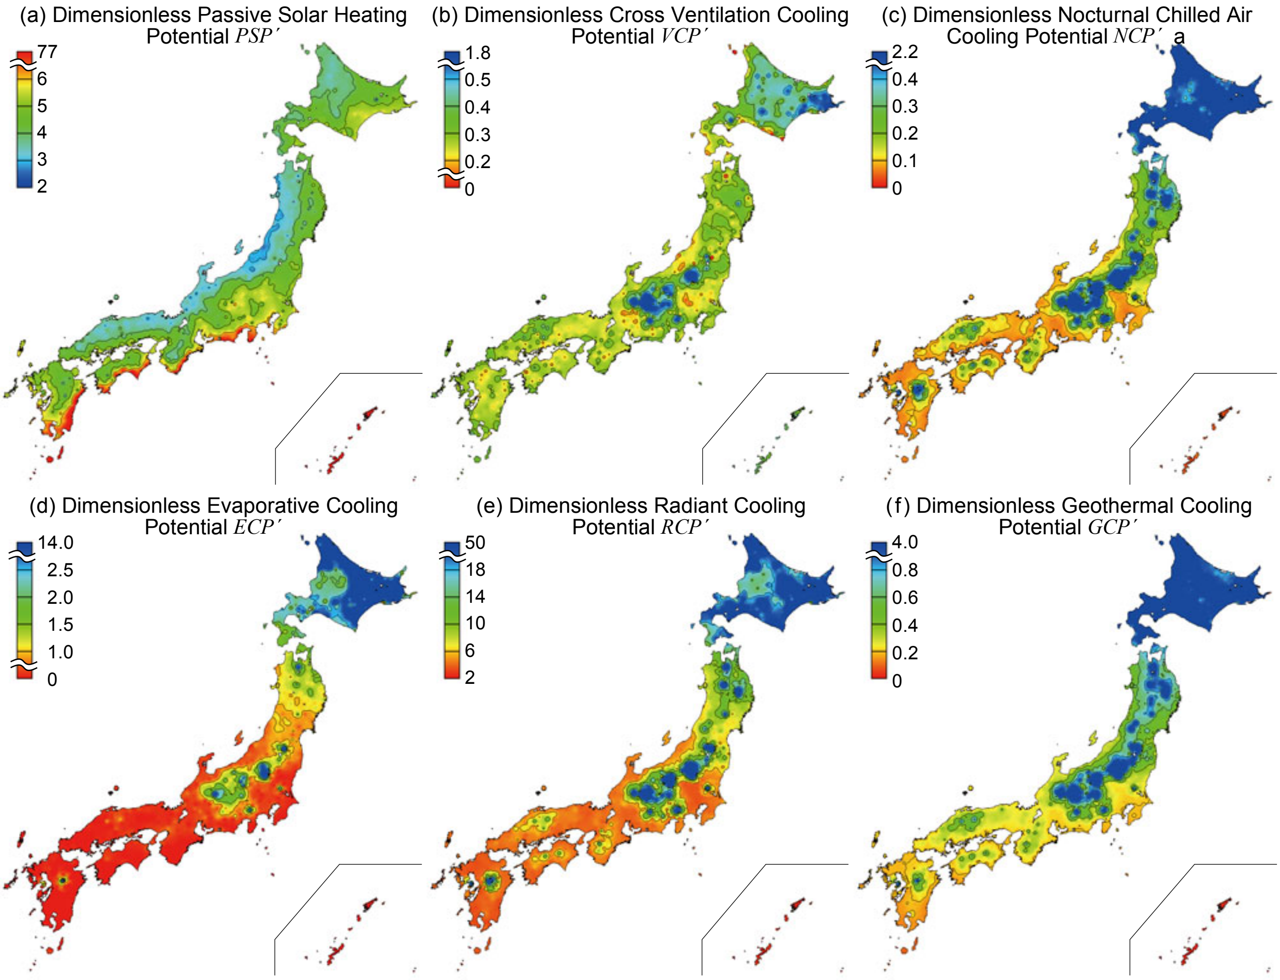

Figure 4 Maps of the dimensionless indices to indicate the passive heating/cooling potentials

us to enlighten house builders, architects and related engineers about reasons why the point of view from bioclimatic design is important to make buildings sustainable.

However, there are two weak points never to forgo in information from these maps: One is a simple point that some indices were explained as indicators of the cooling loads reduction effect but they never vary between 0 and 1 due to their mathematical expressions and there are some singular locations having extreme index value(s); The other is more important point that these potential indices never tell significance or necessity of application of passive heating and/or cooling strategies. For example as shown in Figure 4 (c), distribution of the cooling potential by nocturnal chilled outdoor air NCP' is quite great in Hokkaido, which is Japan's second largest island and the largest, northernmost of its 47 prefectural-level subdivisions, in spite of having little space cooling loads during the very short cooling season. For this reason, some other indices to indicate quantitative requirements of heating and cooling should be expected.

3. Strategy Requirement Indices and Passive Design Indices

3.1 Description of Watson and Labs' method Based on Givoni's Bioclimatic Chart

A literature survey was conducted to get ideas of new indices to indicate requirements of space heating/cooling. The main finding from the survey is that a method proposed by Watson and Labs (1992) is quite suitable for our aim. Their method is based on the famous Givoni's bioclimatic chart (1976), which is a psychrometric chart added boundaries defined by psychrometric parameters as to show 17 zones related to the passive strategies. Using that chart, Watson and Labs proposed to plot outdoor air condition data for a whole year and count plotted frequency for each zone to quantify requirements of several strategies as shown in Figure 5, which also illustrates the authors' original computer program applied their method to the EA Data.

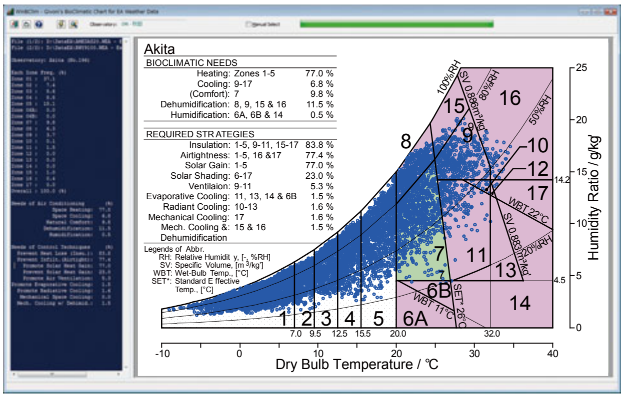

Figure 5 Computer program to analyze strategy requirement

3.2 Definition of the Strategy Requirement Indices

Table 2 includes the explanations of the five indices selected to combine with the potential indices. They are designated as "Strategy Requirement Indices" to tell their differences from the potential indices. These indices are also dimensionless because they are just plotted frequencies of whole year data. Since the EA Data DVD includes quite a lot of data for 20 years (approx. 175,000 hours), all of them are inputted to WinBClim as to get statistically stable values.

Table 2 Summary of three series of indices to get the passive design information

Applied Season	Utilization Strategy	Name of Index Group (Class of Indices)					
		Potential Indices		Strategy Requirement Indices		Passive Design Indices	
		Index Name / *Mathematic Expression*	Abbr.	Index Name / *Defined Zone (see Fig.5)*	Abbr.	Index Name / *Mathematic Expression*	Abbr.
Heating Season	Promote Solar Gain	(Dimensionless) Passive Solar Heating Potential *see Eqs.(3) & (4)*	PSP (PSP')	Solar Gain Requirement Index *Zones 1-5 in Fig.5*	SR	Solar Heat Gain Design Index $SDI = Norm(PSP \times SR)$	SDI
Cooling Season	Promote Cross ventilation	(Dimensionless) Cross Ventilation Cooling Potential *see Eqs.(6)-(9)*	VCP (VCP')	Cross Ventilation Requirement Index *Zones 9-11 in Fig.5*	VR	Cross Ventilation Design Index $VDI = Norm(VCP \times VR)$	VDI
	Promote Cool Air Gain	(Dimensionless) Nocturnal Chilled Air Cooling Potential *see Eqs.(11) & (12)*	NCP (NCP')	Cooling Requirement Index *Zones 9-17 in Fig.5*	CR	Night Purge Design Index $NDI = Norm(NCP \times CR)$	NDI
	Promote Evaporative Cooling	(Dimensionless) Evaporative Cooling Potential *see Eqs.(13) & (14)*	ECP (ECP')	Evaporative Cooling Requirement Index *Zones 11, 13, 14, & 6B in Fig.5*	ER	Evaporative Cooling Design Index $EDI = Norm(ECP \times ER)$	EDI
	Promote Radiant Cooling	(Dimensionless) Radiant Cooling Potential *see Eqs.(15) & (16)*	RCP (RCP')	Radiant Cooling Requirement Index *Zones 10-13 in Fig.5*	RR	Radiant Cooling Design Index $RDI = Norm(RCP \times RR)$	RDI
	promote Cool Air Gain	(Dimensionless) Geothermal Cooling Potential *see Eqs.(17) & (18)*	GCP (GCP')	Cooling Requirement Index *Zones 9-17 in Fig.5*	CR	Geothermal Cooling Design Index $GDI = Norm(GCP \times CR)$	GDI

$Norm(V)$: Function to normalize the variable V with the average and the standard deviation

4. Passive Design Indices

4.1 Definition of Passive Design Indices

Here proposed are the new indices designated as "Passive Design Indices" which are combined indices of the potential indices and the strategy requirement indices. The combination is quite simple as summarized in Table 2. In order to ease a comparison of the indices, each index is normalized by the well-known z-score conversion technique. This idea seems to be a good answer to reinforce one of the weak points mentioned in Subsec.2.3, but their physical meanings may be thinner than those of the dimensionless indices. Nevertheless the indices keep some bioclimatic properties.

4.2 Maps of the Passive Design Indices

Distribution maps of the passive design indices are illustrated as Figure 6. The figures have quite different tendencies from those found in Figure 4. The authors' knowledge on regional distribution of practical building examples designed well with the passive strategies is more coincident with tendencies read from Figure 6 rather than Figure 4. Additionally, it seems that the passive design indices are sensitive to local climate as well as the potential indices and have worth to analyze carefully.

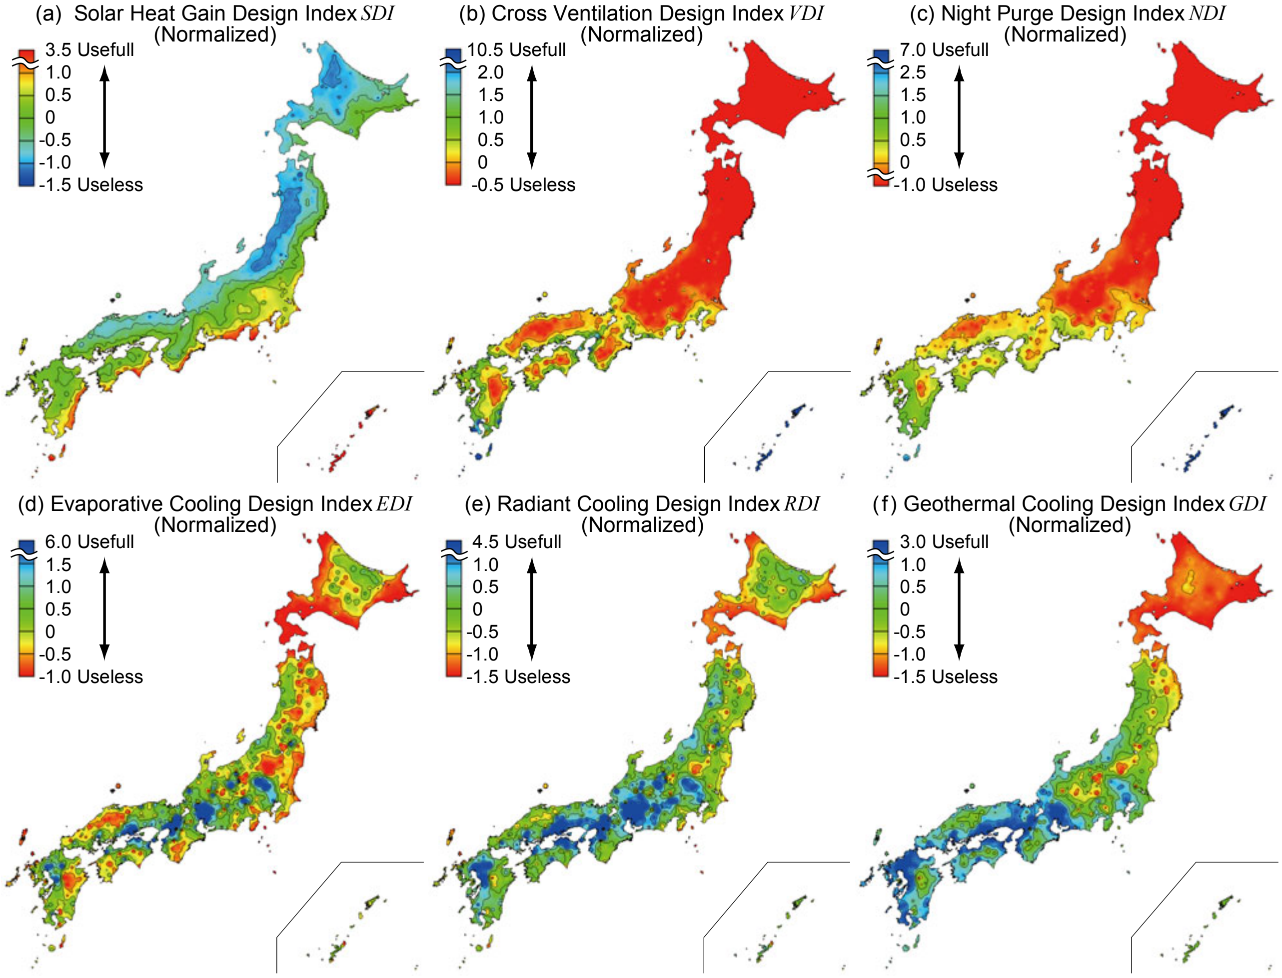

Figure 6 Maps of the passive design indices SDI etc. defined in Table 2

5. Regional Passive Design Concept Map

5.1 Analysis Procedure

A careful reading of Figures 4 and 6 tells that some combinations of passive design techniques are commonly utilized for a certain region and regional design concepts may be classified. A regional concept map with brief description is drawn finally to give comprehensive design information.

In order to find clear regional classification, the k-means cluster analysis method by MacQueen (1967) is applied for the design indices. The analysis program in a commercial statistical software is used.

5.2 The Regional Design Concept Map as an Analysis Result

Figure 7 on the last page is an illustration of the regional concept map based on the analysis. Total number of categorization classes were decided by trial and error to be seven, considering with the interpretation of regions. The authors would like to say Figure 7 is a conclusive fruit of this paper because the illustrated concepts are quite reasonable and informative.

6. Conclusions

The summary of contents and main findings of this paper are itemized as follows:

1) Two different types of indices and the combined indices of them were proposed;
2) The indices were calculated and expressed in the color-contour maps for discussion and practical use. It was clarified that they were useful to obtain design information on passive heating/cooling techniques;

3) A scientific procedure to classify bioclimatic regions was proposed and the procedure was practically applied to conduct a regional passive design concept map. It can be said that the procedure was established well. The established procedure would have a worth to apply for for the other countries or regions.

The research related on this paper was supported by Japan Society for the Promotion of Science (JSPS), Grant-in-Aid for Scientific Research (B), 17360285, 2006.

THE ENERGY AND WATER SAVING, AND OTHER BENEFITS, WHEN USING TRANSCRITICAL CARBON DIOXIDE REFRIGERATION FOR BUILDING COOLING AND HEATING

Klaas VISSER, Hon. M.IIR, M.AIRAH, Mc-dig, M.Eurammon [1]

[1] KAV Consulting Pty Ltd, Kangaroo Flat, Vic, 3555, Australia kavconsult@bigpond.com

Keywords: CO_2 emissions, sustainability, energy, water, CO_2 refrigeration, legionella

Summary

A major benefit of transcritical CO_2 refrigeration is the gliding temperature available when cooling the transcritical fluid from the final high temperature at completion of compression to as low a temperature as practicable. This property may be exploited when requiring simultaneous cooling and heating in building air conditioning applications. The CO_2 compressor discharge can usually heat enough water for heating, reheating and hot water purposes thereby obviating the need for a boiler and its fuel supply.

Using USA Department of Energy and Australian Greenhouse Office data for energy consumption in multi-category commercial buildings in the USA and Australia respectively, it is shown that CO_2 cooling reduces energy consumption, combined water consumption at the power stations and cooled office building, and CO_2 greenhouse gas emissions by at least 60%, 60% and 50% respectively in the existing building stock when coupled with a 25% reduction in airflow and a two thirds reduction in lighting energy. Incorporation of energy recovery from exhaust air and economizing cycles will produce additional reductions in all three areas. The absence of cooling towers entirely eliminates the danger of Legionella disease.

1. Introduction

1.1 Data from USA Department of Energy

Westphalen et al (1999) prepared a report dealing with Thermal Distribution, Auxiliary Equipment and Ventilation in the Energy Consumption Characteristics of Commercial Building HVAC systems comprising 3,345 million m^2 of cooled building floor space plus 4,459 million m^2 of heated building floor space. The total annual HVAC primary energy consumption was 4.85 x 10^9 GJ. Primary energy is the calorific energy in the fuel used. See Fig. 1 [Westphalen et al (2001)].

Figure 2 [Westphalen et al (1999)], shows that of the total Parasitic Primary Energy use in HVAC systems, the supply and return air fans consumed 50% of a total of 1.58 x 10^9 GJ i.e. 0.79 x 10^9 GJ. The exhaust fans consumed a further 33% of parasitic primary energy.

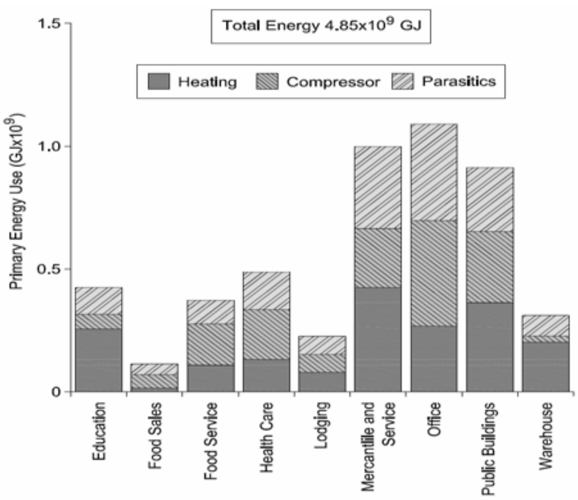

Figure 1 Total HVAC Primary Energy Use by Building Type

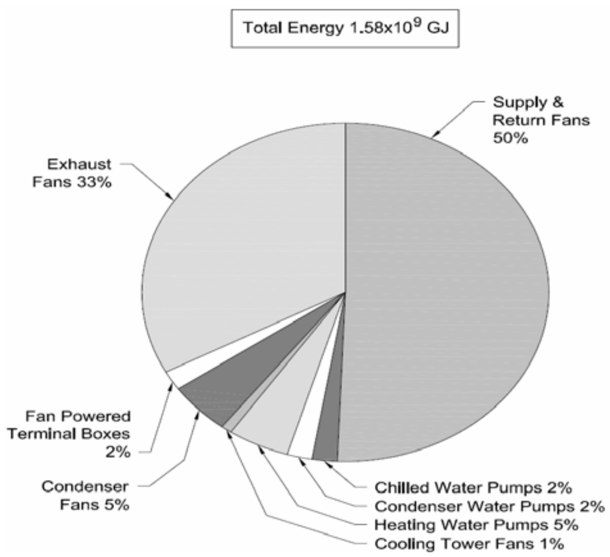

Figure 2 Parasitic Primary Energy use by Type of Equipment

Table 1 shows the equipment seasonal efficiencies over a whole year running. [Westphalen et al (1999)].

Table 1 Equipment Seasonal Efficiencies Coefficients of Performance (COP's)

Equipment	COP		Equipment	COP	
Centrifugal chiller	4.4		PTAC, PTHP	2.49	(2)

1.2 Data from the Australian Greenhouse Office (AGO)

Table 2 shows the primary energy consumption of the Australian commercial building sector by source and quantity determined by Emet Consultants Pty Ltd et al (1999) in a study commissioned by the AGO. The study projected the primary energy consumption on a Business as Usual (BAU) scenario up to 2010.

2. Principles of Reduction in Energy Consumption

2.1 Building Heat Load Components and AC Plant and Heating

The heat loads generated in a building are contributed to by heat gains through the building structure and windows, power consumed by office machines, lighting, fresh air leakage into the building, ventilation air, people and so on.

Once the heat load has been determined, an air conditioning plant usually comprising both heating and cooling functions is designed and installed. The compressor heat is rejected to atmosphere via a cooling tower providing cooling water to a condenser or via an air cooled condenser. Chilled and hot water is pumped around to Air Handling Units (AHU's) for cooling and reheating or heating only during Winter. Fans circulate air through ducts and return air fans return air to the AHU's. Exhaust fans remove a quantity of air.

2.2 Reduction in Energy Consumption

To reduce energy consumption in buildings it is necessary to reduce the amount of heat generated during hot weather by all constituent components and ensure that the cooling plant runs at the Most Energy Efficient Operating Point (MEEOP).

The supply and return fans constitute a large energy consumer and add a significant heat load to the system as well. The fan laws state that a 25% reduction in air flow reduces the energy consumption to 0.75^3 i.e. a reduction in energy consumption of $1 – 0.75^3 = 57.8\%$. There is also a corresponding decrease in compressor power requirement equivalent to the fan power reduction divided by the COP.

In existing buildings, a reduction in air flow needs to be compensated for by a lower air temperature which in turn requires a lower chilled water and/or refrigerant evaporating temperature To. A lower To reduces the compressor COP, which would tend to increase compressor specific energy consumption. In new buildings, it would be possible to design ductwork for lower velocities, thereby saving considerable energy.

Initially, the reduction in fan and resulting compressor energy consumption is greater than the increase in compressor energy consumption due to a reduction in the compressor COP. This constitutes an optimization problem identical to that found by Visser (1976) when blast freezing export meat cartons. This shows that it is frequently more energy efficient to select a compressor with a lower COP which needs to handle a much lower heat load. This principle is not widely understood, but universally applicable in cold air chilling and blast freezing systems, including air conditioning cooling.

3. Carbon Dioxide (CO_2) Refrigeration

3.1 Background

CO_2 refrigeration was commonly applied in building cooling until about the mid 1930's after which CFC's became dominant and CO_2 was relegated to the dustbin of history. When the Montreal Protocol outlawed CFC's following the disastrous Ozone Layer Depletion, CFC's were replaced by and large by a new series of chemical refrigerants called HFC's. HFC's have significant Global Warming Potential (GWP), which puts them under increasing pressure in the European Union with a country like Norway applying a Global Warming levy of Euro 79.00/kg of HFC. Other EU countries like Austria, Denmark et al are doing the same. Natural refrigerants like propane, butane, etc. are flammable and not recommended for building air conditioning. The toxic natural refrigerant ammonia is not recommended for building cooling.

The CO_2 properties lend themselves to heat pump applications with tens of thousands of small CO_2 heat pumps being used for water heating in Japan and now also in Europe. The German Motor Vehicle Manufacturer's Association has decided to install CO_2 systems for car air conditioning and heating in all cars by the year 2012. CO_2 is also an ideal refrigerant for the cooling and heating of buildings.

3.2 CO_2 Properties and Performance as a Refrigerant

The properties of CO_2 relevant to this paper are low critical temperature of 31.1^0C, a high volumetric refrigeration capacity due to the high vapour densities and a large pressure differential per degree C. CO_2 is non-toxic, non-flammable and has a GWP = 1. It is a totally natural substance with the average adult human producing about 1 kg/day.

Figure 3 shows the COP of sub critical CO_2 compressor performance as extracted from a CO_2 compressor manufacturer's rating tables. Dorin (2007). Figure 4 shows the COP of transcritical CO_2 compressor performance again from the Dorin (2007) compressor ratings.

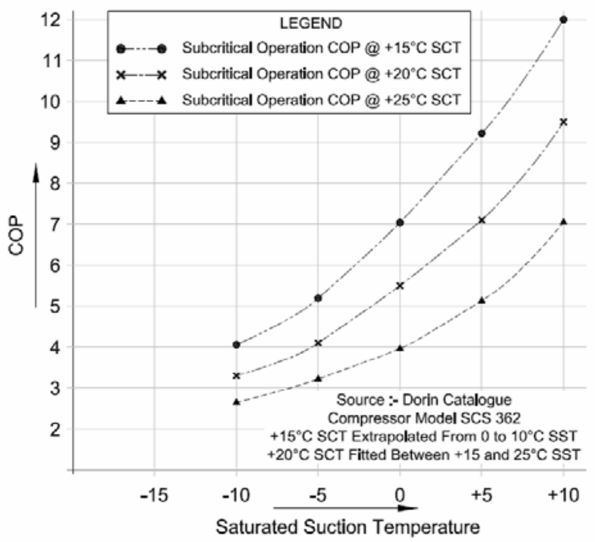

Figure 3 CO_2 Compressor COP Values Variation with Sat Suction and Condensing Temp

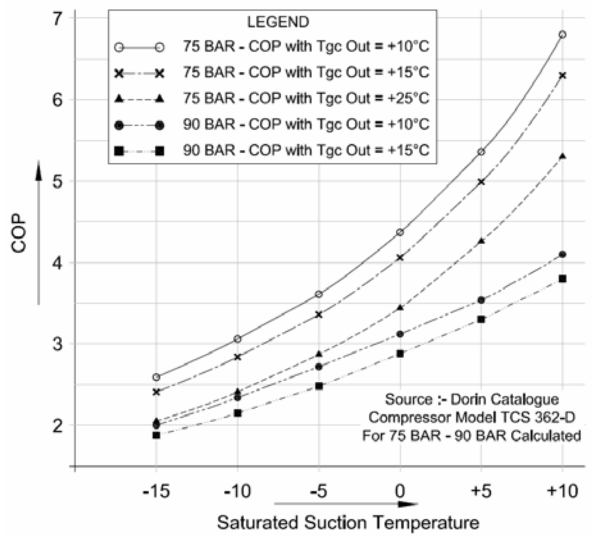

Figure 4 CO_2 Compressor COP Value Variation with Sat Suction Temp, Transcritical Discharge Pressure and Gas Cooler Outlet Temperatures

4. Australian Capital City Ambient Dry and Wet Bulb Temperatures

Dry and Wet Bulb Temperature (DWBT) data was obtained form the Australian Bureau of Meteorology (2008) for all Australian Capital cities except Darwin. See Table 3.

Table 3 Ambient AC Design Dry and Wet Bulb Conditions – Australian Capital Cities 6am – 10pm

City	DB, ^{0}C	WB, ^{0}C
Adelaide	37	22
Brisbane	33	25
Canberra	34	20
Hobart	30	19
Melbourne	35	21
Perth	37	22
Sydney	35	23

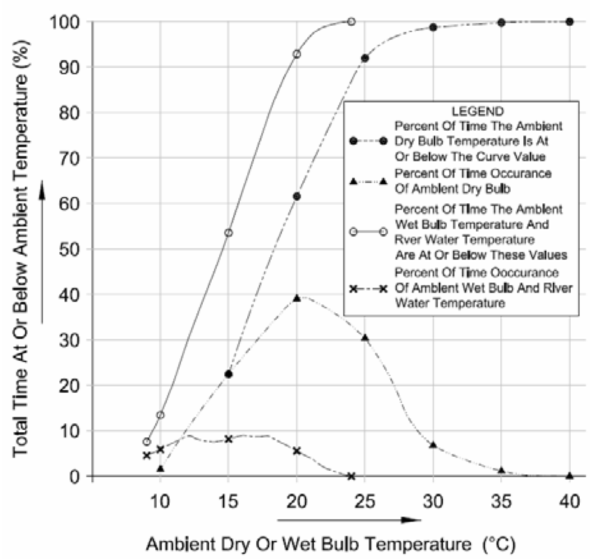

Figure 5 Ambient Dry & Wet Bulb Temperature Profile – Sydney Airport 6am – 10pm

In Figure 5, the ambient DWBT occurrence has been plotted from a total of 199,520 data readings taken at Sydney International Airport between 6am and 10pm for the past 10 years. We have selected a Sydney design condition of +35^{0}C dry bulb, +23^{0}C wet bulb, which are exceeded only 0.2% and 0.3% of the time respectively. After Brisbane, Sydney has the second most humid climate and is Australia's largest city. Sydney was therefore selected as the city for which to project potential energy and water savings to be had from CO_2 refrigerated cooling in both existing and new buildings.

In Table 4, we have evaluated the Seasonally Weighted COP (SWCOP) based on the Sydney climate. An advantage of CO_2 is its high pressure, which allows close temperature approaches between condensing temperature and cooling air or water. The lower the ambient temperature, the higher the COP and the higher the heating load will be in addition to hot water requirements, but the lower the cooling load will be. It has been assumed that on average 25% of the plant capacity would run in transcritical mode to provide heat for all purposes.

Table 4 Evaluation of Weighted COP with Ambient Temp Conditions for 12 Months Running of CO_2 Cooling in Sydney in:

5. Calculation of Energy Savings and Reduction in Global Warming Emissions

In Table 5, the calculated primary energy consumption for CO_2 refrigeration is tabulated. This enables the calculation of the total primary energy consumption of CO_2 refrigerated AC systems as shown in Table 2. The air handling primary energy consumption is reduced by 57.5% due to a 25% reduction in duct air velocity and the lighting primary energy is reduced by two thirds.

Table 5 Calculation of conventional Cooling Capacity, and CO_2 Cooling Capacity and Primary Energy

Year		1990		2010
1. Primary energy consumption conventional cooling, PJ		27.4		50.9
2. Say 30% of primary energy to compressors, PJ		8.22		15.27
3. Average COP of top four from Table 1, 3.66 say		4.0		4.0
4. COP primary energy multiplier (motor losses)		0.85		0.85
5. Effective COP, conventional system		3.4		3.4

5	**Percentage of water saved by CO_2**		**60.0**			**66.7**	

7. Summary of Reductions in Energy and Water Consumptions and Global Warming CO_2 Emissions

This is shown in Table 7 in both quantity and percentages. Table 7 also shows the entire elimination of the legionella disease threat and the total absence of HFC fugitive gas escapes. Note the significant quantities of water saved at the power station, which is commonly not taken into account.

Table 7 Summary of benefits of CO2 Refrigerated Cooling for Air Conditioning with Heat Recovery Coupled with 25% reduction in building airflow and $^{2}/_{3}$ Reduction in Lighting

Year	1990		2010	
Variable and unit	Qty	%	Qty	%
Reduction in energy consumption, PJ (from Table 2)	93.4	61.8	193.5	67
Reduction in resulting emissions, kT (from Table 2)	16704	51.8	35693	56.8
Reduction in water consumption, Gl (from table 6c)	20.6	60	46.9	66.7
Legionella and fugitive HFC escape eliminated	Yes		Yes	

Figure 6 shows the reduction in annual primary energy consumption if the entire Australian Commercial Building stock were refrigerated by CO_2. Figure 7 shows the corresponding reduction in greenhouse gas emissions, which is greater than that which would have been required under the Kyoto Protocol.

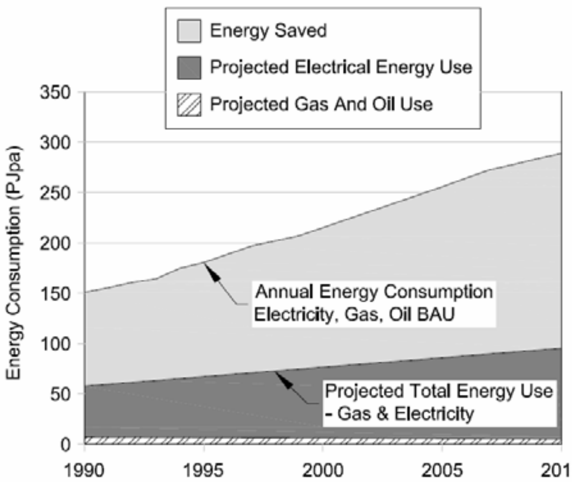

Figure 6 Projected Reduction in Primary Energy Consumption in Australian Commercial Buildings Based on the Sydney Climate

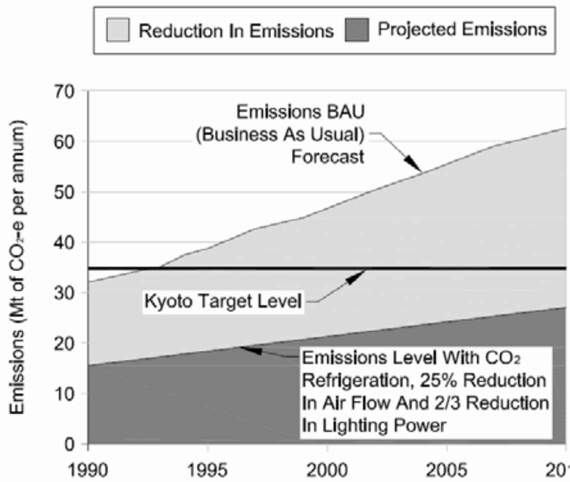

Figure 7 Projected Reduction in CO_2 Emissions in Australian Commercial Buildings Based on Sydney Climate

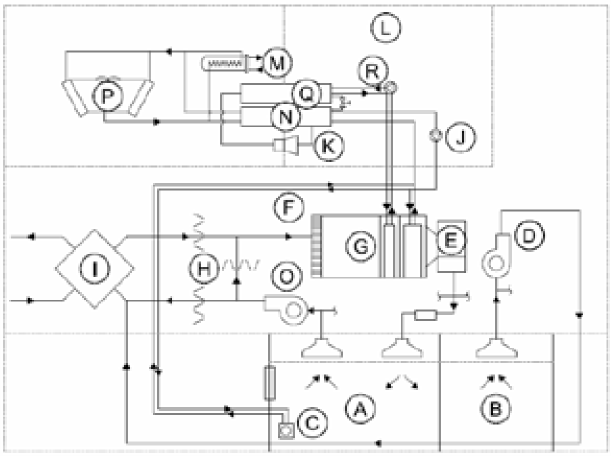
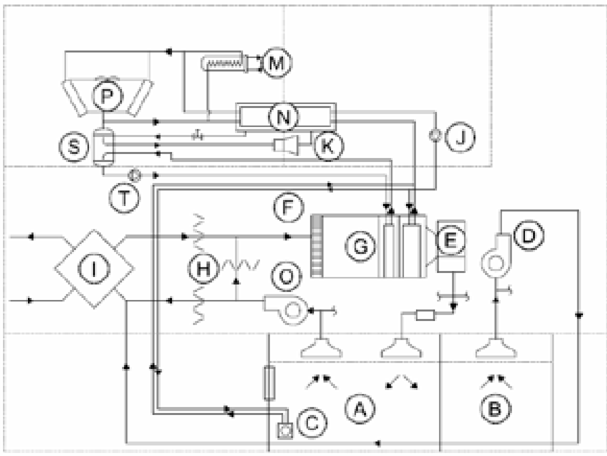
8. Implementation

8.1 Applied to Existing Buildings (See Figure 8)

In an existing building the chiller set, cooling tower and boiler would be removed. These would be replaced by CO_2 compressors, water chillers, a water cooled gas cooler for heat recovery and air or water cooled gas coolers to remove the balance of the heat. Existing pumps would be used to circulate chilled and hot water through the building to existing air handling units. The supply and return fans would be slowed down to 75% of their current speed and lights would be changed to save two thirds of lighting energy.





COMMON LEGEND

Figure 8 Schematic of a Central System with CO_2 Cooled Water Chiller, Exhaust Air Energy Recovery and Economising Cycle and Two Stage Water Heating

Figure 9 Schematic of a Central System with Direct Pumped CO_2 Evaporators, Exhaust Air Energy Recovery and Economising Cycle and Two Stage Water Heating

8.2 New Buildings (See Figure 9)

A total system would be designed to circulate CO_2 refrigerant or chilled water to air handling units throughout a building. Re-circulated CO_2 would be the most efficient and this would require custom design of the refrigeration systems similar to industrial refrigeration design practices.

All components are available in the market, but the required compressors would be expensive and on a long lead time. The entire system such as ducting and fans, hot water systems, etc would be designed using well established energy efficient design practices.

9. Conclusions

As shown in Table 7, the revival of CO_2 for air conditioning cooling applications has outstanding benefits in terms of reductions in primary energy consumption (62 to 67%), water consumption (60 to 66%) and CO_2 greenhouse gas emissions (52 to 56%) when applied in Sydney. These are all greater than mentioned in the summary. Furthermore, the threat of legionella is entirely eliminated, as are the dangers of HFC fugitive gases with high GWP. There is no other refrigerant, natural or chemical, which can deliver such superior and sustainable results. Greater savings would be possible if economizing cycles and exhaust air energy recovery systems would be implemented as well. Greater reductions would be expected in Adelaide, Hobart, Melbourne and Perth with smaller reductions predicted for Brisbane. Having regard to the outstanding environmental benefits of CO_2 refrigeration evaluated in this paper, it is abundantly clear, that the revival of CO_2 refrigeration for air conditioning cooling is a sustainable process far superior to current practices.

Sustainable building policy evaluation criteria and the application to Japanese policies

Shoichi Ando Dr.

Coordinator of Disaster Management Planning Hyogo Office, United Nations Centre for Regional Development (UNCRD), 1-5-2 Wakihama-kaigan-dori, Chuo-ku, Kobe city, Hyogo 651-0073, JAPAN, andos@hyogo.uncrd.or.jp

Keywords: policy, evaluation, sustainable, building, Japan, effectiveness, economic, efficiency

Summary

The building and housing market is now saturated in Japan, and demand for quality is growing in importance. Both the environmental initiatives of the construction sector and the demands of users are key factors. The condition cannot afford to scrap and build houses and building stock any longer. The aim of this document is to help policy makers to evaluate and introduce appropriate policies and strategies in order to achieve sustainability of residential and commercial buildings

Government can give a considerable impulse to sustainable buildings by encouraging these developments. The Japanese government has been trying to facilitate the supply of sustainable buildings by taking various measures. With regard to the evaluation of the "sustainable building policies", the following four criteria are proposed; 1) Environmental effectiveness, 2) Economic efficiency, 3) Technological incentives, and 4) Administrative feasibility.

The author applied these criteria to the recent Japanese sustainable building policies such as performance-based building codes, housing quality assurance system, and new tax systems. The sustainable building policies are classified according to the following five types of policy tool; 1) Regulatory policy, 2) Voluntary policy, 3) Economic policy, 4) Information policy, and 5) Research and Development (R&D) policy.

1. Trends and Actual Condition of Policies

Buildings have a considerable impact on the natural and built environment. In the 1980s, the ideas of energy saving in the building sector were developed according to the increasing social concern and the creation of regulations. The efficient use of energy moved into the forefront, when the mitigation of global warming became an urgent policy object after Rio conference in 1992. According to the statistics by the IEA, the building sector accounts for around 30% of all energy consumption of the OECD countries.

The environmental policy instruments are usually evaluated by the following four principal criteria; 1) Environmental effectiveness, 2) Economic efficiency, 3) Technological incentives, and 4) Administrative feasibility. According to the survey results, the building policy instruments for the energy efficiency objective could be classified as regulatory, voluntary, economic, information-based, technology-based, and comprehensive. Policy examples of the OECD countries including recent Japanese cases are analyzed.

