It seems that information between the involved stakeholders in a construction project is one essential and missing part, especially regarding complex relationships and interactions related to sustainability issues. The communication of sustainable issues can be the difference between a successful project and a failure. In order to obtain acceptance to construct a facility from its various stakeholders, it is often a requirement to communicate the triple bottom line impact that the facility brings. Communication should thus be seen as an essential part of project manager's efforts to manage stakeholder interests with respect to the purpose of the project and to the impacts of the sustainability that it brings. If the project management team, through communication, can create a working dialogue, it may be easier to pinpoint the real conflicts in a project and eliminate false conflicts and misunderstandings, thus reaching acceptance for the project (De Laval 1999). In other words it is essential to know who the stakeholders are and their needs and concerns in relation to the purpose of the project. In the construction sector, stakeholders include a wide range of entities that directly or indirectly can provide support or resistance to the accomplishment of project objectives (Walker 2000). Karlsen (2002) argues that there are at least four reasons for performing a stakeholder management process. First, to be acquainted with the project's stakeholders; second, to ensure the balance between contribution and reward in the relationship with stakeholders; third, to plan and define how to manage stakeholder concerns; and last, to set a base for deciding which stakeholders are to be involved in determining the project goals and the measurement of success. Stakeholders can be divided into internal and external (Gibson 2000). The external stakeholders are those affected by the project in a significant way, but not directly involved in execution of the project (such as neighbours, the community, the general public, as well as trade and industry)

Often, both proponent and opponents to a construction project argue their case from a perspective of sustainable development, which means that it is important for the project management team to clearly and openly evaluate all possible options to obtain the project purpose with respect to the relevant sustainable issues from the perspective of the project stakeholders. It is thus relevant for a construction project manager to have tools and methods to combine the goals and purpose of the project with the concerns and needs of various stakeholders divided into the triple bottom line aspects of sustainable construction.

5. Conclusions

As argued before, the broad spectra of sustainability increase the complexity of the number of decisions the project team has to make during the process of a construction project. Information is circulating in the companies, but the companies lack any system for transforming this into knowledge needed to move the process towards sustainable construction. When it concerns to involve the stakeholders in the process, internal and external, there is a need for a combined method/tool for the project management team in relation to the process of the project's sustainability, environmental and quality aspects towards a sustainable building. Using the model of STURE, the team could make a structure of sustainability, environmental and quality issues linked to the project and to the demands of the stakeholders alongside the technical solutions. This may not guarantee the all best solutions regarding sustainability, as shown in *Figure 3*, but it could reveal the best path towards a sustainable building from the specific project's conditions, the project team and the client's ability to deal with the subject and demands from the users and other involved stakeholders. However, we have seen that this area is important in a larger context and we have been inspired by ongoing research in other countries and research groups which confirms this research direction as valid.

Keywords: life cycle assessment, building performance, 3Rs

Summary

There is a connection between buildings usage conditions and environmental performance. It is admitted that most efficient ones consume less resources over time. Those which are assessed as inefficient tend to be replaced, disposing used resources and consuming new ones. The worsening in performance indicates that a building life cycle is coming to an end, even if some of its components and systems are still in good usage condition. It is possible to intervene to extend its life and prevent its demolition, before performance is mainly unfavorable and maintenance becomes impracticable. This can be done by adapting it to current needs and new regulations on accessibility, safety, health and energy efficiency, but it depends of appropriate assessment tools. Among the approaches on sustainability, one that can serve as a reference for decisions is 3Rs (recycle, reuse and reduce), widely used in environmental education initiatives. This paper discusses the applicability of reduced consumption, reuse of products and recycling of materials principles for the assessment of building components and systems in order to optimize its performance and increase its life cycle. Its goal is to propose a simple tool, easy to understand and in public domain, which may contribute to spread concepts of sustainability among different stakeholders and minimize the impact of demolition, refurbishment and construction on the environment.

1. Introduction

A significant part of the existing built space was made without taking environmental issues into account. The assessment of the environmental performance of these buildings based on current tools can lead to a very poor result. In this case, would it be appropriate to substitute these buildings for others, more adequate to current needs and with better environmental performance (even though this would generate demolition residue and consume new resources)? Or would it be better to extend its life cycle through the recovery of its performance?

The life cycle of a building has a significant relation to its conditions of use: while the physical and functional performance is adequate, it can still be useful. Significant buildings, of recognized cultural value, can have quite a long life. Common ones, made to cater to very specific needs of a certain moment, tend to have a short life: declining performance indicates the approach of the end of its life cycle.

Comparative analysis between an existing building and a new one, based on their life cycles, can bring answers in terms of the best alternative: refurbishment, up to a certain deadline; substitution, after that. The problem is that the instruments for assessment are not yet developed enough for their use on a large scale, the databases are incomplete and the methodologies are not yet consolidated to assess existing buildings. This kind of analysis, then, does not occur and the decisions as to demolish or to recover are taken without proper criteria, not considering impacts on the environment.

The Federal University of Santa Catarina, a governmental higher education and research institution in the south of Brazil, illustrates the dilemma of the discussion of the management of the built environment. It is an institution that is growing to facilitate access to higher education and to promote changes in the living conditions of the population. A significant part of its buildings were done in the eighties and already present a decline in performance. This case must be seen in the perspective that education, research and government institutions should lead the search for sustainability through the exemplification and application of the Best practices, according to the Agenda 21 for Sustainable Construction in Developing Countries (CIB, 2002).

Even if in the current state of the art it is not possible to measure with precision the effects of decisions, the urgency of the environmental issue makes it necessary that the parts involved seek to minimize impacts. Any initiative that seeks to reduce the use of new resources or the best use of resources already employed or yet the possibility of recycling the resources that have no further use can contribute to the reduction of the weight of construction, reform and demolition activities on the environment. Thus, it may be possible to apply the 3 R's approach (reduce, reuse and recycle), that are used in environmental education and waste management as a guide for decisions on built space.

Objectives

This study has as its objective to verify the applicability of 3Rs principles, reduce, reuse and recycle, in the assessment of parts, building systems and buildings for the management of built space.

Procedures

The article is divided in five titles that correspond to the stages of the study. The introduction presents the research problem, the objective of the study and the methodological procedures adopted. The theoretical basis builds a framework based on the literature on: sustainability assessment; life cycle and performance, and; 3Rs approach. The proposition formulates an instrument for the analysis of built space, building systems and components. The application exemplifies the use of the instrument in practice, taking as a reference buildings made for the Federal University of Santa Catarina, UFSC. Finally, the conclusions evaluate the results, the attainment of the objective of the study and points out some paths for the sequence of the research.

2. Theoretical basis

The theoretical framework of this study is formed by approaches to the environmental issue and management of built space, with a quick discussion of: sustainability and assessment systems; life cycle and performance of buildings, and; on the 3Rs as a principle for the reduction of residues.

Sustainability assessment

Sustainability is a condition where the necessities of the present are met without compromising the possibilities of future generations meeting their own necessities. The Agenda 21 highlights the importance of the refinement of production through technologies and processes that use resources more efficiently, doing more with less (CIB, 2002). Attaining sustainability implies stabilizing, or reducing, environmental loads. This load is a function of three factors: population, consumption capacity and technology. Due to the impossibility of reducing population or consumption (that tends to increase through the improvement of the population's living conditions), sustainability can only be obtained through radical changes in the technologies employed today to generate wealth, so that the conditions to provide what is essential to all exist (HART, 1997).

A sustainable building seeks to maximize the operational efficiency while minimizing its environmental impacts (GBC, 2008; ACE, 2001). A way of demonstrating the environmental adequacy of a building is through certification, with the voluntary adoption of performance criteria and standards. Certification seeks to attain the performance standards voluntarily. Most existing buildings were constructed before the establishment of environmental performance criteria, which makes a favorable evaluation more difficult. However these criteria can guide interventions for improvement.

Environmental performance certification systems, such as BREEAM, LEED and CASBEE, converge in the sense that they take into account the consumption of natural resources, which corresponds to around 40% of the weight of the assessment. In the other aspects they vary according to concerns and regional aspects that make it difficult to use in a indiscriminate way. The prescriptive characteristic of the assessment, as a check list, does not necessarily guarantee the best performance. In truth, there is the risk that buildings are evaluated more for their equipment than by their global environmental performance. That is why there is a tendency to seek quantitative evaluation systems that take into account the buildings life cycle. It is a transition from the 'green building' approach, where its environmental performance is qualified, to a 'sustainable building' approach where the impacts of the production process are quantified, from its use until its demolition (SILVA, 2007).

Life cycle and performance

Life cycle analysis, LCA, is a tool used to quantify the environmental emissions or impacts throughout the life of a product, system or process. In the case of buildings, this approach ranges from the extraction of raw materials for the production of components until demolition and residue disposal. However the complexity of construction, that demands and infinity of processes and materials, and regional specifics, makes it difficult to establish the limits of analysis, to form a consistent database and to define the impacts in order to allow the understanding of information. Several authors (SILVA, 2007; KAWASE, 2005; ACE, 2001) recognize the difficulty of its use in civil construction, which restricts the analysis to a few theoretical exercises or very specialized applications. From the practical point of view, its limited application permits a comparison of alternative solutions. However, there is no way to present a number that expresses the environmental impact of a building from 'cradle to grave' nor is it possible to determine a more sustainable alternative between refurbishing or substituting an existing building (LUETZKENDORF, 2005).

One must take into account that the performance of a building does not maintain itself unaltered throughout its life cycle. Over time the building's components and systems suffer wear which affects their conditions of use to the point of total wear or ruin. Performance can be recovered by maintenance interventions. These interventions must be made before the component or system goes from 'good stand' to 'partial outworn', so that the edifice's performance can be preserved and great and costly renovation interventions avoided (KESKKYLA, 2005).

Another aspect to be considered is that the performance of the buildings also varies according to the activities that occur there: more intense use tends to be more sustainable. If the buildings are not used, if their spaces become unused, there is no way to assess them positively from the environmental point of view, even though no negative impacts and effects are perceived (ELLE, 2005). This, initiatives to improve the use of existing spaces can reduce the demand for the expansion of built space and for the consumption of new materials; in other words, intensifying the use minimizes consumption.

3Rs Principles

Sustainable development demands a reduction in consumption of natural resources and a reduction of the environmental load (HART, 1997). The lack of concern with practices directed to the efficient use of materials in construction results in the excessive use of natural resources and in the generation of large quantities of waste that are rarely recycled. Data indicates that approximately 40% of all waste globally are originated in the construction and demolition activities. In general, construction waste have a lot of volume, are heavy and not suitable for incineration or composting (NITIVATTANON, 2007; JOHN et al, 2001).

The approach of reducing waste, reusing artifacts and recycling resources is frequently called 3 Rs. Reduce means the option of using materials or objects taking care to minimize waste and the amount of residue. Reuse involves the repetitive use of items or parts that still have useable aspects. Recycle means the use of the residues themselves as a resource. The ease of comprehension of these principles makes the 3Rs a powerful environmental education tool for the reduction of residues in human activities. The application of these principles can lead to a fuller use of the materials in their life cycle (MoE, 2005). For its implementation, some governmental initiatives have been taken forward, especially in Asia, such as the creation in 2006 of the 3Rs KNOWLEDGE HUB (www.3rkh.net) intended to produce, systemize and disseminate knowledge.

The 3Rs principles are not applicable only to the management of waste. In truth, these principles tend to modify the standard of behavior when they demand a reduction in consumption. This induces the individual and society to think of their needs and expectations. The search for satisfaction can give way to a more responsible attitude that does not depend on the acquisition of another artifact. We know that just by minimizing the consumption of natural resources we can manage to reduce the environmental load. We must admit with urgency that faced with the environmental crisis, and for the possibility of survival of future generations, we must change (UNEP, 2007; MMA, 2005; MANZINI 1998; HART 1997).

3. Proposition

The way in which the 3Rs principles are presented is not for free: first we must seek to reduce consumption, then reuse what is already available and only then recycle, when there is no more possibility of use. This sequence permits a parallel with the life cycle of industrial products, the extraction of materials for their manufacture, from their use until their disposal and final discarding of residues. Buildings can be seen in the perspective of this cycle: first, the use of resources for construction, that must be minimized by design initiatives; after, the maintenance activities, that assure the continuity of its use and the full use of the resources employed, and; at the end, the demolition, when there are no more conditions for use and when the recycling of materials should occur.

The perspective of the 3Rs as a life cycle approach allows that other more complex readings be made. For our analysis, buildings can be broken down into several levels: by their materials, their components, their building systems and even their spaces of use. Each one of these entities can be seen as a resource in its repetitive life cycle (of creation, use and discarding) and can always be submitted to questioning as to: hoe to reduce, how to reuse and how to recycle. This leads to thought on the use of resources employed in the construction, maintenance and demolition phases. Table 1 presents possible meanings for the 3Rs in relation to resources, in every level.

Resource and level	approach	meaning
Edifice Level 1	1. reduce	Reduce the demand for built space
	2. reuse	Use intensively built space
	3. recycle	Attribute new uses to built space
Environment Level 0.1	1. reduce	Reduce the space occupied by the environment
	2. reuse	Use intensively the available environment
	3. recycle	Attribute new use to the unused environment
Building system Level 0.01	1. reduce	Reduce the demand n the building system
	2. reuse	Make better use of the installed capacity
	3. recycle	Susbstitute components and recycle
Component Level 0.001	1. reduce	Reduce the quantity of parts and material
	2. reuse	Make use of the component
	3. recycle	Substitute the component and recycle
Materials (and energy) level 0.0001	1. reduce	Reduce the consumption of materials
	2. reuse	Use materails intensively
	3. recycle	Attribute new uses to the material

Table 1 – possible meanings of reduce, reutilize and recycle by resource.

These different meanings for the 3Rs share a common goal of smaller consumption, better efficiency and the possibility of recycling. Despite it may present conflicting answers, in many cases, such as in the substitution of the components of a system which implies in discarding in order to achieve better efficiency, the 3 Rs can be useful as a guiding principle for less impacting practices, and therefore more sustainable ones.

4. Experimental use

The use of the 3Rs principles can be exemplified in buildings made for the Federal University of Santa Catarina, UFSC, in the city of Florianopolis, in the south of Brazil. It is a built area of over 300.000 square meters, to house educational activities, research and extension. The standardized buildings that characterize the environment of the main campus were built for the most part in the 70's and 80's. They are classroom blocks, laboratories or administration in three pavements that organize themselves around a connecting block, where the vertical circulation and sanitary installations are concentrated. The constructive technology is conventional in reinforced concrete, panels in ceramic blocks with no revetment, fibrocement roof and aluminum windows. These austere buildings are in a good state of conservation despite few maintenance initiatives, which demonstrates the quality of its construction.

In terms of performance however, these buildings do not meet current regulations concerning accessibility, security, cleanliness and energy efficiency: there are no adequate bathrooms and elevators or access ramps for people in wheelchairs, there is a lack of alternative routes for emergency escape and the natural lighting and ventilation are hampered by inadequate solutions of sun shades on the building facades. In the same way the buildings do not meet current needs in a satisfactory manner: the infrastructure for information technology and communications was implemented later in an improvised fashion, the configuration of the space makes it difficult to adopt renewed approaches to teaching and learning and the austerity of the buildings is not recognized as value in an environment that is naturally marked by diversity and by youth and for a desire for social ascendance through education. For the future, these buildings will have to be adapted to changes in climactic conditions.

Despite the growing involvement of society in the discussion of environmental issues, even in a higher education institution like UFSC, management decisions of physical space still consider that constructions, building systems and entirely new components have better performance and a longer useful life ahead of them. Difficulties inherent to the reconditioning process are pointed out to justify demolition and disposal. This logic of the new does not consider the possibility of reducing, reusing and recycling. In the case of the UFSC, it also does not consider that a good portion of the components of the building systems of the buildings are in full useful life and still perform as foreseen in their design. Foundations, structure, cover, seals and door beams, as well as significant parts of the building installations can represent around 2/3 of the total cost of the building. This value can be recovered with investments towards meeting current legislation and new necessities. It is doing more with less. In this context the 3Rs can be adopted as a simple instrument for analysis and decision-making. Figures 2a, 2b and 2c exemplify the application in a standard UFSC building. In 2a the effects of reducing energy consumption are dealt with; in 2b, the effects of reutilizing the illumination system, through the intensification of its use, and; in 2c, the recycling of the building, through the alteration of its use.

resource	item	initiative	principle	effect
building	Class block			Intensify the use of the building
environment	Class room			Intensify the use of the environment
System	Lighting			Diminish demand
Part	lamp			Reduce the number of lamps
material	energy	Improve performance	reduce	Diminish energy consumption

Figure 2a: effects of performance improvement - reduce energy.

resource	item	initiative	principle	effect
Building	Class block			Intensify use of the building
Environment	Class room			Intensify use of the environment
System	Lighting	Improve performance	Reuse	Intensify use of the existing system
Part	Lamp			Intensify use of lamps
material	Energy			Intensify use of installed capacity

Figure 2b: effects of performance improvement - reuse lighting.

resource	item	Initiative	principle	Effect
Building	Class block	Improve performance	Recycle	Alter use of the building
Environment	Class room			Alter use of the environment
System	Lighting			Intensify use of an existing system
Part	Lamp			Intensify use of lamps
material	Energy			Intensify use of capacity

Figure 2c: effects of performance improvement – recycle building.

There are numerous actions that can lead to an improvement in performance. Just an example: in 2a, a reduction in the consumption of energy can be obtained through changes in the covering of walls and ceiling (recycle); in 2b reutilizing the lighting system can be obtained through the intensive use of the environment (reuse), and; in 2c recycling an building can be a result of the use of unused environments (reduce). What is interesting to observe is that the better use of a resource positively affects the use of the others; the improvement in the performance of a resource affects the performance of the entire building.

In deciding between demolishing or renovating, be it a system or an building, an institution like the UFSC must take into account that in the case of demolition the existing resources that are at an inferior level are no longer fully used. In the case of renovation, on the contrary, the resources at a superior level become better employed. Thus, in the perspective of a better use of resources, one can have as a principle that it is better to renovate than to demolish. Renovating permits a reduction in the consumption of new resources, reusing those already consumed and recycling the conditions of use of the existing one.

5. CONCLUSIONS

The example of application at the UFSC permits that we infer that on any scale from a bolt to a building it is possible to question the possibility of reducing, reusing and recycling the components, the building systems and the spaces of the buildings. The 3Rs is a tool that permits a rapid assessment of any item, from the simplest to the most complex. The focus on the intensive use of resources induces a concern with the maintenance of the performance of the building so as to prolong its useful life.

The great advantage of applying the 3Rs as a principle in the management of physical space is its simplicity and ease of comprehension; both the layman in thinking about his needs as the specialist proposing solutions to complex problems can base their decisions. Despite that in some cases it may seem difficult to find the answers on how to reduce, how to reutilize and how to recycle, the approach points clearly in the direction of more sustainable practices.

As a principle, in the perspective of the use of resources, better use of what already exists is more favorable than disposal and the consumption of new resources. Thus, before building a new building, one must seek to make better use of the current supply of buildings with the recuperation of their performance and the extension of their useful life. Perhaps the most sustainable building is the one we avoid building.

Keywords: Life-cycle cost analysis, process modeling, residential windows, Turkey

Summary

This paper is the third one reporting an on-going research within an ITU funded research project which aims to develop a dynamic model supporting life-cycle decision-making in the selection of energy and cost efficient window systems for residential buildings in Turkey. HiPerWin life-cycle cost analysis process model which is a sub function of the HiPerWin process model is presented by using IDEF0 function modeling method in detail. In IDEF0 method the functions describing the conceptual model are illustrated with a graphical representation of a set of components that are presented with hierarchical parent – child diagrams. HiPerWin IDEF0 model is composed of a series of diagrams that hierarchically indicate increasing levels of functions and their interfaces in detail. Inputs, outputs, controls and mechanisms of each function are expressed. The shortages and difficulties which are faced by the users in life-cycle cost analysis in Turkey are also introduced.

1. Introduction

1. 1. Research Project

Windows are the most complex and interesting elements in residential design and owners are often confused about how to decide the most efficient window for their residence since there are many complex issues that are difficult to balance. This decision is important in terms of creating a more sustainable built environment, which provides a healthy indoor air quality for occupants and increases energy and cost efficiency. Understanding the energy and associated cost implications of different window systems will help the owners or contractors to make the best decision for their particular case, whether it is a new building or a window replacement. Although up-to-date, reliable and accurate, time and cost data can be provided from various sources such as manufactures, contractors, and research institutions, time and cost data regarding the residential window systems are not well-organised in Turkey.

Recently, a research project has been initiated to develop a dynamic model to design and select energy and cost efficient windows for residential buildings, namely “High Performance Window Design and Selection Model for Residential Buildings in Different Climatic Regions of Turkey (HiPerWin)”. The model aims to assist the owners, designers, manufacturers, vendors and contractors to provide their understanding about the potential and performance implications of the new window products in different climatic regions of Turkey. The challenge is to attain a basic source which supports the user to provide the energy and cost data required for the decision making in the design and selection of the residential window systems (Tavil et.al., 2006 and 2007).

The ultimate objective is to develop a relational database (RDB) which comprises the whole data and processes data into information regarding the window systems and helps the comparison of the alternatives. Therefore query parameters are presented for helping the users to define the built environment and housing unit characteristics of their own case to find out the appropriate window alternatives by comparing their total annual heating/cooling energy consumption and associated capital and ownership costs at the end of the research project. The HiPerWin model will accomplish the user to select the most energy and cost efficient window system for their own case by considering the issues which have influence on the residential window performance.

In this paper, after discussing the HiPerWin process model briefly, HiPerWin life-cycle cost analysis process model is presented by using IDEF0 function modelling method. The shortages and difficulties which are faced by the users are also introduced.

1.2. Life-Cycle Cost

There have been considerable research and development carried out in the field of life-cycle cost (LCC) in the US, Canada, Australia and EU member countries. The literature on life cycle costing is mostly conceptual in nature, the potential benefits of LCC and the technical issues regarding the application of the approach receive most of the attention in the literature. There is a considerable body of literature relating sustainability assessments on a life cycle basis and, in particular, to one of the main assessment methods – Life Cycle Assessment (Davis Langston, 2007).

The LCC concept was initially applied by the US Department of Defence. Since then a large number of documents, guidelines, standards and reports are available. For instance ISO 15686-5: Building and constructed assets – service life planning (draft), ASTM E917-05 Standard Practice for Measuring Life-Cycle Costs of Buildings and Building Systems, The Norwegian Standard, NS 3454: Life cycle cost for building and civil engineering work – principles and classification, Task Group 4: Life cycle costs in construction, Procurement guide 07: Whole-life costing and cost management, The Green Book by HM Treasury in UK.

ISO 15686-5 draft defines life-cycle cost as the total cost of a building or its components throughout its life, including the costs of planning, design, acquisition, operations, maintenance and disposal, less any residual value. The National Institute of Standards and Technology (NIST) Handbook defines life-cycle cost as "the total discounted dollar cost of owning, operating, maintaining, and disposing of a building or a building system" over a period of time (Fuller & Petersen, 1995). Furthermore in ISO 15686-5 draft life-cycle costing is defined as a technique which enables comparative cost assessments to be made over a specified period of time, taking into account all relevant economic factors both in terms of initial capital costs and future operational and asset replacement costs. (Davis Langdon, 2006). This technique is measured over the asset's "effective" life, generally considered as its economic and or operating life (Langston, 2005).