1. Resource Efficiency	(Durability, Waste, Recycle etc.) **Waste Minimization Policy**
2. Energy Efficiency	(Energy saving, CO_2 gas etc.) **Energy Conservation Policy**
3. Pollution Prevention	(Indoor air quality, Noise etc.) **Pollution Prevention Policy**
4. Harmonization	(with Natural and Social environment etc.) **Urban Development Policy**
5. Systemic Approach	(ISO14000's, Urban planning etc.) **Industrial and Urban Policy**

Table 1: Policy Area of Sustainable Building by the OECD Sustainable Building Project

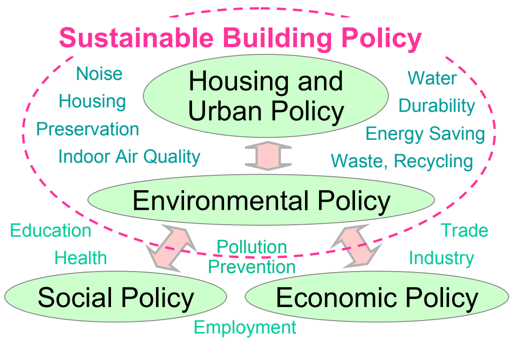

Figure 1: Policy Areas on Sustainability

2. Criteria for Policy Evaluation

The four principal criteria by which energy policy instruments are usually evaluated are as follows.

2.1 Environmental Effectiveness

There is a degree of uncertainty associated with the introduction of all environmental policy measures. This is particularly true when life-cycle and substitution effects are recognized, emphasizing the importance of policy co-ordination. However, some measures provide a greater degree of certainty about the likelihood of the achievement of a given policy objective (e.g. emission reductions, energy use) being realized.

2.2 Economic Efficiency

An economically efficient energy policy instrument is one, which equates the marginal benefits of reducing adverse environmental impacts with the marginal costs of doing so. A measure, which does not equalize marginal cost, will result in relatively higher total costs for meeting a given policy objective.

2.3 Dynamic Technological Incentives

While “static” economic efficiency effects are clearly important, in the longer run, the most important effects of energy policies relate to the incentives that they provide for research, development, innovation, and adoption of environmentally preferable technologies. To be effective such incentives must be predictable and continuous since the research-innovation-diffusion chain is very protracted and there are significant commercial risks involved at all stages.

2.4 Administrative Feasibility

Irrespective of the “ideal” properties of different instruments, they need to be administratively feasible at reasonable cost. While some costs are particular to the instrument itself, the relative feasibility and cost of a given instrument is largely a function of the degree of complementarity, which exists between the policy and the existing institutional and policy framework.

3. Evaluation of Representative Policies

The effects of the different instruments can be reviewed by taking representative policies from each category and assessing their potential advantages and disadvantages relative to the criteria for policy evaluation listed above.

3.1 Regulatory Policy Tools

Specification-based standard

In this case the household or firm is required to introduce particular conservation measures (e.g. energy conservation codes such as mandated levels of loft insulation for new dwellings or technical standards for heating equipment). They are likely to be environmentally effective at the level of the building. They are unlikely to be economically efficient unless there is considerable disaggregation of the standard, but this will tend to result in considerable administrative costs. As such there is usually a trade-off between economic efficiency and administration costs. They do not provide continuous incentives for the development and diffusion of new technologies, even in cases where leading-edge technologies are mandated.

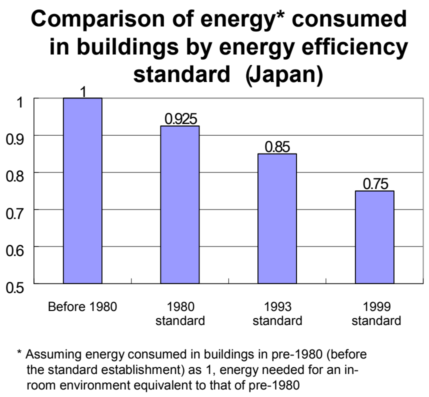

Figure 2: Trends of Japanese energy standard 1

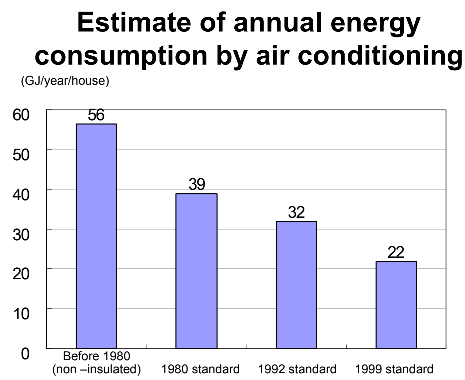

Figure 3: Trends of Japanese energy standard 2

Performance-based standard

These standards are expressed in terms of the actual performance of the appliance (e.g. conversion efficiency) or thermal characteristic (e.g. Heat-loss coefficient, K-values). They give the household or firm flexibility in how it achieves the standard, resulting in greater economic efficiency.

Depending upon how they are elaborated they may also allow for differences in local conditions or building characteristics. In addition, relative to specification -based standards these provide greater incentives for technological change. However they may be more administratively costly since information is required at a more detailed level. They are likely to be environmentally effective at the level of the individual building according to the analysis of the Japanese case and other countries.

Policy example	Environmental effectiveness	Economic efficiency	Technological incentives	Administrative feasibility
Specification-based building standards	**High**	Un-certain	Low	**High**
Performance-based building standards	**High**	**High**	**High**	Middle

Table 2: Regulatory Policy Tools

3.2 Voluntary Policy Tools

Assessing voluntary measures is exceedingly problematic. On the one hand, they are quite recent policy innovations, which complicate assessment. Secondly, they are heterogeneous in nature, containing elements of all of the other tools discussed above. However on the basis of an OECD review of actual experience with voluntary agreements, the following eight points are thought to be key in implementing a voluntary program:

1) Clearly defined targets;
2) Characterization of a business-as-usual scenario;
3) Credible regulatory threats;
4) Credible and reliable monitoring;
5) Third party participation;
6) Individual penalties for non-compliance;
7) Information-oriented provisions; and
8) Provisions for reducing the risk for competition distortions.

These characteristics reveal the close links, which exist between voluntary measures and other instruments, highlighting their role as complements to (rather than substitutes for) other policy measures.

Comparison of per Household Energy Consumption for Particular Uses in European Countries and the U.S. (2001)

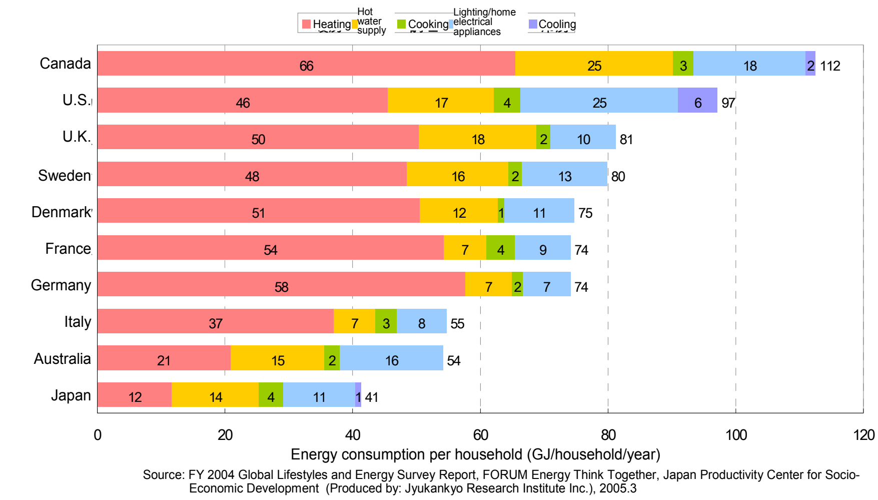

Figure 4: Energy consumption per household

3.3 Economic Policy Tools

Energy Taxes

These are likely to be economically efficient since costs of conservation measures will be equalized. They are also administratively simple, particularly since most energy use is already taxed.

(However, for other environmental objectives such as air pollution emissions where monitoring equipment is required or where damages depend upon location of emission, there is a trade-off between administrative costs and economic efficiency.) They provide continuous incentives for technological change. However, their degree of environmental effectiveness is dependent upon the extent to which household responses to energy price changes can be predicted.

Subsidies/Credit Schemes

In theory these can be economically efficient since costs of conservation measures will be equalized across households and firms if the schemes are implemented in a nondiscretionary manner (e.g. as analogues to universal taxes). However, in practice such measures are usually introduced in a differentiated manner, with access dependent upon household/firm characteristics.

Interestingly, if they are targeted at firms and households that are particularly affected by market failures (information failures, capital market failures, etc…), this differentiation may actually increase efficiency. They are usually relatively administratively burdensome. They can provide continuous incentives for technological development, but they are often targeted more toward increased diffusion of existing technologies. Their degree of environmental effectiveness is very uncertain for the same reasons as taxes, and for the additional reason that take-up may not be predictable. The Japanese case of the Governmental Housing Loan Corporation (GHLC) shows considerable policy effects.

Policy example	Environmental effectiveness	Economic efficiency	Technological incentives	Administrative feasibility
Taxation systems for energy saving	Uncertain	**High**	Middle	Middle
Incentive loans / Subsidy	Uncertain	Middle	Middle	Low

Table 3: Economic Policy Tools

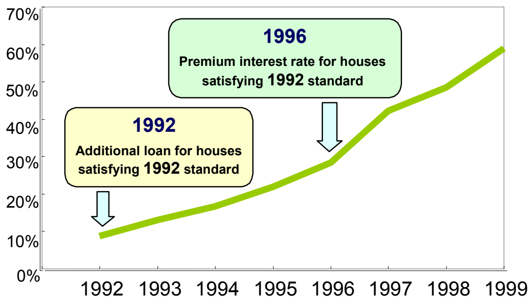

Figure 5: Effectiveness of GHLC Loans Proportion of houses satisfying 1992 standard

3.4 Information Policy Tools

Appliance and Building Labeling

These measures are likely to increase economic efficiency in cases where there are market failures related to information. In general, labeling may be administratively costly for some environmental concerns, but this is less likely to be true for energy use since the data is easily obtainable and can be standardized quite simply. Building labels are likely to be more administratively costly than appliance labeling since information is required at a much more disaggregated level. Depending upon the nature of the label, they may or may not provide incentives for technological change. Building labels have the advantage that they can encourage technological improvements in both the new and existing building stock. Environmental effectiveness is dependent upon the extent of the information-related market failure, and household responsiveness to the information provided. It is also dependent upon whether or not the labels are single-criteria or multi-criteria.

The CASBEE (Comprehensive Assessment System for Building Environmental Efficiency) method developed in

Japan is one of the effective examples of building labeling. This assessment scheme becomes popular in Japan. In the housing sector, the housing performance indication system based on the Housing Quality Assurance Law was established in 2000 and has become popular as well in Japan.

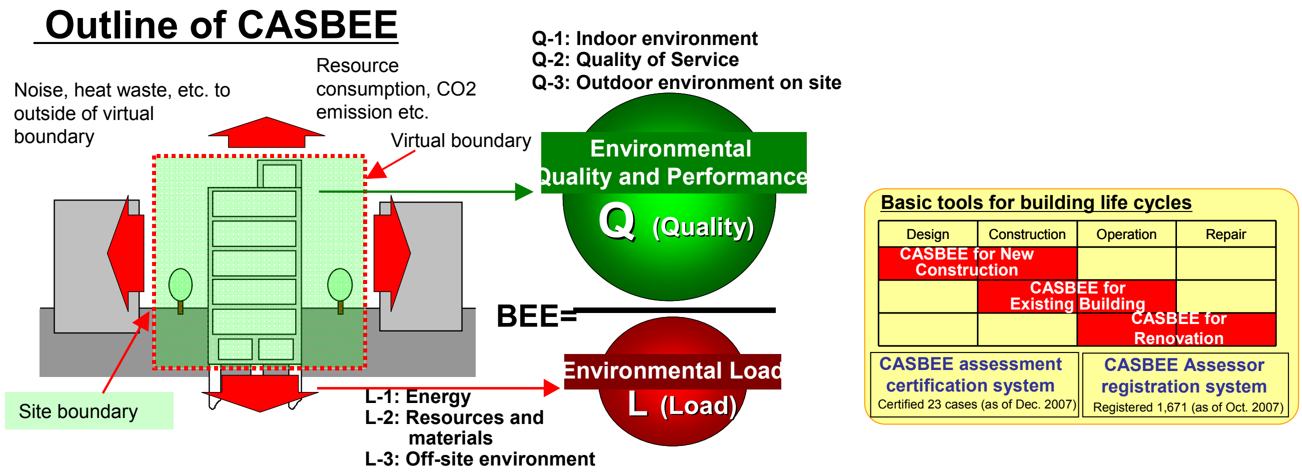

Figure 6: **CASBEE:** Comprehensive Assessment System for Building Environmental Efficiency

Name	BREEAM	LEED	GBTool	CASBEE
Founded	UK	USA	Canada	Japan

Table 4: Comparison of evaluation tools

Dissemination and Diffusion Programs
As with labeling and certification schemes, these are primarily designed to overcome information-related market failures. As such, they tend to have the same advantages and disadvantages. While they are likely to increase rates of adoption for better existing technologies, in general they are less likely to result in continuous incentives for technological change since only specific technologies are usually eligible.

Policy example	Environmental effectiveness	Economic efficiency	Technological incentives	Administrative feasibility
Labeling / rating for energy saving	Uncertain	**High**	Middle	Middle
Information diffusion to consumers	Uncertain	Middle	Low	**High**

Table 5: Information Policy Tools

3.5 Research and Development Policy Tools

Research Programs
These are targeted toward the development of more efficient heating equipment and thermal retention materials. Given the propensity for market failures in the area of research and development, well-designed policies may

increase economic efficiency and provide incentives for technological change. However, it is important that such measures do not require the government to "pick winners", a task for which they are often ill-suited. Environmental effectiveness is very uncertain since there is considerable uncertainty in all stages in research -innovation -commercialization -diffusion chain. Administrative costs will also vary widely, but are likely to be less in cases where the program "piggybacks" on existing technology and innovation policy frameworks.

Policy example	Environmental effectiveness	Economic efficiency	Technological incentives	Administrative feasibility
Research and Development (R&D)	Uncertain	**High**	**High**	Middle

Table 6: R&D Policy Tools

4. Conclusion

Energy policy consists of supply-side and demand-side measures. The largest subject of the demand-side policy is to reduce the amount of energy consumption with securing the efficient use of energy. Recently, the efficient use of energy has become exceeded the frame of an energy policy, and the global warming prevention through an energy efficiency becomes more important policy subject.

In particular, the building sector, which has been behind in advancing energy efficiency, is an important sector, likewise the industrial sector and the transportation sector. The investigation on the sustainable building policy shows that energy policy measures account for approximately half of the environmental measures for a building. The figure below shows the recent trends of the Japanese building energy efficiency in cases of new construction with its improvement.

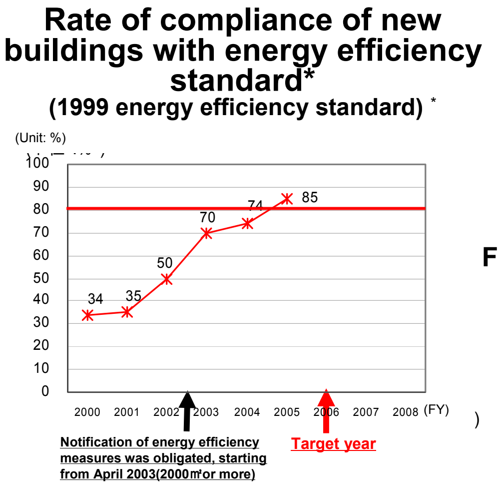

Figure 7: Compliance condition of new buildings with updated energy efficiency standard (2000 – 2005 Japan)

STANDARDISATION IN THE FIELD OF SUSTAINABILITY OF THE BUILT ENVIRONMENT

J. LAIR[1], ISO TC 59/SC17 chairman, and Al.

[1] French Building Contractor Federation (FFB, France), Sustainability in building construction, ISO

Keywords: sustainable development, buildings, construction assets, general principles, environmental declaration, environmental performance, indicators, international standardisation

Summary

Buildings and civil works are different, by their lifespan, by the numerous transformations people make in, and also, by the fact each building is unique. The impact of construction activities is very important in our present world for people everyday life, for their environment and health. Significant improvements can be quickly expected in building construction and civil works by reducing the environmental impacts, by anticipating and controlling long term costs, by being more concerned about social goals and consequences of a construction.

ISO TC 59/SC17 "sustainability in building construction" got for aim, with a most efficient and humble global approach based on the mutualisation of the expertise of more than 20 countries (North and South), to develop tools, in the form of ISO standards, for their use among construction actors in their economic and own technical activities. Such standards are published or currently being developed in different field:

- general principles and terminology (what the aim? Do we all understand the same things under each same term?)
- sustainability Indicators (proposal for a set of basic indicators)
- environmental declaration of products (based on ISO LCA methods)
- environmental performance of buildings
- and more recently “civil engineering”

The purpose of the proposed presentation is to make a panorama of the standardised tools offer and their dissemination among construction actors all over the world, how they can be experimented and how to get a good feedback for the benefit of all. Finally, the article concludes, at this time, on the level of contribution to sustainable development and the road still to walk.

Introduction

The issue of sustainable development is broad and of global concern, and, as such, involves all communities and interested parties. Both current and future needs define the extent to which economic, environmental and social aspects are considered in a sustainable development process.

The built environment (buildings and civil engineering works) is recognised as a key element in determining quality of life, and contributes to cultural identity and heritage. As such, it is an important factor in the appreciation of the quality of the environment in which society lives and works.

The building and construction sector is highly important for sustainable development because:

- it is a key sector in national economies (more than 1000 milliards Euros (EU 21) for Europe, 10% PIB, 2.3 millions of contractors (of which 97% have less than 20 employees, 7,3% employment in Europe and more than $US 4 trillion dollars and about 110 million workers in the world.) ;
- it has a significant interface with poverty reduction through the basic economic and social services provided in the built environment and the potential opportunities for the poor to be engaged in construction, operation and maintenance;
- it is one of the single largest industrial sectors and, while providing value and employment, it absorbs considerable resources, with consequential impacts on economic and social conditions and the environment (to simplify 40% CO_2 emission, 40% of natural resources, 40% of waste);

- it creates the built environment, which represents a significant share of the economic assets of individuals, organizations and nations, providing societies with their physical and functional environment;
- it has considerable opportunity to show improvement relative to its economic, environmental and social impacts.

Construction activities may or may not take place within a legal and regulatory, or other administrative framework present within a country or region. In either case, aspects of governance are relevant to sustainable development, in addition to those aspects related specifically to building construction. Well established administrative frameworks may contain requirements that can act as drivers and help to move the building and construction sector towards sustainability.

Over their life cycle, construction works absorb considerable resources and contribute to the transformation of areas. As a result, they can have considerable economic consequences, and impacts to the environment and human health.

While the challenge of sustainable development is global, the strategies for addressing sustainability in building construction are essentially local and differ in context and content from region to region. These strategies will reflect the context, the preconditions and the priorities and needs, not only in the built environment, but also in the social environment. This social environment includes social equity, cultural issues, traditions, heritage issues, human health and comfort, social infrastructure and safe and healthy environments.

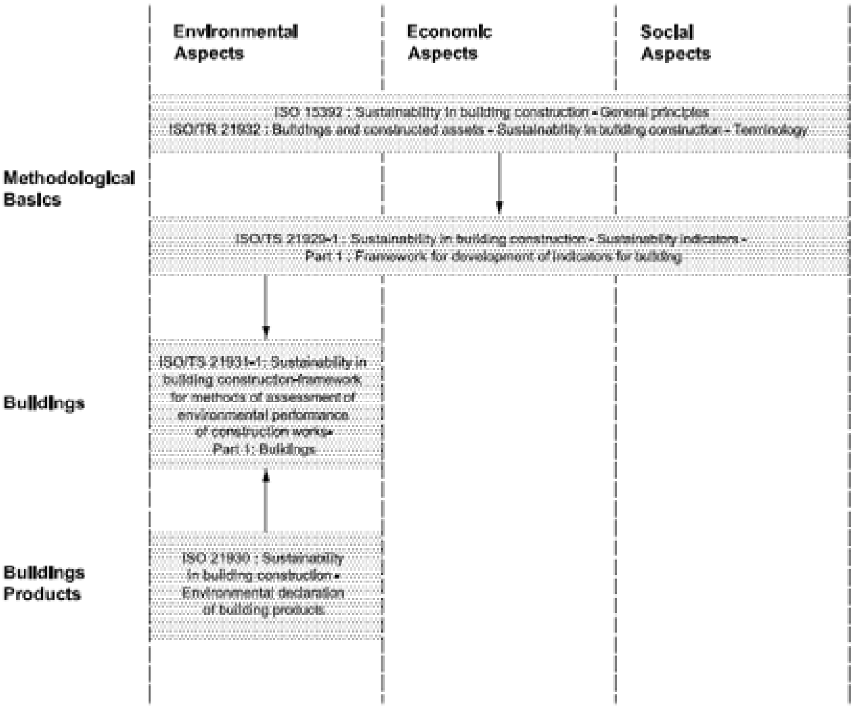

Figure 1 Suite of related international standards for sustainability in buildings construction and construction works

It may, in addition, particularly in developing countries, include poverty reduction, job creation, access to safe, affordable and healthy shelter, and loss of livelihoods.

Applying the principles of sustainability in building construction, including all related processes and activities, requires the direct and responsible involvement of all interested parties. While their legal responsibility and liability is subject to national or regional regulation, individual commitment and responsibility is voluntary.

Nevertheless, this commitment is a basic principle of the application of sustainable development, including application in the building and construction sector.

Applying the concept of sustainability to specific buildings or other construction works includes an holistic approach, bringing together the global concerns and goals of sustainable development and the demands and requirements in terms of product functionality, efficiency and economy. Different target audiences will have a different perspective on these challenges and the preferred solutions.

For all these reasons; ISO TC59/SC17 "sustainability in building construction" tired and succeeded to establish internationally recognized principles for sustainability in building construction and to establish a common basis for communication of the information required. Interested parties, such as product manufacturers and designers will then be able to provide information (by example, from a tool called environmental products declaration [EPD]). Such information can then be communicated internationally and to a wide range of target audiences, extending from policy makers and regulators to manufacturers, building owners and consumers.

The recipients of information can elaborate and interpret information according to their own perspective, reflecting other aspects of decision making, including fields of responsibility or constraints.

The concepts involved in sustainability are highly complex and under constant study. There are no definitive methods for measuring sustainability or confirming its accomplishment. These general principles do not provide a benchmark against which a claim of sustainability can be made. Nevertheless, they may be useful when considering the completeness and validity of claims of, or calls for, sustainability.

The aim of this International Standardisation work is to set out the objectives for sustainability in building construction and from these derives general principles. For the current standardization work, see Figure 1. This work forms now the basis for deriving evaluation criteria and indicators for the assessment of the contribution of buildings to sustainable development, and it enables decision makers to apply the principles in their decision making.

This set of tools does not (and have not to) set the political agendas, or provide priorities related to specific concerns which are established in international agendas, e.g. Agenda 21. However, requirements and targets related to political goals can be related to the identified general principles for sustainability in building construction (see Figure 2 "differences between green and brown agenda").

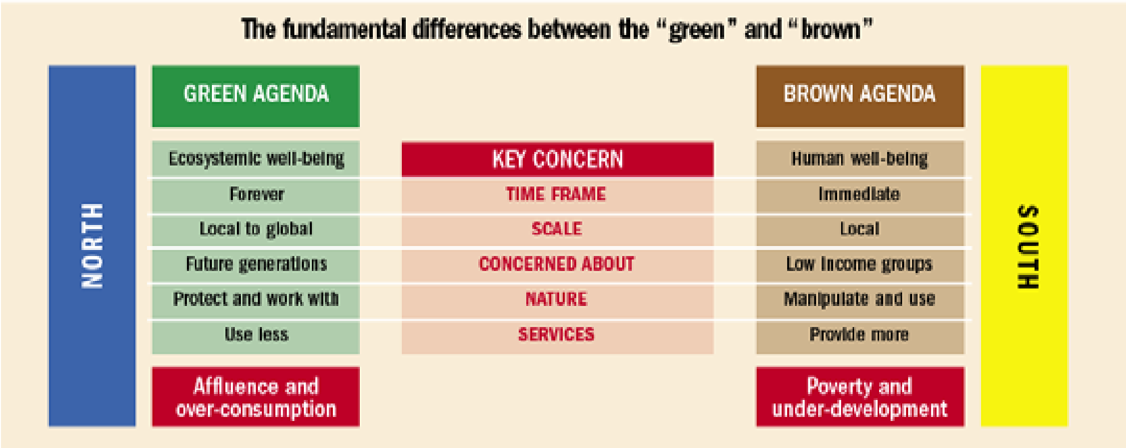

Figure 2 (source : from Ron Watermeyer, Iso Focus June 2007)

2- Overview of the ISO TC59/SC17 work

The purpose of TC59 SC17 is to propose a standardization frame for sustainability in building construction. The objectives of ISO /TC59 /SC17 is focused on the providing of an open forum for all member bodies for the processing, implementation and maintenance of ISO standards relevant to the scope in this SC (see figure 3).

The following objectives are those that the SC has selected as most important:

- assess, identify and meet the market requirements for standards,
- the quality of the standards,
- the standards shall be developed within time schedule laid down in the ISO Directives
- increase the number of participating countries in the SC,
- enlarge the participation to developing countries.

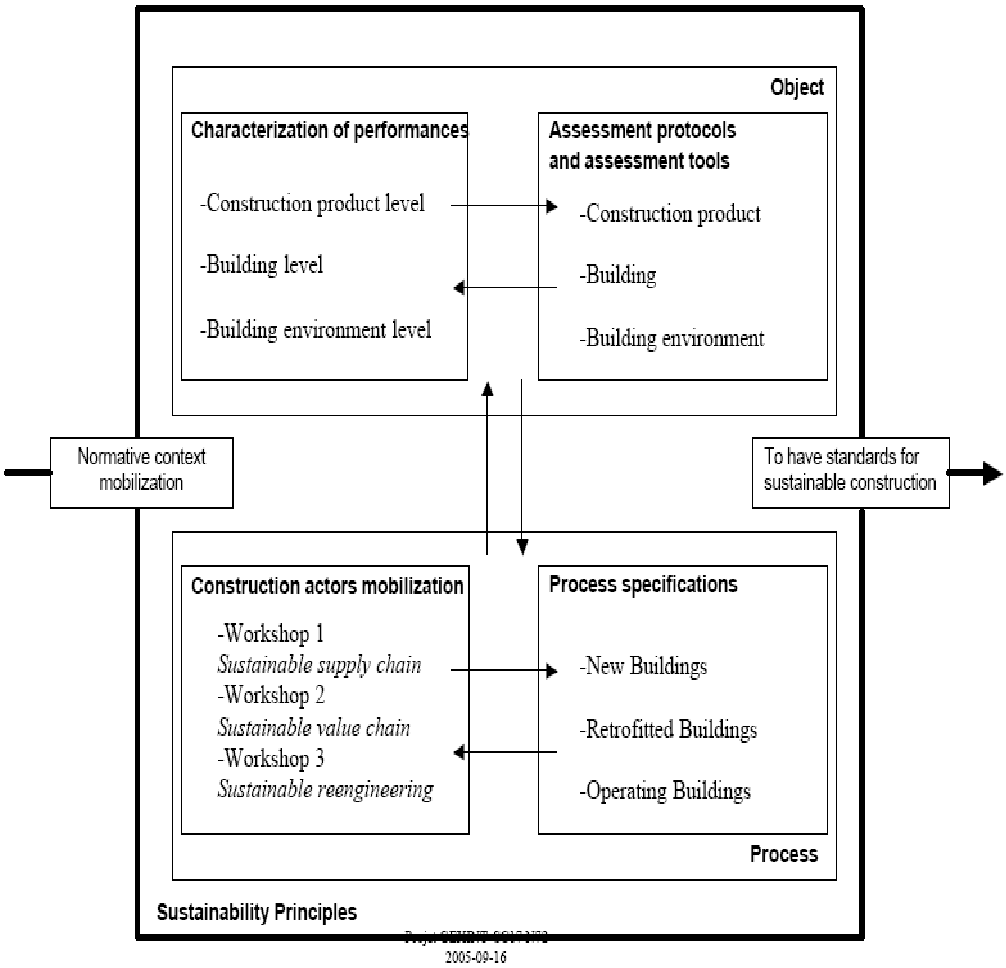

Figure 3 - Thematic and process for ISO TC 59 works

2.1 Organisation and structures

Directly contributing members of ISO TC 59/SC17 are coming from 17 different countries:

> Belgium (IBN), Canada (SCC), Denmark (DS), Finland (SFS), France (AFNOR), Germany (DIN), Italy (UNI), Japan (JISC), Korea Republic of (KATS), The Netherlands (NEN), Norway (SN), Poland (PKN), Spain (AENOR), Sweden (SIS), Switzerland (SNV), United Kingdom (BSI), USA (ANSI).

Some are regsistred as Observer countries and have either welcomed SC17 plenary meetings or WG meeting or have sometimes technically contributed : Australia (SA), Austria (ÖN), Brazil (ABNT), China (SAC), Czech Republic (CNI), Russian Federation (GOST R), Turkey (TSE).

SC17 is also working with some organizations in liaison for their active work in the domain of sustainable building or because they can bring at any time part of their own expertise in a particular domain: ISO/TC 59 SC14 Design life, ISO/TC 59 SC16 Accessibility and usability of the built, ISO/TC 163 Thermal Performance and Energy Use In the Built Environment, ISO/TC 205 Building Environment Design, ISO/TC 207/SC 3 Environmental Labeling.

ISO/TC 207/SC 5 Life Cycle Assessment, Liaison with CEN/BT/WG174 CEN/BT/WG174 Integrated environmental performance of buildings and further CEN/TC 350, Organization for Economic Cooperation and Development (O.E.C.D.), Federation of European Rigid Polyurethane Foam Associations (BING), European Aluminium Association (EAA), European Insulation Manufacturers Association (EURIMA), Council of European Producers of Materials for Construction (CEPMC), Extruded polystyrene Insulation Board Association" (EXIBA), International Federation of Consulting Engineers (FIDIC)

2.2 Five working groups :

WG 1: General Principles and Terminology Convenor – SIS (Sweden)
WG 2: Sustainability Indicators Convenor – SFS (Finland)
WG 3: Environmental Declarations of Building Products Convenor – NSF (Norway)
WG 4: Framework for Assessment of Environmental Performance of Buildings and Constructed Assets Convenor – JISC (Japan)
WG 5: sustainability in civil engineering Convenor : Aenor (Spain)

Table 1 - Working Groups under subcommittee SC17

3- Focus on products – The ISO 21930 standard .Sustainability in building construction — Environmental declaration of building products - Bâtiments et ouvrages construits — Développement durable dans la construction — Déclaration environnementale des produits de construction

3.1 Introduction

Designers of buildings, manufacturers of building products, users of buildings, owners of buildings and others active in the building and construction sector are increasingly demanding information that enables them to make decisions to address environmental impacts of buildings and other construction works.

These demands are currently being addressed only through various national initiatives applying a variety of approaches.

It is essential that there be uniformity in the means of expressing environmental product declarations. This includes having a consistent way of arriving at the declaration that is based on basic life-cycle inventory data and additional information not based on life-cycle assessment (LCA). The user expects non-biased information, which is expected be consistent with the best current practice and understanding over the lifetime of the standard.

According to the set of four International Standards dealing with environmental labelling, (ISO 14020, ISO 14021, ISO 14024 and ISO 14025), environmental labels and declarations are divided into three principal types:

- General principles: ISO 14020;
- Self-declared environmental claims, type II environmental labelling (ISO 14021);
- Principles and procedures of environmental labels and declarations, types I and III environmental labelling (ISO 14024 and ISO 14025).

The purpose of the international standard work was to describe the principles and framework for environmental declaration of building products, including consideration of the reference service life of the building products, seen over a building's life cycle. This work is expected to form the basis for type III environmental declaration programmes leading to type III environmental declarations of building products as described in ISO 14025.

Note EPD is an abbreviation used to represent both the single and plural full form designation of "environmental product declaration", which is intended to be synonymous with the designation "type III environmental declaration". In the practice of developing EPD, programmes or their declarations are referred to by various names such as eco-leaf, eco-profile, environmental declaration of product, environmental product declaration (EPD), and environmental profile.

3.2 Objectives of EPD of building products

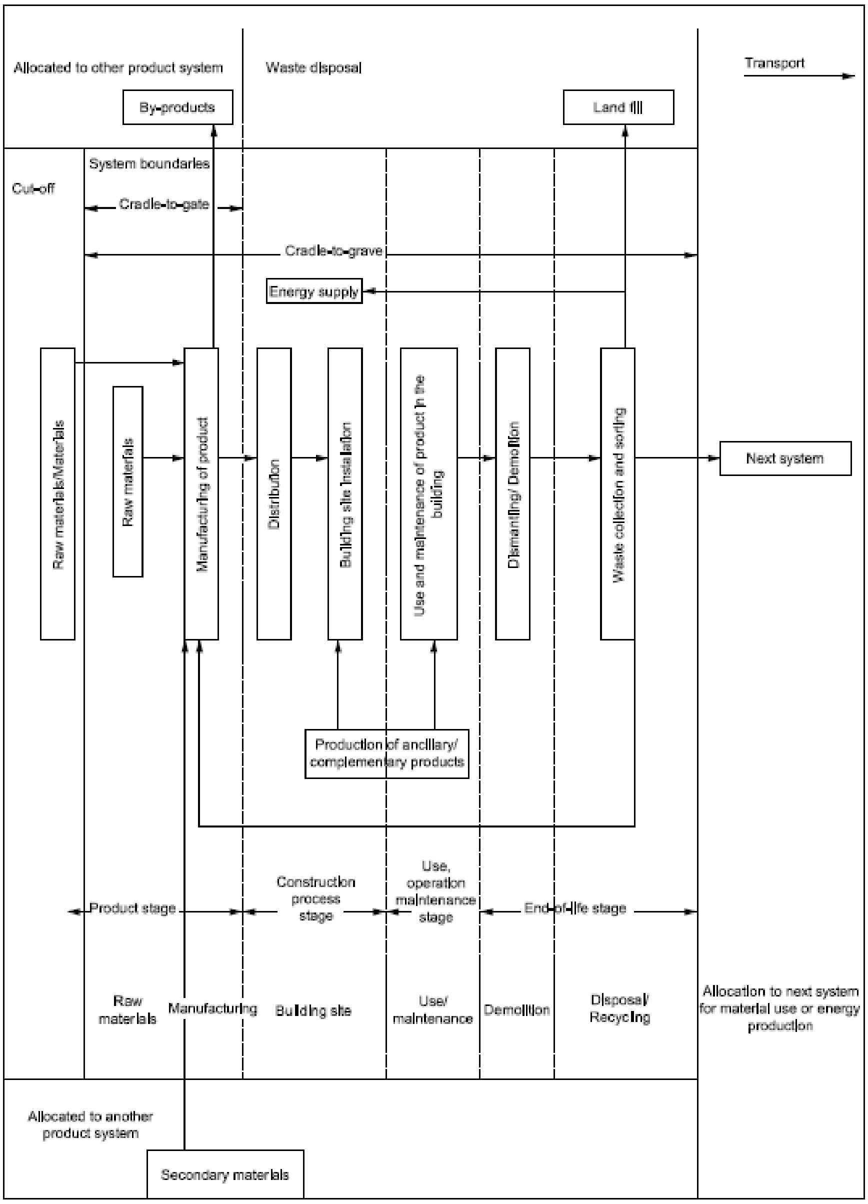

Figure 3 — Example of system boundaries, information modules and life-cycle stages of building products

The overall goal of environmental declarations is to encourage the demand for, and supply of, building products that cause less stress on the environment, through communication of verifiable and accurate information on environmental aspects of those building products that is not misleading, thereby stimulating the potential for market-driven, continuous environmental improvement.

The manufacturer, or group of manufacturers, of the building product is the sole owner of the data and takes liability and responsibility for the EPD of the building product.

The aim is to ensure the transparency of the methodology applied for developing the EPD for building products. The methodology should be consistent, scientifically robust and should ensure that all environmental impacts are completely accounted for without double counting.

In addition to the requirements of the principles and procedures set out in ISO 14025 and ISO 15392 shall apply when considering building products. For this reason, additional specifications and requirements for the EPD of building products were added. Where there are more specific requirements, ISO TC 59/SC17 complemented ISO 14025 for the EPD of building products.

In addition, the environmental declaration principles as described in ISO 14020 apply. The EPD of building products are intended to provide information for planning and assessing buildings. EPD can also be used by other interested parties, such as purchasers, architects, etc., to compare the environmental impacts of building products under certain conditions. EPD are based on LCA, LCI and/or information modules. Relevant environmental aspects that have not been covered by LCA are addressed as additional environmental information;

Environmental information of an EPD covering all life-cycle stages ("*cradle to grave*") is subdivided into at least the four life-cycle stages below. In addition, the stages may be further subdivided; see Figure 3 :

- product stage (including information modules from raw material supply, transport, manufacturing of products and all upstream processes from cradle to gate);
- construction process stage (information modules from transport to the building site and building installation/construction);
- use stage/operation [information module 6 contains information of the impact from the building product during its use and operation (e.g. installed services and appliances)]; use stage/maintenance (information modules 7, 8, 9, and 10 contain information on impacts from maintenance, repair, replacement and refurbishment, including all transport);
- end-of-life stage (information modules from deconstruction, reuse, demolition, recycling and disposal, including all transport).

3.3 The main relevant principles and information provided by an EPD:

3.3.1 Involvement of interested parties

In accordance to the rules set by this standard, the process of developing EPD should include an open, participatory consultation with interested parties and reasonable efforts should be made to achieve a consensus throughout the process. The interested parties for type III environmental declaration programmes may include, but are not limited to, material suppliers, manufacturers, trade associations, purchasers, users, consumers, non-governmental organizations, public agencies and, when relevant, independent parties and certification bodies.

3.3.2 Information modules of building products

An EPD can include all life-cycle stages, such as production, installation into the building, use and maintenance, replacements, demolition, recycling and disposal, the EPD is said to be "*cradle to grave*" and becomes an EPD of building products based on LCA (see ISO series ISO 1404x standards). The material and energy flows for an EPD based on LCA are expressed per functional unit (i.e a functional unit is a quantified performance of a product system for a **building product** for use as a reference unit in an **EPD** based on LCA). .If the information modules considered in a type III environmental declaration do not cover the life cycle, then it shall be stated.

Important: all hazardous and toxic materials and substances shall be included in the inventory (Life cycle inventory) and the cut-off rules do not apply.

3.3.3 Comparability of EPD of building products

Comparison of building products using EPD shall be carried out only at the building level. This comparison requires a scenario and the product category rules (PCR: set of specific rules, requirements and guidelines for developing **type III environmental declarations** for one or more **product categories**) shall describe the rules and requirements for that scenario.

For example, the French standard NF P01-010 is the PCR for all building products. This was a consensual choice of the whole industry.

There are some data quality requirements: the data quality has an influence on the content of an EPD. depending on the goals, the data quality requirements shall be formulated with regard to accuracy, precision, completeness and representativeness.

3.3.4 Reporting

It is an important part of the EPD, allowing it to be publicly communicated and published. The reporting is also used for the verification (by a third party) and the review of the EPD. The ISO 21930 set rules for the project documentation.

3.3.5 Rules for data confidentiality

Product-specific data are very often confidential, because of competitive business issues, intellectual property rights, or similar legal restrictions.

It is not required to make such confidential data publicly available. Normally, the EPD present only data that have been aggregated over the four stages of the life cycle or relevant portions of it and the aggregation obscures the underlying competitive information. Confidential business data provided for the independent verification process can be kept confidential upon request of the body supplying the data and with the approval of the programme operator, in accordance with programme operational rules.

3.3.6 Declaration of environmental aspects

A Environmental impacts expressed in terms of the impact categories of LCIA

- . climate change (greenhouse gases);
- . depletion of the stratospheric ozone layer;
- . acidification of land and water sources;
- . eutrophication;
- . formation of tropospheric ozone (photochemical oxidants).

B Use of resources and renewable primary energy — Data derived from LCI and not assigned to the impact categories of LICIA)

- . depletion of non-renewable energy resources;
- . depletion of non-renewable material resources;
- . use of renewable material resources;
- . use of renewable primary energy;
- . consumption of freshwater.

C Waste to disposal — Data derived from LCA and not assigned to the impact categories of LCIA)

The waste allocated to the building product during its life cycle shall be classified in the EPD as

- . hazardous waste, or
- . non-hazardous waste.

The division between the various categories shall be expressed in percentage terms or as mass per functional or declared unit.

D Emissions to water, soil and to indoor air

Releases to ground- and surface water, as well as emissions to indoor air, shall be declared in accordance with national standards and practice. Information on human health and comfort due to chemical, biological and physical emissions is required for further evaluation on the building level of human health and comfort.

E Additional environmental information

An EPD shall include, where relevant, additional information related to environmental issues, other than the environmental information derived from LCA, LCI or information modules and other than emissions to water and to indoor air. This information shall be separated from the information described in C and D. The manufacturers shall report this information according to the provisions in the PCR document. Such 10 kinds of information can be information on environmental issues, such as :

- impact(s) and potential impact(s) on biodiversity,
- toxicity related to human health, the environment or both, and
- geographical aspects relating to any stages of the life cycle (e.g. a discussion on the relation between the potential environmental impact(s) and the location of the product system)

3.4 Conclusion One

The environmental information on building products is intended mainly for business-to-business communication and its prime purpose is to provide measurable and verifiable input for the assessment of the environmental performance of buildings. However, some EPD may be used in the business-to-consumer marketplace and the user of this International Standard ISO 21930 shall follow the provisions of ISO 14025:2006, Clause 9.

The users are both the information providers and information users, including those setting up type III environmental declaration programmes. Users may include trade associations or other bodies organizing programmes for type III environmental declarations, manufacturers in the manufacturing chain, designers, developers, architects, contractors, facility managers and their clients.

Figure 4b- BRE (UK) Environmental profiles

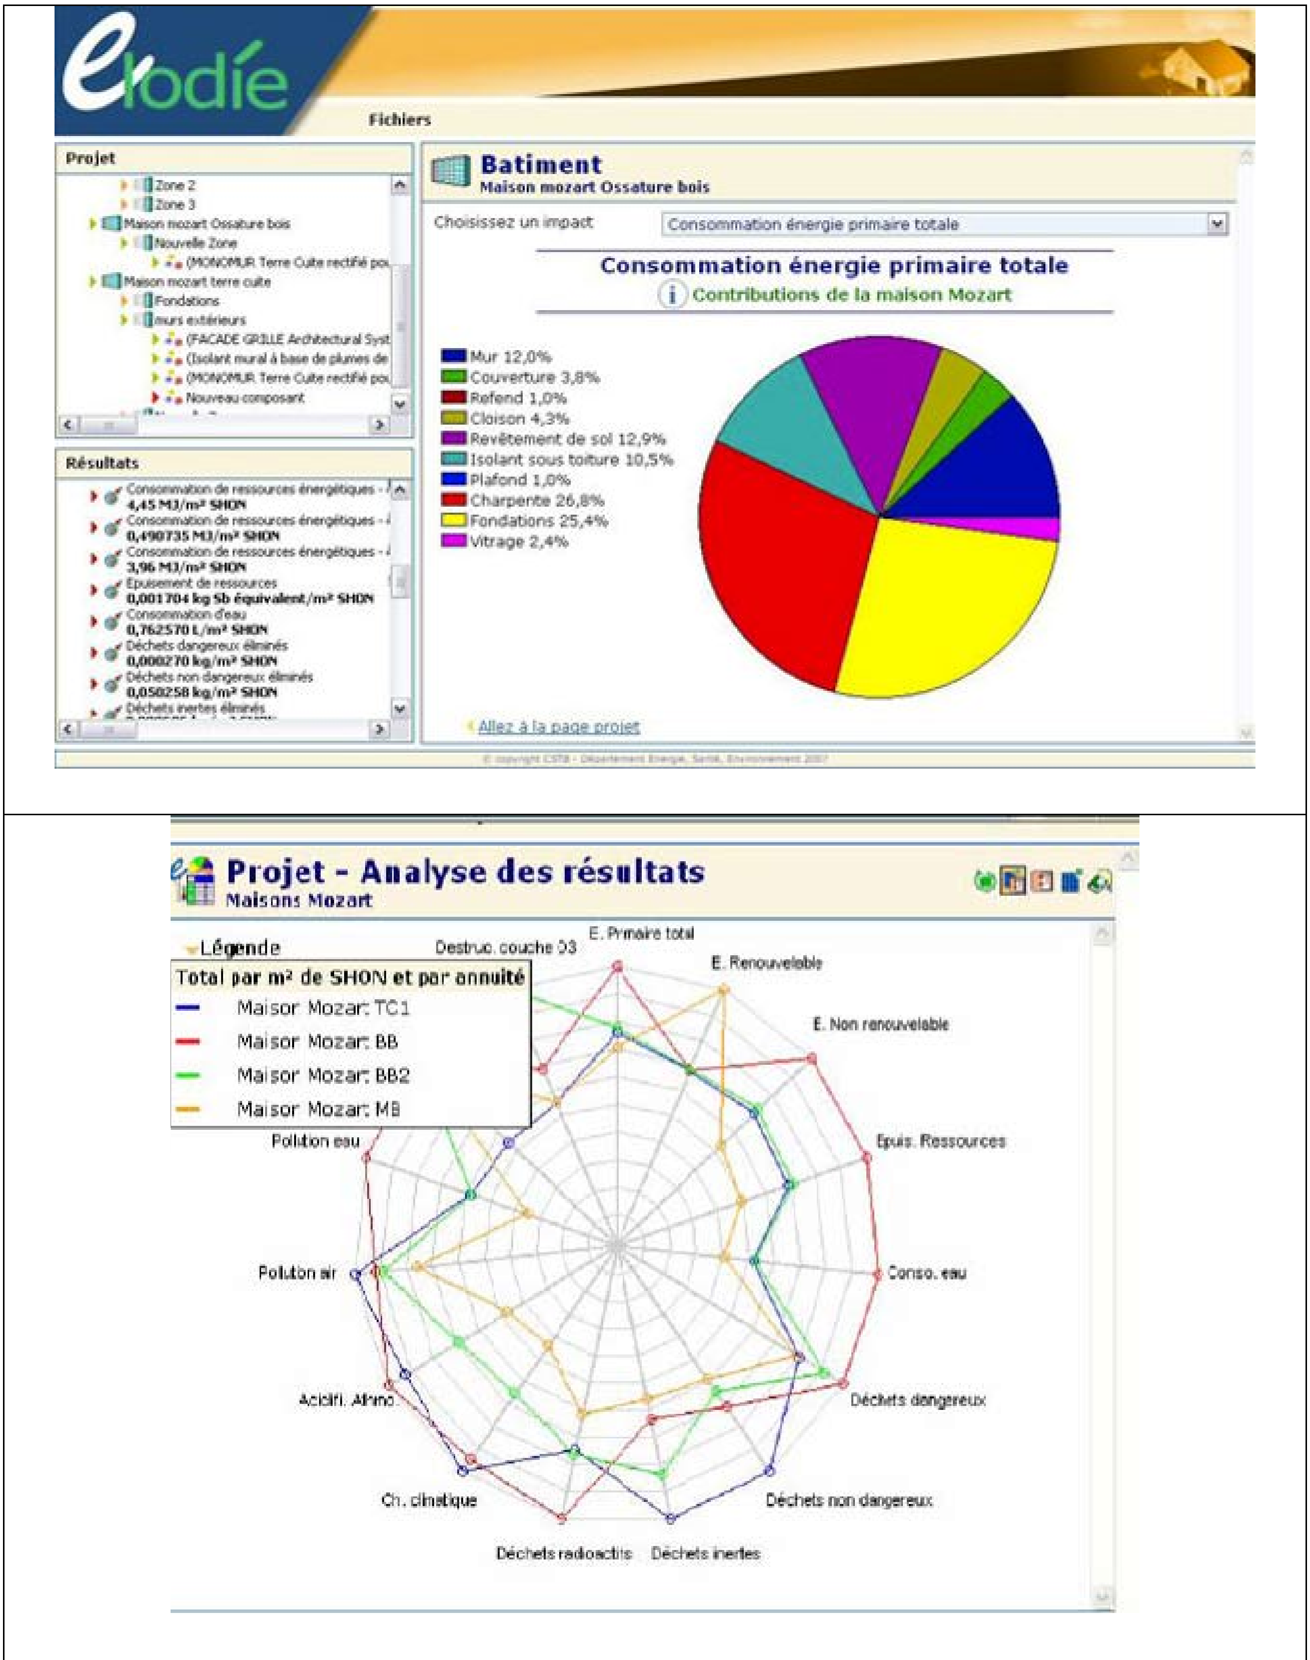

Figure 5 - Elodie (EPD aggregation tool for implementation at building level)

Different verification or third party verification are currently being performed in The Netherlands (MRPI), Germany (AUB) and France (Afnor verification scheme), Sweden (and countries participating in Gednet programme [EPD scheme]), UK 'BRE ecoprofile'.

More than 12 different European countries have set up an EPD-like scheme 5 (in the world: Japan, South Korea, USA, etc.)

In conclusion to the road toward a “green” building construction process, products and materials are part of the basic steps. Priority is given to the production of an objective scientific information (common language) and to its dissemination toward the scientific community (mainly laboratories, LCA experts, etc.). First results are more and more building product production process introducing ‘eco-design’ methods. Second steps should business and consumer oriented in order to make users more environmentally consciencious for their own activity (project, construction, purchasing, etc.). Such tools as Elodie project (CSTB, France) shows the way. That goal shall not be forgotten.

4- Focus on buildings – the ISO TS 21931 : ISO/TS 21931-1, Sustainability in building construction — Framework for methods of assessment for environmental performance of construction works — Part 1: Buildings - *Développement durable dans la construction — Cadre méthodologique pour l'évaluation de la performance environnementale des ouvrages — Partie 1: Bâtiments*

4.1 Introduction

Building construction shall now take into account a more sustainable approach. First steps were made through products EPD (more and more available on the global market) and through different assessment methods that each country tried to develop and implement. There was again a lack of common language in order to make comparable the different assessment methods and, more important, their basic principles. The goal driving the ISO work was to be able to set up a common framework inside which (or from which) the different existing assessment and design methods could benefit to improve, and prepare the next generation of integrated assessment and design tools.

ISO – through TC/59 SC14 (building service life planning) and SC17 and with TC 205 (building indoor environment design) made a great job trying to gather their effort.

4.2 Aim of the work

The aim of this part of ISO/TS 21931 was to define a framework for methods of assessment for the environmental performance of buildings. In order to be able to communicate information to interested parties regarding the potential environmental impact of buildings, in relation to the concept of sustainability, it is important to understand how the buildings themselves perform in this respect and to benchmark their progress towards achieving improved performance.

To this end, assessment methods for environmental performance of buildings have been developed and have been in use worldwide since the early 1990s. These developments have been prompted by

a shift from single performance measures to a more comprehensive set of environmental considerations, a recognition of the benefits of proactive voluntary measures, and the need to meet market demands for information on environmental performance.

Assessment methods for the environmental performance of buildings are the basis for demonstrating and communicating the extent of the proactive commitment of a building’s suppliers toward achieving higher levels of environmental performance. The methods attempt to establish an objective and comprehensive means of simultaneously assessing a broad range of environmental considerations against explicitly declared criteria, and to offer a summary of environmental performance.

Assessment methods for the environmental performance of buildings provide a common and verifiable set of criteria and targets so that building owners striving for higher environmental standards have a means of measuring, evaluating and demonstrating that effort, provide a reference as a common basis by which building owners, design teams, contractors and suppliers, can formulate effective environmental performance improvement strategies, gather and organize detailed information on the building that it can be used to lower operating, financing and insurance costs, lower vacancy rates and increase marketability, and assist the design process by providing a clear declaration of what are considered as the key environmental considerations and their relative importance.

Life-cycle approaches will inevitably play a greater role for setting performance criteria within methods of assessment of overall environmental performance of buildings. However, the collection and maintenance of current data sets for the multitude of systems and elements is not practically achievable at the moment.

Consequently, to achieve the practical goals noted above, assessment methods for the environmental performance of buildings need to refer to a limited number of criteria and seek a balance between rigour and practicality. This means that the deployment of LCA within the methods of assessment of overall environmental performance of buildings must consider the significance of the individual performance criterion within the context of the overall building performance.

Considering all these issues, there was a need to formalize an International Standard that will ensure the quality, and comparability, of assessment methods for the environmental performance of buildings.

The purpose of ISO/TS 21931 is to describe the framework and the principles behind the assessment of the environmental performance of both new and existing buildings, taking into account the various environmental impacts these buildings are likely to have.

The standard identifies and describes issues to be taken into account when using methods for the assessment of environmental performance for new or existing building properties in the design, construction, operation, refurbishment and deconstruction stages.

The building is the object of the assessment defined in this part of ISO/TS 21931, and this encompasses the building itself, the site and the associated facilities on the site. It is recognized that environmental performance is only one of a number of significant factors in a building's overall performance.

This part of ISO/TS 21931 is intended be used in conjunction with, and following the principles set out in, the ISO 14000 (environmental management) series of International Standards.

4.3 Description of the approach

The aim of an assessment of the environmental performance of a building is to examine the ability of the building to contribute to sustainable development with regard to the environmental dimension. It also aims to communicate and/or to improve the building's environmental performance. This can be achieved by supporting the decision-making process in design, construction, transfer, operation, refurbishment and demolition.

An improvement in environmental performance requires the appropriate operation of the building over its lifetime. In existing buildings, this could be enhanced through the use of an environmental policy and the implementation of a management system.

The intended use of the assessment and the life-cycle stages covered by the methods of assessment can be varied by the aim of the assessment.

Buildings can be considered under different angles of view which are not self-exclusive:

- **as an end-use product of itself**.

  A building physically consists of various elements, such as construction materials and components, which are parts of a building and its technical systems. Therefore, a building can be considered as an integrated assembly of component products, which are manufactured, used and disposed of, according to their service life. The manner of assembly is customized having regard to the project-based specific requirements of the building.

  Then, the environmental performance, which relates to the characteristics of the building as an assembly of elemental products, is subject to systematic maintenance management of the component products during their service lifetime.

  The environmental performance that relates to the characteristics of a building as an assembly of component products has relevance to the issues described in ISO 21930. Environmental product declarations (EPD) may be utilized in the assessment of buildings as established on the basis of agreed product category rules (PCR) according to ISO 14025.

- **as supports for active processes**

  According to systemic analysis, a building can be considered as supporting an active process. Through its operation during the utilization stage, a building provides a number of services to its users as well as conditions appropriate for living, working, studying, provision of health-care, leisure activities, etc. The provision of these services involves input and output flows to make this process function. It can also be considered as an active process when, combined with other buildings or industrial equipment, it performs, for example, as part of an ecosystem (when pollution or waste from another building or equipment can be used as resources).

  Therefore, the environmental performance of the building relates to the quality of services to users as well as to relevant conditions that a building generates when perceived as an active process. As an active process and in order to function, the building is provided with energy, water and various resources. Under these circumstances, a building yields the services for which it was intended and flows are incurred, including atmospheric emissions, wastewater and other waste. In addition to this, a building is linked to infrastructures both upstream and downstream, which also require energy, water and transportation energy and which generate wastes. These processes also have input and output flows.

  Consequently, the environmental performance of a building relates to input and output flows that a building generates as a process.

- **as places of activity**

  A building can also be considered as a place of activity, such as place to live and work, where it makes an effective contribution to the creation and the life of the urban context.

Therefore, the environmental performance of the building relates to the comfort and health of its users, such as occupants, site workers, maintenance staffs and neighbours and interested parties, over the building's life cycle.

4.4 Basic principles of the approach

4.4.1 Relevance to local context

The environmental performance of a building depends on the characteristics of the climatic, social, economic and cultural context of the nation and region where the building is located.

For comparison purposes between countries or regions, transparency is required and, as far as possible, standardized calculation methods shall be used. The standards underlines that the characteristics and relevance of local contexts make possible the co-existence of regional and national methods for the assessment of the environmental performance of buildings, providing that the methods are within the framework given in this part of ISO/TS 21931.

4.4.2 Framework for assessment of environmental performance

Any assessment method built to follow the standardized framework shall involve the following elements:

intended use of the method ;

- definition of the system boundary ;
- statement of assumptions ;
- structured list of issues for environmental assessment ;
- means of quantifying the environmental performance of a building ;
- sources of information (generic and specific database, etc.) ;
- evaluation and interpretation ;
- reporting of results of assessment and communication format

4.4.3 Intended use of method

The intended use of the methods of assessing the environmental performance of a building shall be clearly stated.

The intended use may encompass:

- design of a new building,
- assessment of an existing building,
- improvement of operation,
- design for modernization, and
- design for deconstruction and disposal.

The environmental performance of a building should be assessed in operational activities, including new construction, refurbishment or retrofit.

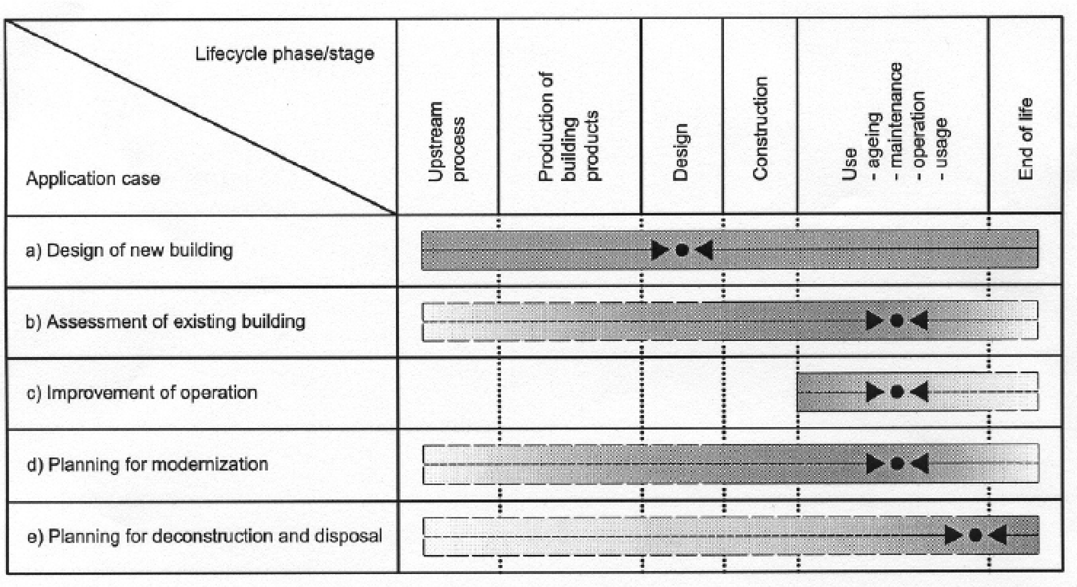

Figure 6 — Relationship between application cases and life-cycle stage

4.4.4 System boundary

The system boundaries are determined by the intended use of the methods of assessment, by the intended users and beneficiaries of the method, by the intended stages of the building life cycle to which the methods are applied, and by the assumptions underlying an assessment.

4.4.5 Statement of assumptions

A particular attention is paid toward two specific cases. Indeed, critical assumptions have to be made concerning the scope and context of the environmental performance assessment of buildings:

- Newly built or refurbished buildings
- Existing buildings

4.4.6 Structured list of issues for environmental assessment

Environmental issues of concern related to		**Additional (where relevant)**
environmental impacts of buildings climate change; destruction of the ozone layer. and destruction of non-renewable resources; formation of pollutants; formation of photochemical oxidants; acidification of land and water sources; eutrophication.	**environmental aspects** a) **energy and mass flow during life cycle**: 1) material use, differentiated into • depletion of non-renewable material resources, • use of renewable material resource, and • use of substances classified as hazardous or toxic according to national or international regulation; 2) primary energy use, differentiated into • depletion of non-renewable primary energy, and • use of renewable primary energy; 3) water use; 4) land use; 5) waste production, differentiated into reuse/recycling or energy recovery, and waste production for disposal. b) **local impacts** 1) on soil, 2) on ground water, 3) of noise, and 4) of odours. And : wind damage by the microclimate around building, including tunnel effect; load on local infrastructure; sun shading and glare on the property in question and any neighbouring property.	**aspects of building performance usefulin assessing environmental aspects in view of the entire life cycle** (to be integrated into the technical description for this purpose): • accessibility; • adaptability; • durability; • deconstructability; • recyclability; • maintainability; • safety. NOTE The environmental performance of a building utilizes outputs from various sources, including the LCA. Issues dealing with energy and material flow could have relevance for the inventory-oriented and/or impact-oriented results of an analysis of the energy and mass flows within a building's life cycle, including an examination of risks for the environment.
Issues of concern related to building management Additionally, where relevant: limitation of waste production; recovery of waste; reduction of nuisances; reduction of pollution; pollution control; water saving; wastewater treatment; maintenance; rehabilitation of the environment to promote biodiversity; environmental emergency management.	**Issues of concern related to indoor environment** (influence the comfort and health of the users and occupants.) where relevant: indoor air quality; quality of ventilation; hygrothermal conditions (air temperature and humidity); noise and acoustics; glare, access to daylight and exterior views; quality of light; odour conditions; quality of water; intensity of electromagnetic fields; radon concentration; hazardous substances; existence of unwanted micro-organisms, e.g. black mould.	**optional, issues**: relevance to the environmental issues of concern that the interested parties have to take into consideration in the decision making; effective communication of the result of assessment among interested parties who have various concerns; expected use of the result of the assessment; compliance with local regulations; relevance to significant environmental aspects of building in the local context; traceability, transparency and verifiability of process of assessment; technical feasibility of assessment; avoidance of double-counting when assessing the env^{tal} performance.

All issues shall be fully described, including their calculation and evaluation rules. In addition, the process involved in the selection of optional issues by the designer of the assessment method of the environmental performance shall be explicitly documented as reference information accessible to all interested parties.

4.5 Methods for quantification of environmental performance

4.5.1 General

The measurement of the environmental performance of a building requires indicators for the environmental criteria selected by the designer of an assessment method. Indicators may be either qualitative or quantitative.

Methods for quantification of environmental performance are composed of

a) a methodology for measuring the environmental performance by specific criteria, and

b) a methodology for aggregating the results of environmental performance measurement from multiple criteria.

4.5.2 Principles

- Data quality
- Transparency
- Traceability
- Assessing qualitative information
- Functional unit
  - The functional unit of a building may include information on the following:
  - type and use of building (offices, factories, public housing, etc.);
  - occupancy (period and pattern of use);
  - floor area and volume;
  - expected service life;
  - adaptability.
- Reference level
- Weighting

  The relative importance of criteria for environmental performance could necessitate the use of a weighting system for aggregation. The weighting system will vary depending on national, regional or local contexts and conditions and should provide a method for addressing such variances. If a weighting system is used, a method for addressing such variances shall be provided, justified and documented. The underlying data of the method shall also be documented. The weighting factors shall appear explicitly in the assessment method documentation.
- Aggregating results of measurement of environmental performance by multiple criteria.

  The environmental performance relating to a specific category of environmental issue of concern may be aggregated from multiple indicators. Aggregation methodologies may incorporate the use equivalency factors, which comply with generally accepted scientific or engineering principles, or weighting. Weighting should only be used if no such equivalency factors are available. The method used to aggregate the results of measurement of environmental performance by multiple criteria shall be consistent. Where ordinal data is used, it shall be stated whether there is a difference in the distance of the ranks.

4.6 Sources of information

The sources of information used in the assessment shall be clearly indicated in the assessment method documentation and shall be accessible to the interested parties of the assessment.

4.7 Evaluation and interpretation

A particular attention is paid to the possible choice for a “singe score” evaluation which is not necessarily relevant depending the use of the assessment.

4.8 Reporting of assessment results and report format

5 Conclusion Two – involving actors in the dissemination and the appropriation of standardized based assessment tools

When considering the figure below, the span of use of ISO 21931-1, very soon followed by another part including civil engineering approach, is very large. It is hoped, from the industry and building owners they will benefit quickly from this framework. A challenge could be launched "test and measure"- like with the help of SB organisation to make a learningful significant feedback from efforts of the construction community to improve, through the use of this framework, its global practices. Surely, impacts on the economic and social activity could come quickly.

Intended users of the assessment information	Intended stage

Figure 7— Interests of intended users of assessment information and intended life-cycle stages

Overview

The ISO Technical Specification **ISO/TS 21929-1** - **Sustainability in building construction — Sustainability indicators —** Part 1: **Framework for the development of indicators for buildings /** *Développement durable dans la construction — Indicateurs de développement durable — Partie 1: Cadre pour le développement d'indicateurs pour le bâtiment*

ISO/TS 21929 defines a framework for sustainability indicators for buildings based on the premise that sustainable construction achieves the required technical performance of the construction with the minimum of environmental impact. At the same time, sustainable construction encourages economic, social and cultural improvement at a local, regional and global level.
Indicators are figures or other measures that enable information on a complex phenomenon like environmental impact to be simplified into a form that is relatively easy to use and understand.
The three main functions of indicators are quantification, simplification and communication. Changes over time and the development of changes in relation to stated objectives can be monitored with the help of indicators. One of the important functions of an indicator with reference to decision-making is its potential to show a trend.

Indicators should be objective and the results should be repeatable.
When developing and selecting indicators, the starting point is the identification of the main users and user needs. Sustainability indicators for construction works are needed by a number of interested parties in the building and construction sector. Indicators are needed in decision-making by investors and owners of real

estate; occupiers and users of buildings; planners, developers and designers; manufacturers of products; contractors; facility managers and real estate agents; public bodies (housing, building, traffic, environment). The building and construction sector needs sustainability indicators both for its own decision-making within design, production and management as well as for indicating the economic, environmental or social impact of products and processes to the public and to clients.

The aim of this part of ISO/TS 21929 is to define the process that shall be followed when addressing the economic, environmental and social impacts of a building using a common framework and a set of indicators.

This part of ISO/TS 2192

- adapts general sustainability principles for buildings;
- includes a framework for the assessment of economic, environmental and social impacts of buildings;
- shows indicators as examples;
- shows how to use sustainability indicators with regard to buildings and shows the process of using
- sustainability indicators;
- supports the process of choosing indicators;
- supports the development of assessment tools;
- defines the conformity with this specification

This document is under revision both to consider integration of civil engineering aspects and to take into account the publishing of ISO 15392.

5- ISO 15392 Sustainability in building construction — General principles - Développement durable dans la construction — Principes généraux

5.1 Introduction

This International Standard, approved at unanimity in the very beginning of 2008, identifies and establishes general principles for sustainability in building construction. It is based on the concept of sustainable development as it applies to the life cycle of buildings and other construction works, from their inception to the end of life. Its application is dedicated to buildings and other construction works individually and collectively, as well as to the materials, products, services and processes related to the life cycle of buildings and other construction works.

Thus, it should be underlined that this standard provides neither levels (benchmarks) that can serve as the basis for sustainability claims,or the basis for assessment of organizations or other stakeholders. From the whole participants in this work, it would have been very uneasy to pretend to have written the only criteria for sustainable development. This standard is therefore written for an active experimental use.

Several notes explain the philosophy of the work:

- the principles established are intended to be applied broadly in the context of buildings and other construction works. Specific applications are the subject of other related international standards.

- buildings and other construction works are designed to meet numerous requirements, expressed and established in national and international standards or regulations. None of these requirements is replaced or changed by this international standard.

- sustainability aspects relative to organizations are sent back to future ISO 26000 (social responsibility).

5.2 Definitions

It is also relevant to focus interest on the definition of “sustainability” given is article 3.20:

sustainability

state in which components of the ecosystem and their functions are maintained for the present and future generations

NOTE 1 Sustainability is the goal of **sustainable development** (3.21) and can result from the application of the concept of sustainable development.

NOTE 2 In building construction, it relates to how the attributes of the activities, **products** (3.17) or services used in the **construction work** (3.7), or the use of the **construction works** (3.8), contribute to the maintenance of ecosystem components and functions for future generations.

NOTE 3 While the challenge of sustainability is global, the strategies for sustainability in building construction are local and differ in context and content from region to region.

NOTE 4 “Components of the ecosystem” includes plants and animals, as well as humans and their physical environment. For humans, this includes a balancing of key elements of human needs: the economic, environmental, social and cultural conditions for societies’ existence.

Finally, this document proposes the application of sustainability to building construction needs to reflect the context in terms of goals, priorities, preconditions, possibilities and constraints (such as poverty, accessibility and access to services). And, following the basis of the work philosophy of the SC17, it does not provide the prioritization, but recognizes that an application will balance the aspects according to overarching goals of development targets.

5.3 Structure of the document – Objectives and principles

For sustainability in building construction, the **objectives** and **principles** should be considered in their entirety, without regard to the prioritization of aspects. The extent, to which these objectives and principles can properly be addressed, also depends on the scope and the scale of the project. The significance and magnitude of impacts also may depend on and change with the life cycle stage under consideration.

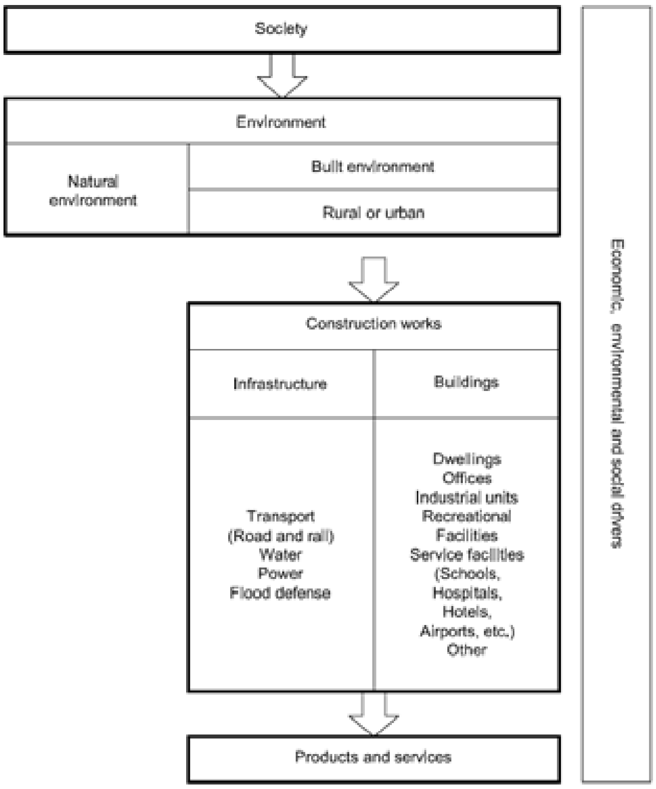

Figure 8 - Requirements posed to the built environment, its parts and related drivers

5.3.1 Objectives

Whilst applying the concept of sustainability to buildings and other construction works, and at the same time promoting sustainable development, the objectives are:

improvement of the construction sector and the built environment;

NOTE 1 Sectors interacting with and supporting the construction sector are to be addressed by the objectives where relevant, e.g. real estate sector, financial and insurance sector, transportation, etc.

reduction of adverse impacts while improving value, where impacts as well as value may be judged against any combination of the three primary aspects of sustainability;

NOTE 2 “Value” embraces performance, but is conceptually broader and is not intended to refer solely to “economic value”.

- stimulation of a pro-active approach;
- stimulation of innovation;
- decoupling of economic growth from increasing adverse impacts on the environment and/or society;
- reconciliation of contradictory interests or requirements arising from short-term and long-term planning or decision making.

5.3.2 Principles

The principles applied to reach the objectives are, without indication of importance and in alphabetical order: continual improvement, equity, global thinking and local action, holistic approach, involvement of interested parties and long term consideration, precaution and risk, responsibility, transparency.

9 principles	**global**	**local**
	(Global thinking and local action) *the consideration of the global consequences of local actions taking account of local and regional concerns, to ensure that:* a) when acting locally, the regional and global relevance and consequences are considered; b) when establishing and applying global strategies, the local implications, relevance, demands and resources are considered.	
Involvement of interested parties	*the taking into account of the contribution and requirements of interested parties relative to their respective areas of responsibility, and the timing of their involvement.* ☞Due to the nature of the building and construction sector and its products, a wide range of stakeholders has interest in this industrial sector and its outputs. These stakeholders may demonstrate significant differences in their appreciation and understanding of the building sector. Such differences explain the multiplicity of views that exist in the interpretation of sustainable development in the context of building and construction, particularly in terms of scope, content, level of detail, priorities, etc.	
Long term consideration	*the taking into account of the short-, medium- and long-term implications in decision making. As a minimum, it includes the following:* *a) performance over time (as the ability of fulfilling a defined level of function throughout the use phase);* *b) life cycle thinking (i.e. considering the consequences of a choice made in one stage of the life cycle, on the other stages);* *c) legacy – the consideration of the impacts that are handed down as a result of development. The legacy may extend well beyond the physical boundaries of the development.* ☞ The legacy can be physical (e.g. the buildings and infrastructure), environmental (e.g. environmental benefit or damage), social (e.g. cultural heritage, skills, capacity building) or economic (e.g. employment, economic growth).	
Precaution and risk	*the avoidance of risks by applying the precautionary principle, or considering the most unfavourable impacts through risk management.* - Precaution (avoidance of risks): The precautionary principle aims to avoid risks – it sets concerns of future generations as the basis for the analysis of risk potentials. ☞ Adoption of new technologies or new products should include a precautionary perspective without unduly compromising innovation. - Risk management (management of identified risks): Risk management is a set of coordinated activities including risk assessment, risk treatment, risk acceptance and risk communication.	
Transparency	*the presentation of information in a manner that is open, comprehensive and understandable and, like the underlying data, traceable, with verifiable credibility.* ☞ For sustainability of buildings and other construction works, transparency relates to information about products as well as decision-making processes. For that purpose, an appropriate review and verification route of relevant documentation may need to be established.	
Responsibility	*the moral responsibility for, rather than legal or financial consequences of, actions carried out by individuals or groups of individuals. The development of local skills and institutional capacity supports the sustainability of construction works.*	

Continual improvement *the improvement of all aspects of sustainability related to the built environment including the buildings and other construction works over time.* It includes the performance of construction works as well as processes, and addresses means of assessment, verification, monitoring and communication.	**Holistic (Systemic) approach** *the inclusion of all relevant and related aspects of sustainability when considering and assessing sustainability aspects of buildings and other construction works.* A holistic approach ad dresses all aspects of sustainability over the life cycle of the building or other construction works.	**Equity** *the balanced and objective consideration of intergenerational, interregional and intra-societal ethics, including environmental protection, economic efficiency and social needs.*

Illustration: a French view of "9 principles" applied to works and construction process :

Continuous improvement
Equity

	WORKS	PROCESS
Interested parties	Allow the progress of the foreseen activities at an acceptable price.	Build while taking into account all the interactors.
Long term	Allow an adaptation in order to face changes over time.	Plan over the whole life cycle of the built work.
Precaution	Contribute to the operation of the system at all the other spatial scales.	Minimize the negative impacts of the work and bring the corrective elements.
Transparency	Assist the users in their use practices.	Be ready to justify the choices which have been made.
Responsibility	Give responsibilities to the users so as to assume the good use of the works.	Assume the good use of the resources (including production means)

6- Difficulties and further standardisation works

Common language construction, as anyone knows since temps immémoriaux, is one of the most difficult exercise for standardisation experts. Lot of reasons for this : technical backgrounds, business views, regulatory background, cultural issues, etc.

It can be now acknowledged that the success of SC17 standardisation work, after some years of "try-to-know-each-others-meetings", comes from the will of each participants to bring the best of their knowledge and practices (experimental or building works/.production) to raise a bet : go toward a better world, more sustainable. The spirit of G.H. Bruntlandt probably.

New stages are to be crossed over, among which:

- integrating civil engineering : products, works, probably with another complementary approach linked to land management (anotherr level for sustainability).

- succeeded revision and getting more completeness for the building approach and the sustainability indicators setting up?

- involving more participation from South countries and welcoming UNEP as a full contributor, if possible.

- getting feedback from the existing and new experience from each actors and building up this expertise.

The ultimate goal is the SC17 work be brought to the whole users for their practical benefit, from the laboratory and manufacturer to the contractors and final clients.

Keywords: Funding, statistics, regulations, sustainable, building, planning, construction, operation

Summary

Norway's climatic conditions, low electricity prices, high standard of living and a relatively large building construction industry has resulted in a very high energy consumption per capita. The paper focuses on three major challenges concerning how to achieve more sustainable buildings, and describes the most important governmental policy instruments used to meet these challenges. The three major challenges are:

Planning.

Holistic planning and design are important. Sustainable building materials, building framing, site criteria, solar angle utilization etc. must be given high priority.

Construction

Good construction workmanship. Due to high construction activity construction periods have shortened and there is a shortage of labour, especially skilled labour. This has caused a massive import of foreign labour which has led to challenges regarding language and differences in building traditions etc.

Operation

Good operation implies effective energy monitoring systems and energy management etc. The Ensuring skilled maintenance staff is crucial.

Building regulations, EU building directives and Enova's funding programs are the main governmental instruments used in meeting these challenges. The paper presents a general view of how these instruments make an impact on planning, construction and operation. In particular, the paper describes Enova's programs, energy statistics and the impact these programs have on the above challenges.

1. Norwegian conditions

Number of degree days in Norway varies from 3442 to 7160, dependent on latitude and topography. The huge variation in the amount of energy required, is also due to the proximity to the Gulf Stream, as well as the length of the country (1200 miles from south to north). Due to the northern latitude (from 58 to 71 degrees), the solar angle during the summer season is low and this makes air conditioning units a normal solution especially in non-public/non-residential buildings.

Traditionally the use of electricity for heating in buildings in Norway exceeds 30 % of total electricity consumption pr. year. The main reason for this is that Norway historically has had access to cheap electricity due to a big national hydro-power industry. A mountainous country and precipitation conditions are the main reasons for this.

2. Three major Policy Instruments

The building sector represents 40% of the Norwegian overall energy consumption. Thus, the building sector can contribute to considerable reductions in CO2 emissions through more energy-efficient and sustainable buildings.

The authorities' initiatives to reduce energy consumption in buildings include stricter regulations and control requirements, an energy marking system and the establishment of Enova.

2.1 Directive 2002/91/EC – Norway adapts to EU Regulations

The Directive on Energy Performance of Buildings (Directive 2002/91/EC) of the European Parliament and of the Council of 16 December 2002 pertaining to the energy performance of buildings, states that the Member States must apply minimum requirements concerning the energy performance of new and existing buildings, ensure the certification of their energy performance and require the regular inspection of boilers and air conditioning systems in buildings.