The LCC technique is especially useful when the project alternatives which fulfil the same performance requirements, but differ with respect to the capital and operating costs, have to be compared in order to select the one that maximizes net savings. For example, LCC analysis will help to determine whether the incorporation of a high-performance HVAC or glazing system, which may increase the initial cost but results in dramatically reduced operating and maintenance costs, is cost-effective or not (Fuller, 2007).

Based on these studies, in this paper, LCC technique is selected to make the comparative assessment of different window systems. This technique helps to find out the most appropriate choices among proposed window systems which satisfy the performance requirements related with energy and cost efficiency in different climatic regions. In that point, realistic evaluation of present value becomes significant by considering multi-criteria which affect window system.

2. HiPerWin Process Model

Since the issues affecting the window performance are complicated and include complex relationships, the functions/activities; inputs/outputs; the issues that control the functions; internal/external mechanisms used for implementing the functions and the interrelationships among the functions within the context of the project are explained by using "IDEF0 (Integrated Definition for Function Modelling) method" (see Figure 1) (web link 1). In IDEF0 method the functions describing the conceptual model are illustrated with a graphical representation of a set of components that are presented with hierarchical parent – child diagrams. HiPerWin IDEF0 model is composed of a series of diagrams that hierarchically indicate increasing levels of functions and their interfaces in detail.

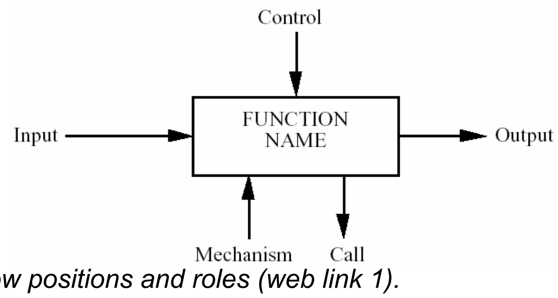

Figure 1 IDEF0 method arrow positions and roles (web link 1).

The top level (A0) diagram of the HiPerWin IDEF0 model consists of six main functions which are briefly described below (see Figure 2):

1. Determining the Outdoor Environment – The impact of windows on building energy use can considerably vary with the location because of the climatic differences. The analysis has been performed for three different climatic regions of Turkey.

2. Describing the Built Environment – Estimating the energy consumption of a building with various window alternatives is possible with the determination of an appropriate set of values for the parameters associated with outdoor environment and built environment. The parameters attributed to the built environment are considered on the basis of a building settlement, a single building block, a housing unit as a thermal zone and a functional building element. All the constraints such as local regulations, limitations and statistical data related with the cities are taken into account as the control issues used for modelling the building settlements for the parametric study.

3. Designing a Typical Residential Block – Every building involves a set of unique features and requiring customized solutions. Therefore, the reference building blocks are designed to represent the scale and

occupancy patterns of a Turkish single-family resident in general. Orientation of the building, position of the building among other buildings, building shape factor (rectangular and square plan shape) and building dimension are the built environment parameters used in designing the typical buildings in the project. Four basic 5 storey high residential building block types with different plan shapes of 100 m^2 each are designed and seven residential building types are generated for the standard representations by orienting the buildings to different orientations.

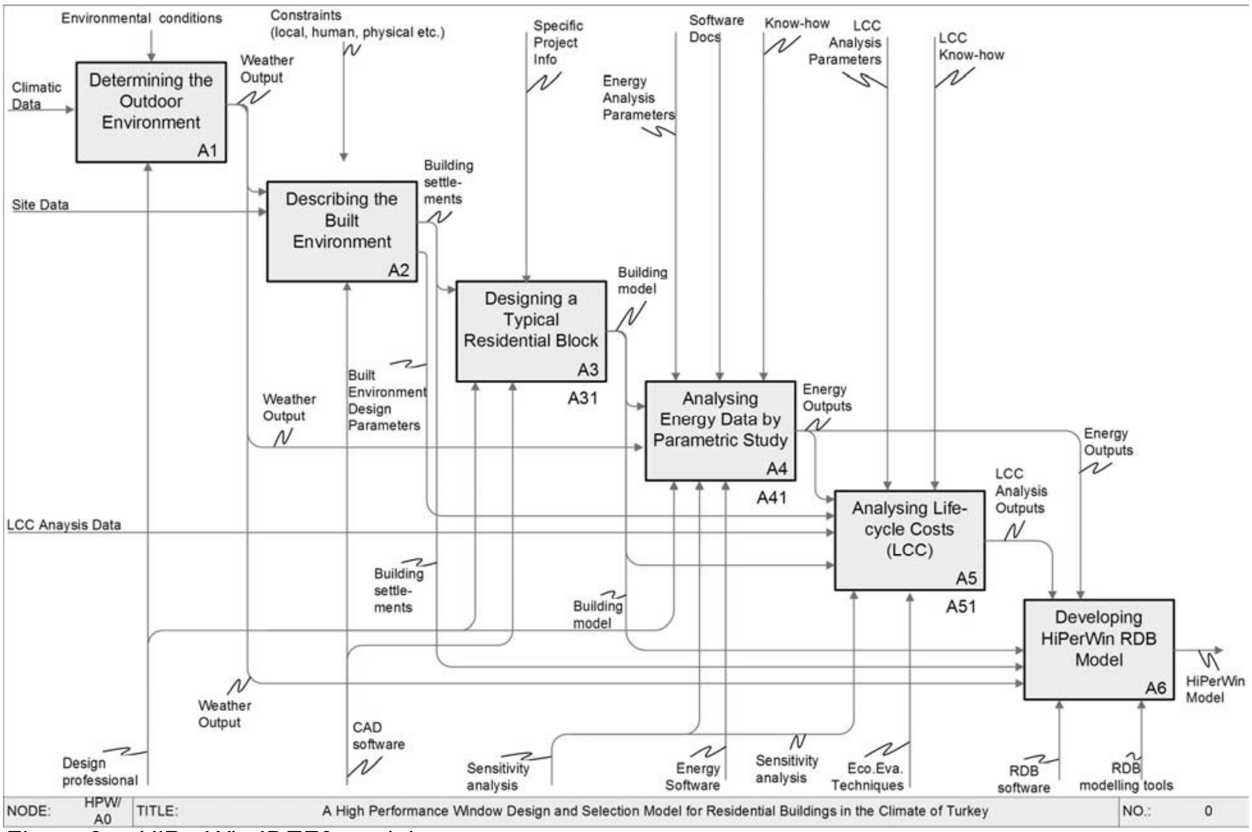

Figure 2 HiPerWin IDEF0 model.

4. Analysing Energy Data by Parametric Study – In accordance with having many parameters such as climate, building type, orientation, window area, shading devices and window components, a comprehensive parametric study is required for preparing the energy consumption and associated cost data of each case for the model. Obtaining the actual energy consumption in a specific climate, for a specific period, for specific environmental conditions and for a specific building and occupants' lifestyle in accordance with control actions is a complex phenomenon in analysing the energy and cost efficiency of a window system. Hence Energy Plus software, which is a powerful and comprehensive simulation tool, has been used to develop standard representations of buildings (i.e. building model), involving geometrical and semantic properties.

5. Analysing Life-Cycle Costs (LCC) – A5 level diagram which comprises the HiPerWin LCC analysis approach which is the major topic of this paper is given in Figure 3. The parent boxes are detailed with child diagrams at the next lower level until all of the relevant detail of the whole viewpoint can be adequately exposed. A sub-function of the A5 parent diagram is decomposed by the child boxes in A54 diagram.

6. Developing HiPerWin Relational Database (RDB) Model – A dynamic model is required for keeping records and facilitating the comparison of the available window alternatives by providing self-representation of each case. Query parameters related with the characteristics of the built environment and housing unit options are presented in order to specify the particular cases. The model has to dynamically realize this self-representation via computational applications. For reaching the ultimate objective, a RDB is required to be developed for helping the users to select energy and cost efficient window systems for a particular case. RDB will be used to store and retrieve up-to-date, reliable, timely and the most accurate life-cycle cost and technical information as the results of the all possible cases.

3. HiPerWin Life-Cycle Cost Process Model

LCC methodology is an iterative process in general. From inception to disposal at each stage, decision and procurement processes, the calculation of LCC should be refined to provide increasing certainty of the total LCC of the project. The ultimate goal for carrying out LCC calculations is to aid decision-making in (Davis Langton, 2006):

- assessing and controlling the costs and identifying the cost significant items
- producing the selection of work and expenditure planning profiles.

In this paper, the conceptual model of the HiPerWin LCC analysis process is given in detail by using IDEF0 method. HiPerWin LCC analysis essentially takes into account of post-construction, i.e. operating phase of a building production process. The objective is to arrive at an analysis plan and the profiles in service period of a window component depending on the owners' purchase and replacement decision which can be considered as a key factor in a sustainable building design.

As seen in Figure 3, functions of the HiPerWin LCC analysis process model can be addressed as follows:

1. Planning the HiPerWin LCC analysis,
2. Determining HiPerWin LCC analysis requirements,
3. Grouping window alternatives and
4. Performing HiPerWin LCC analysis.

3.1. Planning the HiPerWin LCC analysis

The first function of the HiPerWin LCC process model is planning the LCC analysis in order to determine the objectives and constraints for developing the plan that will be followed throughout the analysis. A work breakdown structure (WBS) is generated to determine the tasks which have to be performed during LCC analysis and thereafter the WBS is used to classify cost breakdown structure (CBS). Window components (frame types, glazing, thickness of the gap and infill gas material options etc.) to be included in life-cycle costing are also determined. Available resources and the building model are the major inputs of the planning function. The building model consists of built environment data, outdoor environment and climatic data. Planning function is controlled by user requirements and guided by LCC methodologies and know-how. While numerous information technology tools are available on-the-shelf, expertise and advisory are the indispensable mechanisms of the LCC analysis.

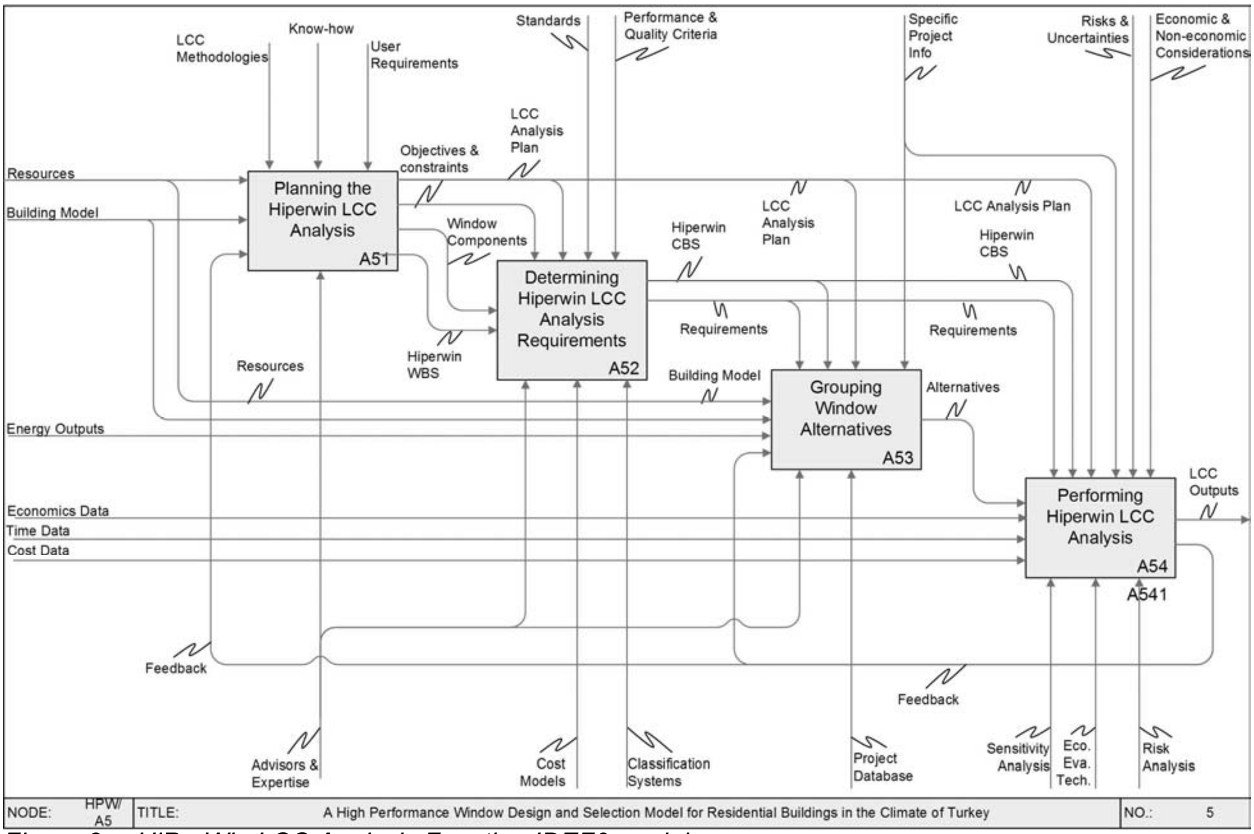

Figure 3 HiPerWin LCC Analysis Function IDEF0 model

3.2. Determining HiPerWin LCC analysis requirements

The outputs of the planning function are used as the inputs of the second function in which HiPerWin LCC analysis requirements are determined. The objective of the LCC analysis requirement determination is basically as follows (Davis Langton, 2006):

- available LCC analysis approaches and techniques,
- current information technology tools,
- data requirements,
- cost calculating and estimating methods and techniques,
- risk and sensitivity analysis requirements.

Not only the purchase or owning costs but also a number of costs including operating, maintaining and disposing costs as well as the benefits occurring throughout the life-cycle of the window alternatives which are crucial for the performance prediction of windows are considered as the life-cycle cost issues.

One of the main outputs of the function is HiPerWin cost breakdown structure (CBS) in which cost data can be classified are essential in the life-cycle cost analysis. HiPerWin CBS can be summarized as follows:

- Capital Costs
  - Purchase Cost: It consists of the construction costs of each window component (glazing unit, frame etc.) as well as the professional fees of the designer and engineer.
  - Installation Cost: Material, labour, equipment, fixtures and fittings costs arising from the fitting out of window components including overhead and profit rate.
  - Finance Cost: It consists of non-construction costs of purchase phase such as interest, cost of money, rates, insurance costs, fees and local taxes etc.
- Operating Costs
  - Ownership Cost: Regular or periodical operating costs, such as cleaning, security, waste management, facilities management, etc.
  - Maintenance Cost: Annual or periodical repair and maintenance costs, such as periodic replacement or planned renovation costs.
  - Selling or Disposing Cost: Salvage value of replaced window components which will be used as second hand.
  - Energy Consumption Cost: Annual or periodical energy consumption costs.

Requirement determination function is controlled by the standards (such as ISO 15686-5 draft), performance and quality criteria and finally LCC analysis plan developed in the planning function. Available cost models and classification systems (such as Uniclass, Uniformat II etc.) can be used as the mechanisms as well as advisory and expertise in order to determine HiPerWin CBS.

3.3. Grouping window alternatives

Outputs of the requirement determination function are used to group window components to be used in life-cycle cost calculations. Recent technological advances in window systems offer many alternatives in the energy and cost efficient window design. In the context of the research project, a set of glazing unit alternatives with various glass types, coatings, thickness of the gap and infill gas are obtained from one of the leading glass company in Turkey. The window dimensions are defined according to window to wall ratio (WWR) of 45%, 30% and 15% representing large, moderate and small area windows, respectively. Timber, aluminium and PVC frames are the frame options considered in the project. Both interior and exterior shading devices are taken into account in the window system combinations. Annual heating and cooling energy consumption of each housing unit having various properties with the combination of these different window components is calculated with a whole building simulation program, EnergyPlus Software. Window alternatives in the evaluation can be increased by adding new window parameters such as advanced glazing types, composite frame types or different shading types, etc.

3.4. Performing HiPerWin LCC analysis

Performing HiPerWin LCC analysis is the last function of the upper level decomposition. HiPerWin CBS which is one of the outputs of determining analysis requirements function and the LCC analysis plan are used as the main inputs of this function. LCC analysis reports and tables are the outputs of the implementation function. Economics and time data are used to convert cost to a common base. Cost data is used to identify the cost of each window alternative of each particular housing unit. Sensitivity analysis, such as Monte-Carlo simulation, can be used to evaluate the effects of a parameter on the value of another one. As investment decisions often made under uncertainty and risk, different methods such as Delphi technique or operations research method can be employed in dealing with uncertainties and in preventing from the effects of the possible variations. Although these methods are out of the context of this paper which mainly covers the interactions of the LCC analysis functions, the effects of uncertainty and risks will be taken into account during the implementation phase. LCC analysis output tables and documents are used as feedback signals to select new alternatives and/or to refine existing alternatives or to take corrective actions in the LCC analysis plan.

Since the ultimate objective is to develop a relational database, cost issues related to window components have to be integrated in the “conceptual model”. For this aim, HiPerWin LCC analysis function is decomposed by the child boxes in A54 diagram at the next lower level until all of the relevant detail of the whole viewpoint can be adequately exposed (See Figure 4). HiPerWin “information model” will be carried out by using IDEF1X “Integration Definition for Information Modeling” method after completing “function model” mentioned above. Up-to-date, consistent, reliable time and cost issues are the two major data class used in the calculation of LCC. In LCC calculations cost data is classified by using CBS, while time data is taken into account in terms of analysis period and service life of window components in concern. The data is provided mainly from manufacturers, contractors and research institutions. There is a lack of structured data collection mechanism in Turkey where real time and cost data are stored; hence the data have been collected from the current local market individually.

3.4.1. Identifying Cost of Each Alternative

The capital and operating unit costs of window systems used in each housing unit are determined. The sub-costs within capital and operating unit costs are classified and expressed in HiPerWin CBS to satisfy the specific requirements of the window system alternatives. The capital unit cost includes purchase, installation and finance costs, while operating unit cost includes ownership, maintenance and energy consumption costs and salvage value if applicable.

The unit cost identification of each option is carried out under the control of specific project information. Square and rectangular shaped 7 residential block types consisting 100 m2 housing units are considered in the project. Each block is 5-storey high, faces different orientations and has 2 or 4 housing units at one floor. The capital costs of each window option are calculated according to 3 different WWRs of each housing unit. In the calculation of the unit capital cost of a window system, all components such as window frame, window ledge and hardware (casement, sash, hinges, handle etc.), double glazing, window sill, sealant, gaskets and weather strips are taken into account. The unit prices of the material and the installation are obtained by having an average of the offers of four Turkish leading vendors. Window areas of each façade are multiplied by the unit capital cost acquired from the market search. Overhead and taxes are included in the unit costs; however design and engineering costs are not demanded by the contractors. Total price is calculated by considering the purchase of the windows for cash. In case of monthly payments 1% interest is added for the finance cost.

Operating costs are the costs arising from the regular and periodical operations which have to be incurred by the occupant after the installation of the window systems. Ownership, maintenance and energy consumption costs and salvage value are the basic items in the procedure of calculating the operating cost of the window systems. Periodical cleaning and security costs are included in the ownership costs for each housing unit. Maintenance costs are the replacement costs of windows at the end of their service life. The salvage value is added to operating costs depending on window frame material, for instance PVC is not a recyclable material while timber and aluminium frames can be reused.

Heating systems with natural gas and wall-mounted split air conditioner are assumed to be used in each housing unit in heating and cooling periods of each climatic region. Heating and cooling energy demands are simulated for housing units with different window systems, facing various orientations and having different shading strategies in different climatic regions with the help of EnergyPlus software. Heating energy costs are determined by multiplying the current natural gas unit price in KWh with annual, monthly or peak day heating energy demands of the housing unit in concern. The heating system efficiency factor (HEFF) is taken as 0.8. Natural gas unit price used in housing and commercial buildings in Turkey is announced as 0.569220 YKr/m3 which is equivalent to 0.0535 YTL/KWh (Web Link 2) for March 2008. However, the valid current price on the invoice, which is 18-20% above the nominal unit price, is determined by adding taxes and the other factors. Additionally, cooling energy costs are determined by multiplying the current electricity unit price in KWh with annual, monthly or peak day cooling energy demands of the housing unit in concern. Electricity unit price used in housing in Turkey is announced as 0.121050 YTL/KWh while the valid current electricity unit price is 0.19 YTL/KWh by adding taxes and the other factors.

3.4.2. Grouping Cost of Each Alternative

The costs determined for each option must be grouped by year over a number of years equal to economic service life of the window systems. Determining the life of window systems and the analysis period in years are crucial in grouping the cost of each alternative. The life of window systems and their components can be described in different ways such as design life, working life, service life, economic life, useful life and technological life. The estimated number of years during which a window system will perform its functions required is the useful life of it. It is a well-known fact that there are significant differences between the useful or service life of window components and the design life which is introduced by the manufacturers depending on different materials used in window systems. A database in which cost and time data of window components are stored is necessary in acquiring historical and realistic data.

On the other hand, the analysis period is the period of time, over which the life cycle cost is to be analysed. The length of analysis period is dependent on the users' preference and the life of the product. In addition, the analysis period should not be too long, since the discounting factor applied in the analysis tends to make the future costs less significant and besides, the risks and uncertainties in the future cannot be effectively defined based on the existing data. Window systems can be handled as "repairable or replaceable with some more efforts" along with the "assumed working lives of works and construction products" table of EOTA (EOTA 1999). Thus, analysis period is assumed as 25 years regarding the service life of window systems and time requirements.

3.4.3. Converting Cost to a Common Base

The costs of alternatives must be converted to a common base using a discounted cash flow method which incorporates interest rates and inflation in order to account for different operations taking place during the analysis period. The present value of future cost of window system can be calculated by using the factors and indices, especially those related to operational energy costs. However there is a lack of national source of factors and indices that will be used in LCC analysis in Turkey. Therefore it is assumed that a nominal discount rate can be determined by using long-term Treasury bond rates averaged over 12 months as described in Federal Energy Management and Planning Programs of Department of Energy in the USA (Fuller & Rushing, 2006). The nominal Treasury bond rate, i.e. market rate is converted to a real discount rate by subtracting the long-term average rate of inflation from nominal rate to correspond with the constant-dollar analysis approach. The nominal discount rate, i.e. Treasury bond rates averaged over 12 months is 16.25%, long-term average rate of inflation is 8.39%, and therefore real discount rate is approximately 8%.