The Building Energy Directive is designed to provide information to the purchaser or lessee about the building's energy performance. There are great expectations of this new directive.

The introduction of the Building Energy Directive in Norway is planned to be during 2008.

2.2 Technical Regulations – Public Authority Regulation

The Norwegian Government (public authority) regulates the building sector through national building codes. The building regulations are being revised every 10th year from 1987, thus the latest revision is from 2007(TEK 07). The latest revision lists detailed requirements for the design and properties of the climate shield and also functional demands for technical installations (lighting, heating and ventilation). It also describes two separate methods used to calculate maximum allowed energy consumption in new buildings. These methods are an Initiative Method and an Energy Framework Method. Both of these methods are supplemented by minimum requirements that must not be exceeded, regardless of the applied method.

2.2.1 Initiative method.

The initiative method has specific requirements for maximum energy requirements in building sections and technical installations. Exemption from one or several of the energy initiatives is permitted, provided that the compensatory initiative does not lead to an increased use of energy.

2.2.2 Energy framework method

This method sets requirements for the building's maximum energy requirements (net requirement). The limits are differentiated according to building category. The building regulations have stipulated ambitious energy framework requirements. The set requirement for office buildings, for example is 165 kWh/square metre, year.

The latest revision of the Norwegian Building Codes also stipulates a requirement that heating shall be provided by another energy source than electricity, provided this does not lead to extra costs beyond the building's lifecycle.

All buildings' energy requirements shall be documented at the planning stage via energy and effect budgets.

2.3 Enova - a Public Authority Policy Instrument

Enova SF is the government's most important environment-related project and the annual allocation to Enova is approx 250 million Euro. Enova provides support to projects that involve increases in energy efficiency or projects in which local and environmentally-friendly forms of energy are used. Enova is responsible for increasing the efficiency of energy consumption and for increasing the production of environmentally sound electricity and heat (renewable energy). Enova currently supports major projects within industry, domestic use, technology, remote heating, wind energy and construction.

Enova SF enters into goal-oriented contracts with property owners, construction firms and contractors in Norway. This is to ensure that the goals for a reduction in energy consumption and the transfer to renewable forms of energy are quantified in terms of kWh per year and that this goal is clearly stated in the agreement.

The energy figures must be verifiable. If the goals are not reached, Enova has the right to reduce the amount of financial support. When the project is completed, the recipient must provide a final report that specifies the actual, completed initiatives and the results achieved in the form of energy accounting. The final report shall also include a set of audited project accounts.

When Enova enters into a contract with an operator for energy-effective construction projects, the project is followed up by Enova's operating agent throughout all phases up to the completion and final commission.

The progress of a project supported by Enova may be thus:

The building owner holds an introductory meeting with Enova, along with an external advisor.

The building owner surveys the buildings, energy consumption and the potential for energy reduction.

The building owner applies to Enova for support in accordance with the funding programs.

Enova processes the application and issues a letter of acceptance.

Both the building owner and Enova sign the letter of acceptance.

The building owner is responsible for the completion of the project – this takes normally from 3 to 5 years.

The results are documented at the building object level and sent to Enova via a database. Statistics are collected and collated annually by Enova on the basis of the data from the database.

Table 1 Owner structure for buildings in Enova's statistics 2007.

Building owner	Heated floor space	Number of buildings	Average floor space
	m2		m2
State	3 551 990	405	8 770
County (public)	947 460	149	6 359
Municipality	3 209 426	937	3 425
Commercial	5 676 681	910	6 238
TOTAL	13 385 557	2 401	5 575

Enova's support is paid out after the initiatives are implemented, up to 4 times per year.

The level of support corresponds at the present to 0.08 Euro/kWh. This is a popular system for large, established companies. Both private and public building owners can apply for support.

All projects are followed up by Enovas own staff and operating agents.

Table 2 Buildings reported to Enova's statistics in 2006 and 2007. Decrease in energy consumption.

Building category	Number of buildings	Specific energy consumption Corrections made for temperature and location		Energy consumption decrease
		kWh/m2		%
		2006	2007	
TOTAL	1810	285	279	-2,3 %
Block of flats	40	227	246	8,5 %

Industry	98	333	319	-4,3 %
Storehouse	23	490	443	-9,6 %
Office	236	247	234	-5,3 %
Commercial building	370	426	428	0,3 %
Expedition building	43	330	319	-3,4 %
Garage	8	342	334	-2,2 %
Hotel	73	244	245	0,7 %
Motel	13	236	235	-0,1 %
Restaurant	8	299	297	-0,7 %
School	516	185	179	-2,9 %
University	41	315	282	-10,5 %
Laboratory	9	563	531	-5,7 %
Museums and library	6	237	237	0,1 %
Sports centre	45	275	261	-5,1 %
Culture building	16	267	237	-11,0 %
Church	79	279	284	1,9 %
Hospitals	45	328	317	-3,2 %
Nursing home	103	263	255	-3,1 %
Health care centre	10	214	212	-0,8 %
Prison	8	377	302	-19,9 %
Emergency centre	7	427	415	-2,8 %

Almost 50 000 companies exist within the building and construction industry. It is a notoriously difficult industry to influence. The public authorities expect solid results from Enova's cooperation with the market and there are great hopes that Enova can help and persuade the industry to increase their overall energy awareness.

Enova has since 2001 entered into approx. 500 contracts with major operators in the construction industry - these contracts represent approx. 20% of total business enterprises. Enova is a successful enterprise, exemplified by its large budget framework.

3 Planning Phase: What kind of Issues Influence Planning?

Holistic planning and design are of vital importance. Sustainable building materials, building framing, site criteria, solar angle utilization etc. must be given high priority. The consequences of wrong/poor choices at this particular phase are complex and costly, if they are to be rectified later.

3.1 Norwegian Building Regulations regarding Planning

The new building regulations of 2007 affect almost 10% of Norway's workplaces and the entire construction industry. New commercial buildings are directly affected by the regulations. The regulations are designed to have a major impact on the planning of new buildings. After the previous amendment to the Norwegian building regulations in 1997, national approval systems were introduced for both planners and contractors with self-control on both project planning and practical sides. An important experience has been that the system of self-control has led to construction of buildings of a considerably lower energy standard than that contained in the national building regulations as a minimum standard, with a consequent increase in energy consumption. This is evident, from among other sources, Enova's energy statistics. The introduction of an independent, third-party building control body is now under consideration.

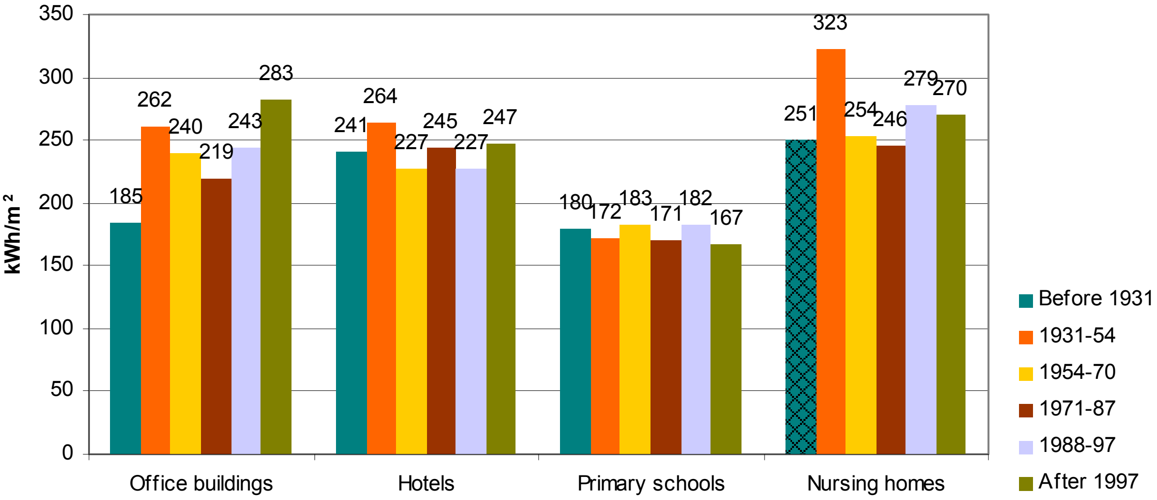

Figure 1 Specific energy consumption in 2006 by construction year for 4 of the largest building type groups (Corrections made for temperature and location). From Enova energy statistics 2006.

3.2 The Directive on the Energy Performance of Buildings in relation to Planning

The Building Energy Directive applies to buildings that are sold or leased and the directive thus has no direct influence on the planning of buildings.

The aim of the authorities, via the introduction of the directive, is to encourage builders, architects, consultants and real estate agents to plan for increased energy efficiency. The construction industry is sensitive to changes in the market and it is thus of vital importance that the energy marking system leads to an increased awareness concerning a building's energy qualities, such that buildings with a 'sound' energy label are especially sought-after and consequently easier to sell at higher market prices. It is feasible that property owners and contractors wish to offer the market a higher energy classification than the minimum standard contained within the Norwegian building regulations.

The organization and implementation of the energy marking system is of vital importance to avoid indifference to the system (which may be due to a lack of faith in the marking itself, lack of influence on the buildings' end users, i.e. no consequence of a 'lower class' mark). If the energy marking system does not succeed in becoming an important parameter in the evaluation of the qualities of a building, the mark will have little influence on the planning of new buildings.

3.3 Enova and the Planning Phase

Enova's goal is to influence operators, to encourage them to make demands for energy efficiency in the early phases of building projects. To be able to influence this phase, Enova has entered into project agreements with the operators that have the greatest influence at the early stage of construction projects. There are mainly major construction firms, property owners and larger contractors. The goal is to persuade these operators to demand stricter and verifiable energy requirements for new buildings.

A main consideration when entering into an agreement with Enova concerning energy-effective buildings is that the building owner is obliged to exceed the minimum requirements of the building regulations, in regard to energy consumption, in order that the project shall qualify for support from Enova. It is therefore required that the building project goes even further than the specific initiatives in the building regulations. In practice this will often lead to investment in on-demand control systems for technical installations.

Enova supports projects that set ambitious energy goals. The reference point is defined as "current practices" for annual energy consumption in a corresponding building category. "Current practices" is as defined in Enova's annual energy consumption statistics.

4 Construction Phase – the Issues that Influence the Construction Industry.

The construction industry is large, fragmented and has problems with language and cultural issues. Approx. 10% of all employment in Norway is within the construction industry and it is the second largest industry in the country. Approx. 50 000 companies are registered and 97% of these have less than 20 employees. It is a considerable challenge for the authorities to raise the quality of the construction industry and to influence a large number of these companies to cooperate with their plans.

The construction industry in Norway experiences the same high conjunctures as other industries and enterprises and there is constant competition for the supply of necessary labour. The solution for the building industry has been to import labour from the former eastern European countries, mainly Poland. Available figures from the authorities show that there are currently approx. 10-15 000 registered foreign workers within the construction industry, in the Oslo area alone. This type of situation in the labour market produces even greater challenges in the form of communication issues, work routines, professional performance and knowledge and an understanding of the importance of finer details in construction projects. One of the unintentional aspects of this situation is the risk for increased amount of energy used in building projects.

4.1 Building Regulations regarding Construction Phase - They are Not Respected!

A relatively high number of non-skilled workers, tight project deadlines and budgets contribute to (both intentional and unintentional) undesirable methods of construction that have long-term negative consequences for the energy consumption of buildings. Enova experiences that negligence occurs in both insulation and weather protection.

In order to compensate for cost excesses in the planning and building phases, simpler and less effective technical systems are installed. Energy-saving initiatives (regarded as costly) are omitted, as budgets have a tendency to “balloon”. The reason for this is that costs of future energy consumption are charged the lessees and many operators wish to build as cheaply as possible and sell at maximum profit. This is a situation that is not merely restricted to Norway. The purchaser/lessee thus receives a “cheap” building, however the operational costs of lighting, heating, ventilation and cooling are considerable in comparison with those actually attainable via modern technology.

The authorities have indicated that they will introduce more stringent regulations regarding the control of building sites. This type of control is controversial as the construction industry claims that it already has adequate measures in place. The authorities wish to prevent unscrupulous operators and will therefore introduce stricter controls for construction sites.

4.2 The Directive on Energy Performance on Buildings related to Construction

The Building Energy Directive applies to buildings that are sold or leased and so has no direct influence on the construction phase; however, the Building Energy Directive will motivate the industry to supply better products.

In the construction industry guarantee and compensation cases are significant areas of conflicts. Thus, increase in the level of skills, attitude training and control are important issues. In order that the Building Energy Directive will become known within the industry, a good deal of effort will be applied to information and training within the industry. The public authority policy instrument will actively contribute to construction industry organisations putting the Building Energy Directive on the agenda and informing their members. The Building Energy Directive’s influence on the construction phase is, as for the planning stage, dependent on the consequences of a ‘lower’ energy classification. If faith and interest in the energy classification mark is weak, then buildings will not be influenced by it. It is hoped that the energy classification will lead to better construction of buildings, better follow-up on site and less negligence.

4.3 Enova regarding Construction Phase – a Successful Policy Instrument!

Enova supports the major property owners, administrators and contractor companies that build more energy-effective buildings. Support is provided to contractors that build on their own behalf, or on behalf of others, that can document a high level of competence, major building programs and clear and ambitious goals. Enova has signed contracts with Norway’s largest private and public building firms, administrators and contractor companies. This is a successful program that has contributed to heightened competition and good results.

Through a contract with Enova, the project is secured against changes made as the project progresses. Enova has regular follow-up meetings concerning each project, from the point in time the support is allocated, via the planning and construction phases.

Enova’s support represents approx. 10% of the extra costs involved in incorporating energy effective solutions. Enova’s most important effect is however that the concept of energy-related, effective solutions becomes firmly embedded in the senior management of the property owners and/or construction companies and this seems to contribute to maintaining focus and status throughout the project period. Another important factor is that Enova’s support is reduced or withdrawn completely, if the operators fail to implement the energy-saving solutions that form the basis for the contract with Enova.

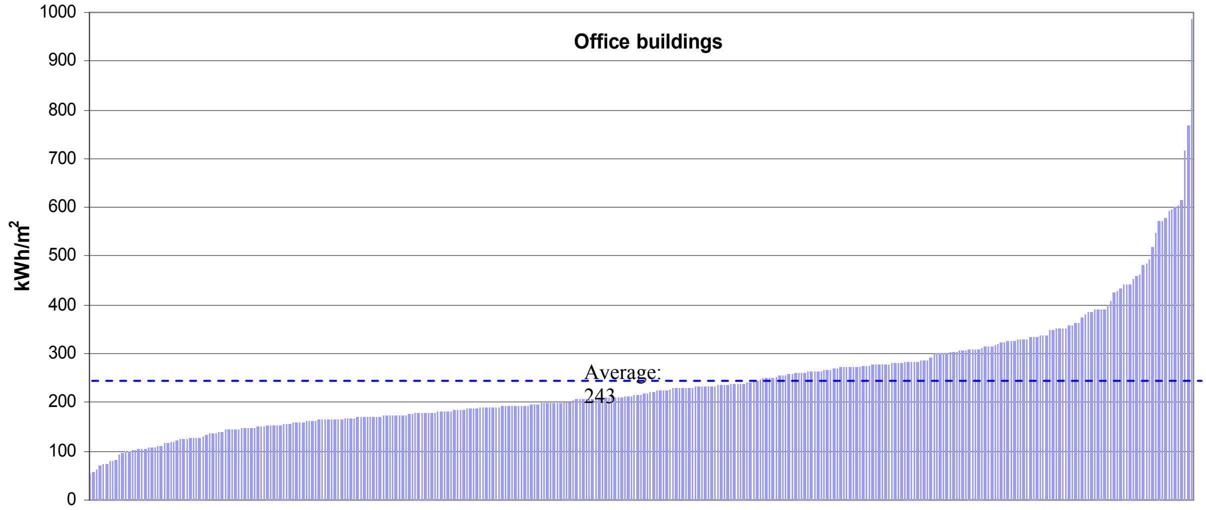

Figure 2 Enova's energy statistics. Specific energy consumption for 343 office buildings in 2006.

5 Operational Phase – a very Large and Complicated Market

Enova experiences that the phase from completion of projects and handover of finished buildings until the building has settled into a normal operational phase, is disproportionately long. Good operation necessarily involves energy monitoring systems and energy management etc. The reasons for this can be defined as follows:

Time constraints on operators during the handover phase.

The lack of coordination between the interface of technical professions and control systems. leads to the control systems functioning less than optimally, on handover.

The absence of operational personnel and lessees participating in the final phase of construction.

Lack of proper training of operational personnel in programming and use of control systems for technical installations.

Inadequate focus on the operational phase by planners, project managers and operational personnel.

Inadequate focus on follow-up. Delayed responses to rectifications and defects on handover often lead to unstable operations during the first year.

In order to change this trend it is of principal importance that greater focus is placed on the final phase of construction projects, such that the coordination of operation periods, temperatures, air flow and necessary training is carried out much more effectively. The construction industry has a great deal to learn in this respect, for example, from the Norwegian oil industry's methods and strict requirements concerning the handover of installations.

Table 3: Average heated floor area per "unit" for office buildings and primary schools in 2007, corrections made for temperature and location.

Building category	Number of buildings	Unit	Heated floor area [m2/unit]				Energy consumption [kWh/unit]			
			Average	Min	-	Max	Average	Min	-	Max
Office	10	Employee	40	10	-	71	9 030	3 007	-	20 084
Elementary schools	63	Employee	19	8	-	86	3 284	901	-	15 589

The division of technical infrastructure and systems, in combination with an on-demand control of lighting, heating, ventilation and cooling will lead to an energy-effective operation of installations.

One of the main premises of effective operations is, of course that the responsible operative personnel have been given adequate training in the use and controls of installations before the buildings are commissioned. The presence of skilled maintenance staff is crucial.

5.1 Building Regulations concerning Operational Phase

The building regulations' requirements are designed to influence energy-effective operations via the construction of buildings.

5.2 Building Energy Directive concerning Operational Phase

The Building Energy Directive is designed to influence customers that purchase or lease a building, to demand the most effective energy solutions.

2.1 million dwellings and 120 000 commercial buildings in Norway are to be given a classification 'mark' that is to be valid for a maximum of 10 years. This means that the certification must be renewed many times during the building's lifecycle. The energy classification will thus be an incentive to improve the building's energy properties during the operative phase. Just how much this will actually be the case, depends on how the energy classification influences the sale price of buildings.

If the market only will be based on the calculated normalized values and not the actual operating energy consumption, the energy classification mark will not have any influence on the effective use of the building's existing installations. The Norwegian Parliament will probably make the conclusions through a new Act during 2008.

5.3 Enova concerning Operational Phase

Enova's survey of several larger office buildings built after 1997 shows that energy consumption has been up to 20% higher than estimated during the first two or three years of operation. After the operations personnel have been given the necessary knowledge and training in the control of their 'own' buildings and technical installations, consumption has gradually become normalized.

In contrast to building regulations (TEK07) and the building energy directive, Enova stimulates operators to use more effective operative measures by optimising the use of the building's existing installations (for example, the adjustment of technical systems to the actual usage times of buildings). One premise for receiving financial support from Enova is that an energy consumption control system is set up to monitor the consumption of various types of energy relative to the outside temperature. The energy monitoring is carried out via registration of the collective net energy consumption per week and the values are measured against the average outside temperature for the same period. In buildings with several lessees, Enova encourages operators to meter the energy used at the actual place of consumption. This means that all lessees in an office building, shopping centre etc. is able to document their energy consumption each week. Via analysis of the collected data in these systems, it has become apparent that new buildings have unusually high energy consumption in the first and second year of operation, in comparison to the designed and estimated energy consumption.

Table 4 Share of buildings with Building Energy Management System

Building category	Building Energy Management System (Share of heated floor space, %)
Nursing homes	48 %
Office	45 %
Hospital	42 %
School	41 %
Commercial building	40 %
Sport centre	35 %
Expedition building	35 %
Industry	29 %
Hotel	26 %
Storehouse	18 %
Church	4 %
University	2 %

Enova supports the establishment of energy management and investments in initiatives. Energy reductions and conversion to new and environmentally-friendly heating systems is also supported. Great emphasis is placed on the reduction of the energy requirements and ensuring that the discharges of CO_2 are kept to a minimum. Norway's largest energy source for heating is electricity, followed by oil. Enova works purposefully towards the replacement of electricity and oil with remote heating, bio-energy and heat pumps. In addition, operators are stimulated to reduce heating demands to a minimum via effective climate shields, high-efficiency heat exchangers and automation systems that ensure that lighting, heating and ventilation systems are only in operation when there are persons present in the buildings.

6 Summary and Conclusions

Building regulations, EU building directives and Enova's funding programs are the main governmental instruments used in meeting the national challenges. On the basis of 7 years' experience with Enova and cooperation with the building industry, the following recommendations and conclusions are made:

There has been a very limited demand in the market for effective energy consumption in buildings, energy prices have been at a low level, combined with a surplus of electricity and fossil energy.

Enovas impression is that the building regulations are not followed especially in private office and hotel buildings in the period of 1997-2007. This is despite stricter requirements and a high level of expertise in the industry.

Despite good profitability and low additional costs for energy-effective solutions, these will not be implemented without stronger future involvement of public authorities.

During the last few years, new office buildings often have had a significant increased energy requirements compared to older buildings.

Enova has established a considerable amount of contacts within the construction industry, both within existing commercial operators and decision makers in the new building sector. Results have been comprehensive and significant.

At present time Enova's contribution to the reduction of energy use in Norway makes 8 % of the domestic stationary energy consumption.

Enova's support regime complements regulatory measures and has been a success that other countries can draw valuable experience from.

Table 5 Enova and regulatory measures' influence on energy in the building industry:

Buildings lifecycle	Building regulations	EU-directive	Enova
Planning phase	Expected great impact	Expected medium impact	Possible impact
Construction phase	Expected impact	Possible impact	Great impact
Operative phase	Indirect impact	Expected great impact	Great impact

NEW TRENDS IN SUSTAINABLE EDUCATION DESIGN

Sean McArdle BA (Arch), B. Arch (Hon).[1]

[1] Deakin University, Australia

Keywords: schools, education, sustainable design, Green Star, learning outcomes, curriculum integration

Summary

The focus in educational design is shifting from cost effectiveness, space efficiency and energy savings to 'fitness for purpose'. More attention is being paid to the qualities of the space and their ability to support the role of the teacher and to improve conditions and comfort for the learner. Many of these more tangible qualities can be categorised as Indoor Environment Qualities (IEQ). IEQ is a cornerstone of holistic sustainable design. If a structure must be erected then it should be designed to fulfill its role as well as possible. It should be economic in operation and environmental impact whilst maintaining high levels of comfort and function.

A shift in focus from financial to environmental is symptomatic of an increasing awareness in society of the issues in and around climate change. Educational institutions are taking the opportunity to lead by example and to provide education for the next generation in a more responsible manner. The design industry is responding with a more dynamic and integrated approach to design.

Sustainable Built Environments (SBE) is a unique environmental design consultancy firm consisting of both engineers and architects. Sustainable design opportunities must be pursued beyond the traditional boundaries that exist between the design disciplines. With a mix of disciplines working in collaborative teams, SBE can promote a more holistic approach to sustainable design. Some of SBE's current thinking on Educational design and some recent projects are discussed in this paper.

1. IEQ and learning outcomes

There have been several reports published over recent years linking improvements in Indoor Environment Quality (IEQ) to increases in productivity and learning outcomes. The Heschong Mahone Group (2003) has published a series of papers suggesting that in their studies increased levels of daylighting and ventilation have lead to improved child development and learning. Questions remain about the rigour of the analysis. The number of variables that would need to be isolated to determine with empirical certainty the proportion of influence of each IEQ enhancement is beyond comprehension. However, the report found across a significant sample that performance (learning outcomes) did appear to be improved in spaces with good daylighting and ventilation compared to a base case without.

A recent office renovation was completed at 500 Collins Street in Melbourne Australia. It was the first refurbished tall city office building in Australia to receive a 5 star Green Star Office rating in October 2006. There was a particular focus in the renovation on improvements to IEQ, including ventilation and thermal comfort. The owners of the building, Kador, commissioned a Post Occupancy Review (POE) of the renovation in terms of workplace productivity. The research was conducted by the firm 'Business Outlook and Evaluation' on two building tenants; law firm Oakley Thompson and stockbrokers Lonsec. The study involved staff surveys, examination of sick leave records, typing tests and billable hours ratios. Carbon dioxide and carbon monoxide levels, along with temperature and relative humidity, were also measured.

The results of the POE suggested

- average sick days per employee per month were reduced by 39%
- sick leave costs reduced by 44%
- speed and accuracy of typing increased
- lawyers' billing ratios increased, even as average hours declined

A similar study was commissioned to evaluate the contributions of enhanced IEQ to increases in staff productivity at the City of Melbourne's recently constructed 6 star office building, known as Council House 2 (CH2). The authors of the POE. Paevere P and Brown S (2008), claim that after one year of operation the City of Melbourne's staff productivity has improved by 10%, resulting in a cost saving of over $2 million in reduced sick days. In the report the author states "In terms of IEQ impacts on productivity, it is concluded that improved thermal comfort and air quality are likely to have had an enhancing effect on productivity perceptions."

It is generally accepted that IEQ initiatives such as improved thermal comfort, access to fresh air, daylighting without glare, eye relief and good acoustics can and do contribute to a person's sense of comfort within a building. If a person is comfortable they are likely to be least hindered or distracted by their surrounds when attempting to concentrate on a task and so should have a better chance to be productive in an office or to learn in a classroom.

2. Pedagogy and learning outcomes

Changes in teaching styles are leading to changes in classroom layouts and space requirements. The desire for spaces for large group, small team and individual working has taken classroom design away from the traditional cellular model of the past.

There are instances where changes to pedagogy and improvements IEQ can be complimentary. A series of well connected spaces can be easier to condition with cross flow ventilation. It can be easier to provide even levels of daylighting if there are fewer obstructions. Access to views and the potential for eye relief can be enhanced when spaces are opened up.

However, there are times when pedagogy and IEQ may be at odds. A pedagogical requirement for a large central space connected without walls to adjacent smaller spaces can present acoustic problems with a potentially detrimental effect on IEQ. Equally, the increasing demand for 'infinite flexibility' in the reconfiguration of spaces and the conversion of corridors into mode 2 learning spaces presents a serious challenge for design teams attempting to cater for all manner of unforeseen uses. The challenge for design teams will be to create buildings and spaces that accommodate and support both pedagogy and IEQ without wasteful over servicing and excessive energy use.

3. Ventilation and fresh air

Access to fresh air is an important consideration for classrooms. Much of Australia's climate is relatively benign and traditional classroom design has relied on openable windows as a primary source of ventilation. However, even in this benign climate there are times when ambient conditions will be unfavorable for open windows. In such cases windows are likely to remain closed and access to fresh air limited. Compounding this problem is the demand for high volumes of fresh air to a typically densely occupied classroom. According to AS 1668-2-1991 'Ventilation' a classroom requires 10l/sec/person of fresh air as a minimum (12 l/sec/person for students under 14). Given a classroom may conceivably accommodate 30 students or more the volumes of fresh air required begin to tally. Without a continual supply of fresh air CO2 levels will rise and a classroom will begin to feel stuffy. This is likely to hinder learning outcomes. The Green Star Office design tool V3 developed by the Green Building Council of Australia suggests that where CO2 levels can be monitored they should be maintained within a range of 640 ppm to 800ppm for optimum comfort.

A classroom should not be sealed up and unventilated in order to ride out periods of unfavorable ambient condition. Instead, good educational design should ensure students have access to guaranteed increased rates of fresh air throughout the year. The Education version of the Green Star design tool mentioned above awards projects with points for achieving guaranteed levels of fresh air provision at 50, 100 and 150% increases over the minimum stipulated in the Ventilation standard. Where passive ventilation measures are insufficient to guarantee these fresh air rates all year a back up ducted ventilation system becomes necessary. This is known as a hybrid ventilation approach.

Ducted ventilation offers some advantages over purely natural. Ducted ventilation allows fresh air rates to be controlled and maintained in adverse conditions. A ducted ventilation system can introduce untreated outside air into a space at a greater range of temperatures than an openable window. For example, 14° air striking a person from an adjacent window may be uncomfortable whereas 14°C air delivered up high into a space can mix with (and be diluted by) the existing air before it strikes a person.

Ducted ventilation also enables fresh air to be filtered, tempered and modulated. A ducted system can avoid the acoustic problems associated with openable windows and finally it can permit secure and automated night purging of a building.

4. Comfort with less energy

Some would say that providing air conditioning for children sends them a poor message and gives them unsustainable expectations. Others would argue that providing good levels of comfort will help improve learning outcomes and that if energy is required to do so then it is energy well spent.

Both schools of thought need not be contradictory. Good thermal comfort does not necessarily require traditional energy intensive air conditioning.

A perception of thermal comfort is influenced by several factors:

- Air temperature,
- Radiant temperature of adjacent surfaces,
- Relative air velocity,
- Humidity,
- Activity levels, and
- Clothing.

By careful attention to building design and local climate response many passive opportunities can be harnessed to target these contributors to thermal comfort without consuming energy.

Examples of passive comfort contributors:

- By orientating and shading a building in the appropriate manner the impact of unwanted heat from the sun can be reduced.
- Effective insulation and the use of improved glazing in a space can reduce the number of surfaces that may radiate cold into a space on a cold day (or heat on a hot day). At the same time having exposed thermal mass within a space can help absorb heat in summer (effectively radiating 'coolth') and improving comfort.
- Permitting sun to radiate into a space in winter can provide warmth and a sense of comfort, even if the air temperature is lower than normal.
- Having good levels of air movement can allow the skin to cool itself with the evaporative effect, permitting higher than normal air temperatures to be perceived as comfortable.

By tackling these contributors to thermal comfort the reliance on a controlled air temperature can be reduced. An indoor air temperature range of 20-26°C can be perceived as an acceptable and comfortable based on this approach.

When air temperatures threaten to fall outside an accepted range tempering may be required. Tempering can be provided by low energy means such as labyrinths, solar air heater, night sky cooling and flushing a building at night with cool outside air to recharge internal thermal mass.

If low energy tempering systems prove incapable of maintaining comfort throughout the year low energy active systems should be explored. These might include evaporative cooling, low energy radiant heating and cooling systems (such as hydronic heating and chilled beams).

By making the energy consuming active component the last in the list of comfort control measures a project stands a better chance of providing comfort with less energy.

5. Other current trends

5.1 Curriculum integration

By making systems visible and their function apparent students can begin to learn about sustainability issues. With appropriate metering and monitoring systems students are offered the opportunity to link cause with effect and action with consumption (or saving). The availability of detailed and easy to comprehend building user guides and metered data will allow teachers to introduce the building and its ongoing operation into the curriculum. The building can become an aid to teaching, a 3D textbook.

This enterprise has two important consequences. As well as teaching students about sustainability it also makes it clear to both students and parents that the educational institution values the issue of sustainability.

5.2 Materials

Concerns about Volatile Organic Compounds (VOCs) arising from off gassing of materials and finishes has encouraged an industry of low VOC alternatives for applications ranging from paints to sealants, adhesives, finishes and furniture.

Concern over the origin of materials and their environmental impact is also rising. The specification of timber from sustainably managed forests is a case in point. The independently monitored standard of the international Forest Stewardship Council (FSC) has become the accepted indicator of a stick of timber's sustainability status.

Third party certification of the environmental credentials of a material or product will make environmentally responsible specification an easier and more certain task in the future.

5.3 Controls

There has been some call for designs to move away from complicated engineering systems and automated controls back to good passive design, basic active systems and manual control. This approach works particularly well in classrooms where the occupants are permanent, as in a primary school. In such cases the students are able to take ownership of the classroom and are able to closely monitor and manage the operation of systems such as opening and closing windows, blinds, fans, lights etc. Students can take charge of comfort within the classroom and become champions of their local environment.

In secondary and tertiary instructions where a classroom's occupancy is transitory the same approach can be problematic. A lack of ownership of the space will mean occupants are less likely to take the time and trouble to learn about the space and operate it to its full potential. Automated systems (with manual overrides) can help ensure systems are not left on when the room is unoccupied.

The ability to take some control of the local environment grants the user an increased perception of comfort and a level of satisfaction that is worth pursuing. A balance needs to be struck between automation and manual operation. The best solution might combine automated control with temporary manual override of systems such as lighting, ventilation and comfort.

5.4 Transport

The combined impact of children’s transport to and from school has the potential to be greater than the operation of the classroom itself. Schools should seek to encourage the use of public transport and to discourage use of the car. Alternatives such as walking and cycling should be encouraged by enhancing connections to adjacent paths and routes as well as by providing adequate storage and change facilities.

5.5 Community Use

By making Educational Facilities available for use out of hours by others the need for additional community facilities may be displaced. It is better that one building is used for longer hours than two intermittently. Interestingly, this increased use may alter the servicing solution so opportunities for integrated community use are best considered during the design phase

6.0 Future trends

6.1 Design tools

In the past, sustainable design may have been evaluated using different methods of measurement with varying levels of rigour and to different standards. With the advent of widely accepted design evaluation methods, such as the Green Star suite of tools, agreed benchmarks have been established.

The Green Star tool requires the design assessment to take into account a set of protocols for the standardisation of variables (such as times of occupancy, clothing, activity, internal gains and green house gas emission coefficients etc). With this approach it is possible to compare one design’s predicted environmental performance with another on a fair and even basis.

Using agreed protocols and pre-set variables will limit the accuracy of the predicted performance of a building. For example the hours of occupancy must be standardised to an agreed set of days (and times). For the Green Star Education tool this equates to Monday to Friday for the entire year. However, in a Victorian school it is usual for a school to be closed during January. Because of this the predicted performance from the Green Star tool may vary from actual.

Calls for design assessments that are closer to actual performance misunderstand the value of a common assessment method that permits fair benchmarking and relative comparison. With fair benchmarking comes the added incentive of recognition both national and international.

6.2 Carbon Neutral and Autonomy

A Carbon Neutral school may become a reality. To succeed the primary focus must be on reducing the school’s demand for energy. After all passive measures are incorporated and sources of free energy adopted (such as the solar air heater, labyrinth and thermal mass examples listed above), efficient active systems should be explored and only after that should on site generation be contemplated.

Subscribing to the purchase of accredited Green Power might be a more practical alternative to on site generation in many instances. However, the benefits of onsite generation are social as well as environmental. With a properly metered and monitored Photo Voltaic (PV) array students can observe the passage of the sun and the impact on generation capacity through the day and the seasons. If supply and demand can be tracked simultaneously on a visual display then students have the opportunity to learn valuable lessons about cause and effect and the consequence of actions.

SBE’s recent educational work has concentrated on providing classrooms with good levels of comfort and reduced energy consumption. After introducing a suite of passive and efficient active systems (including evaporative cooling) on a recent Victorian school project it became apparent that lighting and heating were the two remaining areas of significant energy consumption. Sourcing environmentally free heat (from solar hot air collectors for example) became an initiative worth pursuing as a result. Investments in lighting efficiency were also explored, including more efficient luminaires, time and motion sensing and switching and daylight dimming.

With the above building operating comfortably and with a reduced energy demand it became conceivable that it could be provided with a degree of autonomy (in terms of energy demand). The project explored the opportunity to match the base building load with an appropriately sized Photo Voltaic (PV) array. It was proposed the PV array be linked to the grid as an insurance against occasional peak loads or intermittent spikes of demand. At the time of authoring this paper the project was in budget review. Suffice to say that without access to additional funding the likelihood to installing a PV array is low.

In December 2007 England's Schools Secretary Ed Balls announced 200 new Educational projects, costing £110m over three years. Each will include using greener technologies such as wind turbines, solar power and biomass boilers. Under the ‘Children's Plan’, there is a target for all new school buildings to be carbon neutral by 2016.

On 8 May 2007 the Australian Government announced a $150 million extension to the Photovoltaic Rebate Program over 5 years, bringing the Government's total investment in photovoltaic rebates to $201.8 million.

6.3 Outcomes

If a child learns at their optimum in a comfortable classroom and in the process about how to live in a sustainably responsible manner then a school or classroom could be said to have delivered a very worthwhile outcome.

The ultimate Holy Grail for educational design would be the ability to link investments in improved IEQ to improved learning outcomes in a measured and empirical manner. If a value could be placed on learning outcomes then justifying the initial investments in improved IEQ would be a matter of course.

7.0 Conclusion

Sustainable design is an interesting and evolving field. There appears to be many new and innovative approaches to servicing buildings and enhancing comfort and productivity while using less energy. However, the most cost effective design influences are also the oldest. The importance of good passive design has been rediscovered. SBE's founding director, David Oppenheim, himself a recognised pioneer of solar design in Australia, would have said that we were on the right track if we were adopting the lessons of our ancestors and applying in his words 'nanna' technology'.

8.0 Some examples of recent work

SBE has a large portfolio of educational work in design and under construction at present. We have explored many of the ideas discussed above in some of the following examples.

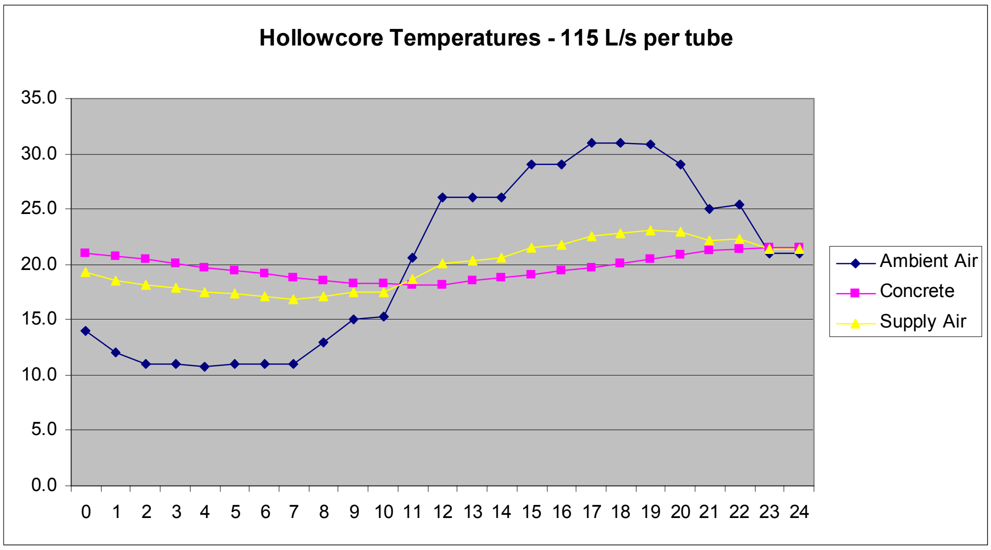
8.1 Dandenong Education Precinct (DEP)

Then DEP project involved the design of a 200 student self contained teaching building that could be replicated a number of times to cater for the growth of an Education Precinct over a number of years. Each teaching building is known as a 'Schools within Schools' (SWIS) and has two storeys with classrooms and staff offices opening off a central studio like space.

The Architects, Hayball Leonard Stent, have deployed the latest thinking on Pedagogy in the building's design. The mix of open and semi enclosed spaces enables activities of different sizes to take place in a range of locations and configurations. Instead of having one teacher and 30 students there are six teachers and 200 students working in flexible group arrangements.

The open planning will present acoustic challenges and these will be addressed with a series of acoustic panels on walls and ceiling as well as absorbent partitions and furniture.

This building has achieved a guaranteed 50% improvement on fresh air rates and a daylight factor of 2.5 for over 60% of the floor plate. Thermal comfort has been achieved by a combination of good passive solar design and orientation, good shading, increased levels of insulation, improved glazing, free cooling from the active use of thermal mass (hollowcore) and evaporative cooling. With evaporative cooling the building will be able to maintain comfort for up to 90% of the occupied hours in February, the hottest part of the school year. Night purging recharges the building's internal thermal mass with coolth in summer.



Free Summer Cooling. This option utilises the "Hollow-core" floor slab, planned for the first floor of the SWIS building, to pre-condition the ventilation air. Fresh air is drawn through tubes cast into the Hollow-core slab by an auxiliary fan and delivered to the air distribution system: in summer this process will cool the air and warm the slab. At night, cool air is drawn through the slab to "re-charge it ready for the next day.

The building has a predicted energy consumption of 397 MJ/m2/annum or 77 kg/CO_2-e/m2/annum, which equates to 5 points in the energy calculator for the new Australian Green Star Environmental design assessment tool for Educational Facilities. The building is targeting an overall star rating of 4 stars (Australian Best Practice).

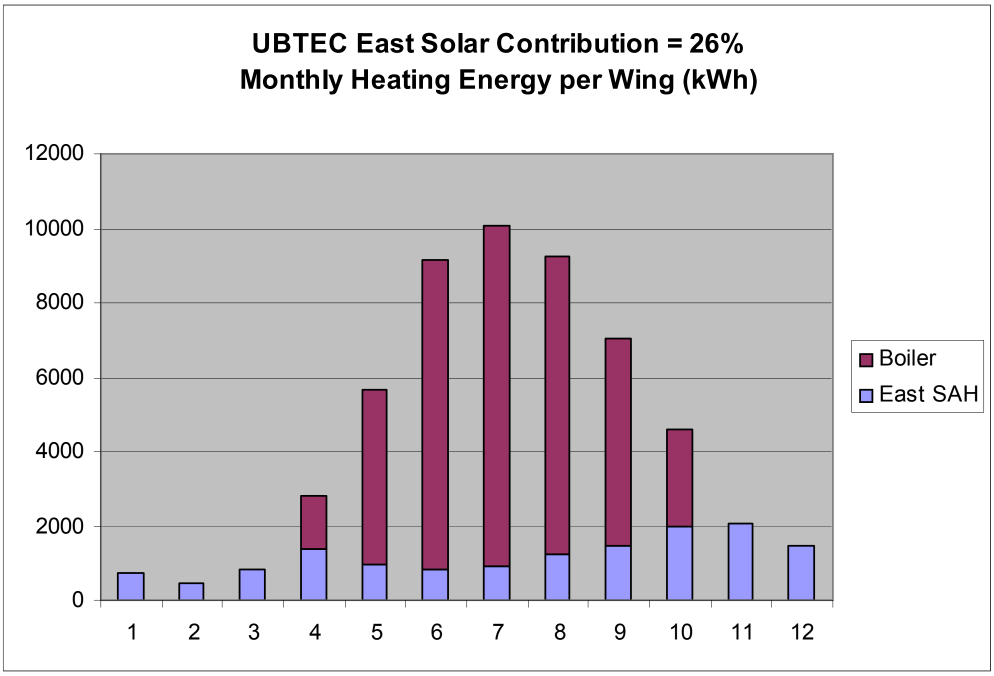
SWIS. *Image courtesy of Hayball Leonard Stent Architects.*

8.2 University of Ballarat Technical Education Centre (UBTEC)

The University of Ballarat Technical Education Centre (UBTEC) is aiming for a 5 star Green Star Education rating. The building will cater for the general education of first year apprentices. The building will have designated classrooms as well as centralised shared spaces for informal learning, computing and socialising.

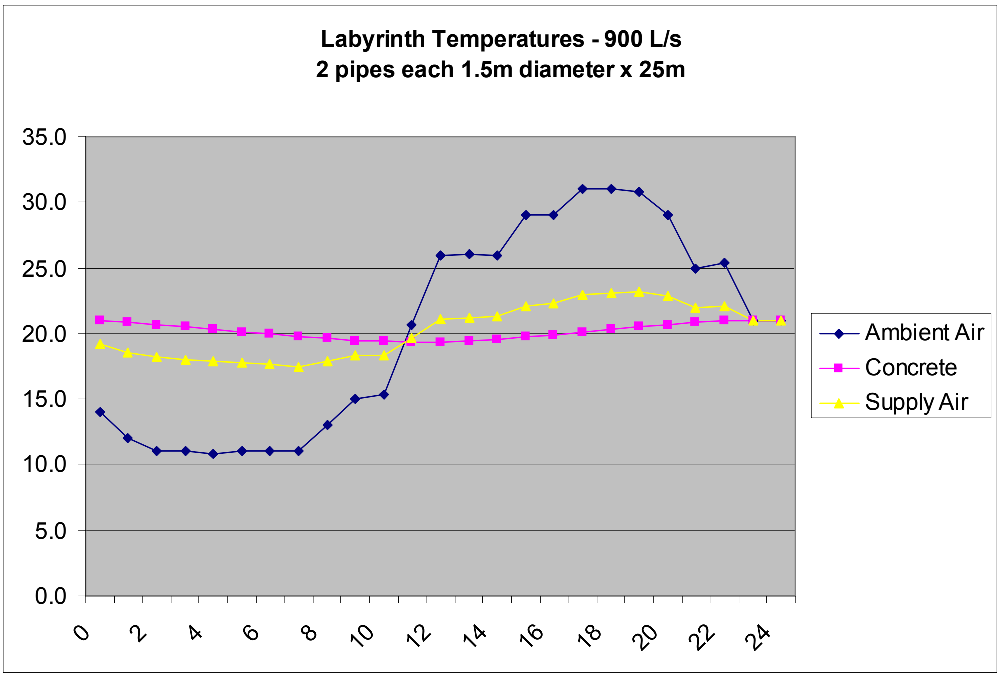
A fundamental influence on the design of this building was the desire to guarantee consistent levels of fresh air and thermal comfort. The building will deliver a guaranteed 50% improvement on fresh air rates compared to the relevant Australian Standard and will achieve Predicted Mean Vote (PMV- Accepted measure of comfort) of +/-1, which is the design target for a high grade city office tower.

The building features a ducted ventilation system linked to a thermal labyrinth and solar air heaters. The labyrinth tempers the fresh air supply in summer and the solar air heaters in winter. The solar air heaters facing east are designed to assist with morning warm up and it is anticipated they will satisfy 26% of the annual heating demand of the building.



This graph shows the expected contribution of the East facing Solar Air Heater (SAH) to building heating loads. The model allows for a number of cloudy days per month and only counts the contribution if there is a load to offset. i.e. During summer there is available solar energy that cannot be used.

The labyrinth under the building is designed to help temper ventilation air in summer before it is delivered into the building. It is anticipated the labyrinth will reduce ambient temperatures by 5-7°C on a 32°C day.



Free Summer Cooling. This model shows the impact of the labyrinth as proposed. At 4pm, outside air is cooled from 29°C to 22°C. The velocity of air through the concrete pipe is approximately 0.25 m/s, thus taking 100 seconds to pass through the full length.

The building is open over two floors and achieves a daylight factor of 2.5 to over 60% of the useable floor area.

The high levels of daylighting, fresh air and thermal comfort achieved will compliment the flexible teaching and learning models being adopted in this building.

This building will feature a series of metered and monitored systems connected to a visual display to teach occupants about the building's operational and the energy and water savings being achieved during operation. The surrounding landscaping features a purpose designed 'wetland' that will help detain and filter peak stormwater flows thus reducing the impact on the local stormwater infrastructure and ensuring that stormwater leaving the site has been filtered and cleaned to an acceptable level.

The building has a predicted energy consumption of 151 MJ/m2/annum or 48 kg/CO_2-e/m2/annum, which equates to 5 points in the energy calculator for the new Australian Green Star Environmental design assessment tool for Educational Facilities. The building is targeting an overall star rating of 5 stars (Australian Excellence).

8.3 Environmental Design Standards.

SBE recently authored new Environmental Design Standards for the Victorian Department of Education in Australia (now called the Department of Educational and Early Childhood Development – DEECD). These new standards incorporate measureable environmental performance requirements. They will provide the Department with the opportunity to mandate a level of environmental performance that can be benchmarked against national and international best practice.

The department has taken into consideration the recent focus on learning outcomes. They will use their new design standards to mandate environmental design initiatives that will improve access to fresh air, thermal comfort and daylighting and in so doing will lead to improved learning outcomes.

The new Design Standards are designed to interface with the Australian Green Star Education tool, and will reference its various calculators and benchmarks where useful. In this way the DEECD Standards will adopt the accepted industry jargon and will maintain currency as the Green Building Council of Australia have undertaken to keep the suite of Green Star tools updated.

Redevelopment of Public Rental Housing Estates in Hong Kong

Mrs. Connie Lai, Chief Planning Officer
Hong Kong Housing Department

Summary

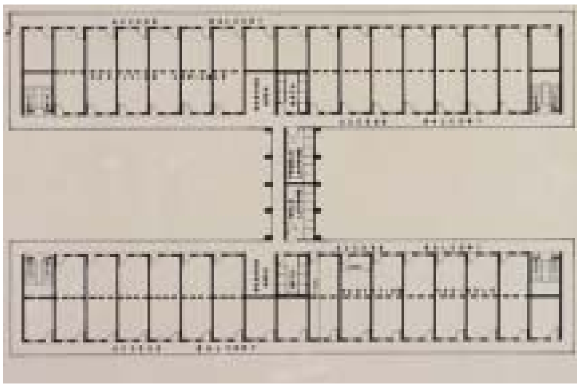
In response to the growth of economy and increased housing demand, the Hong Kong Government prepared the 'Long Term Housing Strategy' (LTHS) to review the housing policies in 1987. One of the key policies under the LTHS was to establish a Comprehensive Redevelopment Programme (CRP). The target of CRP was for the Hong Kong Housing Authority (HA) to redevelop 57 public rental housing estates built before 1973. After 21 years of redevelopment, the CRP has achieved its objectives of improving the living environment of the residents. However, it also exerted a heavy drain on land, manpower and financial resources. As such, the Government recognized that in future, redevelopment should be undertaken only when necessary to replace housing blocks which were no longer safe or economic to maintain. This principle was reinforced by the HA in 2005. Safety and cost-effectiveness are the major considerations in determining the sustainability of existing public rental housing estates. To ascertain the condition of the estates, the HA will conduct comprehensive structural appraisals for estates which are over 40 years old where there are often soaring maintenance and repair costs. For estates which remain structurally sound but require functional improvements, appropriate works will be arranged so that no further major structural strengthening will be necessary for at least 15 years. This paper will examine the impact of CRP on public housing development since 1988 and highlight the future plans for sustainability of public housing in Hong Kong.

1. INTRODUCTION

Comprehensive redevelopment of old public rental housing estates contributes significantly to urban renewal in Hong Kong. It marks the era of success in providing self-contained public rental flats, as well as improving the living environment of millions of residents.

Shek Kip Mei Fire in 1953

Public housing initially emerged in the form of transit housing, i.e. the resettlement estates following the disastrous fire at Shek Kip Mei in the Christmas Eve of 1953 when over 53,000 people were left homeless overnight. The old resettlement estates were the 7-storey Mark I & II blocks with communal toilet facilities between two linear blocks.



Typical Floor Plan of Mark I Block

Mark I blocks in Shek Kip Mei Estate

With the influx of immigrants from Mainland China, the demand for public housing increased throughout the 1950's and 1960's and these transit housing gradually turned into a form of permanent housing. A total of 240 Mark I & II blocks in 12 estates were built during the period. By 1970's public housing blocks have evolved from Mark I & II to Mark VI. In 1972, the Government announced the Ten-year Housing Programme with a view to providing permanent self-contained flats in a reasonable environment by building new public housing estates and redeveloped the non self-contained Mark I & II blocks.

Mark VI blocks in Lam Tin Estate

In April 1973, the new Hong Kong Housing Authority (HA) was established by the Government to develop and implement the public housing policies and programme. The HA is responsible for all aspect of public housing developments including the public rental estates, Home Ownership Scheme (HOS) flats for sale, flatted factories and ancillary commercial and other non-domestic facilities. To implement public housing development, the Housing Department (HD) was formed to act as the executive arm of the HA.

In 1980, about 45% of Hong Kong's population lived in public housing estates. The HA initiated a review of the structural condition of its housing stock, which indicated growing maintenance problems with the old estates. The first survey in March 1984 showed that approximately half of the buildings inspected at that time were likely to require significant repair work. As a further follow-up action, a more intensive structural coring survey was conducted which recommended the HA to demolish 26 structurally unfit blocks. To enable such large-scale demolition to proceed, an ***Extended Redevelopment Programme (ERP)*** was developed, giving priority to rehousing the affected residents in the same district wherever possible within 3-year period. This required the urgent acquisition of supplementary public housing sites in addition to offering residents priority status to purchase their own flats through the Home Ownership Scheme (HOS), where available without affecting the programme of redeveloping the Mark I & II blocks.

2. COMPREHENSIVE REDEVELOPMENT PROGRAMME (CRP)

In 1988, the **CRP** was drawn up after the announcement of the Long Term Housing Strategy (LTHS) in April 1987. It recommended that redevelopment should be extended to clear all older public housing stocks including all Mark I to VI Estates and Former Government Low Cost Housing Estates.

2.1 Objectives of CRP

The objectives of redeveloping the old public rental housing stocks include:

- To improve the living conditions and liveability of the public housing estates.
- To optimise the development potential of the individual housing sites.
- To implement comprehensive social and environmental improvements.
- To stimulate revitalisation of the larger community.

Priorities for redevelopment are determined largely by the availability of reception estates, structural conditions, age and build-back potential of the old estate.

Reprovisioning of social welfare, school, transport and commercial facilities are all carefully planned to avoid creating serious disruption to the local community.

Tsui Ping Estate (Before)

Tsui Ping Estate (After)

In view of the massive scale of the CRP involving clearance of over 560 domestic blocks affecting 240,000 households and 630,000 persons, it has to be executed by phases from 1988 to 2009. The redevelopment programme is being reviewed periodically to suit the changing circumstances. A 5-year Rolling Programme is announced at the beginning of each financial year to keep the public informed of the planned redevelopment operations over the period. The following Table 1 shows the progress of the CRP since 1988. The whole Programme will be completed by 2009 with only 7 blocks or 5,410 flats remain to be cleared as at March 2008.

Table 1. Progress of Comprehensive Redevelopment Programme (CRP) (as at 31.3.2008)

Redevelopment Programme[Note 1:]	Year	No. of Blocks Cleared	No. of Flats Cleared	No. of Persons Affected[Note 2]
Completed CRP	1988 - 97	326	138,340	391,710
	1997/98	33	14,810	37,200
	1998/99	35	15,490	35,620
	1999/00	17	5,870	14,680
	2000/01	49	13,590	36,180
	2001/02	55	32,360	66,880
	2002/03	9	4,510	11,760
	2003/04	7	5,170	9,930
	2004/05	4	490	1,000
	2006/07	15	2,170	3,750
	2007/08	9	5,480	13,970
Sub-total for completed CRP		***559***	***238,280***	***622,680***
Remaining CRP[Note 3]	2008/09	(7)	(5,410)	(8,840)
Total for CRP		***566***	***243,690***	***631,520***

Note 1 : Based on Completion Report of CRP, HD.
Note 2 : Figures excluding residents already moved out before the target evacuation date.
Note 3 : (No.) of blocks, flats and persons not yet cleared.

2.2 Process of Redevelopment

Redevelopment of a large estate operates in cycles. A reception site must be identified, wherever possible, in the nearby area or within the estate due for redevelopment to rehouse tenants affected by the first phase of the redevelopment scheme. Once the affected tenants are rehoused to the new blocks, the old buildings will be demolished and the vacant site will be used for building reception flats for the subsequent phase. This process continues until completion of the whole redevelopment scheme. Some large estates take more than twenty years to complete the whole redevelopment process.

The redeveloped estates are planned to be self-contained with basic necessities such as retail and social welfare facilities, local open space, primary schools, car parks and Public Transport Interchange etc. During the redevelopment process, views and expectations of the local residents and District Councils are seriously considered and taken into account, wherever appropriate, by the HA. As such, tenants moving in the new redeveloped estates can enjoy a better quality of living and healthier environment.

The ensuing paragraphs highlight the HA's established policies to assist the removal of domestic and commercial tenants.

2.3 Arrangement for Domestic Tenants

In order to minimize disturbances, the HA gives sufficient notification to the affected tenants through annual announcement of the 5-Year Rolling Programme and formal notification of about 18-24 months prior to the target evacuation date. Tenants are offered designated rehousing within the same district as far as practicable. Their preferences for other districts will also be considered if resources are available. Face-to-face interviews with tenants to identify individual problems are conducted after formal notification. CRP tenants are given priority to purchase Home Ownership Scheme (HOS) flats. Financial assistance in the form of Domestic Removal Allowance is payable to assist tenants to meet part of the removal cost as well as decoration expenses.

Briefing of redevelopment arrangement to tenants

2.4 Arrangement for Commercial Tenants

Commercial tenants will have their existing rent levels frozen upon formal notification which is about 18-24 months prior to the target evacuation date. They are granted an ex-gratia allowance as compensation for disruption of their established business. In addition, they are allowed to participate in restricted tender exercises so as to acquire alternative non-domestic premises in other public housing estates to continue their business. A three-month rent-free period in the newly acquired premise is also granted. For those who relinquish their opportunities to take part in the restricted tender exercises, a lump sum payment in lieu is paid.

2.5 Community Support and Involvement

Service teams led by professional social workers are set up to provide community services required by the affected tenants. The HA will line up representatives from other government departments, Non Government Organizations and volunteers to form an 'Elderly Removal Working Group' to assist the needy elderly in their removal. Special cases will be referred to the Social Welfare Department for provision of counselling service or other assistances required by the affected tenants.

Volunteers assisting elderly removal

Liaison meetings with District Council members, Mutual Aid Committees, local leaders and concern groups are regularly held from time to time with a view to consult and inform them of the redevelopment arrangement for domestic and non-domestic tenants for each CRP operations.

2.6 Achievements of the CRP

After 20 years of redevelopment, the CRP has achieved its objectives of clearing all the oldest public rental housing estates in Hong Kong. It also enables large families to split into smaller units and rehoused within the same locality. Family ties and relationship with neighbours can be maintained.

The quality of public housing has also improved significantly through redevelopment. The newly redeveloped estates are all self-contained with adequate local open space, car parking spaces, commercial, social welfare and community facilities. Tenants enjoy higher standard and better quality of living environment.

New Public Rental Housing Estate

2.7 Problems of CRP

In 1998, the 'White Paper on Long Term Housing Strategy in Hong Kong' ('the 1998 Strategy'), recognized that the large-scale CRP has exerted a heavy drain on land, manpower and financial resources. As shown in Table 2 below, about 30% of the new public rental flats were allocated to the CRP affected tenants during the first decade of the Programme. This arrangement had greatly reduced the allocation opportunities to other needy categories like waiting list applicants.

Table 2. Allocation of HA's Public Rental Flats (by percentage)[1]

Year	Rehousing Category				
	Waiting List	Clearance[2]	CRP	others categories[3]	Total
1987/88	38%	26%	23%	13%	100%
1988/89	38%	15%	26%	21%	100%
1989/90	43%	16%	32%	9%	100%
1990/91	35%	25%	30%	10%	100%
1991/92	38%	21%	33%	8%	100%
1992/93	44%	15%	28%	13%	100%
1993/94	43%	14%	33%	10%	100%
1994/95	38%	25%	20%	17%	100%
1995/96	39%	13%	29%	19%	100%
1996/97	31%	20%	31%	18%	100%
1997/98	38%	15%	29%	18%	100%
1998/99	58%	6%	14%	22%	100%
1999/00	49%	4%	32%	15%	100%
2000/01	50%	1%	38%	11%	100%
2001/02	65%	2%	15%	18%	100%
2002/03	66%	0%	11%	23%	100%
2003/04	71%	0%	1%	28%	100%
2004/05	67%	1%	3%	29%	100%
2005/06	65%	1%	5%	29%	100%
2006/07	66%	1%	5%	28%	100%
Overall Average	49%	11%	22%	15%	100%

Notes:
1. Figures exclude applicants joining the Rent Allowance for Elderly Scheme and Buy or Rent Option Scheme.
2. **Clearance** includes clearance from Squatter Areas / Temporary Housing Areas / Cottage Areas, Interim Housing / Temporary Housing Areas trawling and Urban Renewal Authority.
3. **Other Categories** include 'emergency', 'compassionate', 'junior civil servants and pensioners', and 'transfer and relief of overcrowding'.

Source: Housing in Figures, HA

Financial costs involved in redevelopment are high. It is estimated that about HK$49.3 billion was spent on the construction of reception estates for the CRP between 1987 and early 2007. The additional costs in granting ex-gratia allowances, management and maintenances are not included.

The actual housing stocks after redevelopment has reduced by about 30% due to larger flat size. More land is required for the provision of sufficient local open space, free standing schools, commercial and car park buildings and public transport interchange within the estates.

3. SUSTAINABLE FUTURE OF PUBLIC HOUSING STOCKS

After extensive consultation, the 1998 Strategy has set out the strategy for redeveloping aged public rental housing estates after completion of the CRP. It states that in future, redevelopment will be carried out as required having regard to the actual conditions of individual estates rather than by types of estates or blocks. Clearance will be undertaken only when the estate is structurally unsafe or has become uneconomic to maintain. Following the completion of the CRP, the need for another large-scale clearance of a certain class of old estates is no longer necessary. The need for clearance should hence be considered on an estate or block basis only.

To ensure a safe, comfortable and sustainable living environment for public housing residents and in light of the principles set out in the 1998 Strategy, the HA adopted a new strategy in 2005 for sustaining the existing public rental housing estates. It will be driven primarily by safety and cost-effectiveness considerations, alongside the existing maintenance regime.

4. THE NEW STRATEGY

Under the HA's regular maintenance programmes, the public rental housing stock is kept in good repair through regular inspection and prompt maintenance. Whilst all blocks are structurally safe, the building conditions are deteriorating at varying degrees as a result of ageing and other factors. This has given rise to persistent and multi-faceted problems concerning the upkeep of public rental housing estates. To face the challenge arising from ageing of the public housing stock, it becomes imperative for the HA to devise a holistic and systematic approach to ensure the structural safety of old housing blocks on one hand, and to clear aged estates on the other.

To ascertain the building conditions of individual estates, the HA has commenced a comprehensive structural investigation of ageing estates. The ensuing paragraphs set out the approach of this strategy.

4.1 Comprehensive Structural Appraisal for Aged Estates

In general, comprehensive structural appraisal will be carried out for public rental housing estates around aged 40 or above which are often associated with soaring maintenance and repair costs. Flexibility will be exercised to extend the investigation scheme to other estates taking into account the actual building conditions.

The detailed appraisal aims to determine the material strength and rate of deterioration of the structural elements of a building, focusing on major aspects such as concrete strength, extent of spalling and cracks and corrosion of steel reinforcement bars etc. The findings will facilitate consideration and planning of the necessary follow-up actions such as monitoring, repair, or clearance. If certain blocks or estates were found to be structurally unsafe, demolition would be recommended. For other blocks or estates which remain structurally safe but require improvement works to enhance the structural capacity, appropriate works such as structural strengthening, recasting or normal concrete repair will be arranged so that no major structural strengthening work will be necessary for at least 15 years. Another detailed structural appraisal will be carried out near the end of the 15-year period with a view to mapping out the way forward for a particular estate.

4.2 Financial Appraisal

The expenses on maintenance and improvement works for old buildings will increase with age. While it may be technically feasible to extend the serviceable lifespan of the rental blocks through various upgrading works, the associated costs may at certain point in time outweigh the benefits, thus making it uneconomic to retain the buildings. Hence, in considering whether to undertake repair works for aged estates, a financial appraisal will be carried out to determine the financial viability of the proposal. Demolition may be considered if the cost-benefit analysis suggests that the aged buildings or estates are beyond economic repair.

4.3 Investigation Programme

At present, there are a total of ten public rental housing estates of age 40 or above have been selected for comprehensive structural investigation starting from September 2005, with completion targeted for 2008. Investigation of eight estates have been completed, of which two are considered less cost effective for retaining and are proposed to be cleared. The remaining six estates will be retained and refurbished to enhance their living environment. After completing the current structural investigation in 2008, HA intends to extend the investigation programme to cover another 32 old public rental housing estates which will reach the age of 40 in ten years time. Nonetheless, the actual progress will be subject to the complexities of building conditions of each estate, residents' co-operation, availability of resources and logistical considerations such as availability of vacant flats for on-site testing.

5. CONCLUSION

CRP has greatly improved the living conditions of many public rental housing tenants in the past 20 years. It has also allowed those better-off affected tenants to have priority in purchasing HOS flats which in turn free up the rental flats to those in need. However it is a huge commitment from Government in terms of land, finance and manpower resources. As the oldest blocks have all been redeveloped, it is time to consider whether this commitment should be continued indefinitely.

In view of the 1998 Strategy, Government has decided that redevelopment should only take place when the housing blocks are no longer safe or economic to maintain. In future, comprehensive structural and financial appraisals for old estates will become the key elements of sustainable public rental housing development in Hong Kong.

Summary

Living in the sustainable building should be a good system for both human health and the global environment preservation. That is, it sets the way of living, which approaches zero piece of energy and zero emissions plan newly to the building. Then, it wants to make to master the building and to live become good for the global environment and the health of the human being. When thinking like this, it is suggestive that the sustainable building depends on the environment, the area, the tradition and the climate. It is necessary to influence once again each other and to learn the inventing characteristic according to the green engineering with the present-day material. If unsolvable only by the search for the moral and the building ethics, it is important as the new duty to the building to do the application of the environmental performance evaluation and the addition of the design specification. And the sustainable environment economic system must be immediately arranged. As the follow-up, it is necessary to service the sustainable hospital building where extreme weather, too, can be supported and to do enough health care. It should make“ will to the health” the important theme of the human being.

1. The way that is good for both of the earth and the human being health

1.1 Thinking of Building in the viewpoint of the positive healthy environment making

Living in the sustainable building should be a good system for both human health and the global environment preservation. When there are not comfortable house and health, the human being cannot live. The medicine has continued suggesting a precious matter to make a healthy house. The hospital building, which is the space of the medical care, can show the role in the sustainable times. The hospital building space raises the self-healing power of the patient as the healing-up space. The patient goes to the recovery of the health by own power and appropriate measures of the cooperation of the medical team. When adding a sustainable viewpoint to the health and the welfare, the preservation of the living environment and the cooperation of the wonderful society, which realizes the last-ability of the health in the area, are born. It is understood that there is no clear line between health and unhealthiness; and the value of health is always actually felt, and the maintainable approach is important. It is possible to make a common goal create good healthy environment in the various view of the world. Moreover, the medical facility is well recognized in the value of the health, and is one of them, which need the service of the environment. The value of the health is made wonderful; a value of the time is made very important by the people work at the hospital and at the welfare facility. When thinking of the global environment and the viewpoint of the life of the human being, it is the thing that the health is the most important.

1.2 Clinical Path Based Design

The great health can be brought to both of the global environment and the human being if the scenario and the critical path of the global environment recovery can be created. If the new technical development is necessary, it should accomplish with the path to this “health”. As well as a building, broad cooperation is necessary to accomplish to do this.

The clinical path that a medical team develops in a hospital is the tool, which made a care process the chart by a kind of the disease. And that is prepared for both medical team and patient. “When? Who? What kind of symptom? What medical care has done? How does health care? ” A person, Action, Time are pursued and checked. In case of design, “Where? What equipment used? How safety space prepared? What environment is it?”; the way of the design based on the clinical path should be proposed to complement a place, medical equipment and space more. The clinical path, which the medical team creates at the hospital, is a scenario to the health; for the patient, the field of activities, which is the space of the spiral up revives with the recovery; for the medical team, the safety tool is made, which is incorporated a element in the time into the procedure and the space of the medical care. And the people engaged in medical facilities are well informed of the value of health from various angles. There is a space where the mind and the body are relieved. The space where security to the recovery with a psychological aspect is designed, and the safe space, which make up for a handy cap of physical movement of the patient, is prepared. Appropriate medical apparatus and equipment are arranged in a room of right area for the staff. The system, which checks the medical practice of the staff appropriately and makes an action safe, is arranged. As for the clinical path, a good partnership is shown. The design team does a" hearing" every each department; when reviewing the arrangement of the medical equipment and the furniture in the room space, it is necessary for a element in the place to be added to the clinical path, and for the space to be simulated; it is believed that this way is concluded as the common condition which does the safe and appropriate design. This way is named “clinical path based design” and has been proposed. It should appear that the space, which is the result of this action, is “clinical path space”.

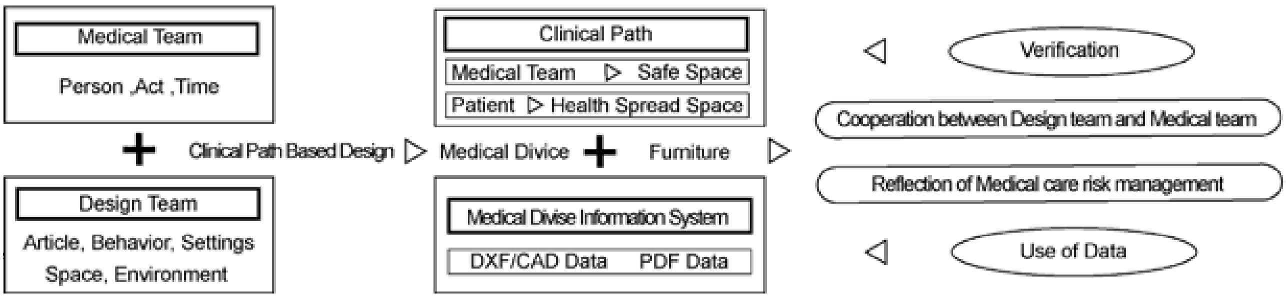

Figure 1 Clinical Path Based Design

The clinical path based design proceeds with the reviewing for each hospital department to become appropriate for the medical care, with the cooperation between the medical team and the design team; introducing a medical equipment information system, the electric capacitance, plumbing equipment, the appropriate kind of medical care gas, which are eligible for the equipment, are accurately chosen. Operation space and the necessary maintenance space are simulated and designed. Here, all at once it is a very important thing for the medical team to make improvement factor, check list and the result by the medical care risk management reflect to the appropriate and necessary space. The clinical path based design should be carried out by the cooperation. At this point, in order to effectively use limited space to the full, both teams should clarify the problems, identify the solutions, exercise ingenuity and run a simulation by Clinical path. Then, after complete of the hospital building, the medical team checks effectively by the actual medical practice. Then, to feed back so as to improve, to clear indication of problems for new plan is important. These things will make also good meeting and treats for patients by Clinical path. There is cooperation between Supply, Processing and Distribution (SPD) and the Hospital logistics in the supply of a wide range of medical equipment such as the pharmaceutical to the patient. Moreover, a bar code is shared and medical equipment information is taken out from the medical care information, the safe check of the medical practice should be done, and it is possible to build the system which supports a medical staff, too, at the same time. There is a big additional value of the medical care of the article management, which can connect safely. It is necessary for the disposal of the hospital waste to be stuck a bar code in the same way and to be made the strict management with trace ability. The clinical path based design let the medical care environment making of Health & welfare facility add the element of the flow of the time; it takes a way of catching in the static space at the facility as the more dynamic one.

1.3 To the viewpoint of the global environment life from the nursing

The healing properties can be more improved if medical ward is in the comfortable environment like the home. Environment at the patients room is requested to be in the nearly atmosphere of the daily life as much as possible. However, there is a problem that the 24-hour control system at the sickroom itself is sometimes bad influence in health. However, there is not a meaning that the environment, which the room at the house of the able-bodied person needs, is the same as the sickroom. As for 24-hour's being managed in the place of the general life except the hospital, the health cannot be maintained is obvious. Nevertheless, it cannot help thinking that there is a defect caused in the air-conditioning system that has not consideration for the global warming prevention through the 24-hour in the building management, and for the freedom of control for resident himself. The system that the resident can participate in his own indoor air quality environment will have to be made. Like the nursing, by the new home economics, the resident arranges a living environment by himself and then, has to create the viewpoint to watch and see it continuously. Sustainable home economics is necessary and should call it just “global environment home economics”. It creates the new home health maintenance life style which also care the state of climate include extreme weather, the global warming prevention and consideration of an earthquake, a tsunami, a fire and a flood occurring. Also, it becomes the way of living to feel simple “will to the health” and to feel a natural environment and also to defend a body against the forces of nature. Therefore, it becomes very important to feed back from the medical ward and the welfare facility environment kept with the nursing science, and to think of the viewpoint of the room environment suitable for the able-bodied person. At a glance, by the freedom of consumption economy and the waste, there is no limitation for citizens to live in their own room space. Therefore, the facility equipment needs the function to forward the energy saving and to stop the running with note sound by checking energy loss appropriately, and also needs the feature which can not do the setting of surplus warm environment. To set the good environmental efficiency of the building for every kind according to the condition of the user, citizen, the health, the age, the climate and the other and to live are valid from viewpoint of the health care. Moreover, every building environment isn't the same according to the location condition with the scale, the spatial arrangement and the kind. Therefore, all buildings should express their own environmental efficiency and doing their best. The comfortable indoor environment 24-hour automatically managed seems to be a space station but is suitable for the healing-up environment at medical ward of some kind. However, the able-bodied person desires to notice the sun, a wind and light; it symbioses with the nature like the yachtsman to look for the wind just like on the ocean and to handle a sail, and will find the viewpoint which lives in the severe global environment. To improve a global environment, the way of human being's living prepares for the new environment, and the moral of the life should be made tough one. It is necessary to control the healthy indoor environment liberally, to maintain the healthy condition to feel nature, and to adapt the life style to the new global environment little by little and to spend, too. It should create a healthy living environment by the cooperation of the industry-university-government. Then, it is necessary to service the sustainable hospital building where the natural disaster of the sudden extreme weather and the earthquake, the tsunami, the fire, the thunderbolt and so on, too, can be supported as the follow-up and to do enough health care. At the facilities, the environment that the health always spreads safely to both of the citizen and the staff should be planned, and arranged inside and outside.

2. The new global environment and building

2.1 Skeleton infill

The picture and the sculpture were independent of the whole building as the former art; and the building has developed a new method of construction, material and a technology and has won liberty in the space. But it welcomed a wide range of chemicals material and surplus artificial environment to the personally opened “Skeleton” again; please let it not become the insalubrious existence, which cannot be controlled as a result. It should be strict from the point of view of the health and the energy consumption about the material, the industrial products that creates a building. Moreover, with the challenge, the preservation of the global environment and the sustainable society of the human being, it should advance towards the direction, which creates the environment, which is good for the health of both human being and the global environment preservation. It gives the “Skeleton” a long-lived structure in 100, 200 years and it plans life cycle cost down and life cycle carbon dioxide down; and “Infill” creates living space by the choice of the best environmental performance at any point in time. The mechanism that the update of a wide range of electric facilities, mechanical and plumbing equipment, too, can be easily supported is required. In the Health & welfare facility, the “Skeleton Infill” can realize the mechanisms, which can renewal medical equipment and building equipment efficiently by the durable period.

2.2 Invisible Environment

2.2.1 Air

The sky is high infinitely because of its transparency; capacity of atmospheric air cannot see the picture by sense. How does the heat budget of the atmosphere in the earth become among the space? Even if a simple equation is supposed to be found, the tactics that the building can be immediately utilized for in the validity isn't found. It is likely to have to think the heat exhaust to the atmosphere to be the limited one. The transparent air pollution like the sick-house syndrome, too, is behind in the cause grasping; the exhaust heat, too, cannot be recognized by sense. The approach, which changes a way of spending unnecessary thermal environment, is necessary. There is important and beautiful thing that is invisible to the eye. It is necessary for human being to make the mechanism, which becomes the life to be zero piece of energy and zero emissions plan, without noticing the finiteness of the global environment and resources by living in the building.

2.2.2 Glass

At the tradition wooden building in Japan, it hung a roof on the structure of the beam with the pillar and it was putting in a simple fittings. The scenery of the nature could be gotten by a natural garden view, through the adjustment band of the thermal environment of the deep eaves, from void picture window of the beam with the pillar. In the summer, fittings were opened largely or removed; deep eaves shaded sunlight; seasonal southeast wind was through so as to be pleasantly and cools off; this is the device. Mud wall range spread but there was a small device, which introduced the consideration of the ventilation in the summer, and of the rays of the sun in the winter as expected in the district where had the need preventing coldness in the winter.

The glass seems whether or not to have left this scenery and to be useful for the coldness in the winter as the transparent wall. The transparency of the glass is beautiful but has changed the traditional way of living by planning house, by control with the fittings, and has changed the study of the essence of the thermal environment roughly. Without noticing the loss of the energy by the transparency, it is reaching global environment times.

2.3 Building on Earth

To create the building which can try to live in the earth healthily is needed. The influence is immeasurable because the building leads a way of living, and the way and the space of the life are in the indivisible relation. The sturdy life to feel a natural environment and to live personally is better than the artificial environment by viewpoint of the energy consumption. Super hi-rise skyscraper penetrating cloud aims at the sky; it has been isolated from the external environment in the creating artificial environment; and it seems to be in the world of the hazard of the space station of the air tightness and the exclusiveness. The technology, which lives in the sky, influences the technology, which lives in the ground just as it is. The dwelling in the earth would take on an aspect which heads for the space station, even if ground dwelling made aim at the sky environment about creating artificial environment in the mechanism that the sky and the ground were the same. As for the global environment, the ability to process the loss of the energy and a heat emission by it is noticed to be limited. As for creating the indoor environment and the thermal environment without interest in the climate around is noticed to beggar a human being at the same time. Without combining the characteristic of the kind of the building to the health of the resident, and to the climate of the area, and moreover to the sense of the climate with the design policy of the indoor environment by the scale, a living environment and a global environment are aggravated. Earth doesn't waste yet as Moon and Mars. The given artificial environment mechanism beggars a human being in the unconsciousness to the environmental destruction. It was liberated from the living to feel nature in the rain, the wind, the thunderbolt, the sun and the moon; but once the extreme weather occurred, a terrible loss got to occur. The building associates with the nature well and creates the mechanism as it finds its own comfortableness in it; and it is the maximum thing for the building to cultivate the feeling and the moral of the living people, and to form these in it. The economy changed the direction for the pleasure, and improved the heat-coldness, which was formerly thought ordinarily, by the development and the introduction of the facility equipment; but it is necessary to reduce this aim; that is simple and moreover big study into the building. Green engineering is added to the building culture and the greatest result is the directionality of the research, the exploration and the popularization to approach zero piece of energy. That is, it sets the way of living, which approaches zero piece of energy and zero emissions plan newly to the building. Then, it wants to make to master the building, and to live become good for the global environment and the health of the human being.