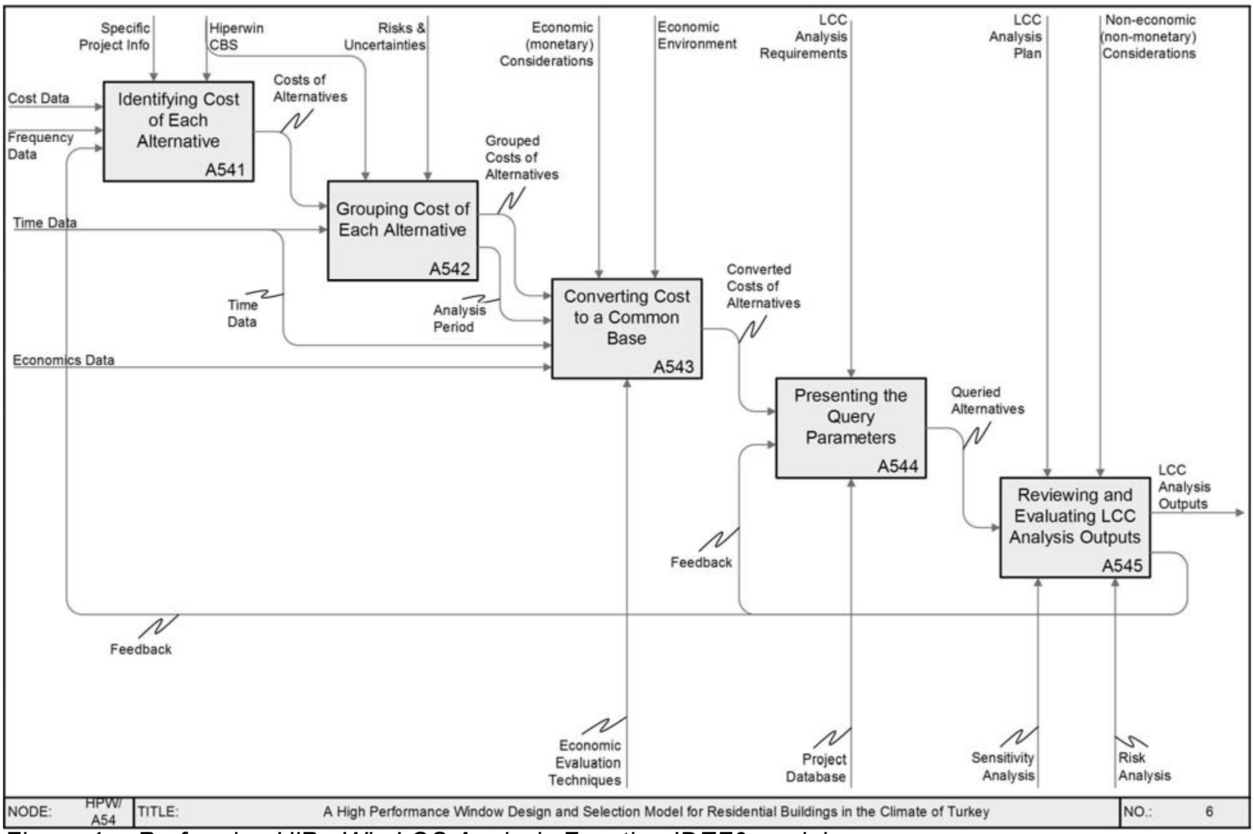

Figure 4 Performing HiPerWin LCC Analysis Function IDEF0 model.

3.4.4. Presenting the Query Parameters

The key items of the built environment and housing unit characteristics which are described at the top level of HiPerWin process model are transformed into query parameters. Query parameters are necessary for helping the users to specify their own case to find out the appropriate window alternatives by comparing their total annual heating/cooling energy consumption and related initial and operating costs. Those are defined for three climatic regions, twenty housing unit types, three window areas and windows with/without shading strategies. They are presented for directing the user to retrieve the appropriate alternatives through the database. The query parameters and LCC analysis requirements are integrated at this function.

3.4.5. Evaluating and Reviewing LCC Analysis Outputs

The energy consumption and cost data of the alternatives are evaluated in order to facilitate the user to select the appropriate window system alternative. Various evaluations and outputs will be presented for different users such as designer, owner, contractor, vendor, etc. Energy consumption, cost information and life cycle cost of the window alternatives for specific cases will be attained by the guidance of the query parameters. The results of the appropriate window systems for the particular case will be listed in order. Comments, explanations and suggestions in the context of the whole process will be made and the user will be able to access the technical specifications of the proposed alternatives. If the user does not satisfied with the energy consumption and cost of the options, he/she can specify another case by changing the query parameters in the design process.

Conclusion

HiPerWin model aims to assist the owners, designers, manufacturers, vendors and contractors to provide their understanding about the potential and performance implications of the new window products in different climatic regions of Turkey. The challenge is to attain a basic source which provides the required energy and cost data for the decision making in the design and selection of the residential window systems. Cost issues are evaluated by LCC analysis. The paper explains the HiPerWin LCC process model for residential window systems in detail which covers planning the LCC analysis, determining LCC analysis requirements, grouping window alternatives and performing LCC analysis.

HiPerWin "information model" will be carried out by using IDEF1X "Integration Definition for Information Modelling" method after completing "function model" mentioned above. For improving the conceptual model information modelling is a significant phase in developing the relational database which is the ultimate objective of this research. Although HiPerWin process analysis comprises the post-construction phase, the model will be utilized at design, construction and operating phases of the building production process. The model can be employed window system selection both in new and retrofitted buildings. Appropriate window systems will be selected among the alternatives by the designer, contractor and owner during the design, construction and operation process, respectively. While the designer can use all the query parameters such as orientation, block type, window area, shading strategy and all window components for the decision making in schematic design and design development phases, the owner only can use the parameters related with the window components and shading strategies for retrofitting. Besides, the vendors can guide their customers and the manufactures can provide feedbacks from the users and develop their products.

Making the energy and cost efficient window system selection prevalent will contribute to the national economy by enabling the usage of the limited resources which supports the sustainable design on country base. Since there is a lack of source which can be used in LCC calculations of the window systems in Turkey, the implementation of the model will serve as a basis of such a source.

Keywords: Sustainable architecture, Education for sustainability, Experiences of sustainable design, Media, Participation in design process

Summary

People interact with architecture not only by living, working or learning in it, but also through indirect messages that architecture represents via its design process, built form, functions, and patterns of use and maintenance. To educate people for sustainability, architecture should be recognised as a tool or medium that encourages people to live more sustainably. The paper presents three scenarios for architecture to promote constructive attitudes towards sustainability. First, are the positive first-hand experiences of a healthy human environment that sustainable architecture could provide to people who have occupied or visited such buildings. Second, is the fact people could learn about the effects of unsustainable design on the environment and society and the benefits of sustainable design from second-hand experience, such as verbal communication, publications and other media. Finally, involving people in sustainable architectural design processes could educate them to look at their environment, create a sense of belonging, and to take part in improving its conditions. Via these three aspects, people will gain positive experiences of sustainable design. They will learn how to interact with their environments and extend their perceptions about appropriate design, which could also lead to more demand for sustainable design in the future.

1. Introduction

This paper is based on research undertaken as part of an investigation into the relationship between sustainable architecture and sustainable education. The research aims are to discover how architecture can possibly be used as a learning tool for sustainable education and stimulate change of attitudes and behaviours towards sustainability. This paper focuses on the first stage of the investigation of the issues. It primarily illustrates a broad framework of the relationship and potentialities of using architecture as an educational tool for sustainability. The framework and possibilities presented in the paper are fundamental and need to be clarified before moving to the other stages, such as further exploration of how people reform their attitudes and behaviours when influenced by sustainable buildings, or making policy to promote the use of architecture as a tool for the change, or putting such the policy into practice.

2. Architecture as a Tool for Education

People interact with architecture in many ways. They commonly use it for living, working and other related human activities, such as storing goods and operating machinery. Many people also visit renowned architecture because of its aesthetic, cultural, or performance reputation, and often all three. Thus people visit the Pompidou Centre in Paris to see the aesthetic created out of the exposed structure and services (aesthetic and performance) and because of its importance as a gallery and for the outside performance activities that happen around it (cultural). People also read about architecture and the relationships buildings have with their contexts, such as their cultural and historical backgrounds, social and economic constraints, as well as any unique or interesting characteristics. Moreover, architecture has always conveyed social and symbolic messages, being the embodiment of the specific ideas and expectations of its designers, clients, and users (Voordt and Wegen, 2005). Several professions are currently involved in architectural design and construction processes, including architects, engineers, project managers, contractors, and builders.. Roles and responsibilities are varied depending on the profession and conditions of the project. Although in most contemporary architecture the people involved with the design and construction process are usually not the same group of people who use the building, in some cases, such as self-built projects, they are, and often in the past in the context of vernacular architecture, future users directly participated in design and construction. Despite the varied roles and actions of each individual being, all people are involved with architecture in some way and experience architecture most of the time.

When interacting with architecture, people have a chance to experience its creation through perceiving the skills and knowledge that led to the design and construction of the building. This experience of the underlying skills and knowledge is often shared between those visiting or using the building and also transferred from one group of participants to other individuals, groups and even the general public. Transfer frequently occurs among people in the same social institutions, such as the same family, the same community, and the same profession. In a family the shared architectural experience can come from looking at photographs taken on holiday by one of the family members. This discussion would be very different from the same building being written up in an architectural journal, but both are passing on experience about a building to people who have never seen it before. Based on the idea of socialisation, which is a process of teaching and learning where every individual and social institution represents the teacher and all members of the society are the learners (Scotter et al., 1979: 119), architecture is undoubtedly able to be a tool and medium to educate and connect people in society. People learn how to create architecture, to use it efficiently, and to maintain it properly. In terms of the natural environment, they can extend their understanding about the relationship between their actions, architecture, and ecology, and consequently develop their attitudes and actions towards better relationships. The process of learning from architecture was described by David Orr (1993; 1994) as 'architecture as pedagogy'. Although people can to some extent always learn from architecture, the capability of architecture to educate people depends on the quality of the architecture, effectiveness of the communication, and method of using architecture as an educational tool.

3. Sustainable Architecture and an Educational Tool for Sustainability

Since the late 20th century, sustainability has become an international concern in many professions, including education and architecture. The important role of education in elaboration of paths to create a more sustainable world became widely known after the promotion of education and public awareness in Chapter 36 of Agenda 21 (UNCED, 1992). The aim of education for sustainability is not only an enhancement of knowledge and concern about the issue, but also involves change in attitudes and promotion of responsible and sustainable behaviours. In the architectural field, concern that buildings are responsible for their impact on the natural environment and quality of life has gradually been accepted and has led to many responses to the issue, such as professional responsibility, assessment methods, and/or other design strategies (e.g. UIA, 1993; Barnett and Browning, 1995; European Commission et al., 1999; Edwards, 1999; Gauzin-Muller, 2002; Sassi, 2006). Furthermore, linking to the idea of education for sustainability, architecture can be used as a tool or medium that encourages people to live more sustainably.

To create sustainability, actions for sustainability are first required. Based on the model of responsible environmental behaviour suggested by Hines, Hungerford, and Tomera (1986-87, as cited in Hungerford & Volk, 1990) and developed by many educationalists (e.g. Hwang, Kim and Jeng, 2000; Kollmuss and Agyeman, 2002; Pruneau et al., 2006), to strengthen actions for sustainability, both internal and external factors should be determined. The internal factor or intention to act is influenced by knowledge of issues, knowledge of action strategies, action skills, and personality factors, including attitudes, locus of control, and personal responsibility. The external influences or situational factors encompass economic constraints, social pressures, and opportunities to participate and choose different actions.

According to the model, to support sustainable actions, architecture could and should encourage individual intention to act and provide an appropriate situation for sustainable practices. A framework of connections between sustainable architecture and responsive sustainable behaviours is presented in figure 1. In terms of external factors, sustainable design is one of the physical results of social demand for sustainable practices. It primarily originates from concerns for environmental and social issues and the number of sustainable design projects can increase only when more people request them. Political, social, and cultural factors in society and the architectural community form the main influences behind the creation of sustainable architecture. Meanwhile, sustainable architecture can also be part of suitable situational factors, as it usually provides opportunities to act in more sustainable ways. For example, a passive solar design strategy, such as maximizing natural lighting and natural ventilation, gives people the chance to use solar energy and hence form a connection with the natural environment. It leads to less demand for artificial lighting, smaller mechanical space conditioning systems, and consequently reduction of energy consumption to operate such a system. In terms of personal intention, there are three scenarios for architecture to promote constructive attitudes towards sustainability, these being direct experiences from sustainable design, indirect experiences of sustainable design and related issues from the architectural media, and participation in the design and construction process.

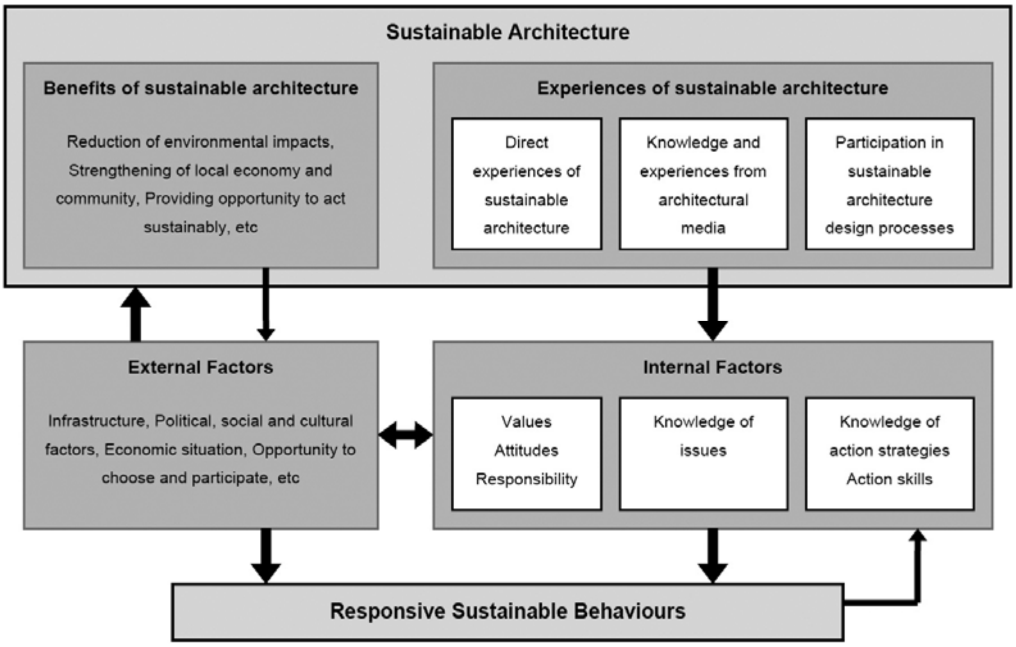

Figure 1 Relationships between sustainable architecture and responsive sustainable behaviours.

3.1 Direct Experiences of Sustainable Design

A healthy environment has emerged as an apparent catalyst for sustainable design and construction. To create a healthy environment, appropriate lighting design, air quality, acoustic conditions, thermal and physical comfort, and safety of use and maintenance have become basic issues for sustainable architecture. Although some issues may be not a direct threat to life, they are concerned with the satisfaction users have with architecture and its conditions and deal with the long-term health of the occupant and passers-by (Williamson, Radford, and Bennetts, 2003: 91). Design based on these issues normally prevents building related illness and responds positively to user needs. Since sustainable design usually maximises natural lighting and ventilation and often provides the occupant an opportunity to do at least some activities outside the building, it promotes natural stimulation that provides a counterbalance to artificial stimulants (Edwards, 2005: 144-145). Natural light, pleasing views, comfortable environments and an opportunity for personal control of light and ventilation also assist in reducing stress, enhance productivity, and improve the quality of work performance (Heschong Mahone Group, 1999; Boyce, 2004; Davis, 2005; Edwards 2005).

Besides providing a healthy environment, sustainable architecture commonly comprises design strategies that aim to reduce environmental impacts. Once occupants have encountered design solutions that provide a high quality of health and comfort and design solutions that are better for the natural environment, they usually feel good about the architecture and may be willing to change their attitudes and behaviours. For example, the occupants of Kingsmead Primary School in Cheshire report that they have a positive attitude to their school that was designed to demonstrate the virtues of low energy design and renewable energy use without jeopardising health (TSO, 2006: 12-19). Basically, the school was designed to make the best use of daylight and adapt to change. It also incorporated several sustainable strategies, such as selection of timber for portal frames from a claimed sustainable source, collecting rainwater for flushing the toilets and urinals, a solar collector to preheat hot water, and electricity generation by photovoltaic cells. The occupants were satisfied with the overall comfort of a building that responds to users' needs. The design intention and how the building is supposed to work and be used is clearly communicated to the occupants. The daylight quality is good enough to encourage users to keep the lights off and blinds up, and the design, as revealed in a post occupancy survey conveys a pleasing image to visitors and lifts perceived productivity at work (TSO, 2006: 19). As a result, the staff and students are overwhelmingly proud of their school and its environmental credentials. This self-esteem consequently influences and changes attitudes and behaviours of staff, pupils and parents. Accordingly, the positive first-hand experience that sustainable architecture could provide to people who have occupied or visited it is the primary encouragement that reinforces positive attitudes to sustainable practices. The experience leads to recognition of the benefits of sustainable architecture and higher demands for such architecture.

In addition, experience of using and maintaining sustainable architecture can form a tool to learn about the relationship between natural and human-created systems. The users can learn about building systems and the use of energy and natural resources to operate them. They can also monitor the building performance.

Several educational buildings, for example, Roy Lee Walker Elementary School in Texas (SHW Group, 2001; Furger, 2004), Sidwell Friends School in Washington DC (AIA, 2007; Sidwell Friends School, n.d.), and the Adam Joseph Lewis Center at Oberlin College in Ohio (Janda and Meier, 2005), have installed equipment and set up their educational lessons or programs to allow students or the community to study the building system operation, monitor the building functions, and measure the health quality of the facility.

3.2 Knowledge about Sustainable Design from the Media

Besides direct experience from actual activities, people could learn about the effects of unsustainable design on the environment and society and the benefits of sustainable design from second-hand experience, such as verbal communication, publications and other media. Since the 1990s, many conferences have been based on themes related to sustainable design (e.g. Passive and Low Energy Architecture Conferences, International Conference on Urban Regeneration and Sustainability, Greenbuild International Conference and Expo, and World Sustainable Building Conferences). These conferences provide a chance for architecture related professions to transfer ideas, knowledge, and experiences about and for sustainability. Moreover, there are now a significant number of architectural publications that deal with models of sustainable practices and/or the process of their creation. Many authors have illustrated environmental problems and the roles of architects and architecture, as well as presenting cases studies (e.g. Vale and Vale, 1991; Steele, 1997; Gauzin-Muller, 2002; Sassi, 2006; Hyde et al., 2007). Some focus on guidelines for architectural practice (e.g. Barnett and Browning, 1995; European Commission et al., 1999; Roaf, Horsley and Gupta; 2004; Kwok and Grodzik, 2007). While some provide the history of green design (e.g. Farmer, 1996; Steele, 2005) some employ the tactics of criticism (e.g. Guy and Farmer, 2001; Williamson et al., 2003; Moe, 2007). In addition, recent films like *Blue Vinyl* (2002), *The End of Suburbia: Oil Depletion and the Collapse of the American Dream* (2004), *Power Shift: Energy + Sustainability* (2004), and *An Inconvenient Truth* (2006) have aroused concerns about environmental impacts and have stressed the importance of change towards sustainable attitudes and habits, which architecture is also able to support.

Despite various sources of sustainable design solutions, knowledge related to sustainable practices still needs to be researched, developed, and frequently updated. The lack of suitable information often deludes architects and clients into inappropriate decisions. Regulations, directives, and standards related to environmental issues have to be promoted not only to the architectural profession but also to the public. The development of appropriate technology and building systems, which affect design decision making, should be publicised. For example, improvements in the appearance of photovoltaic cells offer a variety of choice in transparency, colour, and patterns, and give new application possibilities and potential for architectural integration (e.g. Hermannsdorfer and Rub, 2005). This may encourage more people to accept such a technology. Other established building systems and appliances, such as energy-efficiency appliances, compact fluorescents, low-flush and composting toilets, waterless urinals, and greywater recycling systems, provide wider opportunities to reduce the use of energy and resources, environmental impacts, and operating cost. Knowledge about the effects of building materials and components on human health and environments also influences the choices made by clients and designers. Because of more concern for environmental issues and higher demand for sustainable architecture, information about environmentally friendly products and systems is becoming increasingly available. However, because the green agenda has created a marketing opportunity, often many manufacturers and distributors do not present all the information about the environmental effects of their products but only present some dimensions that relate to sustainable issues (Woolley, 2000: 44-45; Williamson et al., 2003: 10-12). Clients and designers have to be careful about their selection and society should also require fundamental changes in the way the industry operates.

Accordingly, information about sustainable design should be obtained alongside experiences of sustainable design. This will enhance perception and appreciation and ensure accuracy of the information. Often the proposed vision, based on information and calculations undertaken during the design process is different from the actual results (e.g. Janda and Meier, 2005; TSO, 2006). Some building elements, such as sunscreens and building performance monitoring systems, may not be installed according to the design and specification, because of financial constraints, meaning energy consumption is often higher than expected. Higher than expected energy use occurs for other reasons. These might be problems with an installed system, longer-than-expected use hours, and installation and use of additional appliances. Because of this, appraisal and post-occupancy information is an essential way to improve building performance and provide lessons for future projects.

In addition, information and experiences about sustainable design must be provided in various forms, both quantitative and qualitative. While quantitative data are useful for research professionals and scientists, qualitative information is usually suitable for members of the general public who have little experience in integration of quantitative performance data. Moreover, information and experiences should come from various sources, such as designers, clients, builders and users. This is useful to promote sustainability and its practices to a wider range of people and potentially reduce any bias caused by dominant data sources.

Although general ideas of sustainable design could be applied in different situations, it is also necessary to mention the specific contexts of the practices. This helps people, particularly those who do not have first-hand experience, to understand the situation and facilitate the possibilities for applying some of the design concepts elsewhere. Since building systems, materials, and modes of construction that work properly in one place may be not suitable for others, the contextual data will help people who receive such information compare design solutions with their local conditions and apply them rationally.

Apart from information associated with architecture, information about related fields and local conditions, such as a geography and topography, climate conditions, available resources, and local culture, should be publicised. Such knowledge provides a broad view of sustainable issues and encourages comprehension about the relationships between architecture and other fields. It is a fact that design does not solve all problems (McDonough, 1996: 409), so sustainability can only be achieved by simultaneous moves to this goal in every field. The knowledge of related fields enhances the vision of how architecture can support other sustainable practices and, on other hand, how other practices can support sustainable architecture.

3.3 Participation in Sustainable Design Processes

Sustainable design requires expanded interdisciplinary collaboration and a greater focus on process (McLennan, 2004). Encouragement towards involvement in the sustainable architectural design process not only improves design quality, but also plays an important part in educating participants. The process explores the importance of values in addressing and resolving issues related to human and built environments, connects them to the local situation and everyday experiences of learners, and engages people in critical reflection of current lifestyle and actions. Through the process, stakeholders gain knowledge, experience participatory skills, and gradually develop sustainable attitudes.

Because each individual has a limited experience, besides self observation and personal experiences, both first and second hand, sharing ideas, problems, purposes, and visions can increase perception about issues and knowledge about how to solve the problems. Building professionals, including architects, engineers, specialists, developers, and builders, can always learn from each other. They can learn to understand the work and responsibilities of others, to have respect for what each person does, and to work collaboratively. Meanwhile, through the participatory process, building professionals can share their technical knowledge and experiences with the future users, so they can use architecture efficiently and maintain it properly. At the Hockerton Housing Project, for example, the architects of the project, Brenda and Robert Vale, worked closely with other project members who were also the future residents, such as David Leigh, an independent water design specialist, and Nick Martin, an experienced builder of low-energy buildings who acted as project manager (Hockerton Housing Project, 2001). Via the collaborative design process and self-build approach, all project members shared experiences and learned together from the project. Most of the local labour and contractors who were employed for more specialist work, such as plastering and brickwork, also enjoyed the innovative aspects of the construction and gained experience. The project also developed good relationships with many of its suppliers who were providing environmentally friendly building materials. They were keen to be associated with the project, as it helps in the promotion of the environmental aspects of their products. Since this first collaboration the residents from Hockerton have gone on to design and build two more houses on the site using the same sustainability principles and also offer a design advice service to others. This is a good example of skill being learned collectively and passed on. The Hockerton Housing Project also changed the attitudes of those who lived near it and who had watched it develop over the years. The group has just gained planning approval to put up a wind generator in the local village which will be big enough to supply all the village electricity needs and to export a surplus to the grid. This was done at the request of the village residents who are paying for the wind generator. These are the same village residents who opposed the original very much smaller wind generator that the Hockerton Housing Project wanted to install just after the houses were finished. This shows how real projects with real people trying to live sustainbly can change attitudes over time.

Although builder professionals may be the experts in design and construction, as Wates and Knevitt (1987: 115) noted, only users are experts in their lifestyle and relationships. Users can provide noteworthy information about a place, including experiences gained from using the place in many different conditions, and awareness of issues, living patterns and user preferences, which is essential for any analysis prior to design. They can also give details of how local architecture is being used and maintained and participate in evaluation of success and failure of the old and new built environments. Moreover, all participants can share their knowledge of other projects they have participated in or know about. From this they can gain motivation and learn how others overcame obstacles and then apply this knowledge to their situation. Sharing experiences and knowledge also increases people's awareness of responsibility for decision making (Sanoff, 1990).

Via design and planning processes, stakeholders can practice their citizenship skills, including communication, group facilitation and civic engagement. These skills can reduce misunderstandings and conflicts as well as create a sense of community. As suggested by Maser, Beaton, and Smith (1998: 31), good communication means *"respect for both listener and speaker, because one must first listen to understand and then speak to be understood."* To be a good communicator, each person should respect the other in sharing knowledge and ideas to create better understanding and better solutions for their community. The more chances to participate and practice citizenship skills, the greater the possibility of overcoming communication barriers, including lack of common experience or frame of reference, difference of culture and approaches, and inability to transfer experiences from one situation to another (Maser et al., 1998). Participants can also learn together to create an agreement and develop consensual problem-solving. Moreover, achievement and knowledge of past successes can give participants confidence to establish new projects and can help to encourage more people to become involved in such activities (ORTEE, 1994).

As Sanoff commented (2000: 26), typically, people tend to be motivated by self-interest and short-term vision. They are willing to be involved in solving problems when the problems directly affect them. Without valid reasons for driving themselves to act towards sustainability, it is hard for them to change attitudes, values, and actions. Participation in a design process gives stakeholders some sense of ownership and some degree of control (e.g. Alexander et al., 1975; Sanoff, 2000; Hubner et al., 2005) and fosters concerns about design issues and the environment. Consequently, people may recognise that they will be affected by environmental issues and problems of non-sustainability and that they should take part in solving these.

4. Conclusion

In conclusion, architecture, particularly sustainable architecture, can be used as a positive learning tool for sustainability. Constructive experiences of sustainable design can educate people about sustainability and sustainable practices, make them aware, and move them to behave responsibly and sustainably. The people who experience sustainable architecture will learn how to interact appropriately with their environments and extend their perceptions of appropriate design. Based on the framework of the relationship between sustainable architecture and responsive sustainable behaviours (figure 1) the three scenarios for experiencing sustainable architecture, (direct experiences, learning about sustainability issues through the media, and participation in sustainable design processes), act as incentives that encourage people's desire to live more sustainably. In reality, these scenarios can happen simultaneously and support each other to enhance responsible sustainable behaviours. First-hand experience, which is mainly related to the development of sustainable attitudes, can be recognised as a source of knowledge for actions, particularly about how to use and maintain architecture and the built environment. Although secondary information primarily plays a key role in enhancing knowledge of sustainable design and related green issues, this information can be related to action strategies and reinforce concerns about personal responsibility and action. Participating in the sustainable design process is fundamentally related to action skills. During a process of sharing information and visions, discussion, and integrating ideas, both experiences and secondary information are usually used. Such information and experiences in participation also contribute to the improvement of personal attitudes towards sustainability.

In addition, via these scenarios, people who gain positive experiences of sustainable design could also lead the demand for more sustainable design in the future. Conversely, to promote responsive sustainable behaviours in this way, it is essential there be many more sustainable buildings for people to experience. There needs to be a considerable number of examples of sustainable architecture of diverse project types, in many places, and in different conditions. The greater the number of sustainable buildings, the more people can be involved with experience of them. For this to happen it needs bodies like public clients and possibly enlightened developers to come forward and commission many more sustainable buildings. In addition, to advance the idea of sustainable architecture as an educational tool for sustainability also requires more detailed research to find out how attitudes and behaviours do change via the experience of sustainable architecture and how such a change affects the demand for sustainable architecture. This task should be a long term project between architectural, educational, and other fields. The participation of multi-stakeholders and professions in creating sustainable architecture and developing the use of sustainable architecture as a sustainable educational tool is also part of enhancement of responsible social attitudes and sustainable culture. These become one of many external factors influencing responsive sustainable behaviours. The resulting cause-and-effect cycle will lead to higher demand for sustainable architecture and make sustainable architecture a true educational tool for sustainable education.

Keywords: territorial balance, social equity, sustainable economic growth, environmental impact, sustainable building, ecomaterials, reuse, recycle

Summary

Since the Brundtland Report was published, and despite of its ambiguity in the definition of the aims of sustainability, initiatives of all kinds related to sustainable development have increased in every sector of human activity, public or private.

Spain, along with the rest of the countries integrated into the European Union, is deeply committed to the promotion of policies aiming at a greater balance among economic, social and environmental aspects. Nevertheless, despite all the efforts already undertaken in our country in this respect, the results so far, according to the report 'Sustainability in Spain 2006' published by the Observatory of Sustainability in Spain, dependent on the Ministry of Environment, are insufficient, and consequently, a Spanish Strategy of Sustainable Development in accordance with the recently approved European Union Revised Strategy for a Sustainable Development is very much needed. Even more, the last report from the OSE, 'Sustainability in Spain 2007', points out a moderate advance towards more sustainable practices, particularly regarding economic aspects, but still deficient regarding territorial, environmental and social aspects.

During the past years, the convergence of the Spanish economy towards the EU has caused great environmental costs, territorial imbalance and social inequality that must be corrected for better sustainability of our development. The building sector, one of the most important of our economy, but also a great consumer of territory, energy and transport, must contribute to correct this situation by consolidating and increasing the initiatives towards sustainability.

1. Background

In concordance with the hope of reconciling the environment and economic development that gave way to the concept of sustainability, the term should be understood as a specific philosophy -an *ecosophy*, in Guattari´s words-- as a response to our ecological registries. In accordance with this train of thought, partial sustainability does not make sense, and the sum of its parts does not provide us with a sustainable society. Sustainability is a concept based on balancing different aspects, whose results have been defined as solidarity.

Moreover, the imprecise definition of sustainability has arisen numerous critiques, while transforming the concept of sustainability into a type of *symbolic capital* with the added risk of becoming an empty label for the consumer market.

However, maybe it is now more necessary than ever for this new sensibility provided by sustainability to propose a balance between the economic, social and environmental. This affirmation, made in a general sense, is not less realistic for the construction sector, along with all of the sub-sectors it influences; it plays a key role in the Spanish economy and thus for the sustainable development of our society, while also being the one with the largest environmental impact.

As we all know, the construction sector extracts more raw materials than any other production sector, and the creation and operation of the space created (including the energy used in construction processing and transporting materials and products) supposes at least 50% of Europe's energy consumption. Its impact on the land is also evident, keeping in mind that 80% of the inhabitants live in urban areas. To this we must add the high volume of waste from construction, use, maintenance and demolition, all generated by the buildings; this volume continues to increase and this implies serious difficulties for their reuse and/or recycling.

The commitment to a more sustainable development requires the adaptation of all agents implied in construction, going beyond the mere superficial adoption of a series of concepts, techniques and mechanisms "supposedly sustainable." The change must work on a deeper level and affect the method of planning, projecting and constructing. It is also necessary to surpass the current excessive dispersion and join forces, not just sum up the existing forces, but respond to a broader expansion based on this previously mentioned balance between the economic, social and environmental.

2. Spanish Context

In April, 2002, the European Union ratified the Kyoto protocol which gave way to the adoption of measures, programs and both joint and separate guidelines for each country to reach the aims assumed in the protocol. More specifically, the EU committed to a reduction of 8% of its total, but understanding the needs and characteristics of the different countries integrated, the assigned reductions or increases allowed for each country are different. For Spain, a 15% increase of emissions was forecasted.

This same year, the Directive on the Energy Performance of Buildings (Directive 2002/91/EC), which the member states had to incorporate into their national legislation before January 2006, guarantees that the building standards include guidelines on insulation, orientation, energy and hot water consumption. This directive also establishes the obligation to carry out periodic inspections of boilers and air conditioning systems, and to include an energy performance certificate in all newly constructed and existing buildings, with some exceptions. In Spain the European directive's requisites have been incorporated into the Building Technical Code, approved in 17 March, 2006.

If we take a close look at the panorama of activities relative to sustainability in construction in Spain, we see an excessive atomism in terms of the initiatives taken, which results in an unnecessary multiplication -even reiteration- of the efforts instead of a convergence of them towards a common aim. To this we must add that, besides that they all respond to the interests of the specific activity in question, they fundamentally focus on the economic and environmental aspect of sustainability, practically leaving out its social aspect.

However, at this time, as the European Union has recognised, the emphasis should be the development of reliable sustainability indicators, with special attention to social indicators.

Expected impact:

The creation of a reliable index of sustainability indicators for Spain will set, on a permanent basis, a common reference for the assessment of the construction sector sustainability, in the improvement of which all parties involved will be welcome to participate.

At a later stage, and following the Spanish index, it is possible to initiate the same project in other countries of the EU, in order to get a series of national indexes that will allow a comparative base for the assessment of sustainability in the European construction sector and the implementation of measures towards its accomplishment.

3. Aims

3.1. Definition

In accord with that previously stated, and as a response to the current state of affairs, the aim of this research project is to develop an index of sustainability indicators for Spain that should:

- Be representative of and applicable to the complete sector
- Transcend the construction sector's different sub-sector's partial interests, along with those of the different agents implicated in the building process
- Be flexible enough to absorb possible future changes

3.2. Operative principles

For this point we have focused on establishing the main characterising operational principles for the complete index development process, and for the index itself, and keeping in mind the general situation described, the following are essential:

- Focus on the balance between social, economic and environmental factors
- Take the complete life cycle as a reference, both in terms of materials and processes
- Consider the set of agents that intervene in the building process
- Conceptual robustness as a consequence of applying the general principles of sustainable construction

3.3. Developmental framework

To achieve the defined aims, it seems logical and suitable to establish the same guidelines for this project as those used by the National Construction Programme included in the previous *Plan Nacional de Investigación Científica, Desarrollo e Innovación Tecnológica* 2004-2007 [Spain's 2004-2007 National Scientific, Development and Technological Innovation Research], created by the *Comisión Interministerial de Ciencia y Tecnología* [Inter-Ministry Commission on Science and Technology]. The Programme aims to '*configure sustainable construction that contributes to a harmonious growth of our society and that establishes the bases for a better future for the generations to come'.* This aim establishes three key thematic priorities: (1) Materials and products for construction, (2) Technologies, systems and constructive processes, and (3) Evaluative and management systems in construction.

As we can see, the National Construction Programme establishes a broad framework of possibilities for the construction sector and its different sub-sectors to propose initiatives to improve their sustainability and constitute the operational bases in the future.

It is also important to introduce and maintain the European reference, among other things, as a response to the different initiatives of the European Commission for creating a European Research and Innovation Area (ERIA).

4. Methodology

In order to achieve the previously defined aims, we first need a comprehensive analysis of the different phases of construction, always from the perspective of the life cycle, with the aim of being able to establish the most adequate indicators to evaluate the sector's sustainability, but also with the aim of suggesting changes or modifications that can improve its sustainability.

Parallely, and given that construction is integrated by not only a set of processes, but also a wide range of agents of all sorts with their own, sometimes contradictory interests, it is necessary to gather the information on each one of them in order to create an index of indicators that properly represent the sector's complete reality.

In accordance with this general train of thought, we can define the following developmental phases:

- **Phase 1:**
  Collecting and selecting data.

  Stage 1
  Collect documentation on the agents involved in construction (annual reports, publications, articles…).

  An approach to the creation of a construction sustainability index in Spain through indicators for agents intervening in the building process first requires that the indicators be identified. For this, we have started from those agents included in the *Ley de Ordenación de la Edificación* (LOE) [Building Regulation Law] to which others have been added to, not included in the LOE, even though of great importance to the process.

Table 1 Building Agents

Included in the LOE	Not included in the LOE
Developer	Governments (central, regional and local)
Planner/Designer	Credit Agencies
Builder	Insurance Companies
Project Manager	Real Estate Agents
Foreman	Utility Companies (energy, telephone, internet...)
Quality Control Entities	Universities and Research Centres
Product Suppliers	Training Centres (Work Foundations, Professional Training Institutes, etc.)
Proprietors and Users	Standards Entities
	Operators, installers, maintenance…

The final aim of this stage is to create a list of agents linked to the building process, defining the activity and legal framework in which it is developed, besides the responsibilities and obligations for this process.

A legal bibliography has been started from the information collected with periodic updates.

Stage 2
Definition and limits of the different phases and construction processes for future analysis.

Parallely, and keeping in mind that the final aim is to determine the influence of each of these agents in the building process, with the aim of establishing a weight for elaborating the index, we must also organize each of the agents into production or activity sectors, but also according to the construction process phases in which they intervene.

Each of these phases includes a series of operations that are used to identify the different agents implicated. Moreover, the possible appearance of a single agent relative to the various phases may be indicative of their greater or lesser incidence in the process.

The aim of this stage is to configure a comprehensive table linking phases and agents. A list of associations, research institutes, etc. was also created to group the different agents implicated in the construction process in order to contact these entities and obtain updated information on each of the areas of activity.

- **Phase 2**
  Data processing.

  The data collected from the previous phase, which can be presented through annual activity reports, specialized sector publications, conferences, articles, news, etc., are then processed in order to extract a true representation of each activity to create the proposed index.

Conclusions from Phase 1 and 2:

Organising the building agents in tables according to their legal framework and by the responsibility their activity derives, along with a table linking phases and agents, or a list of associations, were initially posed as a necessary tool for the research. However, in practice they constitute a complete map of the sector, which is key to understanding its complete complex performance.

Phases 1 and 2 have laid the foundation to what could be a complete, comprehensive database of the sector, designed for clarity and capable of being periodically updated.

- **Phase 3**
  Selecting the indicators by processes, sectors and agents.

  The currently available indicators relative to the construction sector in Spain will be associated, on the one hand, by their corresponding application phase, and on the other, by the agents implicated in it.

The aim is to identify and organise the numerous indicators currently used in the construction sector, and which have supposedly been chosen for being useful, representative and feasible. Then, they will be selected in accordance with this project's aims. Once the final list of indicators is set, a descriptive file for each one of them will be created to define the application framework of the indicator.

After having finished this phase, a critique-informative conference would be organized with a small number of experts. The researchers will explain the origin and development of the project to the group members, and present the available results for discussion and critical review.

Conclusion of Phase 3:

Phase 3, which was currently in progress when writing this paper, has become especially difficult, mainly in terms of collecting data for the indicators used in Spain, and then the selection of those to be used in the index. This is why we have decided to use some of the leading companies and entities as references: FCC, Ferrovial, the Basque Country's Government and ITEC. It is also necessary to adapt indicators that attempt to measure the same parameters, but are formulated differently.

However, once having finished this phase, the currently used indicators in construction will be greatly clarified, making it possible to add others which are deemed equally necessary.

- **Phase 4**
  Establish the priorities and importance (weighting criteria) of each factor. Development of a mathematical model (application) to manage data.

  The aim of this phase, once the index's indicators are selected, is to establish whether it requires a mathematical model as a function of its characteristics, or a battery of indicators with the appropriate application level allocated.

  Having done this, the most suitable weighting criteria will be set and if necessary, the corresponding mathematical model.

- **Phase 5**
  Reviewing the Index. Corrections. Definitive Proposal.

  The aim of this phase is to review the index. Once a series of preliminary tests are performed, and before proposing the definitive index, it will be submitted to external testing from experts, after which another critical review will be held.

Previsions for the conclusion of Phases 4 and 5:

Given the possible importance of the development of an index, not only for the Construction sector in general, but for its different sub-sectors, we are preparing to participate in Spain's upcoming Congreso Nacional del Medio Ambiente (CONAMA) [National Environmental Convention], as well as taking other actions to disseminate the project's results.

- **Phase 6**
  Parallel initiation of the same project in other EU countries.

  The aim in this phase is to start the same project parallelly in other European Countries (United Kingdom, France, Germany, Italy and Portugal), with the aim of obtaining a series of national indexes that make up a solid comparative base to evaluate the sustainability of construction in Europe and implement measures for achieving it.

5. Conclusions

- Even after having organised critical sessions with experts throughout the development of this project, it seems necessary to establish a more direct collaboration with the different agents and sub-sectors that make up the construction sector in Spain. The aim is to update the information obtained from each one of them, their implication in the process, and a joint effort to adapt and improve the proposed index according to the needs and function of these sub-sectors.

- Moreover, there is an obvious need to constitute a permanent platform to manage the database created during the development and periodic updating of the index. This platform would constitute an open dialogue within the sector, with the same integrating character that marks the index. This way, the platform can articulate the relationships with those EU countries that have started or will start the creation of indexes similar to our own.

SUSTAINABLE CONSTRUCTION AND HIGH ARCHITECTURAL QUALITY – A CONTRADICTION?

Gerhard KOCH Dipl.-Ing.[1]

[1] Verband Öesterreichischer Ziegelwerke, Vienna, Austria, koch@ziegel.at

Keywords: Total Quality, brick, sustainable, passive-house, demonstration, architecture, assessment

Summary

The feedback from designers and architects on several demonstration projects for sustainable construction in Austria was not as positive as could have been expected, the criticism focused on the esthetical and architectural quality of the projects. As a reaction to this situation a new systematic approach was developed to ensure a highest possible level of technical and sustainability quality but going in parallel at the same time with good and modern architecture. Main elements of this procedural approach are the involvement of well-known independent organizations, e.g. architects federations or the like, an architectural competition to guarantee a broad participation of young and ambitious architects and last but not least the involvement of an interdisciplinary team of experts who accompany the planning architects throughout the whole design process. This procedural concept was applied to a newly developed residential area in Innsbruck in The Tyrol.

1. Introduction

Very often one can hear: buildings designed to reach a maximum level of sustainability are probably modern, healthy, ecological, and future oriented, but they are not beautiful or they are even ugly, they show disappointing architectural and esthetical quality. Is that true? And even more important: is that a must? What can be done to avoid this situation?

2. Some Examples of Older Sustainable Building Demonstration Projects in Austria

Since about 7 years the Total Quality (TQ) tool is now in use in Austria. This TQ tool is the national implementation of the Green Building Challenge framework. Very recently the TQ tool has been amalgamated with two other Austrian rating systems, the so-called “Oekopass” of the Institute for Building Biology and the “klima:aktiv” model of the Ministry for Environment and will in the future be called TQB.

The association of Austrian clay brick and roof tile producers (VOEZ) has initiated several brick projects, which were evaluated and certified with the TQ assessment tool. All these projects had very good results in the TQ assessment, and one of these projects – the SOL4 office building in Moedling near Vienna – even reached the highest result of all projects which were assessed with TQ so far.

Figure 1 Project Apartment Buildings Telfs Puite in The Tyrol

2.1 Project "Apartment Buildings Telfs Puite" in The Tyrol

This project is part of a big residential development area in the second biggest city in The Tyrol. Two apartment blocks with 30 flats were designed as brick passive houses with a brick cavity wall construction (U-value 0,15 W/m^{2}K) for the external walls. The heating energy requirement of these two buildings is 14 kWh/m^{2}a. The heating is mainly provided by the controlled ventilation system, but there are also small dimensioned radiators in the apartments for the personal comfort of the users. Warm water is produced by solar collectors. The buildings were assessed with TQ, the rating was 3,78 (out of maximum 5 points – this was the best rating for a residential building so far)

2.2 Project "Semi-detached Houses Hamoder" in Linz / Upper Austria

12 double-houses were built in a very scenic but noisy place on the outskirts of Linz, the capital of Upper Austria. Again a brick cavity wall with external rendering was the solution for external walls (U-value 0,15 W/m^{2}K). The heating energy requirement of these houses is between 12 and 14 kWh/m^{2}a. The heating is mainly provided by the controlled ventilation system in combination with small heat pumps. Warm water is produced by solar collectors. The buildings were assessed with TQ, the rating was 3,38 points.

Figure 2 Project semi-detached houses Hamoder in Linz

2.3 Project "Residential Building Wienerberg City" in Vienna

A big apartment block with 99 flats was built on the grounds of the old Wienerberger factories on the southern outskirts of Vienna. Of the 9 floors 7 are built in concrete frame construction with clay block infill masonry, thermal insulation and different facades (metal, rendering and clay panels), in the two top floors the external walls are monolithic clay block masonry with external thermal insulation compound system. The average U-value of the external walls is 0,14 W/m^{2}K, the heating energy requirement of the building is 15 kWh/m^{2}a. The building has a controlled ventilation system; the small heating requirement is covered by district heating and distributed via the ventilation system. There are also solar collectors for warm water. The building was also assessed with TQ, the result was 3,44 points.

Figure 3 Project residential building Wienerberg City in Vienna

2.4 Project "Office Building SOL4" in Moedling / Lower Austria

The first office building with passive house standard in Austria was built in Moedling, a small town south of Vienna. The external walls are made with clay block masonry and external thermal insulation (mineral foam boards). In big parts of the façade photovoltaic panels replace the rendering. The average U-value of the external walls is 0,12 W/m^2K, the heating energy requirement of the building is 10 kWh/m^2a. The building has a controlled ventilation system with heat recovery; the small heating requirement is provided by two heat pumps. There are also solar collectors for warm water. Electricity is provided by the photovoltaic system. The building was also assessed with TQ, the result was 4,21 points – this was the best result of all buildings which were assessed so far.

Figure 4 Project SOL4 in Moedling

Although all these projects reached excellent results in the Total Quality assessment, which is in principle an assessment of the sustainability of the building, and although the buildings include the most modern elements of heating and ventilation equipment, the resonance from leading designers and architects, especially the young and committed architects, was not very positive. There feedback was that these buildings are probably very innovative and future oriented concerning the technical performance but they do not satisfy high esthetical architectural requirements.

3. Development of a New Procedural Approach for Demonstration Projects

3.1 First Step: Selection of Partners

The situation described above lead to an intensive and deep going process to develop a new approach for demonstration projects which can guarantee that both the technical and ecological requirements and also the esthetical architectural requirements can be met at the same time. The first and most important strategic step was the selection of professional partners with high reputation and here in the first instance the involvement of a well known architectural organization. It was decided to choose an organization which is active in The Tyrol, because this part of Austria is quite open for innovative architecture and new approaches and secondly because we found a very competent and cooperative partner in Innsbruck, the capital of The Tyrol from the sector of the project developers who was willing to make such a project together with us.