3. Plan to Building and Health

3.1 The way of keeping a moral by observing the rules

To spend quietly and delightfully with the earth should be wonderful. It is good and healthy for human being to change the mechanism of the building to notice the finiteness of the earth if not wakening. It is not merely design style of the building group, and it becomes necessary to propose socially as the way of living. When referring to the car, which is the symbolical existence of mass production machine, it is impossible to sell if not passing to setting exhaust regulation; it is necessary to specify building environmental efficiency evaluation such as passive, active, insulation design and various tries by all means. Also, the building is not only the one for the person to live in the wide sense. Even the power plant, the factory, the cleaning factory, the ironworks, the drainage treatment plant and the industrial waste processing plant with machine and mechanical equipment should set environmental performance value strictly, and also should be expected in the safest sustainability to support life as the building. To set high goal value and to achieve it continue to be the wisdom of the human race. To spend the daily life and to think the moral from the individual and the area as same as the earth level can be created with the efforts at the sustainable building. It is very important to lead to the good technical development become valid healthily, to make the environment economic active and to maintain a network. And it is necessary to release the environmental efficiency that has approach as the richness of the global environment home economics, told each other; also it is necessary for the citizen, lives at the building and in the earth, to execute the new direction discovered personally. Also, it is necessary to disclose about the energy consumption and the discharge data after completion, and to feed back into the new plan easy. To build gets the perfect opportunity, which reaches some new global environment times with the social big goal, and is not the expression of the merely building group. It is necessary to display whether or not to live safe like the house structure investigation after the big earthquake occurrence. To display a signal in blue, yellow or red about the environmental performance at the existence building and to forward improvement are urgent necessities too. The factory and the power plant with bad efficiency are an object too.

3.2 Environment Economy

For the life cycle cost and the carbon dioxide reduction, for making the specification which is strong in the fire for protecting, for indoor thermal environment to extreme weather and for adopting the seismic isolator which can show sustainability in the earthquake, if the initial cost increases, environment economy should be created and the society should conquer the problem and make it realize. The investment should be able to be collected easily in making a restoration cost zero boundlessly with the disaster, and in getting longer operating life at the building. Specifically, for the hospital building, this technology and the investment is necessary by all means for the disaster medical treatment. The risk is too large if the direction of an economic activity doesn't agree even if the solution by sustainable building can be presented. The building doesn't automatically give all environments, which the person lives in; but it generates even the show of the way of living to become consciously aware of the global environment, and the responsibility of the explanation to the living person. It is bad for our health not to head for the solved direction quickly, though there is a solved beginning. “Will” is necessary to become healthy, and has to arrange a mechanism and an organization so that all become healthy. It is the mechanism, which can point out health in the pursuing of comfortableness. Consumption economy does not advance in the technique of the building good for health and the direction of healthy technical introduction; but it is not because personal awareness and morals are insufficient. The environment economy, which cooperates with the environmental efficiency evaluation, should be necessary. The life force of the human race with excessive vitality and trying to advance always beyond its own limit, tries to accomplish the choice of the best in the pile of the level of the individual from limitless; however, it isn't possible to think that it grasps the volume of the global environment. The match of the choice of the technology, which is appropriate to ride over the global environment crisis, the mechanism of the environment economy and the life of the building, which nourishes a moral and ethics, is indispensable.

3.3 Hybrid

A good hybrid for environment and health is effective when thinking passive solar is supplemented with active solar as a hybrid. It is thought that to take the rich mechanism of the indoor environment at the tradition house once more with the good material of the low-cost, light-weight and safe environmental performance, too, is the hybrid of the wide sense. The mechanism at the house in the warm district and one in the cold district coexist globally; this has been a global hybrid, and will continue to be. This is also thought to be one of hybrid systems that super hi-rise building and the high, middle, low-rise building, the house and the tradition house make a city with scale, the technique and the environmental engineering, which suited the kind of the building. The mechanism of the propagation of the building culture repeated a hybrid condition and fusing; the buildings become the world heritage is telling it. The global society has won the viewpoint where to see a result at the building all over the world beyond the culture and the tradition in today; it is possible even to find the traditional technique which doesn't propagate to Japan yet. The viewpoint is needed to understand beautiful building not by a form but by an effort of the living environment to the climate. This is the compilation of a tens-of-thousands-of year of human being and an activity at a house. The essential existence value in a dwelling and at a building is there; to take the explored result how it lived in the area environment once more is very valid. It is possible to find the direction, which is not a rebellion against the global environment; not to utilize the thousands-of year accumulation of the area design is wasteful.

4. Sustainability

4.1 Sustainable Building

The healthy environment design by continuous efforts should be the newest theme if buildings in the world search for a new design, a molding, the green engineering and the theme at the house. More specifically, if a collage of a geometric tradition and a traditional building is a study of the building design, it doesn't show essence in the building and dwelling, which is in the symbiosis with the natural environment. The transparent fascinating space should do the device of the ventilation, solar shading, solar radiation and so on, and should improve an environmental performance; and it is necessary to propagate and to become popular. The building in the world can be responded to each other by having a tough will and a sense, with which human being lives in the global environment. The traditional architecture in Japan has been telling a sense to spend a climate of an island in a Temperate Zone in East Asia with a culture. A lot of buildings that is reorganizing search for the house of the culture and the climate by a technology in today can be seen. Life style with zero piece of energy should have an influence on the nowadays building once again now. It attempts to think of the dwelling by the sense at the traditional architecture in Japan, the culture of the world, and the technology, the technical innovation today. The most famous Katsura Imperial Villa made a high floor type because of Katsuragawa-river flood, avoiding moisture in the summer, and repeated enlarging along with the setting of a pond and a garden in the horizontal direction; and also it says that that villa created so as to the wind goes through, to use solar radiation, and to form elegant site plan according to the arrangement with the tour garden. There are an art culture that supports the garden appreciation in noon and the moon viewing in night. In a measure to a flood, it is possible to admire the traditional house in Thailand for the sense, which floats by a buoyant force of bamboos to be put under the floor. High floor can be far seen at the traditional house in the Switzerland shore of a lake, too. As for the ventilation, in today, the tower of the wind of Pakistan that takes the wind of the sky extremely becomes reference. It became difficult in cities in Japan for the wind to be gotten from the horizontal direction; a sense to be taken from a vertical direction harmonizes with a new lifestyle and a form of a house at a narrow site successfully. The room becomes bright because a natural light flows when combining with the skylight, which is often used in

Northern Europe countries in today. There is ground beam structure of the traditional wooden house in Iraq and a measure to the earthquake, which is realized as the quake absorbing structure by new technology. Insulation in roof-top greening like a flowering grasses which had grown in a former roofing with thatch is recommended in today; otherwise to prevent the garret temperature rise with the solar reflective paint is useful to make cool roof that reduce heat flux from roofs to the atmosphere too. The ondoor of Korea becomes a hint of a floor heater and insulation at an outer wall. The sense and the culture in the world each place can be reorganized by the technology in today in this way, too. It is valid to a change of an environment.

Today, we become conscious of seeing an appearance of the blue planet, the earth which rises from the moon of the gray which gotten good reception by the orbiting satellite in the moon and to feel an arrival in the global environment times in the world together. The world agrees about a conservation of the global environment. In this time, the living strategy becomes sustainable building displayed the environmental efficiency with the global environment home economics. There, a living operation manual, then an explanation of how to live with the environment symbiosis is necessary. In addition, as for it, it should be equipped with the preparing checklist in the mechanism to prevent a building from energy loss. It is also necessary the simple rule of global environment preservation for an individual to be permitted common with a company, an area, a nation and the world.

4.2 Sustainable Hospital Building

Sustainable hospital is further follow-up of the environment, which the sustainable building creates and the sustainable hospital building should be equipped with an information power and vitality to do health care and environmental management by discovering a new problem. Because it is simultaneously not only medical care space but also building space, the hospital building reflects efforts of the medical health care directly. The medicine has woken up patient's natural healing power by locating the hospital construction to the good environment place from at first. It is thought that the environment of the patient is not only as "to cure" but also as "to heal". It is a valuable modern problem in the hospital in city that takes "to heal" into construction; because it becomes difficult to choose the geographical convenience that an environmental condition has well. "To heal" has been made the big theme of design for hospital building with neighboring environment. In the clinical path based design, as for the space of the patient, it experiences that the health rises in the spiral with the expanse in the field of activities from a flower of the vase with vital principle, from a healed picture, from the light, the wind and the nature overflowed at the window, from the rooftop green, from the suitable healed interior and exterior design, to daily life. Then, these are the environments of the disease healing-up, which the hospital building creates; at the same time, it should utilize to practice at the very least in the place of the usual life and to keep health. A space of the medical team is safe one by the clinical path based design, reviewing an operation of the medical care facilities, equipment, and patient and staff.

Figure 2 Niigata City General Hospital, Niigata pref.Japan.2007
New generation Hospital Building toward the 21st century. The establishment of functionality and the amenity as the acute period hospital. The making of trusted hospital strong in the disaster, the change of the future can be flexibly supported. Environmental symbiosis and harmony with a new town.

However, it wants to emphasize that a characteristic at the hospital in today, which is different from the other kind of building, is a positive health being united with the environmental development. In any case, there are tough “will” of medical staff that has opened new healthy environment and a high sense of ethics and they are repeating a discussion on the occasion of utilization of a high technique. The development of medical equipment is the extremely good example that high- technology is utilized for the health promotion. Then, various invisible matters have been treated. It is the big characteristic that the environmental infection control based on a clean to dirty airflow, an aerial pure degree and clean room classifications management every zone has been developed and united with air conditioning facilities. The air and the glass are very important to create artificial environment at the hospital; it is mentioned that this is the special consideration to the powerless patient. And the environment “to heal" is demanded; simply because it is the space that entrusts the position to advanced technology. A flower of the vase changes carbon dioxide into vast amounts of oxygen. It is impossible to do planting trees and green in city in any case if not depending on a special way. The environment at the hospital building should be created with the small bloom and planting. To do the health care of the citizen in the vicinity in city is demanded, not in the vast natural environment. It is necessary to release information of the building environmental efficiency equipped with such advanced technology, too.

*Figure 3 Ogachi Central Hospital, Akita pref.Japan.2005.
Green hospital built in the heavy snowfall area, The promotion of the planting, the rooftop planting, Harmony with neighboring environment, The measures are taken against a winter seasonal hard wind, an snowfall, an icicle, a snowdrift and a condensation. The design got close to by inhabitants and a patient.*

Moreover the matter sustainable hospital building should prepare for is following things; skeleton infill system which can update medical equipment at any time; daily environmental information and health information network; the system to appeal a caution to the health care and the environmental destruction to the wide area around; a function that the last-ability of the medical care activity can be shown at the time of the disaster. As a countermeasure against the disaster, it is necessary to be equipped with the energy independent system, the duplication of the lifeline, to stockpile water, food and fuel. The number of the casualties that occurs around, the kind and the quantity of the medicine, which needs for first aid should be understood as pre-disaster. These medicines are always secured as an inventory in a hospital physical distribution; this system plan as one of the lifelines at the hospital is the new goal of the cooperation with the hospital logistics. It is the installation of the quake absorbing structure to the earthquake, the lightening arrester to the electric trunk line to the thunderbolt. The hospital building should be fire-resisting construction. At the same time, to the fire, the fireproofing woods, which prevent the spread from surrounding area, is valid with the planting trees, too. It becomes necessary to improve insulation, water tight and air leakage efficiency, as the countermeasure to the extreme weather such as heat wave, the bitter cold and the extraordinarily large typhoon, and to prevent a rapid change in the room temperature from taking place. It is also important to prepare for terrorism, accident, human damage and drug-related damage, and to bolster security, and to plan a first aid isolation room, and to cooperate with other organization.

5. Will to the Health

There are wide ranges of ways in sustainable building according to the area, the culture, the climate and the technology but they need each environmental efficiency disclosure. It is possible to suppose that it gives a new value to the building, it gives the citizen a relief and safety and it attempts to improve a global environment. This is the new presentation for the new relationship between the human being and the earth. To spend while conscious of this thing is the forward movement of the sense of values of the new human being. It is the new step to grasp relation with the nature again like the human being who lived in the vast nature. The human being is powerless with keeping thermal environment personally by the health care in the closed living environment isolated from the outside world; as a result, it has despoiled the ability and the liberty of the citizen to notice environment and to introduce a natural environment to the thermal one. At the acute-care patients room of the disease healing-up, this way is sometimes very valid but in the daily life of the able-bodied person, it has been possible to advance on the direction of the large energy consumption.

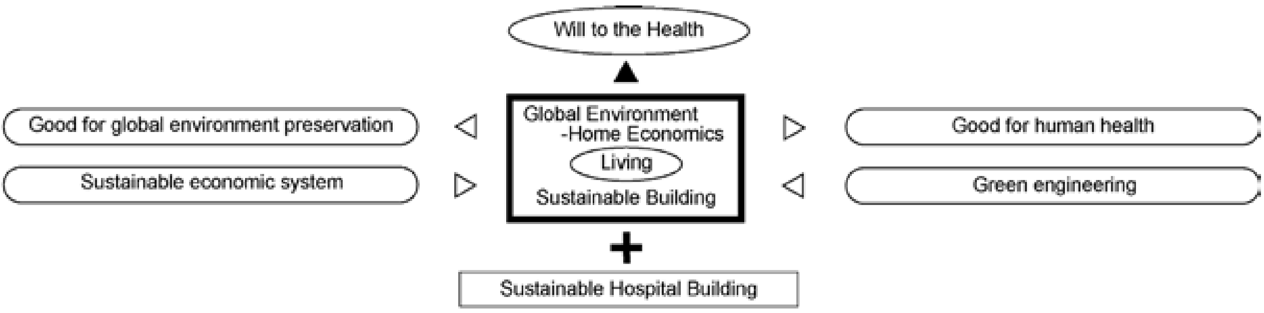

Figure 4 Will to the Health and Sustainable Building

Then, now, the maximum what forming in the building is to expand the comfortable range of the human being, to create the mechanism to the life style to notice environment in the outside world by the skin with the energy consumption as little as possible. The people who try to regain their health are desperate notice environment and are cultivating the self-healing power. It is important for the healthy people to embody the role actively from the near place to the environmental engineering development for the maintenance of the health and to create the sustainable society. The medical equipment which used the most advanced scientific technology has been utilized for the health recovery, but the human being know and use alternative medicine as the living custom too; it is the way which continues to be healthy before becoming an ill. In the same way, it should use the way of maximum of utilizing natural energy to set comfortable indoor environment, not the way that the energy consumption by the development of the scientific technology is big. When it heads for the direction, which reduces energy consumption by the "will to the health" as much as possible, as for the way of sustainable living united with the global environment home economics, the expected living quality becomes wonderful and important. It improves the passive performance of the building as much as possible, and complements it by the active performance; the environment economy for the environmental performance improvement and a wide range of environmental green engineering become necessary. Moreover, not only the way of the living by sustainable building and the show of the living manual to citizen, but also the creation of the new lifestyle and the forward movement of the value of the health become important. It is necessary to make up environment that keeps being healthy before man gets sick. Speaking of the earth, it became clear to worsen the global natural environment state severely by the activity of the human being in city. This is prime task that the sustainable building takes action to rescue and to make it become popular, in the situation that the human being may have robbed even the healing properties of the earth's own. The citizen is sensitive to the sign of the climate change, which is happening in world each place; to continue to build a building with much energy consumption so far goes against the building ethics and the moral. To build is not the expression of the building group and must make agree with the social big goal. The building should aim at the most advanced environment equipment, which can do the maintenance of the health of the human being and the global environment. The building had begun to make order in being disordered from the natural place. The order in the new global environment times must be the disclosure of the building environmental efficiency and search for it together by cooperation.

AN OVERVIEW OF THE *EFFECTIVE SUNLIGHT DURATION* IN BEIJING'S HIGH-RISE AND HIGH-DENSITY RESIDENTIAL BLOCKS

Lan SUN[1]

[1] Faculty of Architecture, Building and Planning, University of Melbourne, Melbourne, Australia, bobbyslan@gmail.com

Keywords: effective sunlight duration (ESD), high-rise and high-density residential blocks, duration of sunlight, sunlighting performance

Summary

Optimum Sunlighting distribution to individual dwelling in high-rise and high-density residential blocks has many difficulties from both internal and external factors. In Beijing, in order to buffer the conflict between optimum sunlight indoors and economical land use in high-rise and high-density residential blocks, a new concept of the Effective sunlight Duration (ESD) as a criterion is introduced into the calculation and assessment of sunlighting performance for dwellings. This paper is to provide an overview onto the concept of ESD in terms of the specifications of urban development of Beijing city, thereby it brings up to a possible balance between optimum sunlight use and economical land use in the future plans of high-rise and high-density residential areas.

1. Introduction: Sunlight Duration

In the development of sustainable urbanization, maximal possible duration of sunlight indoors is taken into substantial consideration in modern dwellings. It is one of the most important measurement units of sunlighting performance. Internationally, the calculation and assessment of sunlight duration indoors are achieved by evaluating the matters to do with the penetration of sunlight on a specific day of year, which is usually selected from the dark months of year. In fact, the selection of the day varies from region to region because of geographical differences and climate diversity. In some countries, the 8th of February as the standard date of assessing duration of sunlight indoors has been in popularity(Grandjean & Gilgen, 1976), whereas the Winter Solstice and the Greater Cold—two alternative standard dates in China are applied(Standard for daylighting design of buildings, 2001).

The need, on the other hand, to achieve equally maximum duration of sunlight indoors for individual dwelling is difficulty approached in high-rise and high-density residential blocks owing to the complexity of spatial layouts and configuration of buildings, especially for the residences in low-levels. In majority of countries, to obtain a balance between optimum duration of sunlight indoors and economical land use, an acceptable minimal duration of sunlight on the standard date is permitted in practice. For example, In Berlin, two hours of sunlight possible on 21st February for at least one room of the dwelling (Grandjean & Gilgen, 1976). The approach is also utilized in China.

Beijing city (Lat39.9056, Long116.3914), located in the climate of Cool Temperate, suffers the prolonged winter period. Hence, the significance of maximizing duration of sunlight indoors is more apparent. Even though the selection of the standard date for the calculation of sunlight duration stipulated in Building Code of PRC is from either the Winter Solstice or the Greater Cold, both the two days as the simultaneous standard dates are utilized in Beijing, so as to maximize the use of sunlight. As far as minimal duration of sunlight indoors is considered, one-hour duration of sunlight in the Winter Solstice and two-hour in the Greater Cold are mandatory.

After the mid 1980s, however, the fact that a vast of high-rise and high-density residential blocks were built to meet the increasing needs for residences in Beijing (Sit, 1995) brought up the conflict on capturing as much as possible sunlight and maximal land use. In a number of residential areas, even minimal duration of sunlight was difficult to reach. In this circumstance, the new concept of the Effective Sunlight Duration in later 90s was introduced into the system of the calculation and assessment of sunlighting performance for residential blocks. This paper is to provide an overview onto the concept of ESD applied in Beijing, thereby it provides potential to balance optimum sunlight use and economical land use in the future plans of high-rise and high-density residential areas.

2. Scope

A number of researches into energy conservation and health issues integrated solar radiation have been done and put into practical applications. Indeed, the most important factor to the completion of these activities is sunlight access. However, in high-rise and high-density residential blocks, the lack of sunlight is a major issue in many regions with finite land use. Therefore, the study scope, in this article, is primarily to describe the concept of ESD as a criterion in the assessment systems of sunlighting performance to balance sunlight accessibility in high-rise residential and high-density blocks. The article will answer the following questions:

What is meant the Effective Sunlight Duration?

Why is the concept of ESD utilized in the assessment of sunlighting performance, especially in the circumstances of current urban development of Beijing high-rise residential blocks?

What are the advantages of ESD, compared to conflicts of maximal duration of sunlight in reality?

How is the calculation of ESD achieved?

It is remarkable, on the other hand, that the achievement of ESD in dwellings may induce positive effects on the increase of energy efficiency and human health from solar radiation. However, the original application of ESD is to ensure as much as possible sunlight indoors, while using land reasonably. Effects on other aspects are not considered. The limitation of researches results now in the impossibility that the contents of ESD related to energy rationalization and human health are presented in this article, but deeper insight into the ESD applications will be written in other papers. For this reason, the article will only discuss the concept of ESD and relevant reasons of its emergence in Beijing.

3. Understandings of ESD

3.1 What is the Effective Sunlight Duration?

The Effective sunlight duration is an assessed criterion of sunlighting performance for dwellings applied in Beijing. Different to prevalent assessment methods considering much more in the quantitative, qualitative or heat-radiation factors of sun's ray, which penetrates into the space, the concentration of ESD is at the consideration of sunlit periods irradiating onto sun-accessible façades or window areas of dwellings. The dominance of the criterion is in ensuring that residents have opportunities to obtain as much as possible continuous solar-time throughout the year, even on severe days of the year.

The key of ESD is the domain to regulate so-called 'effectiveness' of sunlight duration. In the concept of ESD, effectiveness is always linked to solar time rather than solar energy-content or illumination. The confines between effectiveness and ineffectiveness of sunlight duration are clearly delimited when the concept of ESD is proposed by Beijing Municipal Commission of Urban Planning(Design Code for Beijing Residential Buildings, 1994), namely, more than or equal to 30 minutes duration of sunlight is considered as a unit of ESD; conversely, less than 30 minutes duration of sunlight is considered as ineffective sunlight duration.

Taking fully actual time of sunrise and sunset on the standard date of Beijing into consideration, the calculation of ESD is implemented within a specific period of 8am to 4pm, so that the precision and effectiveness of results can be orthodox. In accordance with National Code, two ESD units in the Winter Solstice and four ESD units in the Greater Cold as minimal standards are accepted(Measuring-point: on the window wall), whereas the following different number of rooms in term of different types of dwellings must attain minimal standards:

one room of 1-bedroom dwelling without north-facing room;

one room of 2 or 3 bedrooms dwelling with one north-facing room;

two rooms of 4 bedrooms dwelling with one north-facing room;

three rooms of 5 bedrooms dwelling with one north-facing room.

In the process of design, as many as possible units of ESD on the standard dates should be highlighted with reasonable land use.

3.2 Contexts of Emergence of ESD Concept

Even though the concept of ESD is only utilized several years, its introduction into the assessment systems of sunlighting performance is inevitable. Discussing the emergence of ESD concept, the following contexts that sunlight assessment systems have been in popularity in current circumstances of Beijing urbanization have to be mentioned here:

High-rise and high-density residential constructions as a major type of dwellings in Beijing is immensely developing than any periods in the past because of the increase of population, the limitation of land for residence and the incentive-policy for real estate industry.

According to Beijing Fifth Census Statistics by the year of 2000(Department of Beijing Population Statistics, 2005), total number of population was reached to 13,569,000 with the average population density of 821 persons/ k ㎡, which is approximate 1/4 total population of Australia, whereas its total area of available urban land has only 16,807.8 k ㎡(Beijing Municipal Statistical Bureau, 2002). Such a huge number of population increase and finite land use have already exceeded the national planned target. Increasing the population density by building higher with more living area per unit of building land becomes an obvious solution for improving the average living situation and for accommodating more people.

Beijing as a long-historical city, on the other hand, has constraints on urban development, especially in the historical building blocks of inner area. The inner area of Beijing embodies invaluable architectural heritages. The perseverance of these heritages is significant for city sustainable development. In this circumstance, small number parts of inner area have potential to build new accommodations and heights of the buildings should be strictly controlled to avoid the intrusion into the profile and skyline of the low-rise traditional core of the Ming and Qing Dynasty preservation of the Forbidden City. Besides, to economize residential land use, cutting down the invasion of building land into the good vegetable land in the suburban districts, is vital for Beijing sustainable development. Therefore, constructing the high-rise and high density residential blocks in the vicinity of inner city become a means for reducing the disturbance to inner old city and the use of agricultural land.

In addition, the incentive-policy for real estate industry is another important factor to boost the development of high-rise and high-density resident blocks. Since the year of 1988 when the housing reforms was launched nationwide, new private housing provided by developers has mushroomed in Beijing(Sit, 1995). In the finite residential land, building high-rise and high-density residential blocks becomes a prior way for developers to obtain maximum profits by selling as much as possible living units. Remarkably, official preference for building higher and raising density standards(Laurence & Wu, 2005) impels that most of developers build massive high-rise and high-density residential blocks. Hence, based on the influence of above factors, high-rise and high-density residential blocks are increasingly dominant on the market of Beijing housing. At the moment, the problems of high-rise and high-density residential blocks are apparent. Less sunlight is one of the most serious issues in current environment.

The standards of relevant residential environments qualities should be improved to meet the demands that people desire to live in more sustainable and comfortable residential communities. To achieve higher objectives, the Chinese government has made a clear commitment to increase the standard of living for its population after the housing reforms. On those new objectives, improving environmental quality within and surrounding neighborhoods is an important aspect, including increasing the standards on sunlight access and duration of sunlight (Jia & Hugentobler, et al, 2002).

In the past, the Greater Cold as the standard date of assessing sunlighting performance was widely applied nationwide. One-hour minimum duration of sunlight was the only criterion to assess sunlighting performance in the dwellings. With the increase of living standards, people have more demands on receiving as much as possible sunlight. As a result, the governments increase the standards of sunlight assessment: two-hour minimum duration of sunlight on the Greater Cold. In addition, a new standard date of the Winter Solstice is the alternative. On the day, one-hour duration of sunlight is the minimum standard. Each city can choose either one as the standard date of assessing sunlighting performance in terms of local climate conditions.

Apart from the increase of standards of assessing sunlighting performance, the rapid increase of awareness that people have right to obtain sufficient sunlight in their dwellings is another factor to compel the improvement of the standards. To buffer the conflicts between residents' desires of hoping to obtain as much as possible sunlight and efficient land use, parts of city, especially in large city like Beijing, Shanghai, have applied both the Greater Cold and the Winter Solstice as the standard dates to assess sunlighting performance.

In current Beijing urbanization, the considerations on the closed relationships between sunlight and residents' health—both physical and psychological influences are taken into. As we know, sun's radiation falls into three ranges after it penetrates into earth surface: the long-wave, the medium-wave and the short-wave(Lynes, 1968). All the waves have influences on humans. The long-wave is a type of heat-radiation, which embodies around 98% of energy of the sun's rays. It has significant effects on warming the walls and the space, so as to make for a health indoor micro-climate. The medium-wave, visible rays, provides the visible spectrum around us. It has psychological effects on humans. Obtaining optimum medium-wave makes people feel fine. On the contrary, without sunlight, people may suffer sun-related healthy problems, such as Seasonal affective disorders(Hawkins, 1992) The short-wave belongs to a type of the ultraviolet radiation (UV). Its effects on human life are positive. It can kill germs in the air and the longer short-wave irradiating has beneficial chemico-biological effects on the human body(Pjrek & Winkler, et al, 2004). Based on the irreplaceable benefits from the sun's ray, it is very important to permit as much as possible sunlight into the dwellings.

In retrospection above, massive constructions of high-rise and high-density residential blocks, the improvement of living standards and healthy considerations promote together the development of sunlight assessment systems in current Beijing urbanization. Assessing sunlighting performance has become an indispensable part of design process of residential blocks. However, the traditional approach of assessing sunlight performance—the calculation of duration of sunlight, has its weaknesses in practical applications for high-rise and high-density residential blocks. It is difficult to approach one-hour minimum duration of sunlight on the Winter Solstice or two-hour minimum duration of sunlight on the Greater Cold because of sunlight inaccessibility formed by tight layouts of the high-rise and high-density residential blocks. To achieve current standards of sunlight indoors under finite land use is impossible for dwellings in Beijing. Thus, the concept of ESD as a new criterion is introduced into current sunlight assessment systems.

3.3 Merits of ESD against Disadvantages of Traditional Approaches

The concept of ESD as a new criterion in the assessment systems of sunlighting performance has its merits in reality. Compared with the application of duration of sunlight in the traditional assessment systems, the concept of ESD has overlaps, but there is an important difference—the criterion of defining the length of time that sun's ray irradiates on the sun-accessible facades or windows areas of dwellings. Based on this difference between them, the concept of ESD has obvious advantages over the traditional approaches.

The application of ESD in current residential construction market of Beijing is more feasible. National minimum standards on the assessment of sunlighing performance are one hour duration of sunlight on the Winter Solstice or two hours duration of sunlight for dwellings. Considering climate zones and location of Beijing, however, to achieve the minimum standards has problems in current Beijing urbanization. Building the massive high-rise and high-density residential blocks in Beijing for meeting housing needs has to reduce sunlight accessibility. When the high-rise and high density residential blocks were rapidly built from 1995 (Sit, 1995), in order to meet traditional standards of sunlight assessment, the developers have had to decrease the density of building blocks. However, the negative effects were that economical land use could not be achieved and benefits of developers were reduced. As a result, some of developers retracted the planned investment on the constructions of high-rise and high-density residential blocks, seriously hindering the development of Beijing urbanization. In this circumstance, introducing the concept of ESD into the existing sunlight assessment systems buffers the conflicts. Even though, to a certain extent, the application of ESD diminishes the national standards of sunlight assessment for dwellings, its feasibility in current development of Beijing urbanization is beneficial and marketable.

In addition, the application of ESD for the assessment of sunlighting performance of high-rise and high-density residential blocks is more reasonable. In conventional approaches, the calculation of sunlighting performance is based on a long continuous sunlit period. On the Greater Cold, two hours duration of sunlight is required, which means that there are two continuous hours sunlit time irradiating on the sun-accessible façades and windows from 8am to 4am; or one hour duration of sunlight must be achieved on the Winter Solstice. In fact, only southern facades have full accessibility to the eight hours. The eastern and western facades can only obtain four hours sunlight—8am to 12am on the eastern facades and 12am to 4pm on the western facades. In the dwellings design of high-rise and high-density residential buildings, the Tower-shape building is widely used in current Beijing. Its characteristics are economical land use and more living units per floor. In the meantime, numbers of living units facing eastern or western orientation have to be placed. Those units have actually four hours sunlight accessibility. Hence, in the high-rise and high-density residential blocks that buildings are constructed close to each other, those living units have difficulties to achieve two hours duration of sunlight on the Greater Cold and one hour duration of sunlight on the Winter Solstice because of self-shading and external obstruction.

In the concept of ESD, however, the sunlit period that is defined as the effective sunlight is shortened. It seems to reduce the standards of assessing sunlighting performance, but its reasonability in the construction of high-rise and high-density residential blocks is prominent. Among the close buildings, the small space only permits limited sunlight to irradiate onto the buildings. Especially for those living in low-level, the accessibility of sunlight is very finite. Compared to residences in the medium or high levels, which can obtain the sunlight from both top and the space among buildings, they have only sunlight access via the space among buildings. Besides, for the living units facing east or west, it is extremely difficult to achieve the traditional standards. Providing that traditional standards should be achieved in the high-rise and high-density residential blocks, the height and density of the buildings have to be decreased a lot; thereby the usability of land should be reduced. In this circumstance, the application of ESD introduced into the assessment system of sunlighting performance is likely to balance optimum land use and sunlight access in current Beijing built environment.

3.4 Sunlight Simulation Program- Sunshine2002

The sophistication of current computer programs makes possible to evaluate and refine the building design before its construction by the realistic modeling, and functionally linking to energy consumption or lighting performance to permit rigorous analysis in quantitative and qualitative format. Some of software programs have functions to calculate and assess the illumination level and heat-energy of sunlight integrating the building, but the software programs with the function of calculating and assessing sunlight duration on a day of the year have not been developed widely. Nowadays, most of software programs have been likely to calculate and assess the sunlighting performance at one time-point, which means that the transient performance of sunlight can be measured, but the calculation and assessment of duration of sunlight cannot be achieved. In order to measure and evaluate duration of sunlight on a specific day, the traditional manual methods have to be used, such as the Horizontoscope.

However, in the high-rise and high-density residential blocks, the complexity and diversity of the buildings bring up many problems on the process of manual calculation of sunlight duration. Time-consuming, inefficiency and inaccuracy are the major obstacles. To solve these problems, CAAD Research Center of Department of Architecture, TsingHua University developed the software of Sunshine96 in later 90s, which was developed on the basis of the software of AutoCAD R14 For Windows 95/98 Windows NT(Wang & Zhang, 2003). This program has an evident difference on the calculation of sunlighting performance compared to other sunlight-relevant programs. It has capability to calculate and assess the performance of sunlight within a specific period of time on a day. Initial considerations of applying the program are to calculate and assess duration of sunlight rather than that of ESD. Hence, on the basis of traditional standards of duration of sunlight, the calculation and assessment of ESD units can not achieved. Under the current residential construction market that high-rise and high-density residential blocks take up the majority of share, the software of Sunshine96 is not capable as the tool of calculating and assessing the sunlighting performance.

To meet new demands for the calculation of ESD units, the software of Sunshine2002, one updated version of Sunshine96, was developed in 2001, which has two key features on the calculation of sunlighting performance: a new mode of calculation for ESD units and a high-efficiency sub-program for the calculation of sunlighting performance of the high-rise and high-rise residential blocks(Wang & Zhang, 2003). Its advantages are obvious in current Beijing urbanization. Accurate and quick calculation of ESD units not only ensures optimum sunlight use for each dwelling, but also economizes residential land use. For designers, on the other hand, this program provides the possibility to refine their projects in conceptual phase, integrating sunlighting performance. In order to achieve the objectives of improving people living environment, Beijing Municipal Commission of Urban Planning suggests(Zhang, 2005) that all the design of residential blocks should involve the calculation and assessment of ESD by Sunshine2002.

4. Discussion and Conclusions

This paper introduces the concept of the Effective sunlight duration as a criterion of assessing sunlighting performance applied in Beijing. Its emergence has the inevitability in current Beijing urbanization. Rapid increase of population and finite residential land induce the massive constructions of high-rise and high-density residential blocks, whereas a negative effect caused by enhancing the density of buildings is sunlight inaccessibility. The utilization of traditional assessment systems of sunlighting performance has been not suitable in current environment. By the application of ESD into the assessment systems of sunlighting performance, the objectives of optimum sunlight use and economical land use can be achieved. However, the concept of ESD is only applied into Beijing residential market for several years. Its effectiveness and reliability should be examined in future utilization.

In addition, ESD concept is developed on the specific conditions of Beijing. Its feasibility to be applied in other regions should be examines. Beijing city with huge population and limited land use has to construct massive high-rise and high-density residential blocks. The new criterion has its marketability. For other regions with less population and plenty of land use, as much as possible duration of sunlight for dwellings can easily be achieved. In this circumstance, the concept of ESD does not need to be one criterion of assessing sunlighting performance.

For those regions similar to Beijing situations, On the other hand, the concept of ESD has potential to be utilized as a criterion to balance optimum land use and sunlight access, but 30 minutes as the unit of ESD may need to be redefined in terms of local climate conditions and geographical features. Beijing, located in the zone of cool temperate, suffer certain long winter. 30 minutes sunlight duration is the minimum standard for warming walls and indoors. However, in some regions, 30 minutes sunlight duration as a standard may be insufficient or too much, therefore how long can be defined as an ESD unit in different regions may be different.

The initial utilization of ESD as a criterion in the assessment system of sunlighting performance for Beijing high-rise and high-density residential blocks is to economize the finite resources of land and meet the sunlighting needs for dwellings as well. More possibly, interlinking the concept of ESD with energy rationalization and human health, more reasonable sunlight use in the high-rise and high-density residential blocks can be achieved. It is one of possibilities to realize the low-energy consumption and create a healthy and comfortable living environment in high-rise and high-density residential areas.

In a word, this research on the concept of the Effective sunlight duration as a criterion of assessing sunlighting performance applied in Beijing is to provide a possible balance between optimum sunlight use and economical land use in the future plans of high-rise and high-density residential areas. It is hoped that the work presented would be of interest to designers of residential blocks and others working with the calculation and assessment of sunlighting performance.

SICK BRICKS

Faraz SOLEYMANI M.Arch.[1]

[1] Young Researchers Club, Azad University of mashad, IAUM, Iran, Mashad, faraz_soleymani@yahoo.com

Keywords: sick bricks, children. Abuse, fossil fuel

Summary

Using brick or not using it is not only a moral issue but also a logical one. To clarify the subject, we should answer two important questions: whether we like our children work in brick kiln? If we know to what extent our life is affected by these kilns whether the "sound judgment" allows us to use brick. All brick kilns employ the women, children and aliens have entered the country illegally as workers. Unfair situation of women and children who are working in brick kilns in Middle East specially Iran, Iraq and Afghanistan. All brick kilns employ the women, children and aliens have entered the country illegally as workers. The highest wage for making 1000 bricks is 20000 Rials (2$) and each family with five members makes 3000-4000 bricks daily which means 6$ for five persons in a day in the best condition.

1- A majority of workers are women and children who because of hard physical working have no chance or ability to enjoy education and learning and usually wear male clothes to hide their sex for protecting themselves from sexual abuse.
2-This kind of work brings no technical skill for workers and there is no chance for their development in the future.
3-For supplying the required soil, we have to destroy the high-quality soil layers and this leads to destructive influences on environment.
4-By excavating the earth, some ditches and pits will be formed that generally are used as places for cumulating rubbish and constructional wastes that provides accommodations for addicted persons and offenders.
5- Low quality, intense reduction of the quality of the yield due to the lack of skill
6- Seasonal unemployment due to direct relation to construction ratio
Hypothesis:
Whether the brick based system of construction in Iran has been a proper one in last century?

Introduction

Figure1,Traditional brick kiln

Figure2, girls at work

By entering the industrial brick to Iran, there was a great need to the force work and consequently, constructional workers. This caused that the villagers move from villages to the cities. They preferred constructional work, which was seasonal but had a higher wage to the agricultural work which was permanent but had a lower wage. The job vacancy was filled and supplying the work force became more than demanding work force. Thus , living situation of workers not only was not improved but also it reached to the lowest level (theory of classical economy) and the rate of unemployment was increased .Fertile lands were destroyed and agricultural products was intensely decreased and Iran changed to the one of the most major importers of the wheat. City's population became more than village population and therefore the number of consumers became more than producers. So industrial brick which was the sound of progress in Iran, changes into Achilles' heel.

Figure3, women as the main victim of brick kilns

Brick kiln or Petri dish

Brick kilns, not only because of their hard work conditions but also for their impact on social and economical system should be closed down. A majority of workers are women and children who because of hard physical working have no chance or ability to enjoy education and learning. This kind of work brings no technical skill for workers and there is no chance for their development in the future. For supplying the required soil, we have to destroy the high-quality soil layers and this leads to destructive influences on environment. By excavating the earth, some ditches and pits will be formed that generally are used as places for cumulating rubbish and constructional wastes that provides accommodations for addicted persons and offenders. Since these kilns consume fuel five to ten folds of the usual kilns in Europe and their fossil fuel is including gas and gas oil, they cause increase of greenhouse gases, earth temperature, and finished price of brick. So the government has to give subsidy for fuel and the factories in order to decrease production cost, try to reduce workers' wage and the standards of workplace. The factors such as age and sex of workers (women and children) , minimum wage , lack of standard workplace and workshops for quality control and careful supervision , high rate of demand for brick in the market etc. ……. cause lowering the quality of produced bricks . Low quality of brick leads to occurring cracks during the process of production , transportation and laying as well as less adhesion of brick to mortar, less compression strength etc. …..which in turn lead to increase of maintenance costs and decrease in the rate of construction operations.