The selected architectural organization is called "architektur und tirol (aut)", which plays an influential role in the architecture in The Tyrol. Most of the young and committed architects are members of this organization and regularly participate in the meetings and events organized by "aut". One interesting example what type of events "aut" organizes was an exhibition about the work of the famous South-American architect Eladio Dieste a few years ago.

The selected project developer was "Wohnungseigentum (WE)", one of the biggest project developers in the sector of residential building in this part of Austria. WE is a developer with very high reputation and was already our partner for the above mentioned demonstration project in Telfs.

3.2 Second Step: Architectural Competition

The next important step in the process was the development of a two step architectural competition. Besides the intention to demonstrate exemplary sustainability, lowest energy consumption (passive house standard), high esthetic quality and modern technical equipment it was also a target of the competition to show the possibilities of bricks and clay blocks in their various product types in an innovative way. The idea was that by means of a competition many young and ambitious architects can be motivated to deal with this traditional but sometimes a bit out fashioned construction material and to develop new ideas what can be done with this material, how it can be used to create modern architecture. For this purpose the brick industry offered a special price for the best and most creative ideas for the use of clay products.

The other important criteria for the competition were:

- Economic situation in the construction phase and in the usage phase: the project must meet the requirements of the subsidy regulations in The Tyrol
- Acoustic performance: there is high noise load at the site due to a motorway and a railway which pas by very close
- Energy performance: the project must fulfill the criteria for passive house standard
- Sustainability: the project will be assessed with TQB and should reach a high ranking

It was decided to organize the competition in two steps. In the first open phase all local architects from The Tyrol were invited to send in their project proposals. In this first stage 25 architects forwarded project proposals, which were treated anonymously. The high ranking jury consisting of representatives of the city of Innsbruck, the project developer WE, well-known architects and engineers selected the best 7 projects. In the second phase those seven architects and their teams were invited to rework and detail their proposals based on the comments and recommendations of the jury. During the whole process an interdisciplinary team of experts and also a team from the brick and roof tile industry was available to support the participating architects concerning all relevant sustainability aspects, concerning building physics (thermal performance, acoustic performance) and concerning the use and possible limitations of the use of clay products. By doing so it was guaranteed that the target to get an optimal result integrating technical and esthetical aspects and the innovative use of clay products could be reached.

In the second round the jury selected one winner project and awarded two projects with a second price. The special price of the brick industry was split between three projects, the winner of the architectural price also received the first price of the brick industry, and two other projects were awarded with a second and a third price. The appraisal of the jury for the winner project is very interesting, it says:

- The project fulfills the requirements of a human design and construction and takes into account the needs of the future users
- The structured and membered but at the same time interconnected structure correlates ideally with the use of bricks
- And creates a livable and communication friendly environment with courtyards for the future users
- Additionally the planning allows to realize the individual parts in esthetically different brick variations also with visible facades in parts of the buildings

The winning team is Dipl.-Ing. Andreas Scharner and Dipl.-Ing. Peter Wurnig from Vienna who also have an office in Innsbruck.

4. The Winning Project by Architects Scharner and Wurnig

4.1 Architectural Concept

The basic idea of the architects is a vertically compressed garden city. Important aspects for the architectural design are:

- The creation of an individual living feeling through individual terraces and gardens
- Small units with maximum 20 apartments each, situated around courtyards
- A generous and attractive transition from public to private areas by means of light-flooded staircases and connecting bridges and openings in the building structure
- The membered structure of the buildings allows for the development of an individual living feeling and supports the neighbourship

4.2 Structure and Orientation

The membered structure is grouped around courtyards which open to the south; in north direction to the street the courtyards are closed through the buildings themselves. Alongside the railway on the north side of the site the buildings are higher (ground floor + 3) to protect the courtyards against the noise. The openings between the buildings are closed with glass sound-proof walls and in the openings facing clay brick masonry is used to absorb the noise. Most of the flats have a clear south orientation. Shading interaction between the buildings is avoided by the arrangement of the buildings on the site.

As a result of the structured arrangement of the six buildings the site density is exceptionally high.

Figure 5 Project Sieglanger by architects Scharner and Wurnig – ground floor level

Altogether there are 83 flats with 2, 3, 4 or 5 living rooms and net areas between 39 and 121 m^2. The total net area is 6658 m^2. Some of the flats are maisonettes on two levels. Approximately two thirds of the flats have a south orientation, one third is east-west oriented. Half of the flat have a private garden or a roof terrace.

4.3 Concept for the Green Areas

Green areas are an essential part of the architectural concept. The open structure provides the possibility to have a garden landscape in between the individual buildings, which consists of courtyards, groups of trees, playgrounds and private gardens. Further on the garden landscape is also brought to a vertical dimension by means of the terraces which form sort of “hanging gardens”.

4.4 Facades and Materials

As already said it was an essential target of the project to use clay materials as far as possible. Therefore the greatest parts of the external and internal walls are made with clay block masonry; the external walls have an external thermal insulation compound system with rendering. In parts of the façade in public areas cavity wall construction will be used with facing brickwork with a thin semi-transparent coating.

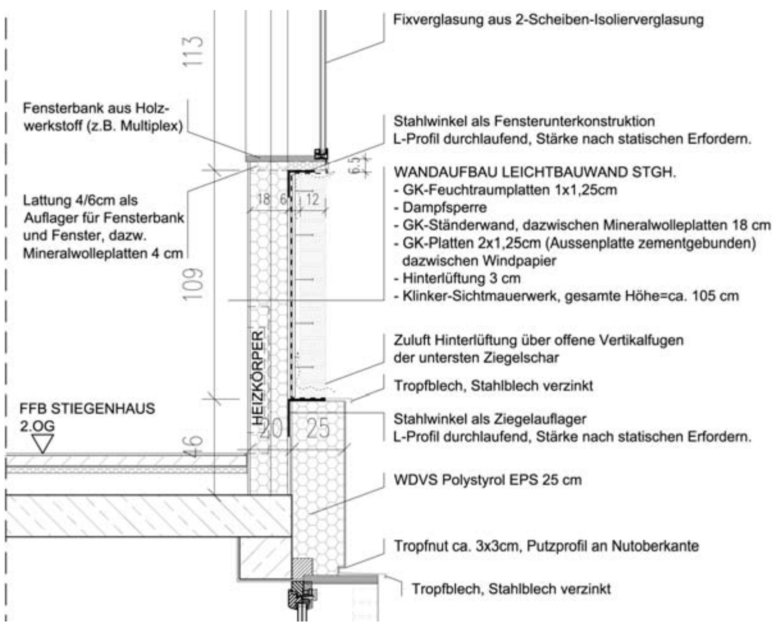

Figure 6 Project Sieglanger by architects Scharner and Wurnig – facade section

4.5 Energy Concept

The whole residential area will fulfill passive house standard which means a heating energy requirement of less than 15 kWh/m^{2}a. In detail the following is foreseen:

- A controlled ventilation system with heat recovery
- Warm air collectors to pre-heat the air for the ventilation system
- Solar collectors for the warm water production.

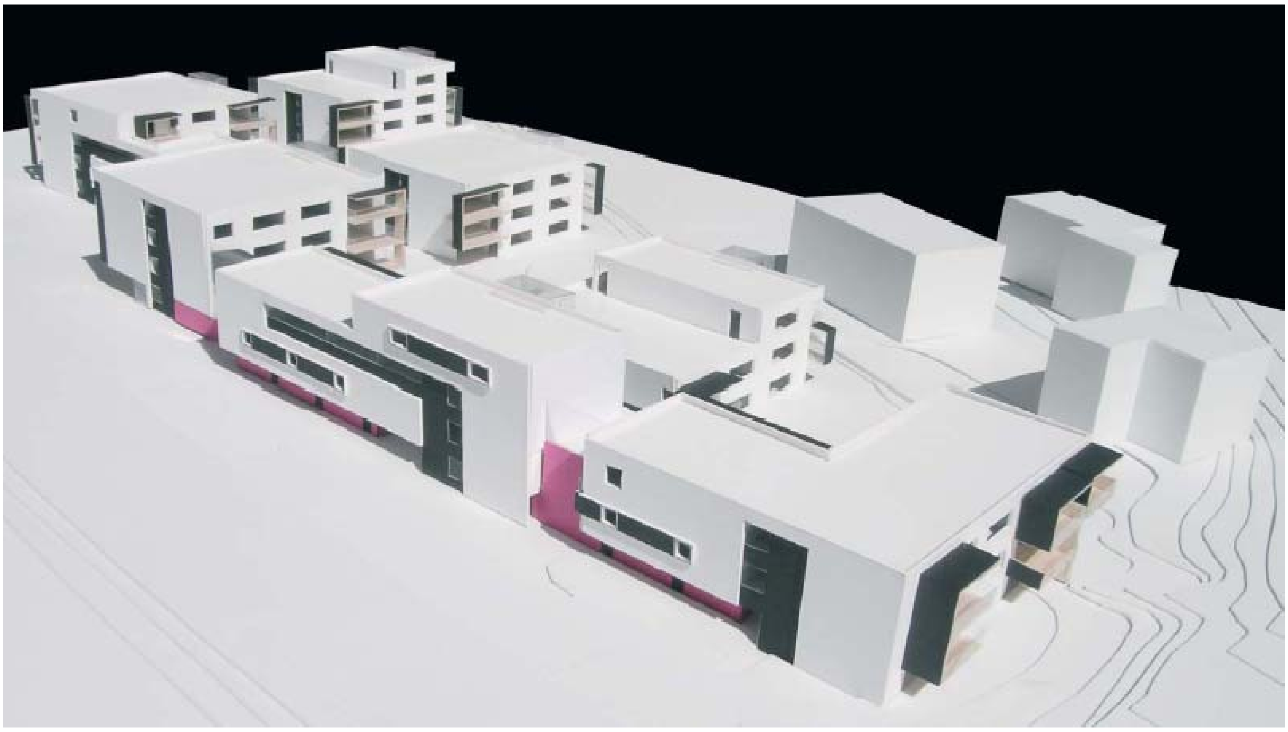

Figure 7 Project Sieglanger by architects Scharner and Wurnig – model photo

5. Current status of the project

Originally it was planned that the project should start in 2007. Due to unforeseen problems with the local building authorities of the city of Innsbruck the start of construction has been delayed until now. Most probably the work will now start very soon and should be concluded until summer 2009.

6. Conclusion

The national implementation of the Green Building Challenge framework, the so-called Total Quality tool has proven to be a valid and easy to apply instrument for the assessment and certification of buildings concerning their sustainability. The Austrian clay brick and roof tile industry has contributed to the development of the TQ tool and its further improvement by applying it to several demonstration projects in both the sector of residential buildings and the sector of office buildings. The feedback from designers and architects was not as positive as could have been expected, the criticism focused on a lack of esthetical and architectural quality of the projects. As a reaction to that a new systematic approach was developed to ensure that a highest possible level of technical and sustainability quality can be reached but going in parallel at the same time with good and modern architecture. Main elements of this procedural approach are the involvement of well-known independent organizations, e.g. architects federations or the like, who accompany the planning process. Another important element is the architectural competition to guarantee a broad participation of young and ambitious architects. Last but not least it proved to be important for the result to have an interdisciplinary team of experts who can accompany the planning architects throughout the whole design process.

This new procedural concept was applied to a residential area in Innsbruck in The Tyrol. Due to unforeseen circumstances we can state for the time being that the planning process is going on very satisfactorily and that the project seems to be very ambitious and will most probably fulfill all the high expectations. Unfortunately it is not possible yet to report about the final result, because construction work will only start in spring 2008 due to a delay caused by troubles with the local building authorities.

EFFECT OF FLY ASH ON PROPERTIES OF CEMENT AND LIME BASED COMPOSITES

Milena PAVLÍKOVÁ Ph.D.[1]
Robert ČERNÝ Ph.D., D.Sc.[2]

Keywords: waste materials, fly ash, sustainable design, energy savings, composite materials, cement, lime

Summary

Fly ash as waste material, that is characteristic by latent hydraulic properties, can substitute certain amount of Portland cement in the composition of cement based composites. However, it can be used as partial aggregate replacement as well. In concrete production, around 90% of all energy consumed is used to obtain cement, which is also a major source of CO_2 emissions. On this account, partial replacement of cement binder with the recycled waste materials is profitable from ecological as well as from economical point of view. Fly ash can also be used as partial replacement of lime. Due to its pozzolanic activity, it can significantly improve particularly the mechanical properties of lime renders where it can be used instead of cement for that purpose. In this paper, basic mechanical and hygric properties of cement and lime based composite materials containing fly ash as partial cement or lime replacement are studied and comparison with materials without any admixture is done.

1. Introduction

Nowadays we are standing behind lack of natural raw materials and our lifestyle brings the pollution and greenhouse effect. On that score is tendency of maximal recycling of all types of wastes and reducing their disposal. The greenhouse effect, discovered by Joseph Fourier in 1824 and first investigated quantitatively by Svante Arrhenius in 1896, causes that the Earth's average surface temperature is warmer than it would be without it. A recent warming of the Earth's lower atmosphere is believed to be the result of an enhanced greenhouse effect due to increased concentrations of greenhouse gases in the atmosphere.

The combustion methods, production of cement and lime for example, are presently considered as significant source of greenhouse gases, especially of carbon dioxide. From the basic calculations we can obtain the amount of CO_2 production. For example, in lime manufacture, from 1,500 kg calcium carbonate according reaction it is produced nearly 38.10^3 m^3 CO_2. Within the production of 1 t of Portland cement, 1 t of CO_2 is evolved in the atmosphere. Each day we emit huge amount of combustion gases together with solid wastes that are formed during incineration processes. These solid wastes can be generally divided into three basic groups: under-furnace grate slag materials, solid wastes from electro-filters (ash materials) and fly ashes from sleeve and catalytic filters. These fly ashes differ in grain size distribution, composition and amount of heavy metals, and many other parameters. Among them, the toxicity is from the point of view of their utilization at the top of the interests. Depending upon the source and makeup of the coal being burned, the components of the fly ash produced vary considerably, but all fly ash includes substantial amounts of silica (silicon dioxide, SiO_2), both amorphous and crystalline, and lime (calcium oxide, CaO). Toxic fly ashes are contaminated with toxic organic compounds, especially with polychlorinated dibenzo-p-dioxines, benzofurans and biphenyls phenols (POP compounds – persistent organic pollutants).

These highly toxic fly ashes should be detoxified by safe technologies because the current practice of landfilling these materials is quite provisional from an environmental point of view. Presently, no effectual legislative limits on the content of toxic POP compounds in the solid wastes from municipal waste incinerators are valid. The legislative process that assessed the limits of the toxicity of fly ash materials was in EU finished in 2007 (EU regulation No. 850/2004, No. 1195/2006, No. 172/2007). On the other hand most of ashes from electro-filters are according to current legislative harmless because of low content of polychlorinated dibenzo-p-dioxines and benzofurans. Electro-filters enable fractional separation of fly ashes with respect to particles size. It can be used for the optimization of composition in the study of fly ashes recycling from the point of view of optimal properties of solidified products for building purposes. Under-furnace grate slag materials represent majority part of solid waste produced in incinerators. However, the amount of solid waste is highly dependent on the type of burnt material. It is possible to say that approximately one weighted third of the total amount of burnt waste will come out of incinerators in form of solid waste. In case of meeting European Union requirements on landfilling reduction to 35% in 2020, the amount of recycled solid waste will be 500 kt per year. It is absolutely evident that successful economical solution of recycling of these waste materials is highly actual topic. Therefore, development of new advanced building materials having higher utility quality is necessary in the sense of the sustainable progress of building industry. However, not only the final advanced properties of materials should be considered. Also the energy and natural materials consumption should be taken into account. Hence, the secondary raw materials (i.e. waste materials) will find widespread use in building materials production.

The application of fly ashes in building industry is oriented first of all into the production of building materials, such as cement, concrete, artificial light aggregates, bricks and ceramics (Jian-Hua (2006), Coelho (2006)). Also, their application in grouting mortar and cast floor layers is possible. Fly ashes from municipal waste incinerators can be applied in a similar way, using all the experience gained at power and heating plant fly ashes. However, their chemical, mineralogical and granulometric composition and the toxicity remainders have to be taken into account. Fly ashes, as waste materials, are characteristic by latent hydraulic properties and hence they can substitute certain amount of Portland cement, in the composition of cement based composites and concretes, or some quantity of lime in lime based composites. However, they can be used also as partial aggregate replacement. Partial replacement of inorganic binders in composite materials with the recycled waste materials is profitable from both ecological and economical points of view.

In this paper, basic mechanical and hygric properties of cement and lime based composite materials containing fly ash as partial cement or lime replacement are studied and comparison with materials without any admixture is done.

2. Tested materials

The sustainable progress brings demands for development of new, advanced building materials having higher utility quality and durability. On this account, we tested commonly used inorganic binders, cement and lime, combined with pozzolana active fly ash, a waste material. The amount of fly ash as a binder replacement was taken as a maximum to give a material with good rheological behaviour. Fine-grained cement mixtures without and with fly ash addition, denoted as FGC and FGCF, respectively, and two lime based composite materials without and with fly ash addition, VO and VOF, respectively, were prepared. Table 1 presents the exact composition of the studied mixtures.

Table 1 Composition of tested mixtures

Type of mixture	Amount (kg)				
	Lime	Cement	Sand 0/2mm	Fly ash	Water
VO	4.80	-	14.40	-	4.80
VOF	4.00	-	14.40	0.80	4.20
FGC	-	4.20	16.70	-	2.50
FGCF	-	3.40	16.80	0.80	2.50

Both inorganic binding materials were of the Czech origin, cement CEM I 42.5R was manufactured in Hranice and lime CL 90 was produced by limekiln “Čertovy schody”. In the tested mixtures, fly ash from Dětmarovice, CZ, with granularity 0-0,7 mm with the content of 29 mass% of SiO_2 and 15 mass% of Al_2O_3 was added. Fly ash was a very fine grained product of powder coal combustion with different chemical, physical, mineralogical, morphological and technological properties; it meant it was a highly heterogeneous material. The reason why fly ash could be used as partial replacement of major binders was that it had pozzolanic properties, reacted with calcium hydroxide at common temperatures (about 20°C) and formed hydrated calcium silicates and aluminates. The products of pozzolanic reaction had porous character. The specific surface measurements using gas adsorption method (Keppert et al. (2007)) showed for cement binder 365 m^2/kg, lime binder 11 100 m^2/kg and fly ash 250 m^2/kg. Sand 0/2 mm fraction was delivered by Heidelberg Cement Group, Brněnské písky Inc., affiliate Bratčice, normalized according to EN 196-1.

Tested mixtures were prepared using laboratory mixing machine with forced rotation for 3 minutes and then compacted using vibrating machine. Each mixture was cast into standard prism forms, with dimension 100 x 100 x 100 mm and 40 x 40 x 160 mm. After two days all prisms were taken out of forms and then cured for 28 days in high relative humidity environment. The specimens were then cut to required sizes depending on the method of investigation.

3. Experimental methods

As fundamental physical material characteristics, bulk density, matrix density, and open porosity were determined. Bulk density was measured using gravimetric method. Matrix density was obtained using Pycnomatic ATC, automatic helium pycnometer with fully integrated temperature control with precision of ± 0.01 °C and real multi volume density analyzer. The samples for the basic material parameters determination were cut from cubic prisms with the size of 40 x 40 x 40 mm and their dimensions were 40 x 40 x 20 mm.

Investigation of mechanical parameters was carried out according to the Czech-European technical standard (ČSN EN 196-1(2005)). The compressive and flexural strengths were determined as the most important mechanical parameters for composite materials. For each measurement standard prisms 40 x 40 x 160 mm were tested with DSM 2500 hydraulic testing device, Inova Praha. The flexural strength was measured using standard three-point bending test. The compressive strength was determined using the same test device on the remainders of the specimens after bending test. The measurements were done after 28 days of hardening period.

The measurement of water vapour transport parameters was based on the method proposed by Roels et al. (2004). Firstly, cylindrical samples with the size of 95 mm in diameter and 20 mm in height were cut from the standard prism 100 x 100 x 100 mm and water-vapour-proof insulated with epoxy resin to ensure one dimensional water vapour transport. The measurement was carried out in steady state under isothermal conditions. It was based on one-dimensional water vapour diffusion and consisted in measuring the water vapour diffusion flux through the specimen and partial water vapour pressure in the air under and above specific specimen surface. The measured samples were sealed into the cups containing burnt $CaCl_2$ (0% relative humidity), then they were placed in a controlled climatic chamber at 25±0.5°C and 45% relative humidity. The sealed cups with samples were weighed periodically. The steady state values of mass gain were utilized for the determination of water vapour transport properties.

Liquid water transport in the sorptivity concept was analyzed using one-dimensional free imbibition experiment (Kumaran (1994)). Specimens sizes of 40 x 40 x 20 mm were cut from standard prisms and then water-vapour-proof insulated with epoxy resin on four lateral sides, and after that dried in an vacuum oven at 110°C. After cooling the face side of each sample was immersed 1-2 mm into water on top of a saturated sponge. The sample mass was measured continuously. The water absorption coefficient was then calculated from the linear part of the cumulative mass of water vs. the square-root-of-time function (Krischer (1963)). Then, the apparent moisture diffusivity was calculated from the vacuum saturation moisture content and water absorption coefficient.

The sorption isotherm presents the dependence between the water content in the porous matrix and the relative humidity in the system. The shape and position of sorption isotherm depends on the type of porous body of tested materials. The water adsorption and desorption in a porous material are based on van der Waals forces between the surface of the porous matrix and water molecules. The dry material mass increases after a contact with moist air because of gradual bonding of water molecules from the air to the pore walls, in the case of adsorption. Desorption is reversed physical phenomenon, the initial state is capillary saturated sample. At the moment of achieving the equilibrium state between the water vapour pressure in the moist material and in the surrounding air the process of adsoprtion/desorption is stopped. Tested samples were cut in the required size of 40 x 40 x 10 mm. In the adsorption isotherm measurement the dry samples were placed into climatic chamber at 25°C and relative humidity was increased into given values after samples reached equilibrium. In the case of desorption isotherm the wet samples were placed into the desiccators with different salt solutions to simulate different values of relative humidity. The experiment was performed parallel in all desiccators in thermostatic chamber at 25 °C. The mass of samples was measured in specified periods of time until steady state value of mass was achieved. Then, the moisture content was calculated for each relative humidity state and the sorption isotherm for each tested material was plotted.

4. Results and discussion

Basic properties of all tested materials are summarized in Table 2. Each result represents the average of five measured values. The measurements of all parameters took place in controlled climatic conditions at 25±2°C and 30±5% relative humidity. Dry material was taken as the initial state for most of the experiments.

Table 2 Basic properties of tested mixtures

Type of mixture	Bulk density (kg m^{-3})	Density (kg m^{-3})	Porosity (%)
VO	1 650	2 605	36.70
VOF	2 005	2 345	22.50
FGC	2 122	2 611	18.70
FGCF	2 066	2 544	18.80

The open porosity was found not to be distinctly affected by the fly ash addition in the case of cement based composite material, bulk density decreased by about 3% and open porosity increased by about 0.5%, but these differences could be disregarded because of the measuring error range which could be estimated as 1%. On the other hand, due to pozzolanic reaction of fly ash the open porosity of lime based composite material decreased very significantly. This is, though, not a positive outcome, because we need the lime based materials to have a high porosity, which guarantees fast water vapour transport, thus its fast removal from load bearing structure.

The survey of mechanical properties of studied mortars after 28 days of hardening is presented in Table 3. Each result represents the average value of six values of compressive strength measurement.

Table 3 Mechanical properties of tested mixtures

Type of mixture	Compressive strength (MPa)
VO	0.4
VOF	0.8
FGC	50.5
FGCF	56.0

The measured values show that usage of pozzolana active fly ash led to about 10% increase of compressive strength in comparison with the basic cement mixture. In case of lime composite material with fly ash addition the compressive strength reached two times higher value than for pure lime mixture which was caused by hydraulic products formation due to chemical reaction between binder and fly ash.

The calculated average values of water vapour transport parameters are presented in Table 4, each result represents the average value from five measurements.

Table 4 Water vapour transport parameters of tested mixtures

Type of mixture	Diffusion coefficient of water vapour (m^2s^{-1})	Water vapour diffusion resistance factor (-)
	0-45% RH	0-45% RH
VO	2.9E-6	9.0
VOF	4.7E-7	50
FGC	4.2E-7	55
FGCF	4.6E-7	51

In the case of fine grain cement composite with fly ash addition the measured values of water vapour diffusion resistance factor were similar to those of the basic FGC material. The differences were on the edge of the error range of the measuring method. For the studied lime based materials the water vapour transport parameters were very different. Lime mixture with fly ash addition had nearly six times higher water vapour diffusion resistance factor than the reference lime mortar as a result of calcium silicates formation in lime matrix. From the practical point of view, the obtained value of water vapour diffusion parameter of lime based material with fly ash addition may be considered as a negative finding (as already anticipated and pointed out in the analysis of porosity measurement) because water vapour can not be easily transported out of the load bearing structure.

The liquid water transport parameters of all tested materials are presented in Table 5; each result represents the average value from three measurements.

Table 5 Liquid water transport parameters of tested mixtures

Type of mixture	Water absorption coefficient ($kg\ m^{-2}s^{-1/2}$)	Saturation moisture content ($kg\ m^{-3}$)	Apparent moisture diffusivity (m^2s^{-1})
VO	2.30E-1	359	4.10E-7
VOF	1.20E-1	224	2.87E-7
FGC	1.10E-2	186	3.50E-9
FGCF	1.80E-2	187	9.20E-9

The values of water absorption coefficient of cement mixture with fly ash addition increased almost two times compared to the basic cement mixture FGC. Thus, the apparent moisture diffusivity visibly increased due to fly ash addition. However, the values of moisture diffusivity of both materials remained relatively low. An opposite trend of about the same magnitude was observed in the case of lime based composite mixtures. For a lime mortar the reduction of liquid moisture transport into material structure is a very positive feature.

The results in Figs. 1a, b show the sorption isotherms of all tested materials.

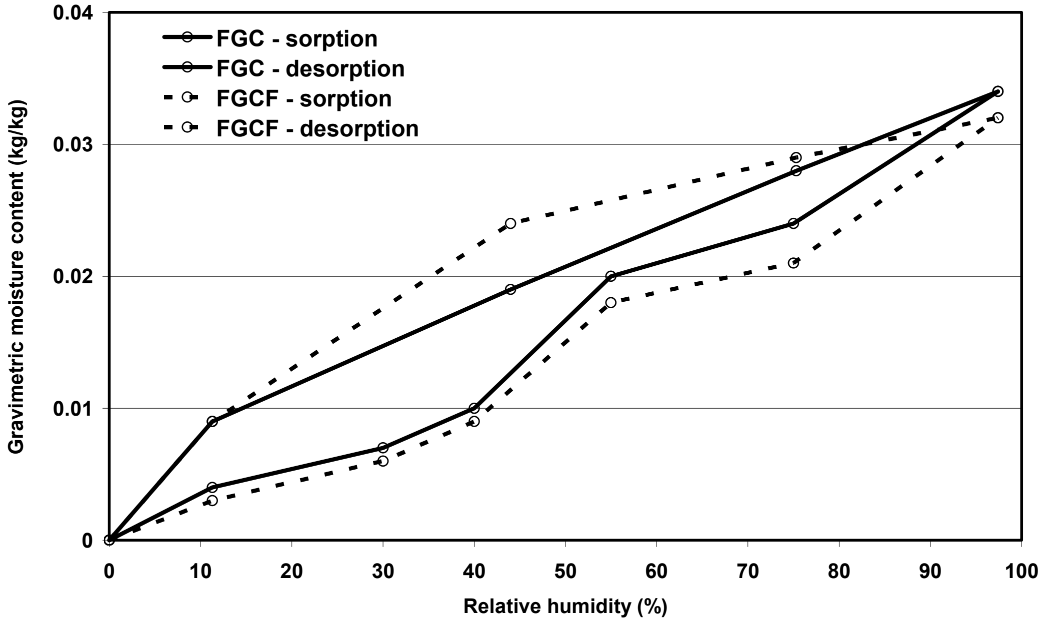

Figure 1a Sorption isotherm of cement based materials.

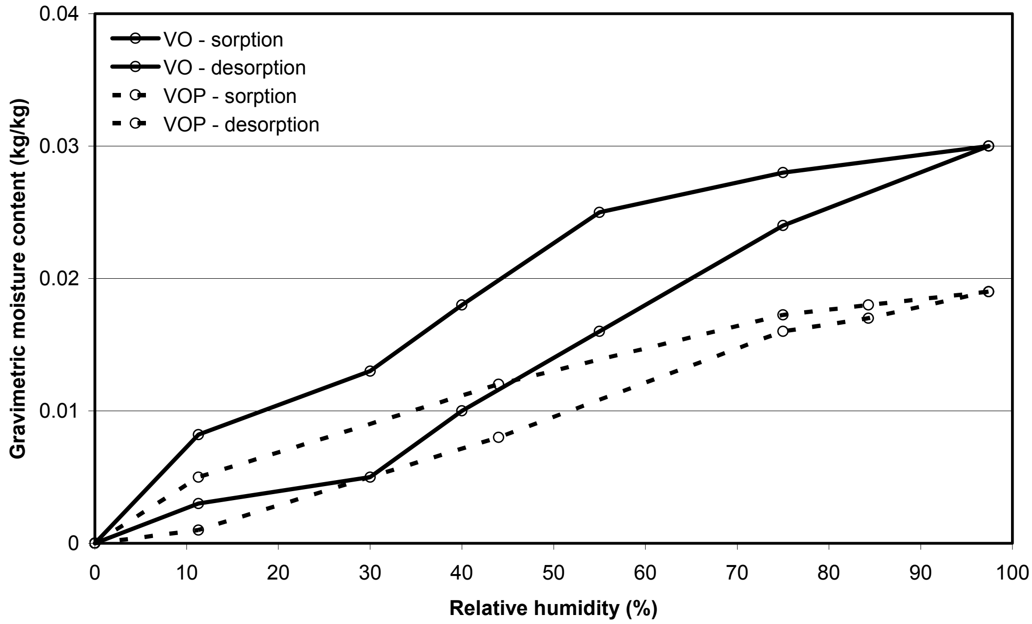

Figure 1b Sorption isotherm of lime based materials.

The sorption isotherms of all tested materials exhibited relatively low hygroscopicity and low hysteresis. The effect of fly ash on the water vapour sorption capability was important for lime based composites where the maximum hygroscopic moisture content decreased by about one third as compared to the reference lime mortar. This seems to be a consequence of the lower porosity of lime mortar with fly ash. Water vapour sorption of cement based composites was found basically unaffected by fly ash.

5. Conclusions

The results presented in this paper have shown that fly ash can be effectively used as environmental-friendly replacement of a part of common inorganic binders, which production presents a significant source of greenhouse gases, in composite materials applied in building industry. The use of fly ash as partial replacement of cement resulted in an about 10% increase of compressive strength of the analyzed fine-grain concrete. The water and water vapour transport parameters were higher than in reference concrete but the increase was not so high that it could harm the water protection ability of the concrete in a significant way. The application of fly ash as a binder in lime mortar led to more pronounced effects on hygric properties, in particular. The fly ash addition to lime binder had the most important influence on water vapour transport which was reduced almost six times. This finding has to be taken into account in further considerations concerning the application of the mortar; its higher strength compared to the reference lime mortar indicates that it should be used as walling mortar rather than plastering mortar.

Acknowledgement

This research has been supported by the Ministry of Education, Youth and Sports of Czech Republic, under project No MSM: 6840770031. The authors would also like to express thanks to Radka Pernicová and Martin Keppert for their help with the experimental work.

Keywords: SBTOOL, Sustainable Building, Building Performance Assessment.

Summary

An international collaborative effort called the Green Building Challenge (GBC) is developing a building environmental assessment tool that exposes and addresses controversial aspects of building performance based on harmonized criteria and indicators. This research will use SBTOOL which has been developed by GBC to assess Taiwan buildings located north and south of the Tropic of Cancer, analyze and discuss the difference in terms of sustainable development.

1. Purpose

Sustainable development needs explicit consideration in context of time and space, and a holistic n-Bottom line (nBL) approach. The International Initiative for Sustainable Built Environment (iiSBE), following the standards formulated by the International Standardization Organization like ISO14025 and ISO21930, developed an SBTOOL. The previous research in 2005 analyzed the operations of GBTOOL in the assessment of Taiwan cases and discussed the difference in the performance results between local weights established by experts and GBTOOL's default weights. See Figure 1. This research now applies SBTOOL to assess two building cases located in the north and south regions of Taiwan, with the purpose of finding out the key regional factors influencing operating, applying and processing the results of SBTOOL. This study also hopes to provide references for relevant researches at home and abroad.

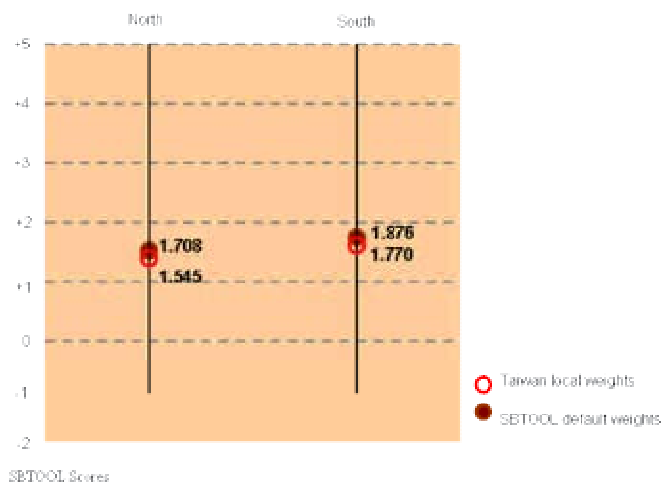

Figure 1. Assessment results of GBTOOL cases in previous research

2. Overview of Taiwan Region

2.1 Geographical and climate Conditions of Taiwan

Located in a subtropical zone, Taiwan as a whole has a high-temperature and high-humidity climate. Taiwan is a long and narrow island along north-south direction with the Tropic of Cancer at 23.5 degrees north latitude passing through it. See map below. The climate in the area north to the Tropic of Cancer is subtropical, and that in south is more tropical and warm. Therefore, Taiwan plays an indicative role in terms of environment. In Taiwan's present residential building environment, existing buildings account for 97% and new buildings only 3%. Urban areas are narrow and densely populated, without large hinterlands for use, so the buildings there develop towards high-rise/high density forms whereas, buildings in countryside towns or mountain areas are of low density, without limitations of space. The goal of sustainable development is more easily reached in countryside towns and mountain areas.

2.2 Development of Green Building Evaluation in Taiwan

To get a full knowledge of the environmental performance and quality of buildings in Taiwan, the Taiwan Architecture and Building Research Institute (ABRI), Ministry of the Interior developed a Green Building Evaluation (EEWH) in 1999 and added two more indicators in 2003. Now there are nine indicators in EEWH for green building assessment: biodiversity, greenery, soil water content, daily energy saving, CO_2 emission reduction, waste reduction, indoor environment, water resource, and sewage and garbage improvement. Each assessment item is scored using its respective assessing formula as well as its weight coefficient, and scores are rated into the following ranks: qualified rank(12<=RS<26) bronze rank(26<=RS<34), silver rank(34<=RS<42), gold rank(42<=RS<53)and diamond rank(53<=RS). According to statistics released by the Chinese Architecture & Building Centre (CABC), among new buildings built up during the period from 2004 to 2008, 223 cases have acquired Green Building Labels, and 1072 cases have gained Candidate Green Building certificates. The distribution of green buildings among building types is shown in the chart below.

3. Background of Cases and Descriptions of Their Performance Results

3.1 Background of Cases

3.1.1 Taiwan North case: an apartment building located in an urban area of Taipei city, completed and opened in October of 2005, with 5 floors under ground and 14 floors above ground. The building has an annual average temperature of 20°C, annual average precipitation of 2325.2 cm, and annual average 1381 hours of sunshine.

3.1.2 Taiwan South case: a high-rise residential building located in an urban area of Kaohsiung city, completed and opened in April of 2005, with 3 floors under ground and 27 floors above ground. This building has an annual average temperature is 25.1°C, the annual average precipitation is 1720.2 cm, and the annual average sunshine hours is 2075.4.

3.2 Scores of Cases under Taiwan EEWH

3.2.1 Taiwan North case: This case gained a label verifying it passed seven Green Building Evaluation indicators including greenery, soil water content, Energy conservation, CO_2 emission reduction, indoor environment quality, water resource, sewage and garbage improvement. Refer to Table 2.

3.2.2 Taiwan South case: This case gained a label verifying it passed five indicators of Green Building Evaluation indicators including greenery, soil water content, Energy conservation, water resource, sewage and garbage improvement. Refer to Table 3.

Table 2 Scores of North Case under Taiwan EEWH

Assessment indicators	Designed value in this case	Criteria	Assessment results
Greenery	TCO_2c = 126901.68	TCO2c = 118800 TCO2>TCO2c	2.3
Soil water content	λ = 0.45	$λ_C$ = 0.44 $λ>λ_C$	2.0
Energy conservation	EEV = 0.6	0.80 EEV<=0.80	4.2
CO_2 emission reduction	CCO_2 = 0.81	0.82 CCO_2<=0.8	2.4
Indoor environment quality	IE = 62.4	0.04 IE>=60	2.4
Water conservation	WI = 4.0	4.0 WI>=2.0	4.0
Sewage and garbage	Gi = 10.0	10.0 Gi>=10.0	2.0
Comprehensive score = 18.4 (qualified rank)			

Table 3 Scores of South Case under Taiwan EEWH

Assessment indicators	Designed value in this case	Criteria	Assessment results
Greenery	TCO_2c = 526740	TCO_2c = 277985.7 TCO_2>TCO_2c	5.8
Soil water content	λ = 0.41	$λ_C$ = 0.32 $λ>λ_C$	2.3
Energy conservation	EEV = 0.79 EAC = 0.8 EL = 0.76	0.80 EEV<=0.80	4.2
Water conservation	WI = 5.5	4.0 WI>=2.0	1.7
Sewage and garbage	Gi = 10.0	10.0 Gi>=10.0	2.0
Comprehensive score = 21.6 (qualified rank)			

3.3 Assessment Results of Cases under SBTOOL

The assessment parameters of SBTOOL are grouped into 3 levels; there are 7 assessment parameters at the first level, 29 parameters at the second level and 120 parameters at the third level. The assessment using SBTOOL is carried out using basic data and weights inputted by the third-party authorities and professional design teams. SBTOOL is suitable to handle new and existing buildings, or a mixture of both new and existing buildings. SBTOOL permits assessments to be carried out at four distinct stages of the life-cycle of a building and provides the users/operators with the comprehensive average value of calculated results at each phase thereby allowing the users to have a complete understanding of the conditions of this building.

This research carries out assessment of two building cases on the basis of the default weights of SBTOOL as established by international experts, considering only the design phases of the life-cycle of the two buildings.

3.3.1 Performance results of Taiwan North case: The comprehensive weighted score is 1.5. Among the assessment indicators of SBTOOL, the Energy and Resource Consumption got the highest score of 2.2, the Social And Economic Aspects comes next, getting 2.0, followed successively by the Environmental Loadings, Site Selection, Project Planning and Development, Indoor Environmental Quality, Cultural and Perceptual Aspects, and the Service Quality came last with the lowest score of 0.3. Refer to Table 4.

3.3.2 Performance results of Taiwan South case: The comprehensive weighted score is 1.3. Among the assessment indicators of SBTOOL, the Cultural and Perceptual Aspects got the highest score, 2.0, both the Energy and Resource Consumption and the Environmental Loadings had the score of 1.9, followed successively by the Social and Economic aspects, Site Selection, Project Planning and Development, Service Quality and finally, Indoor Environmental Quality. Refer to Table 5.

Table 4 Score Rating of Taiwan North Case Using SBTOOL

Indicators	Design target scores	Assessment Scores
Site Selection, Project Planning and Development	3.3	1.8
Energy and Resource Consumption	2.3	2.2
Environmental Loadings	3.6	1.9
Indoor Environmental Quality	3.3	1.2
Service Quality	2.9	0.3
Social and Economic aspects	3.1	2.0
Cultural and Perceptual Aspects	4.3	1.0
Comprehensive score	**3.1**	**1.5**

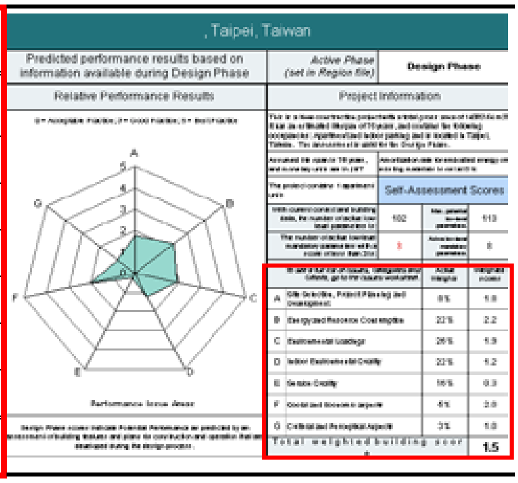

Table 5 Score Rating of Taiwan South Case Using SBTOOL

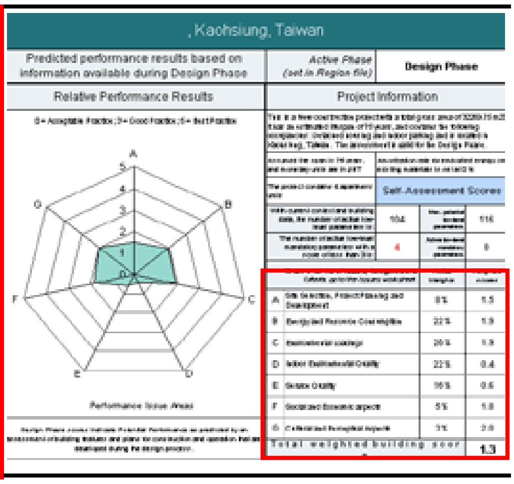
Indicators	Design target scores	Assessment Scores
Site Selection, Project Planning and Development	3.2	1.5
Energy and Resource Consumption	2.2	1.9
Environmental Loadings	3.2	1.9
Indoor Environmental Quality	2.6	0.4
Service Quality	2.6	0.6
Social and Economic aspects	2.4	1.8
Cultural and Perceptual Aspects	4.3	2.0
Comprehensive score	**2.8**	**1.3**



4. Comprehensive Comparison and Analysis

4.1 Analysis of Operation results of SBTOOL in Cases

After assessment on cases using SBTOOL, it is discovered that since the North case is located in urban area and especially in a political administration district, so the development of its site is controlled by strict legislative decrees, therefore, each of its assessment indicators got a higher score than the South case. The South case is also located in urban area, but a general residential district with more households, therefore, the scores of the Energy and Resource Consumption, Energy and Resource Consumption, and the Cultural and Perceptual Aspects are obviously higher than those of the North case. Refer to Figure 3.

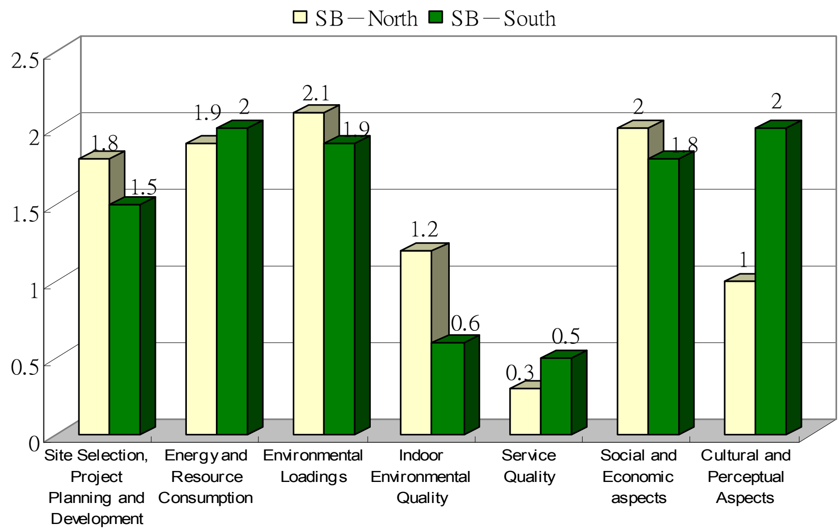


Figure 3. Comparison between Performance results of Taiwan North and South Cases under SBTOOL

4.2 Comparison between SBTOOL and Taiwan EEWH

Compared with Taiwan EEWH, the assessment indicators of SBTOOL put more emphasis on the Service Quality, Social and Economic Aspects, Cultural and Perceptual Aspects, reflecting its orientation in the transformation from green building to sustainable building and emphasizing long-term social and economic development. Refer to Table 6.