Figure4, A woman dresses like men working in brick kiln

One of the most important problems of construction field in which brick technology is used, is its dependence on unskilled force and workers .This is not an advantage but during the recent 100 years it has been the most important problem of this system because the countries including Iran , Iraq and Afghanistan are developing and need construction so there is high demand for blue-collars and the young workforces prefer to be engaged in hard manual labors which don't need any proficiency and skill. The following cases are among the problems of this system:
1-Lack of exporting 2- demolishing of skills 3- Intense reduction of the quality of the yield due to the lack of skill 4- low quality 5-Seasonal unemployment
7-Because of war in Afghanistan, during the recent 30 years, and worse circumstances in Iraq, a majority of population of these countries have immigrated to Iran. Most of them engage in constructional works and since the place of their work is not a certain place so prosecuting them is not possible. On the other hand their home is often the place of their work and this leads to severe increase of insecurity in the construction sites. Every day we can read in the newspapers the news about the murder, rape or rubbery committed in a semi-finished building by Afghani subjects. Villagers, Afghans have instituted the primary core of marginalization in the metropolitan cities including Mashhad, Tehran and province of Sistan and Balouchestan . These persons, who have no identity card and suffer from worse economical situation, can not dwell in the legal suburb of cities. To legalize their residence , these people get marry with poor Iranian so that they can get permit for residence .Thus we encounter with problems such as supplying drinking

water, electricity, lack of educational facilities, waste disposal , prevalence of infectious and contagious diseases, drug abuse, prostitution and so on.. Lacking congruous politics in different executive systems such as municipality , Water and Electric department , Gas , Natural Sources , law enforcement forces, etc.…causes contradictory treatments to be governed over them .One organ provides urban services for them , the other puts them under pressure to evacuate their house .On the other hand , municipality , to prevent from human disastrous events in these marginal districts , render services including disposal of the wastes , supply of water , electric and gas .This leads to contradiction in this matter . The problems such as living outside the suburb of Mashhad , lack of educational facilities , absence of family supervision , drug abuse, etc lead to social and terrible problems . Because of problems such as; outside the vicinities, lack of educational facility, lack of family supervision; difficulties including prostitution, corruption, drug abuse, buying and selling children, rape and … will be resulted

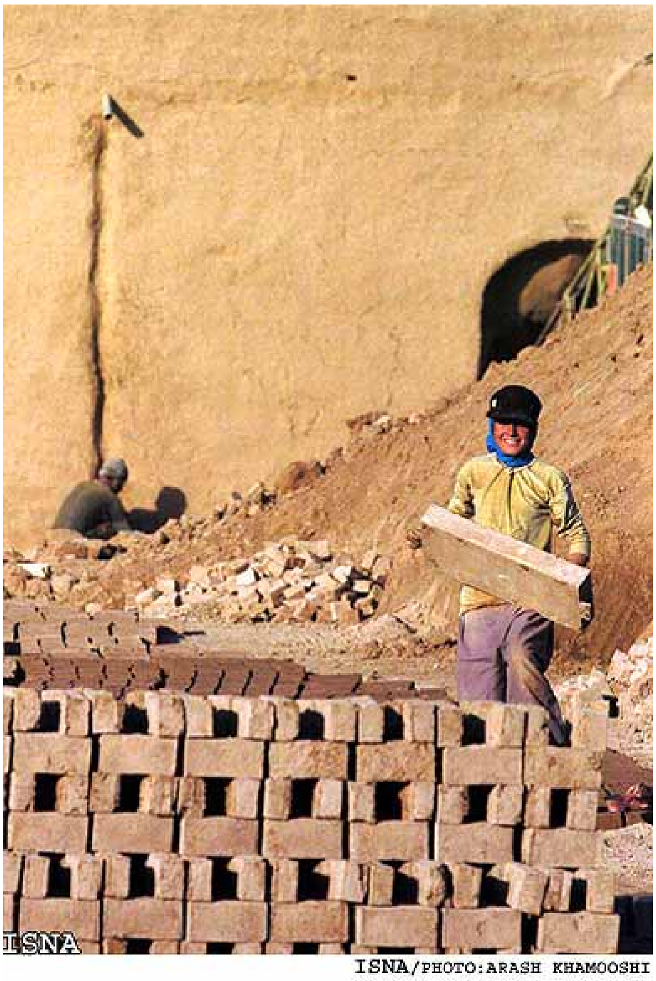

Figure5,An Afghans girl works in brick kiln

Undoing the relation between brick and crime

In 2004, one terrible criminal was committed by one of hut dwellers of south of Tehran. Such terrible criminal shocked all people of Iran .The case was that a boy called *Beize*, an adolescent with 15 years old , kidnapped 29 children during 3 years .He tortured them and after raping them , burned the corpses of his victims in the brick making furnaces .

In 1993, during one night, Mashhad city became the stage of a street fighting. Many banks were fired , many stores were plundered and offices were demolished and many garrison and the Police stations were occupied .After subsidizing commotion , and doing investigation ,the government declared that the origin of commotion were the estates which were formed illegally and as the municipality says confidentially, our enemy (in Mashhad and throughout Iran) is not America, not the opponents residing abroad and not the people who are counter-revolutionists but they are marginal dwellers.

If there is not police, we can not imagine what situation there will be for marginal dwellers .Indeed we are imprisoned inside our homes and automobiles but the marginal dwellers are free to go everywhere and so no law can control them .Among 2.5 million

Figure6, children live and work in very unhealthy and unsafe situation

When villagers migrated to the cities, they began to construct new houses outside the city; it caused the problem of marginalization which accompanied with social abnormalities. Increasing use of brick in buildings located in the margins of the cities caused a texture required to be reconstructed .Due to the characteristics of brick, the houses were not considered as the temporary ones but they were entirely like the urban houses. They could be used as the permanent dwelling so the people didn't attempt to improve their life conditions .According to the official statistics, there are 600000 city margin dwellers in Mashhad.
With respect to the culture of construction in the country, brick benefits from high potential in designing and construction so it can be said that the people participation in the process of designing is somehow acceptable; but in Iran people participation in construction process has no result except wasting resources or nonstandard implementation, and … "people participation" is often used as an excuse for the government to neglect its liabilities.

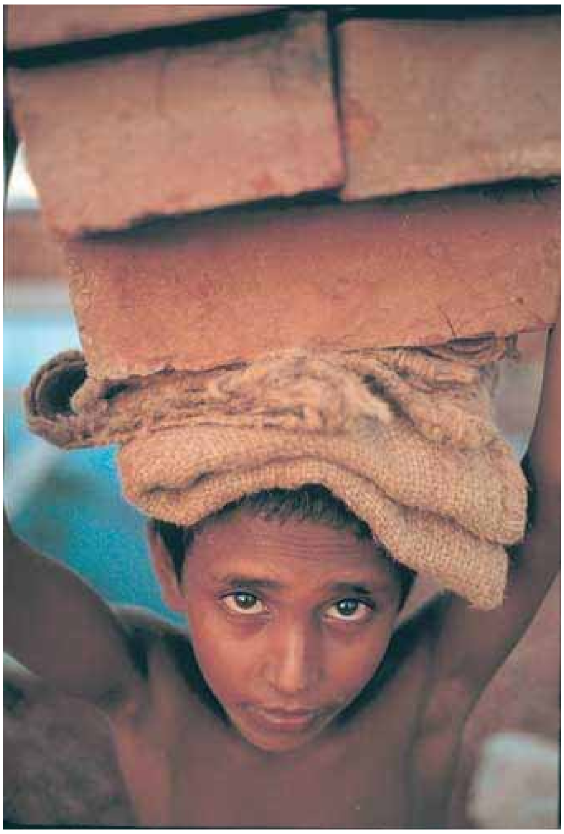

Figure7, Another Great Expectation!

Architect or *Brickitect*

It is important to change the passive architect's role to an active and effective one in order to manage the system of construction effectively, today's selection of materials are just based upon their price, color, texture and availability but it should be based on wider range of factors
Nowadays beauty is not only based on economic, environment and classic theory but also it should be considered on its micro and macro effects in every aspects and scale. Now the question is whether the existence of beautiful building could underlie the creation of beautiful city and whether the existence of beautiful city might underlie the creation of beautiful country, even if the answer would be yes, it is surely not, now one may ask whether the beauty have its classic
Definitions and if we could sacrifice ecological and systematic beauty because of creating visual beauty!
We as architects by selecting each material for buildings create economic potential for that industry and for the same reason we promote these industries, of course if we could entitle them "industry", and therefore we should ponder in their effects in micro and macro scale in all aspects until avoiding unintentionally providing the brick kiln with fuel!

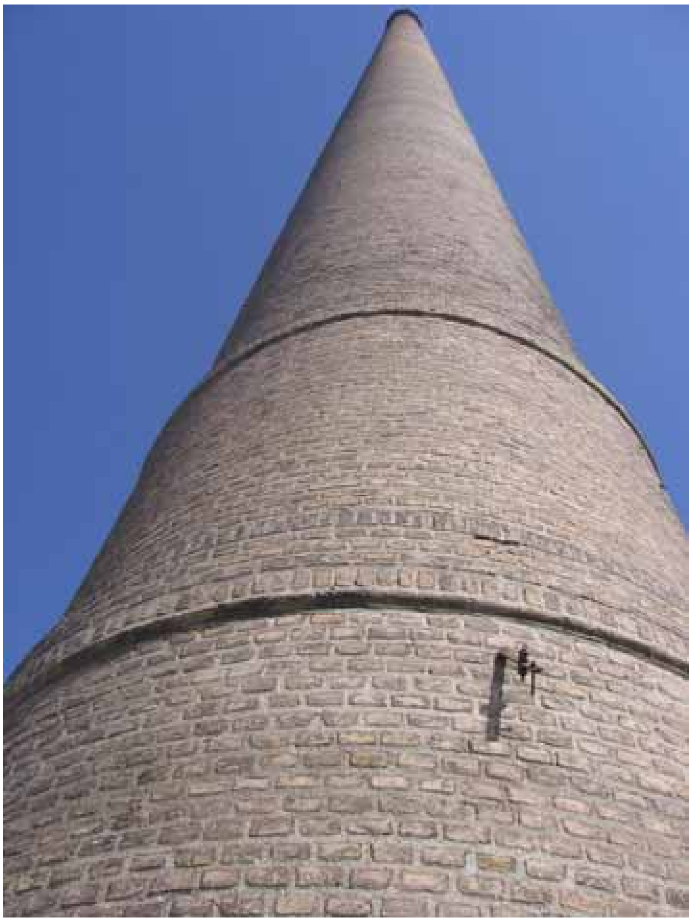

Figure 8, traditional brick kiln's tower

Consuming or devouring the fossil fuel

The entire industry sector in iran consumes approximately 21% of energy in quantities which means 15% in value that means 3.7 billion dollar. Brick industry use more than 5.4% of this amount consisting of 7000 thousand active and major brick kilns which they produce 50 million tones brick annually and nearly they burn 4 billion liters of oil. Fuel consumption in Iran's brick kilns based on theirs technology and oldness is about 1000-2000 Kcal/Kg which in comparison to international standard norms 400-600 Kcal/Kg is reluctantly high.

Table 1, comparison of fuel consumption in Brick industries

Country	Fuel consumption, MJ/Kg
Belgium	1.94
Germany	1.73
Denmark	2.16
Spain	2.14
France	2.29
Greek	2.1
Italy	2.11
Ireland	2.15

Brick or terminator

Deficiencies of using brick based system of construction in building

Façade:

Heavy weight of façade because of the necessity of furnishing on brick due to low quality
Fragile cohesion of brick wall and furnishing stone
Inefficient isolation
Conducting of humidity
Potential danger in earthquake
Collapsing the stone furnishing onto the street due to weight and low cohesion
Using incongruous materials
Heaviness of structure
Low quality of welding, steel, and cement
Over design the structure due to inherit unpredictable process of brick based system
Lacking of unity between structure, floor and wall
Complexity and plurality of details
Lacking skillful worker in welding
Lacking proper welding machine
Lacking knowledge of welding
Inefficient design of joints
Designing the structure as definite
Neglecting the standard distance of two building
Lack of knowledge and expert for isolation

Lack of proper technology and materials due to sanction
Localization of isolation resulting to inappropriate and unscientific product
Increasing the whole weight due to exploiting inappropriate materials
Decreasing useful surface of building
Dependency to foreign market
Increasing the total cost of building but not very effective reduce in energy loss

Figure10, Bam earthquake killed 40000

Figure11,Bam earthquake killed 40000, fragility of Brick-based building

Figure12, Bam earthquake killed 40000, Bricks are falling down

Waste including broken brick
Increasing the cost because of necessity of additional furnishing for façade
Increasing the weight of structure
Necessity of financial aid to reduce the price
Creating seasonal work
Increasing the potential for non productive work

Standard bricks or brick's standards

Selecting brick for building cause to promoting this so-called industry to a wider range of economy possibilities and this would increase the number of brick kiln which would be resulted to more economic and socio-cultural problems. Being standard in traditional point of view does not necessarily means being standard in production process, quality of work place, quality in work force and last but not least in its aftereffects in micro and macro scale

Figure 13, low-tech modern brick kiln

Who is the decision-maker?
As we know that any recommendation that any recommendation associated with using brick for buildings creates motivation and strong economical potential to establish more brick plants and this ultimately leads to more social, economical and cultural complexities. So the best solution is to "prevention" in this way the target group is building sector including architects, civil engineers, contractors and decision makers who can decrease demand for brick effectively so I propose establishing "*Archanalysis*" which performs comparative study about complexities of the cities in the Middle East and analyzes the changes in these regions and provides solutions in the field of brick usage for architects and encourages them to use other construction systems that use more modern technologies and form small construction sites. In these solutions other systems are substituted, the systems which consider technical and productive services, export of services and training specialist forces so that single-product economy based on oil can be discarded. In this way we can control demand of brick by making building sector aware of the importance of their decision and help them to promote much sustainable system of construction.

Conclusion

Architectural problems are extremely complex, multilayer and nonlinear. It's impossible to solve them with linear equations, however, one of the property of these systems are their butterfly effect rules, with exerting a little force the system would be influenced dramatically, so to analyzes the very systems we should search to find these critical points so that to achieve a great extent of results with the minimum change in the whole system. In Iran, because a lot of things but due to some excuses such as national pride, nostalgia, Islamic architecture, identity. We try to use brick as much as possible. It means more dependency to brick-base system and industry and always with this nostalgia we celebrate our triumph while, destroying from inside, exactly, like Trojan myth. What we called triumph and reputation which should serve us with honor in the world was nothing but destroying brutal dreadful enemy that called Brick so I propose the theory of "Brick is Crime" as bellow:

Brick based system of construction in last century in Iran was the worst with the most undesirable aftereffect on environment, society, economy, culture, in macro and micro scale thus it can be said that brick is the Trojan horse of contemporary Iran's architecture.

Figure 14, children are the innocent victims of brick kiln's battle field

PROGRAMMING OF BASE BUILDING SIZE IN SUPPORT OF OPEN EDUCATION ELEMENTARY SCHOOLS IN TAIWAN – A KNOWLEDGE MANAGEMENT APPROACH

Hsiao-Lei WANG Ph.D.[1]

[1] Department of Interior Design, China University of Technology, Taipei, Taiwan, hlwang@cute.edu.tw

Keywords: open building, open education, elementary school, building size, building programming

Summary

A School's educational pedagogy needs to be supported by its buildings. To better support Taiwan's elementary schools of Open Education, a space program based on Open Building that can accommodate the desired Infill changes was proposed in the past. Though the defined Infill capacity of the program has been demonstrated to be effective in terms of education support and building management, its effectiveness is still bounded by the physical structure of the Base Building. Therefore, how to program the physical size of the Base Building that allows the defined Infill capacity to be brought into play effectively becomes one of the critical aspects of the total effectiveness of the space program. Based on Knowledge Management theory on realizing better value of current knowledge objects and knowledge to create better effectiveness and returns, this paper reviews and evaluates past school building size related research and investigation results, sets the program goal to be users needs fulfillment, and proposes a size program of the Base Building that can accommodates the defined Infill capacity mentioned above. By providing a space program that integrates the size of the Base Building with the most desired capacity of the Infill, an Open Education elementary school in Taiwan can be better supported by its buildings.

1. Introduction

A school's buildings need to support the educational pedagogy of the school. In 1996, the first public elementary school based on Open Education pedagogy formally enrolled students in Taiwan (Shiue 2003). Since then, this type of elementary school has become the predominate type for new public elementary schools in Taiwan. Comparing to traditional teaching practice of "Lecturing", Open Education encourages students to learn in many different ways, modes, and/or groupings freely. Teaching/learning practice can be many forms other than traditional "Lecturing" and the role of a teacher is not lecturing but learning facilitating. In responding to the space needs of the educational practices of Open Education, a "Clustered Classrooms and a Multipurpose Space" method was devised to program and design the needed teaching and learning space (Fig. 1). However, this method has an inherent critical drawback, i.e. it may lose its support to Open Education due to enrollment changes (Wang 2005).

To a school, one critical issue of administration is to maintain the school's educational practices when the number of students enrolled changes. The number of classrooms needed and the assignment of classrooms to each grade, division, or department are affected not only by the total enrollment of the school but also by the enrollment total of each grade, division, or department. To be sustainable, a school's buildings need to support the school's administration to maintain its educational practices. Therefore, how to accommodate the enrollment changes and facilitate school buildings to support the pedagogy of Open Education becomes a part of the sustainable issues in school building programming and design for an Open Education public elementary school.

To resolve above said drawback of the "Clustered Classrooms and a Multipurpose Space" method and to make an Open Education public elementary school in Taiwan more sustainable, Wang (2005) took Open Building approach and proposed that an Open Education public elementary school can be better supported if a cluster unit of the "Clustered Classrooms and a Multipurpose Space" can accommodate Infill possibility of three and four classes. However, according to Open Building, the proposed three and four classes Infill capacity is still bounded by the physical size of the Base Building since the Base Building's size will be fixed once it is built. Therefore, programming the size of the Base Building of a cluster unit of the "Clustered Classrooms and a Multipurpose Space" that is neither insufficient nor a waste to support the two different Infill becomes a necessary endeavor to the sustainability and success of an Open Education public elementary school's buildings in support of Open Education. Based on Knowledge Management theory, this paper reviews and evaluates past school building size related research and investigation results and proposes a Base Building size of a cluster unit that can accommodates the defined Infill capacity mentioned above. By providing a space program that integrates the size of the Base Building with the desired capacity of the Infill, an Open Education public elementary school in Taiwan can be better supported by its buildings.

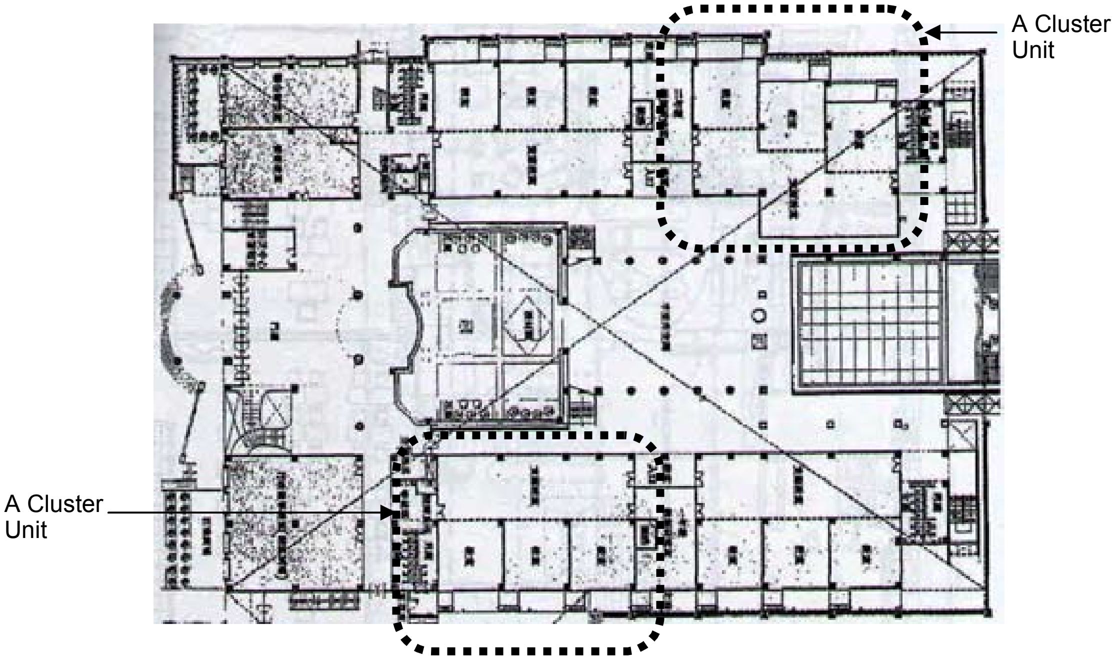

Figure 1 An Example of "Clustered Classrooms and a Multipurpose Space" Design

2. Base Building of Open Building

Open Building responds to the changes of building uses and functions (Kendall 1999). Open Building separates a building into two levels: the Base Building level and the Infill level to provide built-in capacity for changes of uses and functions and to reduce environmental impacts caused by construction for changes.

For an Open Education public elementary school, though the built-in capacity of the Infill of a cluster unit of the "Clustered Classrooms and a Multipurpose Space" has been proposed to comprise only three-class and four-class variations (Wang 2005), the Base Building of the cluster unit, once built, will be fixed in size with very limited potential for changes. Hence, in terms of sustainability of resources, the size of the Base Building of a cluster unit should provide satisfactory space for both three-class and four-class situations without causing inconvenience due to insufficient space and waste due to excessive space. For a cluster unit, the size effect of Base Building in terms of sustainability is shown in Fig. 2.

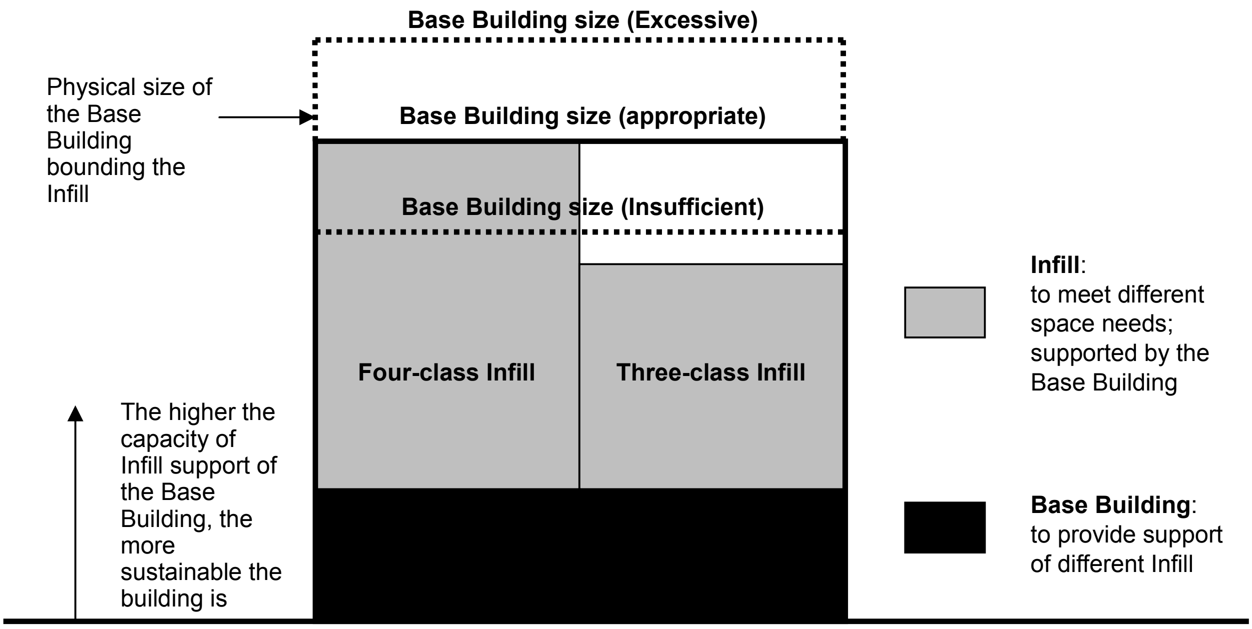

Figure 2 Base Building Size Effect in Terms of Sustainability

3. Knowledge Management

In recent years, in order to improve competitiveness and succeed, knowledge management has become an important tool for individuals, organizations, and nations. The main objective of knowledge management is to realize the best value of knowledge objects and knowledge to create maximum effectiveness and returns (Wiig 1997). Knowledge management has two levels: the object level and the management level. The object level deals with the knowledge item, element, unit or data to be managed and the management level is the management activity itself. To be effective, knowledge management needs to preset its management goals.

Basically, the management level of knowledge management is a cyclic and dynamic process. It can be divided into four stages: Review, Conceptualize, Reflect, and Act (Wiig et al. 1997, Wielinga et al. 1997). Review examines what knowledge objects and knowledge exist and what has been achieved. The outcome of the Review stage is the evaluation results, which provides the foundation for the Conceptualize stage. Based on the evaluation results of the Review stage, the Conceptualize stage constructs a conceptual framework tailored to the preset knowledge management goals and tries to create the most possible value out of existing knowledge objects and achieved knowledge. Following the Conceptualize stage, the Reflect stage is to set up a plan for improvement. This plan for improvement needs also to satisfy the preset management goals. The Act stage is the execution of the plan for improvement. It implements plans set up in the Reflect stage and creates a new state of knowledge objects and knowledge.

A model of the management process adapted from Wielinga et al. (1997) and Wiig et al. (1997) is depicted in Fig. 3. This model shows the sequential relationship of the four activities of the knowledge management process, the position of the outcome of each of the four activities and the cyclic and dynamic nature of the process.

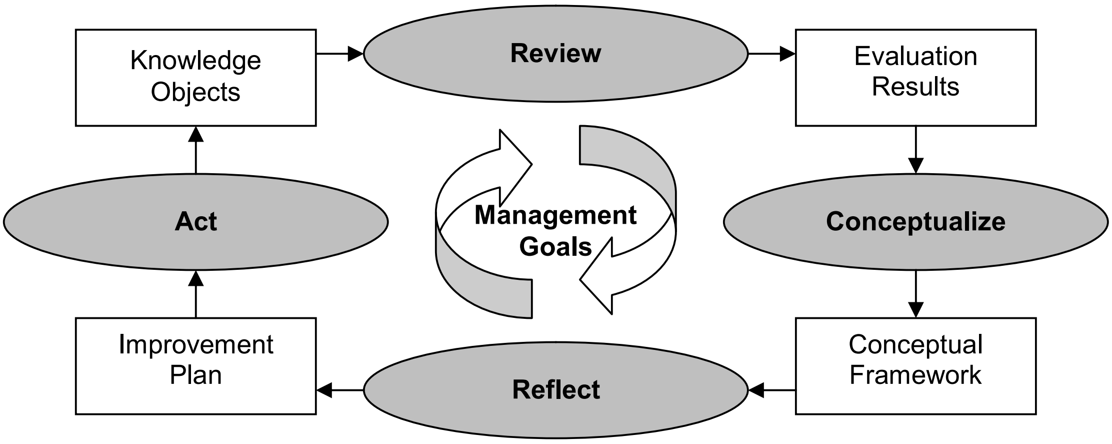

Figure 3 Knowledge Management Process Model

4. Management Goals and Review

Since the size of the Base Building of a cluster unit of the "Clustered Classrooms and a Multipurpose Space" of an Open Education public elementary school should provide satisfactory space for both three-class and four-class Infill without causing inconvenience due to insufficient space and waste due to excessive space, this research sets the management goal of programming the Base Building size of a cluster unit of the "Clustered Classrooms and a Multipurpose Space" to providing enough space as perceived by students and teachers. The reason is straightforward. Students and teachers are the real users of the teaching and learning space. Their perception of the size of the teaching and learning space to daily educational practices is the most direct and first-handed and should be taken into account seriously in building programming and design.

In the past, there were some standards and studies regarding the classroom size of elementary schools (Ministry of Education 1981, Kao 1992, Huang et al. 1998, Lo 2000). However, most of these standards and studies were for non-Open Education schools and the focuses of these standards and studies were either on investigation of existing classroom sizes or providing standards for school administration to use without sound reasoning and further explanations. Table 1 shows the data and results of these standards and studies.

Table 1 Data and Results on Classroom Size Standards and Studies

Sources	Educational Pedagogy Based	Average Classroom Size (unit: m^2/student)	Remarks
Ministry of Education (1981)	Non-Open Education	1.26	Minimum Required Standard
Kao (1992)	Non-Open Education	1.57, 1.48	Investigation Existing (each for one school)
Huang et al. (1998)	Non-Open Education	2.39	Investigation Existing (112 "old" schools)
Huang et al. (1998)	Non-Open Education	2.76	Investigation Existing (11 "new" schools)
Huang et al. (1998)	Open Education	2.04 (for classroom area) 2.11 (for multipurpose area)	Investigation Existing (four schools)
Lo (2000)	Non-Open Education	2.50	Suggested Standard

Furthermore, there was a research showed the results of a study of space adequacy of general classroom as perceived by students and teachers (Chen et al. 2005). Though this study was not on space adequacy of a cluster unit of the "Clustered Classrooms and a Multipurpose Space" of an Open Education public elementary school as perceived by students and teachers, nevertheless, from the points of view of Knowledge Management, the results of this study plus the data and results shown in Table 1 are the existing knowledge objects and knowledge on the subject under research and need to be explored and evaluated to realize the best value of these knowledge objects and knowledge to create maximum effectiveness and returns.

The results of Chen et al. (2005) are:

1. For school type I (the number of students per class is equal to or over 19), about 58% students of schools with classroom size below type I suggested 1.92 m^2 per student expressed their dissatisfactions about the classroom space.
2. For school type II (the number of students per class is less than or equal to 18), about 57% students of schools with classroom size above type II suggested 2.50 m^2 per student expressed their satisfactions about the classroom space and 60% students of schools with classroom size above twice of the type II suggested 2.50 m^2 per student (i.e. 5.00 m^2 per student) expressed their satisfactions about the classroom space.
3. For teachers, the highest satisfaction occurred at schools with classroom sizes in the range of 1.92-3.84 m^2 per student. The less satisfaction of schools with classroom sizes over 3.84 m^2 per student may due to the increased difficulty and tasks in classroom management and administration to teachers.

Based on above and Table 1, the following evaluation results can be concluded:

1. The classroom size of non-Open Education elementary schools seems to be bigger for newer schools. However, the size of classroom still varies among newer schools. Some are smaller and some are bigger.
2. From Huang et al. (1998) and Fig. 1, for Open Education school building based on "Clustered Classrooms and a Multipurpose Space", the size of a cluster unit of the "Clustered Classrooms and a Multipurpose Space" is about twice the size of the classroom area of this unit.
3. For students, though smaller classroom size is perceived as less satisfactory and bigger classroom size is perceived as more satisfactory, it does not necessarily mean that if the classroom size gets bigger and bigger, it will be perceived as more and more satisfactory accordingly. Actually, from the results of school type II, the percentages of students satisfied with their classroom sizes show no significant difference between schools with classroom size above type II suggested 2.50 m^2 per student and schools with classroom size above twice of the type II suggested 2.50 m^2 per student (i.e. 5.00 m^2 per student). Therefore, it seems that, once the classroom size reaches a certain level, it will not change students' perception about the space adequacy significantly as it grows. Therefore, it can be

conservatively concluded that if the classroom size is over 2.50 m^2 per student, students will perceive the space as satisfactory.

4. For teachers, it seems that the classroom sizes of 1.92-3.84 m^2 per student is the most appropriate. Classroom size that is bigger than 3.84 m^2 per student is not so satisfactory to teachers.

5. Conceptualize and Reflect

Since the knowledge management goal of this study is set to providing enough space as perceived by students and teachers, therefore, the classroom size should be perceived as satisfactory by both the students and teachers. Based on above evaluation results, it can be reasonably concluded that if the classroom size is located in the range of 2.50 m^2 per student (lower-bound perceived by students) to 3.84 m^2 per student (upper-bound perceived by teachers) should satisfy both the students and teachers at the same time the most. With this information in hand, the Base Building size of a cluster unit of the "Clustered Classrooms and a Multipurpose Space" of an Open Education public elementary school that can accommodate Infill possibility of three and four classes can be programmed as follows:

1. If the number of students per class is set to 30, then a cluster unit of the "Clustered Classrooms and a Multipurpose Space" that can accommodate Infill capacity of three and four classes needs to provide satisfactory space as perceived by 61 (the minimum number of students for three classes) to 120 students and their teachers.
2. If 3.84 m^2 per student is the upper-bound classroom space perceived as satisfactory by teachers, then 3.84 m^2 per student times 61 students equals to 234.24 m^2.
3. If 2.50 m^2 per student is the lower-bound classroom space perceived as satisfactory by students, then 2.50 m^2 per student times 120 students equals to 300 m^2.
4. Since 234.24 m^2 is smaller than 300 m^2, it is more appropriate to chose 300 m^2 as the programmed size for the classroom area of a cluster unit of the "Clustered Classrooms and a Multipurpose Space". The reason can be explained by fig. 4.

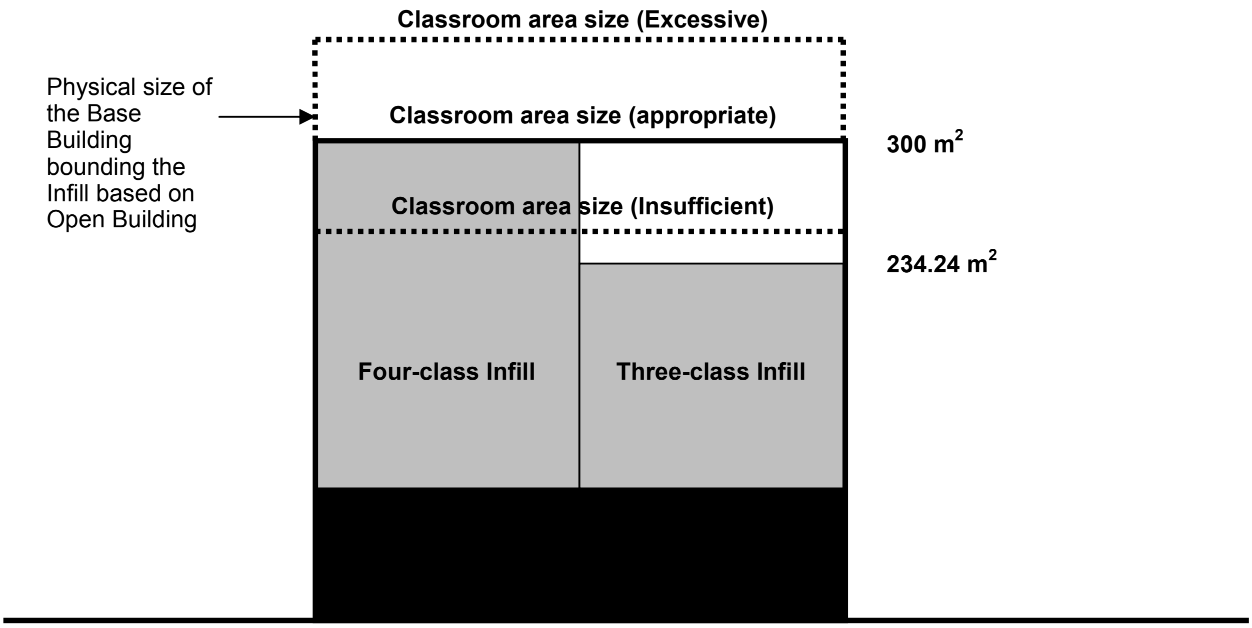

Figure 4 Selections of the Programmed Classroom Area Size of a Cluster Unit

5. Since the size of a cluster unit of the "Clustered Classrooms and a Multipurpose Space" is about twice the size of the classroom area of this unit, the Base Building size of a cluster unit of the "Clustered Classrooms and a Multipurpose Space" can be programmed as 600 m^2 to provide satisfactory space as perceived by students and teachers of three and four classes with 30 students per class.
6. For the number of students per class other than 30, the same procedure 1 to 5 above can be applied to reach the programmed Base Building size of a cluster unit of the "Clustered Classrooms and a Multipurpose Space" for that number of students per class.

6. Conclusion

To an Open Education public elementary school based on the "Clustered Classrooms and a Multipurpose Space" method, the support of its buildings to Open Education needs to be secured as much as possible. Based on Open Building, the programming and design method of "Clustered Classrooms and a Multipurpose Space" can be improved to secure its support to Open Education when student enrollment changes by providing an Infill capacity of three and four classes per cluster unit and by programming a satisfactory Base Building size of a cluster unit as perceived by students and teachers. For an Open Education public elementary school with 30 students per class, the Base Building size of a cluster unit of the "Clustered Classrooms and a Multipurpose Space" is suggested to be 600 m^2 by this research . Though this research is not direct on space adequacy of the Base Building size of a cluster unit as perceived by students and teachers, based on Knowledge Management, the results of this research is valuable for it is concluded by realizing the best value of current knowledge objects and knowledge on classroom size to create the maximum effectiveness and returns of these knowledge objects and knowledge.

Combining with the three and four classes Infill capacity, the proposed Base Building size of a cluster unit is a step further towards sustainability of an Open Education public elementary school based on the "Clustered Classrooms and a Multipurpose Space" method in Taiwan. It takes building sustainability beyond the physical structure and construction of a building itself and integrates the sustainability of educational practices and school's administration in support of education. However, this proposal is still just an advanced step in pursuing sustainability of school buildings. There are other issues need to be studied to better support Open Education such as how to program and design the subsystems of the cluster unit and what the Infill system could be. In addition, the result of this study is based on Knowledge Management, it needs to be implemented and studied to create new knowledge objects to deepen our knowledge on school buildings in support of education and to bring our knowledge on Base Building size in support of Open Education public element schools to the next state.

Keywords: seroepidemiologic, vector-borne, disease, Archilife Symbiosphere I Center, Taiwan

Summary
The GB + Symbiosis = SB has been declared by Archilife Research Foundation (Taiwan) at the SB05 Tokyo. We symbiosis with not only green buildings but also green environment that has been discussed as an important issue previously. With global warming, emerging and reemerging infectious diseases are becoming more serious. To understand the risk and prevalence of vector-borne diseases in a symbiotic environment, rodent serums were analyzed for scrub typhus infection. This study retrospectively analyzed rodent serum collected from January 2005 to December 2007 in the main airports and seaports in Taiwan. By using an enzyme-link immunosorbent assay (ELISA), the sero-prevalence rates of scrub typhus in rodents were found to be 9.48%, 16.41%, and 18.08% in 2005, 2006, and 2007, respectively. Sites with the highest sero-prevalence rates were Su-Ao harbor (northern Taiwan), Mai-Liao harbor (centeral Taiwan), Kaohsiung airport (southern Taiwan), Hualien harbor (eastern Taiwan), and Shuei-tou harbor (an island separate from Taiwan). The Archilife Symbiosphere I Center (ASIC), located in Fulong Village, is near Keelong harbor, Ba-Dou-Zih fishing port, and Su-Ao harbor. The sero-prevalence rate of scrub typhus from 2006 to 2007, however, was 3.12% near ASIC in FuLong Village. This preliminary serologic data from wild rats points out the potential risk from ectoparasites on wild animals in Fulong Village. It will be important to conduct further research that focuses on the management of symbiotic resources and elimination of invading rodents in the local environment.