Table 6 Comparison between Assessment Results of Two Building Cases

SBTOOL Indicators	Self-Assessment Scores		Taiwan EEWH Indicators	Assessment Scores	
	North	South		North	South
Site Selection, Project Planning and Development	1.8	1.5	Green	2.3	5.8
Energy and Resource Consumption	2.2	1.9	Energy conservation	4.2	4.2
Environmental Loadings	1.9	1.9	Soil water content	2.0	2.3
			CD$_2$ Emission Reduction	2.4	-
			Water conservation Sewage and garbage	4.0 2.0	1.7 2.0
Indoor Environmental Quality	1.2	0.4	Indoor Environment Quality	2.4	-
Service Quality	0.3	0.6	—		
Social and Economic aspects	2.0	1.8	—		
Cultural and Perceptual Aspects	1.0	2.0	—		
Score	**1.5**	**1.3**	**Score**	**18.4**	**21.6**

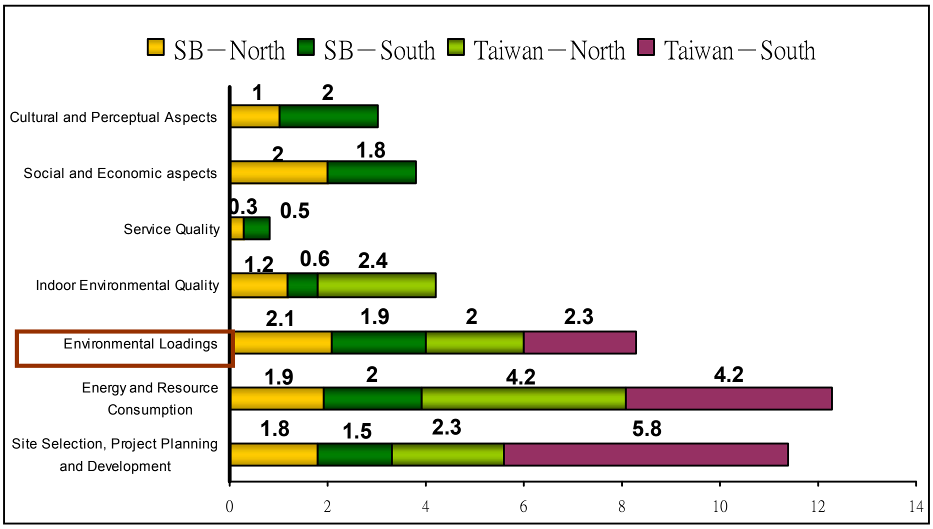

Fig 4a. Environment Loadings using SBTOOL and EEEW

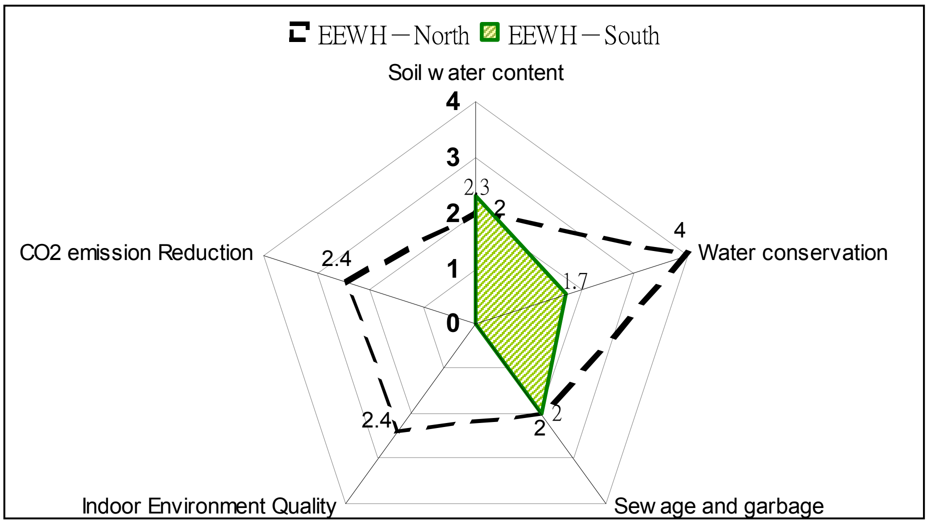

Figure 4b. Score Analysis using Taiwan EEWH

The Environmental Loadings category of SBTOOL covers the assessment indicators of Soil water content, Carbon Dioxide Emission Reduction, Water conservation, and Sewage and Garbage of Taiwan EEWH. Refer to Figure 4a. In the assessment using Taiwan EEWH, all assessment parameters of Environmental Loadings have been taken in account, showing its emphasis on this category. Refer to Figure 4b.

5. Conclusions

This research used SBTOOL as the measuring platform for sustainable buildings in Taiwan region as well as on the comparison with the Taiwan Green Building Evaluation and Labeling System EEWH:

- Assessed using SBTOOL, the North case got a score of 1.5 and the South case got 1.3, both belonging to the Bronze rank; whereas, assessed using Taiwan Green Building Evaluation and Labeling System, the score of the North case is 18.4 and the score of the South case is 21.6, both belonging to the Qualified rank. It shows that the assessment results obtained under SBTOOL are slightly higher than those under Taiwan EEWH. Refer to Figure 5.

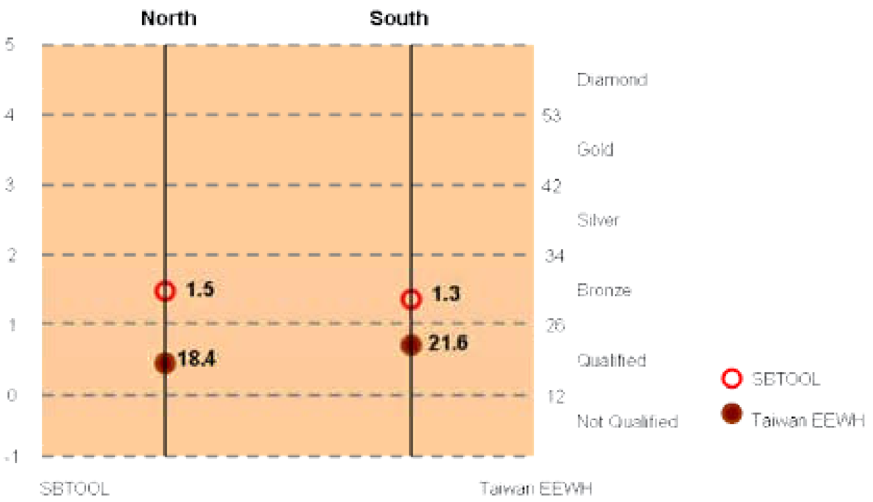

Figure 5. Score Analysis using SBTOOL and Taiwan EEWH

- The comparison between the performance results of the cases in the research and those in the previous research reveals that although the scores obtained using SBTOOL and Taiwan EEWH are different, the calculated results were subjected to the correction using regional expert weights.
- Looking more closely into the score of each assessment item indicates that the environmental loadings in SBTOOL has an influence on the scores of the South case, namely slightly lower than those of the North case. This is because Carbon Dioxide Emission Reduction and Indoor Environment Quality indicators have not been assessed in Taiwan EEWH, showing that the South case did not put more attention to CO2 Emission Reduction and Indoor Environment Quality.

Summary

Recently, for some people the idea of sustainable design has become the basic criterion of architectural design. Frequently, however, many buildings that are claimed as sustainable are only so in terms of the design. All these talk *about* sustainability, only using sustainable techniques without concern for the results or consequences or, worse, the word 'sustainable' or 'sustainability' is attached to an ordinary building. To improve the world so as to become close to sustainable conditions, architecture should be designed *for* sustainability, using sustainable ideas and techniques as the basic design criteria. With the support of a sustainable milieu, including sustainable behaviour and management as well as sustainable political and social conditions, architecture could be part of sustainability or be sustainability. This idea of architecture *as* sustainability shows the interrelationships of people and the non natural environment, of which architecture is a part, and emphasises the aims of development that are not for 'external' goals to achieve sustainability but for architecture for own sake that is sustainability.

1. Introduction

This paper is based on research undertaken as part of an investigation into sustainable schools and the connections between sustainable architecture and sustainable education. It is based on an interdisciplinary approach that suggests all forms of sustainable practice could and should support each other in the creation of sustainability. As a result, study of sustainable practices in the educational field helps to an understanding and enhancement of the meanings of sustainable architecture.

Sustainable architecture and sustainable education share many similarities. For example they both originated from environmental concerns and the promotion of interrelationships between human beings and nature. While sustainable education is mainly developed from preceding practices, like nature study, outdoor education, conservation education, and environmental education that began to be used broadly in the mid 1960s (Palmer, 1998), sustainable architecture has also evolved from earlier practices, such as green architecture, ecological design, and other familiar ideas and practices (Farmer 1996; Ryn and Cowan, 1996; Wine 2000; Steele, 2005). The main influence that has driven the development of sustainable architecture and sustainable education is the environmental movement in the 1960s and 70s, which can be traced through literature, such as *Silent Spring* (1962), *Design with Nature* (1969), and *Limits to Growth* (1972), and environmental events, such as the first Earth Day in 1970, the UN conference on the Human Environment, Stockholm, Sweden, in 1972, and the UNESCO First Inter-government Conference on Environmental Education, Tbilisi, USSR in 1977. In the 1980s, environmental consciousness was revived again as a result of a movement in favour of sustainability as part of what Beder (1996) called the second wave of environmentalism. This involved governments, economists and business people in the promotion of sustainable development. The term 'sustainable development', which was internationally promoted by the WCED report, *Our Common Future* (1987), and the United Nations Conference on Environment and Development (UNCED) in 1992, has led to adaptation of the term 'sustainable' to modify educational and architectural practices. Since then, in the architectural field, sustainably-modified terms, such as sustainable design (Crosbie, 1994; Mendler and Odell, 2000; McLennan, 2004), sustainable buildings (Barnett and Browning, 1995; Maiellaro, 2001), sustainable architecture (Edwards, 1996; Steele, 1997; Gauzin-Muller, 2002; Guy and Moore, 2005), have been used in a similar way to environmental-related texts, such as green and ecological architecture, while in the educational field the terms related to sustainability and sustainable development concepts, such as sustainable education (Sterling, 2001), sustainability education (Shallcross, O'Loan and Hui, 2000), education for sustainability (Huckle and Sterling, 1996; Federico, C. M., et al., 2002), and education for sustainable development (ESD) (UNESCO, 2004), have been used in a similar way and in parallel with environmental education.[1]

In terms of the definition, one of the most definitive models of environmental education is that proposed by Lucus in 1972.[2] It refers to education *in* the environment, *about* the environment, and *for* the environment (Lucus 1979; Linke, 1980). While education *in* the environment is characterised by the use of a particular pedagogic technique that takes place in the environment, education *about* the environment is characterised by the content, focusing on information concerning the environment. In contrast, education *for* the environment is focused on the aims of education to assist preservation or improvement of the environment. As Fensham (1978) observed in the UNESCO/UNEP definition of environmental education, education *in* the environment or *about* the environment is, however, not environmental education. Only education *for* the environment, or any combination which includes a *for* component can be classified as environmental education (Linke, 1980). In the same way, sustainable education can be categorised as education *about*, *for*, and *as* sustainability. While education *about* sustainability focuses on the content and education *for* sustainability places emphasis on the purpose, this being similar to what Gough (1987) called education *with* environment, education *as* sustainability proposes a characteristic of education that enables education to be understood both as an integrated process and as an element of a whole process of creating sustainability (Foster, 2001; Sterling, 2001). Although sustainable education encompasses education *about*, *for* and *as* sustainability, educational activities that are part of sustainable education need to aim at least at being education *for* sustainability, rather than just education *about* sustainability.

The definition of environmental education and sustainable education provide a lesson for revisiting the definition of sustainable architecture. Using a similar approach, sustainable architecture can be categorised into three types, namely architecture *about* sustainability, architecture *for* sustainability, and architecture *as* sustainability. These three possibilities are presented here as being separate, but in practice they may be merged or dominated by each other according to the focus of the approach.

2. Architecture about Sustainability

The most common form of sustainable architecture is architecture that is *about* sustainability. It embraces every building and built environment that contains sustainable components or provides information concerning sustainability. This information is varied ranging from building components, such as building materials and systems, to sustainable design tools and techniques, such as environmental impact assessment (EIA), life cycle assessment (LCA), and building evaluation systems (e.g. LEED and BREEAM), to general relationships between the built environment and environmental and social issues, such as addressing environmental concerns and social benefits in planning policies or architectural programming.

Architecture *about* sustainability usually comprises sustainable elements or sustainable strategies. While the elements encompass sustainable products, materials, and technical devices, the strategies include sustainable approaches in site selection and development, transport impacts, building configuration and orientation, selection of products and materials, energy conservation, use of renewable energy, water conservation, air quality, human comfort, operation and maintenance, renovation, and demolition. Because of differences of project conditions, each project cannot accommodate all sustainable elements and strategies, but select some that support each other and that are likely to respond to the particular approach. The diversity of implementation can be classified in various ways, for example, the three images of sustainable architecture, namely, natural, cultural and technical (Williamson, Radford and Bennetts, 2003: Chapter 2), the six competing logics of sustainable architecture (Guy and Farmer, 2000; 2001), and the ten shades of green architecture (Buchanan, 2005).

Architecture *about* sustainability, however, may not always lead to sustainability. Since many buildings that are claimed as sustainable are only so in terms of applying specific design elements and strategies, without

[1] In the architectural field, although a few authors have pointed out the difference between sustainable architecture and green architecture (e.g. Hengrasmee, 2005; Kwok, and Grondzik, 2007), most authors recognise that the terms are used interchangeably. Meanwhile, in the educational field, many authors (e.g. Jickling and Spork, 1998; Stables, 2001; McKeown and Hopkins, 2003) have discussed the conflicting relationship between environmental education and other educational terms related to sustainability and sustainable development concepts, such as education for sustainable development (ESD). Although priorities and foci are varied depending on definitions and interpretations of concepts of sustainability and sustainable development, as McKeown and Hopkins (2003) have stated, the terms have similarities and can be complementary.

[2] Arthur M. Lucas first introduced this concept of environmental education in his 1972 dissertation, which was then revised and published in 1979.

concern for situational appropriateness and whole-life consequences, their actual results may not create positive effects on society and the environment. For example, timber products may be specified in the design, based on the idea that timber is a natural and renewable resource, but the products may come from unsustainable harvesting and production processes, they may be transported from overseas manufactures, or are traded unfairly. The decision to use timber may thus lead to deforestation, higher energy consumption in transport, or other social problems caused by unjustifiable manufacturing and trading. Meanwhile, setting up renewable energy production systems, such as solar panels, and applying other energy conservation strategies, such as addition of insulation and enhancement of natural light and ventilation, does not guarantee that the building will be efficient and totally rely on renewable energy sources. Without being conscious of the need to reduce energy consumption, the users may carelessly use energy and have too many appliances, so the building consumes a lot of energy and still requires considerable energy from non-renewable sources to satisfy the rising demand.

In addition, because the sustainable agenda is marketable, discourse of architecture *about* sustainability can be just greenwash (Williamson et al., 2003: 10-12). Some clients and architectural firms use sustainable design strategies mainly for creating a marketing opportunity for their products and services, but do very little to create sustainable solutions. These companies often use sustainable design strategies to show their visions or inspiration, but ignore the appropriateness for local conditions and long-term effects after trading. They mainly place their focus on financial profits and selling rates of their products and services. Moreover, they rarely provide adequate information about the products and design solutions or suggest alternatives for the buyers or users to make fully informed decisions. Based on such data, the consumers are therefore deceived into choosing only the products and services they provide. These selling strategies often create negative outcomes for the environment and also create a misleading public understanding of sustainable design and sustainability. In fact, use of sustainable design for selling and marketing strategies is not always wrong. With concern for the whole-life effects and local situation, this method can help to promote sustainable design and enlighten clients, developers, and designers to come forward and commission many more sustainable buildings.

Recently, the number of buildings representing architecture *about* sustainability has increased. Many buildings are labelled as sustainable architecture and increasingly project descriptions mention the words, ‘sustainable’ or ‘sustainability’. This represents an increase in the general concern about sustainable issues and sustainable design. Nevertheless, as mentioned earlier architecture *about* sustainability, particularly as a term bolted onto the pre-existing unsustainable agenda (Willis, 2000; McLennan, 2004), may not necessarily lead to sustainability. To improve the world to be close to a sustainable condition, it is essential to focus on the overall results as well as the intention of the creation.

3. Architecture for Sustainability

Unlike architecture *about* sustainability that focuses on sustainable components and techniques, architecture *for* sustainability is centred on the purpose of architectural creation. Architecture *for* sustainability usually uses sustainability as the objective of the project and uses sustainable techniques as the basic design criteria. Since stakeholders’ objectives are frequently interconnected and conflict between objectives is common (Williamson et al., 2003: 65), when using sustainability as an objective, the particular definition of sustainability should be identified. The definitions may vary but are generally considered in terms of the level of sustainability from an anthropocentric or ‘weak sustainability’ to a non-anthropocentric or ‘strong sustainability’ (Turner, 1993; Bosselmann, 2002: 89-92). For ‘weak sustainability’, which equates to a type of economic sustainability, to achieve the sustainable condition, a balance of three issues – ecology, economy and society – is required. On the other hand, the ‘strong sustainability’ model, which equates to what some call ecological sustainability, is concerned with ecology as the overarching system. In this approach, every action affects others and ecological issues are the most important.

The diversity of sustainability definitions and approaches results in various means to achieve them. For instance, based on the ‘strong sustainability’ approach, architecture should be in harmony with nature, designed within limits of ecological footprints, and ensure the stability and integrity of local and global biodiversity. Examples related to this approach are autonomous house and self-sufficient community design (e.g. Vale and Vale, 1975; 2000; Hockerton Housing Project, 2001; Tlholego Development Project, 2001). Based on the ‘weak sustainability’ concept, architecture should be the result of compromise solutions between ecological, social and economic benefits. Several projects based on the techno-rational and policy-oriented approach (e.g. Catherine, 1997; Ray-Jones, 2000; Broto, 2003) are relevant examples of this category. It is quite clear that ‘strong sustainability’ implementation allows the world to reach a more sustainable situation than the ‘weak sustainability’ approach. In contrast, because of the difficulties of applying the sustainability concept, ‘weak sustainability’ practices are more popular.

Although architecture *for* sustainability obviously shows an intention to create sustainability, it is crucial to consider the process of implementation from objective statements to actual results. Architecture *for* sustainability with inadequate knowledge and skills and inappropriate strategies may lead to unsustainable conditions. Stakeholders should have knowledge about basic environmental concepts, environmental regulations, life cycle assessment and other sustainable design methodologies, and the environmental performance of built environment components and systems (Martin, 2001). If they do not have enough knowledge, they should learn constantly from their own experiences and through information from publications and other media, and can also ask for advice from experts or other people who have more knowledge or experiences. The stakeholders should also obtain skills that facilitate the creation of sustainable architecture, including the ability to understand the circumstances of the community, communication and collaboration skills, and adaptation skills (Maser, Beaton, and Smith, 1998). Furthermore, design tools and techniques should be appropriately selected and accommodated in every phase of architectural design. For instance, as Hyde et al (2007) suggested, setting goals, environmental briefs, specifying principles, checklists, and design phase rating and benchmarking systems are useful during pre-design and schematic design, while monitoring, surveys of building in use, operational phase rating and benchmarking systems are practical strategies for the post-occupation phase.

In addition, since objectives can be changed at every part of design process, to create architecture that is mainly *for* sustainability it is important to examine the purpose of projects frequently. This will help to ensure that sustainability is a main purpose and does not get shifted to be a sub-objective under other purposes, such as to complete a checklist or create more profit, which may limit the visions of development or even misguide the process so projects become unsustainable architecture.

4. Architecture as Sustainability

In contrast to architecture *about* and *for* sustainability, which are both characterized by components and goals, architecture *as* sustainability is characterized by its process. It is defined as a transformative architectural process towards sustainability and as a part of an entire process that leads to sustainability. Architecture *as* sustainability encompasses processes from pre-design, design, construction, operation, renovation, and demolition, to creation of new projects. The processes are considered as a cyclical and dynamic system that is connective, contextual, inclusive, integrative, and that extends the boundaries of care and concern to the social, environmental, non-human and future dimensions. To deal with a complex and vital system, whole systems thinking or the holistic approach is required (Vale and Vale, 1991; McLennan, 2004; Hyde et al. 2007). This mode of thinking indicates that all things are interconnected and the interrelationship of the parts forms the whole. Since building is basically an open system that relies on the import of energy and resources from the environment, sustainable architecture commonly aims to create 'more closed' and 'less open' systems in buildings (Williamson et al., 2003: 82-84). Similar to what Guy and Farmer (2001) have labelled eco-centric logic, sustainable architecture based on this approach tends to draw directly on analogies with ecological systems as living, efficient, self-reliant, closed, and cyclical processes, which oppose the linear, inefficient, dependant and open systems of conventional buildings. Furthermore, related to time-linked dimensions, contemporary sustainable architecture can shape patterns of subsequent projects. While knowledge and skills from one project will contribute to design and construction procedures of future projects, sustainable conditions that the project provides, such as healthy environments and positive attitudes towards sustainable practices (e.g. self-esteem and self-reliance), enhance constructive circumstances for other existing and forthcoming projects.

As an element of the whole process of sustainability, architecture *as* sustainability participates in the process of change from the less sustainable condition to the more sustainable situation, or so-called 'weak' to 'strong' sustainability. Sustainable architecture is thus a subsystem of a whole system of sustainable practices. It overlaps and interconnects with other subsystems, such as the building industry, education, economy, politics and society. Fundamentally, sustainable architecture reduces environmental impacts and improves quality of life. It also imparts positive environmental conditions for other sustainable practices to occur in such buildings. Meanwhile, to create and sustain the conditions, sustainable architecture demands collaboration with sustainable practices in other disciplines (McLennan, 2004). As the list of issues of concern is expanded, it requires participation of various people with specific knowledge in the process. Architects, engineers, specialists, developers, project managers, builders, and users can share their knowledge and expertise to solve problems and create sustainable conditions. Sustainable approaches in local politics frequently lead to policies that demand and support sustainable practices, including sustainable architecture and planning. Innovations in the building industry towards sustainability, such as eco-label materials and products, environmental regulations, as well as environmental design and operational directives and standards, can guide sustainable practices and reinforce participation of various stakeholders in the process. To maintain appropriate conditions, sustainable architecture requires constant sustainable management and users that behave sustainably. Moreover, continual study, research and development in architectural and other green related fields assists in enhancing the quality of sustainable architecture, as well as promoting attitudes to and understanding of the importance and impact of sustainable design.

It appears that architecture *as* sustainability, which can be simply described as a process of continual development, shares a similar characteristic in its continual and cyclical process with other practices, such as an on-going process of educational action and research (e.g. Robottom, 1987; OECD, 1995; Sterling, 2001) and community development (e.g. ORTEE, 1994; Maser, 1997;). The resemblance shows the inherent shared quality of sustainable practices and ensures the possibility of developing architecture *as* sustainability, so that architecture becomes an integrated part of sustainable systems.

In addition, architecture *as* sustainability evokes a shift in approach from the traditional viewpoint that considers architecture as an end product of design and construction and sustainability as a goal that will be achieved some day to the new model that recognises architecture as a whole architectural process from pre-design to operation, renovation and demolition, and sustainability as a process of development, which requires current and continual actions. Under the traditional perception, at present, because sustainability is not yet attained, there is no architecture that can be claimed *as* sustainability. On the other hand, in the new paradigm, architecture can possibly be '*as* sustainability', if it provides sustainable conditions, has concern for the actual context and whole-life results, continually improves its performance, and supports and collaborates with other sustainable practices.

5. Case studies: Sustainable Schools

As this paper is based on an investigation into sustainable schools, two school projects, from developed and developing countries, were selected as case studies to show how the designed could be categorised according to the definitions set out above. These projects are Sidwell Friends Middle School, Washington, DC (2006) and the primary school at Gando Village, Burkina Faso (2001).

Basically, both projects can be classified as architecture *for* sustainability. They both aim to provide a place for learning within an ethos of sustainability, particularly during childhood when value systems are formed. Sidwell Friends School was committed to being an institution responsible environmental stewardship would be practiced. This concept was applied to its curriculum and the selection of sustainable design was a logical expression of its values. As a result, the renovation and addition of its Middle school in 2006, designed by Kieran Timberlake Associates, obtained a LEED Platinum certification and was chosen as an AIA Committee on the Environment (AIA/COTE) Top Ten Green Project for 2007. In contrast to the devotion to promoting environmental awareness of Sidwell Friends School, the Gando Primary School simply aimed at enhancing local social conditions by improving basic education for local children, the first priority of sustainable education in any society (Hopkins and McKeown, 2002). Architect Diébédo Francis Kéré, who was born in Gando and was the first person from his village to study abroad, reinvested his knowledge as an architect into the urgent need for construction of a school in Gando[3]. The school not only provides education for local children, but its construction is part of a process of passing on new skills and knowledge to the entire community. Consequently, it was the recipient of an Aga Khan Award for Architecture in 2004.