1. Introduction
There is a scientific consensus that the global climate is changing, with rising surface temperatures sea levels, melting ice and snow, and increasing climate variability. These changes are expected to have substantial impacts on human health, such as vector-bone infectious diseases. Scrub typhus is a mite-borne infectious disease caused by *Orientia tsutsugamushi* (Tamura et al. 1995). This disease distributed throughout the Asian Pacific rim and is endemic in South Korea, China, Taiwan, Japan, Pakistan, India, Thailand, Malaysia, and northern Australia (Fan et al. 1987, Currie et al. 1993, Yi et al. 1993, Strickman et al. 1994, Chang 1995, Horinouchi et al. 1997). Approximately one million cases occur each year, and more than a billion people are at risk worldwide (Rosenberg 1997, Watt et al. 2000). Taiwan has been endemic for scrub typhus for many decades (Ho 1998, Lee et al. 2006, Wang et al. 2007). The major trombiculid mite of this disease in Taiwan is *Leptotrombidium deliense*. Humans may get sick and have a characteristic skin lesion, known as an eschar, when they enter these areas or are bitten by infected mites. In past studies, scrub typhus was mostly focused on islands apart from Taiwan, such as Kinmen, Lanyu, and Green Island. Surveillance data of scrub typhus from northern Taiwan is limited. Rodents play a key role in the epidemiology of scrub typhus because they serve as maintenance hosts for the vector mites (Philip 1980). Many animals that serve as hosts for chiggers have been implicated as the

natural reservoirs of scrub typhus, such as *Apodemus agrarius*, *Microtus fortis*, *Rattus flavipectus, R. norvegicus, R. rattus, Suncus murinus*, and bats (Jo et al. 1990, Ree 1990, Ree et al. 1991, Lee and Lee 1992, Wang et al. 2004). A serologic survey in rodents performed in 1986-1987 by Lee and others recorded the seropositive rates of the house mouse (5%), *A. agrarius* (58.9%), and *Microtus* spp. (77.7%) (Lee et al. 1989). In Taiwan, higher seropositive rates were also recorded in *Rattus flavipectus* (89.0%), *R. norvegicus* (46.0%), *R. rattus* (80.0%), and *Suncus murinus* (24.0%) in Kinmen County from 1999 to 2000 (Wang et al. 2004).

The Archilife Symbiosphere I Center (ASIC) has semi-open construction. The center has a number of novel designs, including a vertical planting system, dry toilets, a residual food composting system, and a biological greywater recycling system (Su et al. 2002). People living or farming there face many kinds of arthropods, such as mosquitoes, flies, beetles, moths, fleas, mites, ticks, lice, and predator spiders (Tsai 2003). Except for the assault of mosquitoes bites, ectoparasites of small animals are the major vectors (Tsai 2002, Tsai et al. 2005). Moreover, many wild rodents from the local environment are found to be infected by fleas, mites and ticks. With the increase of vegetation and ecological activities, people will be harmed by these small arthropods unless attention is paid to the problem. In this study, we evaluated sero-prevalence rates of scrub typhus in rodents mainly from airports and seaports around Taiwan. The sero-prevalence of scrub typhus in rodents near ASIC was also calculated.

2. Materials and Methods

2.1 Ectoparasites collection and DNA extraction

From January 2005 to December 2007, serums were collected from wild rodents in 13 locations, including airports and seaports around Taiwan (Table 1): Keelong harbor, Ba-Dou-Zih fishing port, Taoyuan airport, and Su-Ao harbor in northern Taiwan; Taichung harbor, and Mai-Liao harbor in central Taiwan; Pingtung fishing port, Kaohsiung seaport, and Kaohsiung airport in southern Taiwan; Hualien harbor in eastern Taiwan; Shuei-tou harbor, Liao-luo bay, and Fu-wo harbor on islands apart from Taiwan. From January 2006 to December 2007, serums were collected from wild rodents at Fulong Village in Taiwan.

2.2 Enzyme-link Immunosorbent Assay (ELISA)

Enzyme-link immunosorbent assays were modified from our previous study (Shu et al. 2002). The whole cell antigen was replaced by a 56-kDa recombinant antigen. Positive and negative samples were randomly confirmed by immumofluorescence assay (IFA).

3. Results

Between 2005 and 2007, a total of 1,494 rodents were collected (Table 1). By using ELISA, sero-prevalence rates of scrub typhus in rodents were found to be 9.48%, 16.41%, and 18.08% in 2005, 2006, and 2007, respectively. Sites with the highest sero-prevalence rates were Su-Ao harbor (northern Taiwan), Mai-Liao harbor (central Taiwan), Kaohsiung airport (southern Taiwan), Hualien harbor (eastern Taiwan), and Shuei-tou harbor (a island apart from Taiwan (Table 1). The number of positive rodents was recorded monthly, in particular during June and July 2006 (Figure 1). The dynamics of sero-prevalence rates shows an increase in positive rates from 2005 to 2007 (Figure 2). The sero-prevalence rate of scrub typhus from 2006 to 2007 in ASIC was 3.12% (Table 2).

Table 1 Serological diagnosis of *O. tsutsugamushi* infection in wild rodents in Taiwan

		Positive rate % (No. positive/No. collection)		
Sites of Taiwan	Locations	2005	2006	2007
Northern	Keelong harbor	2.38 (1/42)	26.32 (10/38)	0 (0/28)
	Ba-Dou-Zih fishing port	13.64 (3/22)	4.00 (1/25)	0 (0/0)
	Taoyuan airport	0 (0/31)	1.41 (1/71)	1.23 (1/81)
	Su-Ao harbor	13.16 (5/38)	5.13 (2/39)	25.53 (12/51)
Central	Taichung harbor	10.26 (4/39)	5.00 (2/40)	3.23 (1/31)
	Mai-Liao harbor	9.18 (9/98)	7.69 (5/65)	6.67 (3/45)
Southern	Pingtung fishing port	7.14 (2/28)	12.50 (2/16)	0 (0/0)
	Kaohsiung seaport	9.33 (7/75)	18.18 (10/55)	19.12 (13/68)

	S. murinus	1	0	0
Total		32	3	9.38

4. Discussion

This is the first detection of scrub typhus in wild rodents by serological study in northern Taiwan. The seropositive rate in rodent collected around ASIC is observed. Recently, mite-borne rickettsioses have been diagnosed in local residents from the local hospital (data unpublished). Higher peaks of mite index and scrub typhus cases reported consistently appealed in May to July and November to January in different locations in Taiwan (Wang et al. 2004, Lee et al. 2006). During these seasons, the weather is suitable for outdoor activities. With the increase in ecological activities, infectious diseases such as scrub typhus have raised concerns regarding vector-borne diseases on grasslands. This preliminary study of vector-borne diseases points out the potential risk from ectoparasites on wild animals in Fulong Village. When performing activities or farming in that ecosystem, people should be alerted to the possibility of bites by mites. Reducing the risk of infection by the application of repellents to skin and clothes, avoiding contact with overgrown grass and brush, and wearing long pants, long sleeves, and long socks should be advised as well (Lee et al. 2006). It will be important to conduct further research that focuses on the immune-response activated by these pathogens in local residents. It will be important to conduct further research that focuses on the management of symbiotic resources and elimination of invading rodents in the local environment.

Keywords: sustainable construction, conferences, differences, North and South perspectives

Summary

This paper is about, from a North and South different perspective, how the international focus of sustainable construction issues has changed over the past ten years. The north part is a review from four different international and regional sustainable building conferences between 1998 and 2007,mostly based of the first author's notes from the conferences, especially from the plenary sessions and discussions. The reviewed conferences are GBC98 in Vancouver, Canada 1998, SB02 in Oslo, Norway 2002, SB05 in Tokyo, Japan 2005 and the regional conference SB07 in Malmö, Sweden 2007. The south part is based on literature reviews, research findings and reference buildings from Mozambique and Tanzania reflecting sustainability. The perspectives presented in the paper are those of construction project and environmental manager from northern Europe and from architects in southern Africa with an interest in sustainable construction. The findings of the paper shows that focus of sustainable construction matters has changed from almost solely environmental aspects to a more broad and transparent complexity of sustainability, including ecological-, economic- social- esthetical- and cultural aspects. It also reflects regional and national differences and some shifting views of focus about sustainability in the construction sector during the past ten years.

1. Introduction

Sustainable development is a subject that has been of increasing interest by the global community the last two decades. The construction sector has adapted this by introducing the concept of sustainable construction. However, the adaptation depends of the level of the sustainability view, global, national, regional or individual level. It also depends of the cultural and social context of the actual society. For example many of the modern buildings and settlements in developing countries reflect an uncritical reception of modern European buildings form without taking into consideration the special climatic and social conditions of the home country. The aim is to make some reflexions of these differences from a North and South perspective through engineers and architects eyes respectively.

The first section, the North perspective, is about how the international (read North) focus of sustainable construction issues has changed over the last ten years by a review from four different international and regional sustainable building conferences between 1998 and 2007. This section is mostly based of the first author's notes from the conferences, especially from the plenary sessions and discussions, but some contributions are also considered and selected from breakout sessions and from the proceedings. The reviewed conferences are GBC98 in Vancouver, Canada 1998, SB02 in Oslo, Norway 2002, SB05 in Tokyo, Japan 2005 and the regional conference SB07 in Malmö, Sweden 2007. The reviewing perspective is a engineer by a project and environmental manager.

The architecture in Mozambique and Tanzania, like in many other developing countries, shows little concern for the local environment and climate. The South perspective exams the contribution architects have made towards sustainable architectural practice for the last ten years in Mozambique and Tanzania. Key information is derived from literature review, existing documents, observation, interviews and experience. The section focuses mainly on the analysis of traditional and modern/contemporary architecture in Mozambique and Tanzania with the aim of understanding the attempts that architects have made in the search for sustainable architecture in the tropical countries. This perspective is by architects with southern Africa matter of sustainable construction

2. The North Perspective

2.1 GBC98, Vancouver, Canada

The aim of the Green Building Challenge Conference in Vancouver, Canada, 1998, was to benchmark Green Buildings with different design and assessment tools of current and next generation. Many design and assessment methods were presented by the participated designers and researchers, e.g. among others: GBC98 Tool (international), Athena (Canada), BEES (USA), HK-BEAM (Hong Kong), C2000 (Canada), BREEAM (UK), EcoQuantuum (The Nederlands), Home Scheme (New Zeeland), Ekoprofil (Norway), LEED (USA), Green Building Adviser (USA), CAAD (Germany), Building Stock Model (Germany) etc. The keys of most of these tools were to minimize energy demand during construction and operation, to optimize energy use integrated with renewable energy and to maximize living and working quality for occupants. To ensure the data quality of the inputs was the most frequent issue about to use these tools. Other comments of the tools regarding usefulness was too much information, too much criteria, too many choices and too little time to assess. Two examples of contributions were:

- A test of different assessment tools (Boonstra et al 1998) on the same building showing the output data was too differentiated to be comparable between the methods and an optimization of data not a goal for most tools. Most of the tested tools were developed for specialized consultants and not for actors in the market
- The introducing of the international GBC98 Tool (Cole and Larsson 1998) developed to assess different buildings in different countries with the same tool.

The general conclusions of the assessment methods were about to recognize differences between the tools and the sites of assessments and differences between local and global conditions. But it was important on the other hand to maintain the big picture by the methods

The conference was mainly a presentation of pros and cons of “second generation” tools where the design methods were looking forward and the assessment methods were looking backwards. The main opinion of the future was to develop more LCA-based methods or applications. Absence of methods or tools that covered the construction process was obvious. Most of the methods and the contributions were about Green Buildings and environmental issues, only a very few regarded the whole triple bottom line of sustainability, balancing economy and social development with ecological considerations.

2.2 SB02, Oslo, Norway

The introducing theme of SB02 in Oslo, Norway, was about the -02 World Summit and issues of economic growth, natural resources, environmental impacts, social and cultural development. It was about the challenge of sustainability with prioritized key issues as:

1. Objectives of sustainable development – find reordering of global priorities
2. Sustainability – realize the closed system of earth, the spaceship view
3. Eco-efficiency – Factor 4 is a minimum, Factor 10 is a vision
4. Ratification of the Kyoto Protocol

The knowledge has to shift from a deductive view to a holistic view. The technologic knowledge is dominated over the socio-related. It has to be an integrated design process. The Building Industry is rather proactive than active and the feedback from the performance stage is very low. The solution has to be in small steps with ISO 14001 significant environmental aspects. It is important with affordable living in a market driven environment.

Presentations were made of assessment and design tools that were developed by Europe and North America countries. Some of them were already evaluated and commercial available as national applications as LEED in USA and BREAM in UK. The methods were environmental oriented with most focus on energy savings. It occurred frequently a lot of confusing interpretation of the terms sustainable construction, sustainable building, environmental sustainable building and green building. One effort of explaining the differences between these terms was by CIB´s Agenda 21 of Sustainable Construction. New parts of the world were introduced by the Developing Countries Agenda 21 (du Plessis 2002) with South Africa and Brazil in the frontline. There was also a couple of construction process oriented contributions from Australia, Finland and South Africa. Discussions of indicators of sustainable construction was made e.g. by the CRISP project (Häkkinen et al 2002)

This conference focused mainly on environmental issues as material productivity, CO2 emissions and assessment tools and methods. But some awareness of the rest of the triple bottom line of sustainability was addressed. Two agendas of sustainability in the constructions sector were presented, one general by CIB and one concerning the developing countries. The latter stated a definition of sustainable construction including the triple bottom line and the necessity of a holistic view. New countries as Brazil and South Africa contributed with thoughts about more socio-economics and management focus. Still, the mainstream research community was focused on solely environmental issues.

2.3 SB05, Tokyo, Japan

The latest world conference about sustainable buildings, SB05, was held in Tokyo, Japan, 2005. The introducing theme was about the importance of reducing CO2 emissions, to reduce environmental loads, about eco-efficiency through Factor 4 and Factor 10. Some new approaches were made as Life Cycle Value and Management of Environmental Ethics i.e. sharing common vision and ideas. New issues about ethics, the global aspect and city development were discussed. The conclusion was that sustainability in construction in general was initiated and has become to gain acceptance but it is still a very long way to go. Concerning the broad spectra of sustainability in different economies and regions of the world follows a few examples of contributed presentations and papers:

- Procurement procedures were discussed by Brophy and Lewis (2005) as barriers to sustainable development and sustainable construction. They found the building projects within their study were procured, the scope of sustainability was lacking. The design teams in the study indicated that client commitment, design team commitment, motivation and expertise as the features that most contributed to the achievement of the project targets
- Sustainable – affordable habitat for the rural poor in developing economies by Nair et al, 2005, is depending on socio-cultural, economic, technologic and environmental factors including strategies and policies
- Sustainable construction contains environmental, economic and social values (Yin and Cheng 2005) where local dimensions are significant. Sustainable construction is a long term objective. It should be in account of an early stage of a facility development. This with a management approach and with a focus on procurement methods.

This conference contained more practical issues as procurement procedures, valuating of assessment methods and social housing issues regarding all triple bottom line values. More of management approach was assigned. Again, the mainstream contributions were focused on environmental issues as energy savings and material productivity.

2.4 SB07, Malmö, Sweden

Before the next world conference in Melbourne, Australia, SB08, there were some regional conferences during 2007. One was held in Malmö Sweden as SB07 Malmö or Sustainable City Development -07. The key issue was to demonstrate good examples of sustainable buildings and sustainable development of a city. The concept of Passive Houses and the importance of local sustainable development were highlighted plus the UK housing agenda – the Green Paper. Some lessons were learned, as S-house in Austria – a factor 10 example, but sustainability in the real mainstream project is still invisible. An ethical commitment is essential. From a plenary discussion of how to make sustainability more attractive there were some summarised keywords as liveability, make it easy, initiative, motivate, transparent, local context, lifecycle value and participation.
Following conclusions was made:

- Sustainability not enough – it is necessary to regenerate.
- Reduce consumption – changes in values and lifestyle is also necessary
- A holistic triple bottom view.

Some good practice of green buildings in Scandinavia was demonstrated as progress in sustainability, but the arguments of sustainability contained only environmental issues. Mainstream project is still in the very beginning to adapt a sustainability view.

3 The South Perspective

The history shows that even the greatest monuments and largest civil and religious buildings, the ancient builders designed in harmony with nature (Barr-Kumar 2003). Buildings were designed and oriented to take advantages of prevailing winds, to block excessive solar radiation for the case of tropics and in other climates to face the warming rays of the sun. Tanzania and Mozambique, like many other developing countries, has abundant natural resources like water, sun, and natural building materials. However, the development of Dar es Salaam and Maputo, the major urban centers in these two countries, does not utilize these abundant resources. The emerging architectural development of these countries has to consider more appropriate architecture techniques in order to contribute to the sustainable use of the available natural resources. This can be achieved by considering micro climate, culture, and the economy of the country and the specific geographical area within the country which the building will be located (Yimprayoon 2005). However, the level of environmental sustainability awareness in the construction industry in Tanzania and Mozambique is very low and government environmental policies are yet to be implemented. Awareness about the use of climatic principles of architecture (Tombazis 2005) and their utility in achieving sustainable architecture has to be increased.

3.1 The Colonial Heritage: a Paradigm of Environmentally Sustainable Architecture

Before the German colonial period in Tanzania most buildings were of typical Swahili–Islamic style that featured simple regular plans utilizing mangrove poles for construction. Swahili–Islamic architecture was characterized by the use of an interior courtyard and a deep covered front veranda. Materials used were wooden sticks, mangrove poles, coral hardcore, and clay soil. The German regime adapted traditional construction techniques in an innovative and sophisticated way giving the colonial architecture of Tanzania a unique character and quality.

The "old Boma" built during the German colonial period is an example of architectural environmental sustainability. The Germans used thick coral hardcore, poles and limestone walls of about 600mm to protect interiors from heat gain and also act as noise barrier. The materials and construction technology used were locally available. Windows were mainly placed on the north and south side to allow cross ventilation since air conditioning was not available. The courtyard design was also adopted from traditional Swahili architecture of Dar es Salaam. The use of a courtyard was important to facilitate air flow through a chimney effect. White colour was an essential part of colonial buildings and was used mainly to reflect solar heat.

The German colonialists learned and adopted local building techniques to suit their own purposes. From the pre-colonial and colonial architecture there are clearly lessons to be learned in order to achieve sustainable architecture for Tanzania. The optimal cross ventilation of spaces, shading against sunshine by walls and other shading devices are things that can still be employed in today's architecture (La Roche 2005). Pre-colonial and early colonial architecture is highly instructive.

3.2 Last Ten Years Development

Since the colonial era Tanzania has invested funds to improve its infrastructure, particularly in the area of transportation, urban planning and public buildings (Lauber, 2005). However, most buildings in Dar es Salaam and Maputo in Mozambique show a minimum concern for the micro–climate, economy, and social cultural conditions of the country. In general, in these last ten years we have seen a gradual disappearance of traditional architectural forms as a result of importing the European, American and Asian technology without taking into consideration the special climatic and social condition of the home country. Some cities of these countries such as; Maputo, Beira, Nampula and Nacala in Mozambique; Dar es Salaam, Mwanza, Arusha in Tanzania, did start to construct some buildings using glass materials. These buildings have many air-conditioners which expend a lot of energy for cooling. The extra energy so used would be better used somewhere else.

Some examples:

- The Kilimanjaro (Kempinski) Hotel, facing Dar es Salaam's harbor, was renovated in 2005. The hotel has a perfect orientation for sun protection; east–west, with the long façade facing north–south. During renovation operable windows on the south and north façade were replaced by fixed glass panels, which necessitates the use of an air conditioning system all the time. This increases energy expenditure for maintaining a comfortable temperature in the building, and prevents any use of the cool breezes from the ocean and the south–east monsoon winds.

- A few blocks southwest from the Kilimanjaro Hotel is the PPF (Parastatal Pension Fund) tower in downtown Dar es Salaam. It was designed in 1996 and features glass facades that are completely exposed towards to the east and west ensuring the PPF tower heats up all day because it must absorb the maximum daily dose of the intense equatorial sun. This leads to a high level of energy consumption for cooling the building.

During the same period, a number of recently built houses, residential and institutional, present different design solutions corresponding to specific local conditions. This is evidence of climatically appropriate architecture. These buildings are well-oriented with optimal natural cross-ventilation of spaces and protection against direct sunshine offered by walls; benefits easy to achieve using local material. Some of these buildings can be seen in Maputo and Dar es Salaam, e.g.:

- A new Central Library at Eduardo Mondlane University, Maputo. The building incorporates the most important aspects of sustainability. The design has been conducted in a very participative way and focus was placed on the need to find innovative architectural and engineering solutions. Local conditions were regarded important and such effort was made to take them into account.

- The offices of The World Bank and Swedish Embassy are other examples of sustainable architecture in Maputo.

- The American Embassy in Dar es Salaam where it is good relationship between natural and artificial situation. It is possible to see the application of Sustainable Construction knowledge.

Both countries have other public and private buildings where this knowledge has been applied.

3.3 Influence from the North

Instead of applying and modifying proven design and construction techniques developed in Southern Africa to meet Southern African conditions, the building industry has become fixated on importing the latest technological developments and new construction techniques from the North with little reflection on their suitability for local conditions. This new phase of building design completely ignores traditional and early colonial architecture. In many ways the building industry reflects larger patterns of economic, political, and social interaction between Southern Africa and the North, where Northern ideas and practices serve as the benchmark to be adopted. In the building industry this has meant the disappearance of efforts to achieve sustainable architecture and its replacement with buildings that use high rates of energy in their daily operation and imported materials for their construction.

3.4 Awareness of Sustainable Architecture

The construction industry by large should be responsible for converting the natural environment into a built environment without destroying its natural state. However, in Tanzania and Mozambique, awareness of environmentally sustainable architecture is very low. In order to make an impact, the basic principles of sustainable architecture will have to be known to all members of the building team - including the client, architect, consultants, contractors, building product manufacturers, and building users. There is a need to change the way in Southern Africa to build and use the buildings from an architecture based on low quality replication of Northern designs to more innovative use of traditional low technology. It is a matter of low energy use designs to achieve greater long term sustainability of the region's natural resources, the economic viability of the client's building and to ensure greater comfort to the buildings users.

3.5 Lack of Architectural Research and Communication

Research in the field of architecture provides an opportunity to link new knowledge with design. It is therefore a fundamental aspect of the architectural profession (Emmitt 1996). It provides scientific knowledge, useful for resolving architectural problems. However, the research element in Tanzanian and Mozambican architecture is not given the importance it deserves in order to promote a positive development of the profession towards sustainable development.

4 Conclusions

Many developing countries in the Southern hemisphere do not apply the knowledge of Sustainable Construction due to many reasons. As a result of this situation, many of the modern buildings and settlements in these countries, in the last ten years, reflect an uncritical reception of modern European buildings forms without taking into consideration the special climatic and social conditions of the home country. The examples from the pre-colonial and early colonial era when mechanical air conditioning did not exist and the use of local materials showing the structures that made use of materials, cross ventilation, colours, and orientation toward/away from the sun that kept occupants comfortable with minimal energy inputs, even under the intense equatorial sun. In comparing this earlier period to modern day architecture in Southern Africa we can see that the principals that underpinned the early sustainable architecture have been forgotten. However, this knowledge has gradually started to be applied and it is making it possible to see some buildings on the basis of this knowledge. The principal of making buildings to fit their environment, climate and culture, rather than aping the architectural styles of developed countries is the key for making sustainable architecture to be achieved in Tanzania and Mozambique.

The economic development that occurs in the North and the South perspective, especially in non-developed countries, in the last decade, is made up of great utilization of the production of energy from the fossil resources. The finite nature of this natural resource, and the environmental impact of its production and consumption, makes these countries to rethink their development plans. New strategies must be found to maintain the current standards of life in developed societies and to help aspiring new developed countries to reach higher standard of life. This has to be developed without compromising the new technology, not only for the benefit of the environment, but also in level of economic and social development.

With a look backwards from the Rio summit in the beginning of the nineties, there has been a long time for the construction sector in the industrial countries to adapt the whole concept of sustainability including the triple bottom line . The research community of sustainable building has moved its focus slowly from solely environmental issues and assessment methods through questions as energy savings and material productivity to a holistic view of sustainable buildings including the triple bottoms. What about the mainstream project and its involved stakeholders as clients, project management team and end users? Where are the process thinking and management aspects of sustainability? The objective is to reach a resource productive factor of Factor 10 or Factor 20 in one generation but the first generation is soon at halftime and we have barely just started. It is time to prioritize the objectives to make it easy to get information how to do and make rules or opportunities to promote the mainstream construction project towards sustainability . It is obvious that a general global agenda of sustainable construction has to be complemented with specific conditions of the actual site, of the specific project or facility, of the ability or knowledge of the design and management team and of course regional and local conditions of the triple bottom lines of sustainability. It is a matter of fact a question of knowledge transfers from bottom-up and top-down perspectives locally adapted, despite if the site is located in a Northern Artic mountain area or in a Southern tropical urban area.

Summary

The management of a construction project in a sustainable way should focus on the entire process from an early design stage towards the final product, and on the benefits and negative impacts that are to be expected during the life of the facility. The research presented here argues that there is a difference between sustainable building and sustainable construction, where the first considers the final product and the latter considers the way to the final product, i.e. the process. To manage such a process, in a sustainable way, there is a need of some kind of management system or tool from the perspective of process owner and the management of the project. To link sustainability with quality and environmental aspects is one way to systemise this process. Common and useful structures are the international standard of the environmental management system ISO 14001 and the international quality management system ISO 9001. This linkage could be achieved by using a sustainability evaluation model, STURE, where the construction project stakeholder's different demands are considered alongside the quality and environmental aspects. The result is a suggestion of a combined system/tool of how to manage the process of a construction project's sustainability, environmental and quality aspects towards a sustainable building.

1. Introduction

At present, actors within the construction sector in Sweden are endeavouring to develop a more effective process than hitherto available for achieving a combination of high quality, economic advantage and sustainable construction management. The management team of a sustainable construction project should focus on the entire process from an early design stage towards the final product, on the benefits and negative impacts regarding the triple bottom lines of sustainability that are to be expected during the life of the final product, i.e. the facility. There are relatively few examples of good practice regarding sustainability in mainstream construction. It seems that clients and project managers face barriers to implement sustainable construction. Williams and Dair (2005) found at least 12 barriers to implementation. The most common were lack of consideration of sustainable measures, real and perceived costs and inadequate expertise and powers.

A common misunderstanding in the construction sector is that sustainable buildings are more expensive in investment cost than 'normal' mainstream buildings. A survey by the World Business Council for Sustainable Development (WBCSD 2008) investigated the difference in investment between a normal building and a certified sustainable building. The result indicated that sustainability concerns should be about 17% more expensive in investment cost. Other sources indicate up to +15% (Lützkendorf 2005). Kats *et al,* 2003, and Matheissen and Morris, 2007, found that a green building is cost effective, no additional cost compared to normal buildings is necessary and the total benefits over the life cycle are over ten times the average initial investment required to design and construct a green building. It seems that the stakeholders to the project, i.e. clients and building professionals, are not well enough informed about the basic linkage between construction and sustainability. It is important to clarify the difference between sustainable building and sustainable construction, where the first considers the final product and the latter considers the way to the final product, i.e. the process. To manage such a process, in a sustainable way, there is a need for some kind of management system or tool from the perspective of the process owner and the management team of the project. To link sustainability with quality and environmental aspects is one way of systemising this process. Common and useful structures are the international standard of the environmental management system ISO 14001[1] and the international quality management system ISO 9001[2]. This linkage could be achieved by using a sustainability evaluation model, STURE (Persson and Olander 2004; and Persson et. al. 2005), offering a triple bottom line perspective where the construction project stakeholder's different demands are considered alongside quality and environmental aspects.

2. Sustainability as Sustainable Building and Sustainable Construction (Product and Process)

Views of sustainability are quite different with shifting focus of content from a regional/national level to the individual level and from different nations/regions to different cultures and societies. The terms sustainable building, sustainable construction, green building and so forth are interpreted quite differently by involved stakeholders depending of education, age, cultural background etc. (Cole and Lorch 2003). It also seems to be quite confusing where differences between the terms, especially between sustainable construction and sustainable building, are concerned. If sustainable building considers the final product, i.e. the building, then sustainable construction is about the whole process towards the final product and during the product's lifetime. The process includes the stages of pre-design, design, procurement, construction, operation, maintenance, refurbishment, re-construction, demolition and recycling. Construction itself could imply everything between site-specific activities to the creation of human settlements. Sustainability on the other hand should imply a holistic view; the whole is more than the sum of its parts with relationships and interactions between humans, society, the biosphere, economy and the state of technology (Plessis 2007).
.

Sustainability in construction has been defined by Agenda 21 for Sustainable Construction (CIB 1999). There is a present standardization process through Agenda 21 known as ISO FDIS 1532:2008 "Sustainability in Building Construction – General Principles". Sustainable buildings, as cited by Trinius and Sjöström (2008), "…provide the required performance with minimum adverse environmental impact, while encouraging improvements in economic, social and cultural aspects at local, regional and global levels"

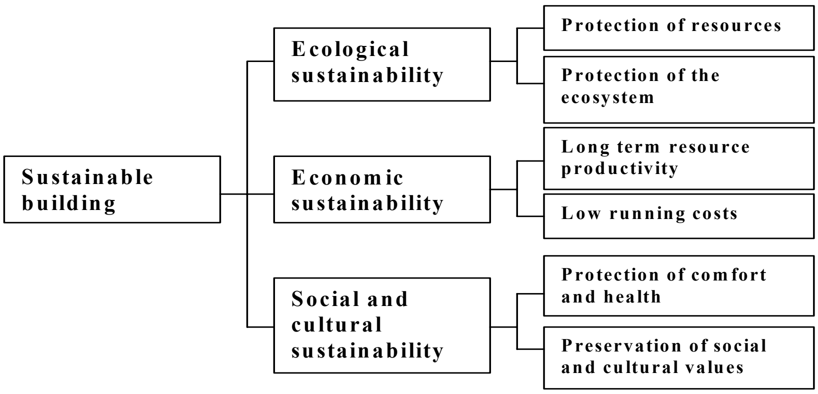

Figure 1 Sustainable building (Kohler 1999)

A sustainable building could also be defined as "buildings that contribute to sustainable development" (Lützkendorf 2005) or as described in *Figure 1* (Kohler 1999). The right column defines the performance objectives of a sustainable building regarding the principles of the triple bottom line of sustainability; ecological, economic and social/cultural development having equal importance (Pope et al 2004). O'Connor (2006) argues for a fourth part or 'sphere' to be involved in sustainability: The political sphere that acts as a rule and regulation setter of, and between, the other three.

Sustainable construction can be interpreted in many different ways. It covers a broad and complex interaction between involved stakeholders, aesthetic issues, material interactions and functionality. To find a definition of this process in terms of sustainable building over its life cycle is one of a few clarifying terms in regard to sustainable construction made by CIB, UNEP and the research institutions CSIR and CIDB of

[1] ISO 14001, 2004: Environmental management systems – Requirements with guidance for use. *ISO 14001:2004*

[2] ISO 9001, 2000: Quality management systems – Requirements *ISO 9001:2000*

South Africa in their Agenda 21 for Sustainable Construction in Developing Countries (UNEP et al 2002, Plessis 2007):
"… principles of sustainable development are applied to the comprehensive construction cycle, from the extraction and beneficiation of raw materials, trough the planning, design and construction of buildings and infrastructure, until their final deconstruction and management of the resultant waste. It is a holistic process aiming to restore and maintain harmony between the natural and built environments, while creating settlements that affirm human dignity and encourage economic equity."

This supports the triple bottom line philosophy mentioned above and should also be applicable in a country anywhere in the world despite its level of industrial development.

3. Project, Knowledge and Sustainability Management Linkage through STURE

As sustainability issues increase total complexity in a construction project, the ability and the knowledge of the project management team has to be deeper and broader. This increasing complexness is visualised by Hacking and Guthrie (2008), who compared the assessment methods of traditional environmental impact assessment (EIA) with a sustainability assessment, *Figure 2.* This requires it to be a more strategic and holistic way of dealing with these issues on the part of the project management team.

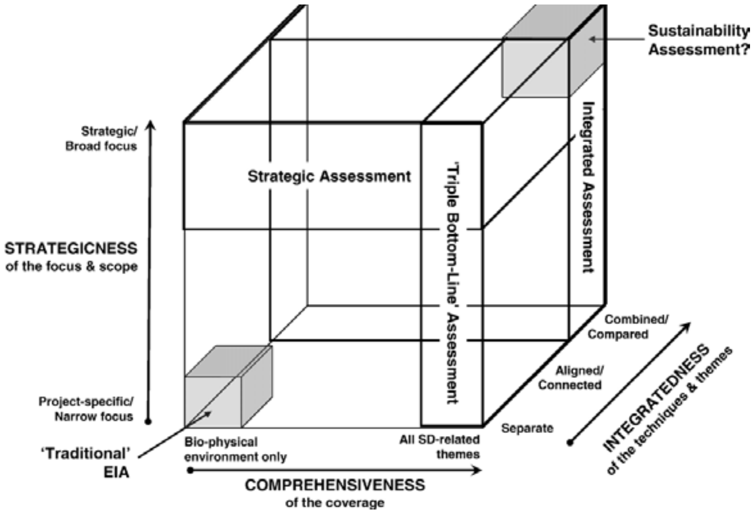

Figure 2 The complexity of assessment methods (Hacking and Guthrie 2008)

The low degree of transfer of experience gained within the construction process to those participating in it has been noted frequently, a weakness that reflects a lack of a natural forum for the distribution of information. There is a need for some system for reporting experience gained in such a way that those engaged in the chain of tasks to be performed can access the knowledge and experience of others, both during a project and afterwards. If no such transfer of knowledge and experience takes place, there is the risk of the firm failing to take advantage of what has been learned and of it making the same mistakes again.

The assembly of information relevant to a project is part of the requirements of the managerial system generally, as expressed in the set of international standards ISO 9001:2000 and ISO 14001:2004, which are common used in the construction sector. The complexity of the construction process means, however, that special measures are called for if the collection of relevant information, including the experience that has been gained and made available to those in need of it, is to function properly. The continual public debate regarding what takes place within the construction sector is considered by many to reflect flaws in the quality assurance system and the lack of a well-functioning system for collecting and distributing knowledge. There is good reason behind the construction sector's endeavour to identify ways in which the functioning of these two systems can be improved.

In temporary organizations, such as those in construction, knowledge of a specific project and the use of routine checklists often play a central role. Knowledge and information often need to be handed on to the next actor in a sort of relay race. It can be difficult at times for the craftsman to understand from explicit sources how a particular step in the construction process is to be carried out to satisfy the demands for sustainable construction. Tacit knowledge can play a major role under such circumstances, meaning doing what one is accustomed to do, without studying drawings or written materials. The willingness to work in this way (i.e. figure things out on the spot) can be a positive trait, especially when no drawings or descriptions of the exact procedures to carry out are available. Yet, it can lead to insufficient precision and result in quality, environmental and sustainability requirements not being met (Persson 2006).

A case study performed at an SME in Sweden serves as an example to illustrate possible ways of coping with problems during the production stage when new systems are tried, e.g. managing sustainability issues. The overall aim of the study was to analyze how knowledge and experience can best be made available continually to those in need of it, with a system being designed to serve these ends as effectively as possible. A specific objective of the study was to investigate how a particular construction company deals with the knowledge potentially available to it and how the organizational work of the company supports its knowledge management efforts (Persson 2006).

Nonconformity as defined in terms of ISO 9000 should represent an ideal point of departure for learning and for the transfer of knowledge (Persson 2006). Nonconformity in terms of ISO 9000 can be noted in managerial reviews, which concern primarily matters of documentation, routines and procedures of a general nature. One reason why it may be difficult in a business organization to deal adequately with both major problems as well as lesser problems is that there is much greater profit for a firm in using most of the limited resources it has for business of major importance than in concentrating on overcoming weaknesses in areas of little financial importance. Managerial reviews should be concerned in part with questions of the quality and environmental management system. Another possible reason for the limited attention of nonconformities and not being documented can have to do with the working culture in the construction sector. Instead, it is a conversational culture in which the social network and people's discussions with each other are regarded as the major ways of spreading knowledge and information, although this is a matter that was not investigated systematically (Gluch 2005).

The protocols of the management reviews make note of significant matters of experience taken up in the meetings for sharing experience (Persson 2006). Certain comments by customers are also contained in these protocols. There appears to be a lack of effort in the protocols, however, in combining and integrating the information from different sources taken up in the meetings.

In order to bridge the gap between project management routines supported by ISO9001 and ISO1400, the knowledge transfer as described above and 'the new and unknown' sustainability management the authors propose to link these issues by using a sustainability evaluation model as the Stakeholder Urban Evaluation Model (STURE) – see *Figure 3* (Persson and Olander 2004, Persson, Olander and Landin 2005). In this decision model the stakeholder's different demands are considered alongside the quality and environmental aspects.

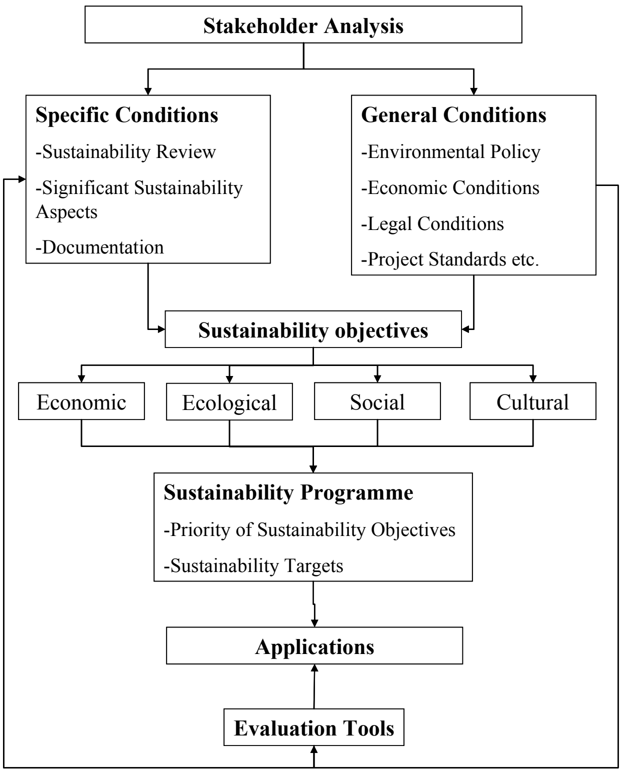

Figure 3 *The STURE model (Persson and Olander 2004; and Persson et. al. 2005)*

The principle of STURE comprises four steps: *stakeholder analysis*, *specific conditions* for the actual application, *general conditions* that need to be addressed and the *sustainability programme.* This last step acts as a synthesis of the other three steps. This concept corresponds to the environmental management standard of ISO 14001 with the distinction of exchanging all terms defined with the prefix or suffix of 'environmental' to the triple bottom line definition of the term 'sustainability'. STURE could be described as an objectives-led integrated assessment (*Figure 4*) applied at the project level, but it also could be the prototype of a sustainable assessment method suggested by Pope et al (2004).

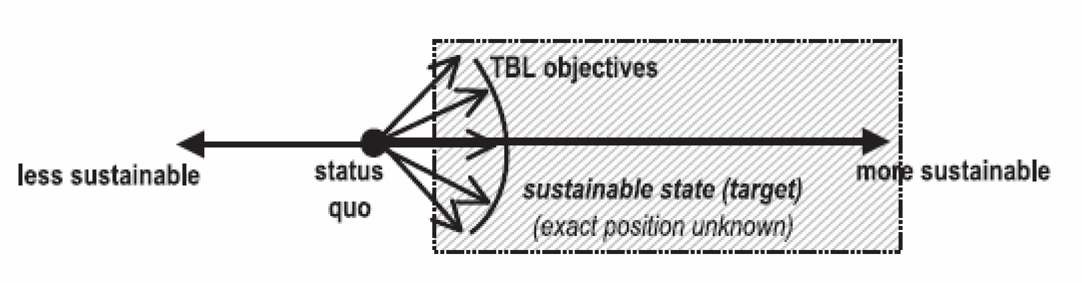

Figure 4 An objectives-led integrated assessment approach to sustainability assessment (Pope et al 2006).

4. Stakeholder Concerns