To respond to their objectives, both schools encompassed several sustainable strategies and techniques. Thus, besides being *for* sustainability, they can be *about* sustainability as well. At Sidwell Friends Middle School, rather than demolishing the existing building, renovation and addition were chosen, because of having less impact on the environment. Maximising the use of daylight, but avoiding glare, was combined with several techniques, such as lightshelves, sunscreens, high-efficiency electric lighting, photosensors, and occupancy sensors. Operable windows and solar-ventilation chimneys were designed to work with ceiling fans and mechanical heating and cooling systems. To reduce storm water runoff and support native habitat, a green roof and a constructed wetland were incorporated. A constructed wetland was also used for treating building waste water on site and forms part of a closed system that recycles the water back to the school lavatories and cooling towers. Furthermore, sensor-operated water-conserving laboratory faucets were used. In terms of material selection, 78% of building materials were manufactured regionally, 11% were from recycled sources, and 60% of construction waste was diverted from landfills and recycled (Sidwell Friends School, n.d.). Since the school was located within walking distance of a subway stop and several bus stops, the design was intended to promote a non-automobile commuting option by providing bicycle storage and showers for bicycle commuters and separating vehicle and pedestrian traffic. The school also offered $35 each month to any staff member who reduced car use by 80%. Since the policy started, the number of people qualifying for this benefit has increased 61% (AIA, 2007). Differing from the manifold solutions at Sidwell Friends School, the design strategies for the primary school at Gando were based on the basic idea of designing for climatic comfort with low-cost construction. In term of orientation, three rectangular classrooms were aligned east to west and separated by covered areas. The structure comprised traditional load-bearing walls made from compressed earth blocks and concrete beams. The beams running across the width of the ceiling supported a ceiling also of earth blocks and provided the structural base for the roof. To overcome the difficulty of transporting large elements to the site and economic availability of large machinery, such as cranes, the architect selected small steel bars to create lightweight trusses with a

[3] Kéré is the main motivator behind the project. He designed the school, secured financial support via a fund-raising association Schubausteine für Gando (Bricks for the Gando School), and also obtained government support to train people in building with local materials (AKDN, n.d.).

roof of corrugated metal sheeting, so people could learn how to build the school with a handsaw and a small welding machine (AKDN, n.d.). Earth blocks, used for walls and ceilings, absorb heat and moderate the room temperature. The overhanging roof shades the façades from sun and rain and, by lifting the roof up on the steel trusses above the clay block ceiling, cooling air can flow freely between the roof and the ceiling.

In addition, the construction of Gando Primary School helped to solidify the community connection by engaging all of the villagers in building the school for their children, created opportunities for young trained Gando villagers to be employed on further public construction projects, and empowered neighbouring villages to follow the same model of community mobilisation to build schools for themselves (Ford, 2007; AKDN, n.d.). This construction process was part of an entire process that leads the communities towards sustainability, and makes the project able to be categorised as architecture *as* sustainability. In the case of Sidwell Friends Middle School, although communal learning was not a focus during the construction process, the finished building was used as a tool to learn about the relationship between natural and human-created systems. Because many parts of the building systems were exposed and made visible, the mechanical, electrical, structural and plumbing systems in the school were able to be used for study. Students monitored the building functions and measured the health quality of the facility. The school has developed a tour and signage program for the community. A real-time monitoring program can also be accessed via the internet (Sidwell Friends School, n.d.). In addition, the school became the subject of study for the Yale School of Forestry and Environmental Studies and a case study for green design, found in the LEED for Schools Reference Guide (AIA, 2007). Through the operational activities that aim to enhance environmental awareness and promote learning community, therefore, this project can also recognised as architecture *as* sustainability.

In summary, these two case studies illustrate the feasibility of sustainable architecture that could be *about*, *for*, and *as* sustainability. They also show the practicability of architecture to strengthen sustainable conditions and collaborate with other sustainable practices, in every architectural process from pre-design (e.g. setting aims of the projects), design (e.g. selection of design strategies and solutions), construction (e.g. participation of local community in the construction), operation (e.g. use of schools as a learning tool), renovation and demolition (e.g. decisions to renovate and add), to creation of new projects (e.g. building on lessons from previous projects). Furthermore, they suggest that the process and design solutions to create sustainability can be varied, depending on local conditions and contexts. This affirms that sustainable architecture is inevitably influenced by economic, social, and environmental systems, and is part of a larger system of sustainable practices.

6. Conclusion

According to the discussion above, a sustainable design project can be related to all three categories of sustainable architecture, architecture *about*, *for*, and *as* sustainability. They are connected and combinations of any two or all three are both possible and sensible. Architecture that aims *for* sustainability usually contains sustainable design strategies and sustainable components, which are the essence of *about* sustainability. Furthermore, it is meaningful to speak of architecture *about* sustainability and *for* sustainability at the same time. Meanwhile, some buildings, such as traditional and vernacular architecture, that are *about* sustainability by accommodating sustainable components (e.g. natural and non-toxic materials and sun shading) and use sustainable design strategies (e.g. natural ventilation and appropriate orientation responding to the solar pattern and wind directions), may not seem to aim *for* sustainability, but because they support sustainable behaviours and local sustainable environments and culture can be recognised as architecture *as* sustainability. Additionally, to create architecture *as* sustainability, stakeholders should aim to create at least architecture *for* sustainability, and not just add on terms *about* sustainability into conventional practices.

These connections suggest the feasibility of enhancing the meaning of sustainable architecture to include its elements, objectives and processes. Particularly, an explanation of sustainable architecture that is architecture *as* sustainability suggests an interdisciplinary approach, which helps to improve quality of design as well as sustainable conditions. It also emphasises the fact that the aims of sustainable architecture are not just approaching the goal of achieving sustainability, but architecture for its own sake that is sustainability. With the support of a sustainable milieu, architecture could be part of sustainability or, better, be sustainability. This transformative process will change the meaning of both sustainable architecture and architecture itself. Eventually, there will no longer be sustainable architecture, but only architecture that is sustainability.

INFORMATION AND KNOWLEDGE SPREADING OF ENVIRONMENTAL FRIENDLY SOLUTIONS IN THE BUILDING SECTOR

Ingunn MARTON General manager Byggmiljø, MSCE[1]

[1] Byggemiljø – Byggenæringens miljøsekretariat, Oslo, Norway, ingunn.marton@bnl.no

Keywords: information, knowledge spreading, cooperation, building sector, government

Summary (*11-point Arial, bold, flush left, 11-point line spacing, style name "Heading 1"*)

The Norwegian government and the construction and engineering industries are cooperating in Byggemiljø – a program running in the period 2005-2009. The main objective for the program is to raise the environmental awareness in the construction and engineering industries. The main focus for the program is to spread information and knowledge about existing environmentally friendly solutions, and the web site www.byggemiljo.no was established at the end of 2005. The web site contents information about how to build environmentally friendly, easy hints, environmental subjects, examples, handbooks, laws and regulations, activities etc.

Byggemiljø is also involved in different projects i.e. how to reduce the building's sector green house gas emission, environmental evaluation of building products and materials, how to use and evaluate LCA. These projects are knowledge the building sector needs to perform more environmental friendly.

Establishment of Byggemiljø has also improved the communication between the authorities and the building sector and between builder, architect, engineer, contractor and the owner and different organizations that work with promoting environmentally friendly solutions.

1. Introduction

In the period 1997-2002 the Norwegian government and the construction and engineering industries had a program running to improve the building sector environmental. One of the program's highlight was SB02 in Oslo in September 2002. After 2002 the construction and engineering industries wanted to continue the cooperation with the Norwegian government and after a long discussion period they agreed in the beginning of 2005 to continue the work but in a smaller scale.

In 2005 the Norwegian government and the construction and engineering industries started up again the cooperation with objective to get the construction and engineering industries more environmentally friendly. The following organizations committed the program Byggemiljø for the period 2005-09:

- Ministry of Local Government and Regional Development
- The Norwegian State Housing Bank
- National Office of Building Technology and Administration
- The Directorate of Public Construction and Property
- Association of Consulting Architects in Norway
- Association of Consulting Engineers, Norway
- The Federation of Norwegian Construction Industry
- Norwegian Association of Technical Contractors

The main focus for the program is to spread information and knowledge about existing environmentally friendly solutions, not to develop new knowledge.

The program is financed by the government while the construction and engineering industries have committed to put 3000 working hours into the program.

The builders, the architects, the civil and technical engineers, the contractors, the owners and the authorities are present in the program. In the program running from 1997 to 2002 the architects were not present. Therefore there has been an improvement that the whole building "chain" now is present in the program.

2. Information and knowledge spreading

Since the main focus for the program is to spread information and knowledge and the program has limited resources, it was decided to canalize information thru a web site. www.byggemiljo.no was established in 2005 (see Fig. 1). The objective is that www.byggemiljo.no will be the web site you start when you look for information about how the building sector can reduce the environmental influence and the building sector's environmental influence. The web site is successful and the number of hits is rising both in visitors and visits.

The web site contents the following:

- Practical and easy hints to become more environmentally friendly.
  The hints are easy to implement and will not give extra expenses.
- When to take care of the different environmental challenges in the building process
- Environmental subjects (i.e. energy, waste, life cycle analysis, environmental management)

3. Projects

Even though the main area for Byggemiljø is to maintain a web site with good and interesting information for how the building sector can become more environmental friendly, Byggemiljø is also involved in other projects. The projects are mainly projects that can improve environmental effects from the sector. Examples are:

- The building sector's green house gas emission and how to reduce the emissions. This project involves the construction and engineering industries and has made discussions of how we best should reduce the green house gas emission; during better energy efficiency in the buildings or better production of building materials. The project is still running.
- Environmental evaluation of building products. Development of a method that will simplify evaluation and comparison of EPD's (Environmental Product Declarations), called ECOproduct.

Generell vurdering av materialer

Innendors maling og lakk	Kjemikalier	Miljobelastning: Råmaterialer, utslipp og avfall	Arbeidsmiljo og inneklima	Tekniske egenskaper
AKRYL- OG LATEKS MALING Forholdsregler: - Spesifikke produkter bør sjekkes mot prioritets-/OBS-listen. - Inneklimarelevant dokumentasjon bør fremskaffes. *Alternativer (alle typer):* - *Alkydmaling* - *Lakk* - *Olje*	Kan inneholde biocider og andre tilsetninger. Kan inneholde isotiazoliner.	Produksjon - Bindemiddel produsert på basis av olje/naturgass. De vanligste bindemidlene er polyvinylacetat og polyakrylat (akryl lateks). Bruk Avfallsbehandling - Ikke herdet maling er farlig avfall. - Tomme, tørre malingsbokser er restavfall.	Arbeidsmiljø - Store forskjeller mellom de beste og de dårligste produktene. Lave emisjoner av løsemidler, men tilsetningsstoffer kan avdampe over lengre tid. Inneklima: - De beste produktene har meget lav avgassing selv kort tid etter påføring. - Det er generelt noe høyere avgassing fra akrylmalinger enn lateksmalinger. - Inneklimarelevant dokumentasjon må fremskaffes og vurderes.	Bruksområder Rengjøring - Middels til dårlig rengjørbarhet avhengig av glanstall og underlag. Egne malingssystemer for våtrom finnes. Levetid Vedlikehold - Akrylmaling gir generelt en mer robust overflate enn lateksmaling.
GULVOLJE Forholdsregler: - Spesifikke produkter bør sjekkes mot prioritets-/OBS-listen. Inneklimarelevant dokumentasjon bør fremskaffes. Vedlikehold *Alternativer (alle typer):* - *Lakk*	Inneholder vegetabilske oljer, kunst/natur harpiks og varierende mengder terpentin.	Produksjon - Ekstraherte vegetabilske oljer (fornybare ressurser) og terpentin på basis av olje (ikke fornybare ressurser). Bruk Avfallsbehandling - Ikke herdet olje er farlig avfall. - Tomme, tørre bokser/kanner er restavfall.	Arbeidsmiljø - Potensielt kraftige avgassinger av terpentin under påføring og tørking/herding. Inneklima: - Potensielt belastende på inneklima den første tiden, og der vedlikeholdsbehandling må gjentas ofte. - Det bør velges produkter med laves mulige YL-gruppe og aller helst med høyt tørrstoff innhold (over 80 %).	Bruksområder Rengjøring - Gir tyngre vedlikehold enn lakkerte overflater. Levetid Vedlikehold - Oljebehandling må gjentas hver 6. mnd - hvert annet år alt etter bruk og slitasje.

Figure 2   Material evaluation list

- Environmental evaluation of building materials. Byggemiljø has summed up an environmental evaluation of different building materials (see Fig. 2). The list contents more than 70 general building materials (not products) and gives general information about
  - Content of chemicals
  - Use of raw materials
  - Emissions
  - Waste
  - Working environment under construction and service
  - Technical characteristics
  - Alternatives
- How to use and evaluate Life Cycle Assessment. Handbook in how to use and evaluate Life Cycle Assessment
- National Action Plan for Construction and Demolition Waste 2007-12.
  - Development of the action plan was partly financed by Byggemiljø
  - Course development about new regulations for mapping hazardous waste and safe waste handling
- Open monthly 2 hours meetings for the construction and engineering industries where different environmental aspects are discussed.

Sjekkliste - substitusjonsvurderinger

Du skal i følge substitusjonsplikten erstatte et produkt dersom
• kvalitet • levetid • vedlikehold • kostnad
blir omtrent lik med et annet produkt som inneholder mindre helse- og miljøfarlige stoffer.

1	**Miljøvurderinger av stoffer og produkter skal utføres før det bestilles/kjøpes.**
2	**Skaff deg oversikt over stoffer og produkter din bedrift benytter/skal benytte på byggeplassen.**
3	**Kartlegg risikoprodukter** - Bestem hvilke stoffer og produkter som skal vurderes, velg først de farligste, eks. byggevarer nevnt i denne folderen, samt de du bruker ofte og i store mengder.
4	**Sjekk om produktene inneholder helse- og miljøfarlige stoffer som står på SFTs prioritetsliste.** - Spør leverandør om produktene inneholder helse- og miljøfarlige stoffer som står på SFTs prioritetsliste. Leverandøren har plikt til svare jf. miljøinformasjonsloven. - Sjekk faresymbol og R-setninger. Finnes under pkt. 15 i HMS-datablad. Inneholder produktene ikke helse- og miljøfarlige stoffer, kan du trygt bruke dem.
5	**Finn ut om det er alternative produkter eller metoder på markedet. Vurder risiko ved bruk av disse.** - Spør leverandør om alternativ produkt/metode. - Spør andre i bedriften om alternativer. - Vurder faresymbol og R-setninger på HMS-datablad/ produktinformasjon for alternativene.
6	**Benytt alternativ produkt/metode** dersom det inneholder mindre helse- og miljøfarlige stoffer og har tilnærmet like egenskaper.
7	**Dokumenter vurderingene** du har gjort eks. i stoffkartotek eller møtereferat.
8	**Sørg for å ha oversikt over alle stoffer og produkter på byggeplassen.** - Sjekk at du har gyldig HMS-datablad/ produktinformasjon for produktene. HMS-datablad skal ha norsk tekst. - Ha en samlet oversikt over produktdokumentasjonen i eks. stoffkartotek (elektronisk/perm).
9	**Substitusjon er en kontinuerlig prosess.** Lag en plan for hvor ofte din bedrift skal sjekke om det er kommet nye alternativer på markedet, eks. årlig.

Hjelpemidler og mer informasjon

Foldere om substitusjonsplikten
Folderne "Kjenner du substitusjonsplikten og ditt ansvar som byggherre" og "Vurdering av helse- og miljøfarlige stoffer på byggeplasser" kan lastes ned fra **www.byggemiljo.no.**

Vurdering av helse- og miljøfarlige stoffer på byggeplasser
(Substitusjonsplikten)

Byggenæringen bruker om lag 50 000 ulike produkter. Mange av disse produktene inneholder helse- og miljøfarlige stoffer selv om de omsettes i Norge.

Substitusjonsplikten
beskriver at alle som planlegger å bruke eller bruker produkter med stoffer som kan være en risiko for helse og miljø, har plikt til å vurdere om de kan bruke mindre farlige alternativer.

jfr. Produktkontrolloven §3a

Figure 3 Booklet about how to substitute product that contents chemicals hazardous to health and environment.

- Substitution of products with chemicals hazardous to health and environment. The regulations in Norway have decided that if a product contents chemicals hazardous to health and environment the user has to evaluate if he can use a similar product or method that contents less chemicals hazardous to health and environment. To inform the construction and engineering industries about this regulation Byggemiljø has cooperated with the Norwegian Pollution Control Authority and published small booklets how to fulfil the law (see Fig. 3). This has been successful, and the booklets have been handed out when the Norwegian Pollution Control Authority has carried out controls in the construction and engineering industries.

4. Cooperation between the authorities and the construction and engineering industries.

The program has improved the cooperation between authorities and the construction and engineering industries. Byggemiljø has regular meetings with the authority departments where we can discuss different subject and challenges. This cooperation has lead to better influence on how to develop and implement new regulations and laws for the construction and engineering industries.

Better cooperation is essential to build more environmental friendly. The program has also improved the cooperation between builders, architects, engineers, contractors, and owners and different organizations that work with promoting environmentally friendly solutions.

TRANSLATING SUSTAINABLE BUILDINGS – THE USE OF NETWORKS TO IMPLEMENT PASSIVE HOUSES IN SWEDEN

Wiktoria GLAD Ph.D. [1,2]

Keywords: passive houses, low-energy houses, actor-network theory, translations, implementation, sustainable innovation

Summary

This paper has the aim to show how and why a sustainable building concept is implemented. The case study chosen is a sustainable building concept called the Passive House (PH). The research presented in this paper was conducted in a Swedish setting and explored PHs in the state of implementation. Implementation is studied as a process, in which the concept is translated by different actors. The translation approach reveals how power structures operate in the building process, how decisions are made and thereby why certain technologies are accepted or rejected. The original concept of the PH was developed in Germany in the 1990's. When the PH concept was implemented in Sweden, the technologies were translated by different actors in order to engage other actors in fulfilling the goals of the project. For some actors the project became a tool to fulfil an overall goal of sustainability in society (this was the goal of the public funding body). To others, PHs were means to reach the dream of a dwelling in an attractive neighbourhood (the residents), or the challenge to build the densest house in the country (the builders on site). A conclusion is that it is possible to use other incentives then pure profit in the short run, when implementing a sustainable innovation like the PH.

1. Introduction, aim and objectives

Energy is of major importance in society, influencing many aspects of our daily lives. We depend on energy to keep us warm, heat our food, run electrical appliances, etc. At the same time, energy-related emissions constitute a major environmental load. Any major reduction of carbon dioxide emissions will require an improvement of energy efficiency measures of the building stock. The housing sector accounts for approximately 40 percent of total energy demand in Western European countries, including Sweden, and fossil fuels are used to produce heat and electricity for housing (Swedish Energy Agency 2007). Goals for a reduction of the energy use in dwellings are set both politically and within the housing sector itself.

A Passive House (PH) may reduce the energy demand for heating in dwellings by 80 percent (Feist et al 2005). Germany has been the main market for houses with passive design, where a limit of 15 kWh per square metre per year has been set for household heating. This is achieved because the dwellings are extremely air tight, have thick insulation and rely mainly on passive sources of heating, for example solar heating through window panes and heat surplus from humans and domestic appliances (Schnieders 2003). In 2001 the PH concept became seriously established in Sweden, when twenty terraced PHs were erected in Lindås Park in Göteborg. This was the result of a four year research and building process, called "Houses without Heating Systems", with the aim to develop PHs for a Nordic climate. This building project has then been followed by several building projects with a PH concept. This paper will focus on Lindås Park, and two projects following Lindås Park: Bottnevägen in Göteborg and Oxtorget in Värnamo.

The overall aim of this paper is to show how a low energy house concept, the PH, was introduced on the Swedish context. The processes behind the implementation of low energy concepts are important to explore since Sweden, among many other countries, has targets on reduced energy use to achieve in the near future. Additionally, bridges and barriers for further development and dissemination in Sweden are recognised. The research objectives are to explore how the processes were facilitated by stakeholders and investigate what resources they used to achieve an implementation. To establish PHs in the building sector it requires that actors in their network accept new ideas and technological solutions. In this paper the PH building processes is analysed by using network theories emphasising drivers behind implementation in socio-technical networks.

1.1 Methodology and theoretical framework

The research field of Science and Technology Studies (STS) provides theories and concepts suitable for research aimed at understanding and explaining a socio-technical system. Socio-technical systems, which buildings are, comprise professional actors, end users like the home owners or tenants, and artefacts. Translation is a theoretical concept used in the transdisciplinary field of STS which focus on the negotiations between stakeholders in the application of knowledge. The socio-technical system of PHs includes organisations, participation, building design, building material and technology for heating and hot water etc.

The analytical tools used in this paper are drawn mainly from the work of Michel Callon (1986a; 1986b; 1987; 1991). The works of Callon show how innovations are disseminated and implemented in the hands of engineers and he has developed a concept of translations within the framework of actor-network theory (ANT) (c f Latour, 1987). Translations are used by actors to engage other actors in fulfilling the goals of a certain project. This process-oriented concept reveals the dynamics of power and how people and artefacts become involved in the process. According to ANT people and artefacts are nodes in a network with different connections between them. Furthermore, Callon suggests technologies and applications are representations of different discourses or policies.

Translations are part of the creation of actor networks and it includes stages of *problematisation*, *intressement, enrolment* and *mobilisation* (Callon 1986b). By problematisation Callon acknowledged that engineers with definitie goals of implementing a new technology make themselves indispensible to the project. They define the problems and present solutions in which they are the key part. Therefore part of problematisation is the definition of *obligatory passage points* which include these solutions. In the next phase of translation *intressement*, actors are locked in their designated roles in the project, determined by the key actor. In the phase of *enrolement* the roles are connected in a network of actors and technical solutions, and in *mobilisation* these actors are trained to represent the idea of the project and the collective acts. To conclude, *translation* is the process in which new networks are formed as a result of new connections between actors and technologies. In his work, Callon discovered how engineers in France who were committed to introduce an electrical car in the 1970's worked as *engineer-sociologists* as they addressed both technical aspects of the new vehicle and social and organizational aspects of the project (Callon 1987). The theory of translations will be applied to the PH development in Sweden.

Energy-saving actions are often seen as the consequences of informed rational action on the part of individual decision-makers, which is criticised by Guy and Shove (2000). They mean it is necessary to understand the social structures and the social networks within these decisions are made. Shove highlights the social and institutional context in which decisions concerning acceptance of innovations and sustainable energy solutions are made (Shove 1999:1107). Following studies of STS-scientist such as Callon and Bijker she emphasis that decisions concerning for example implementation of energy efficiency measures and how we use energy are made in social contexts. Practitioners identify and make energy-related decisions within different networks and different contexts according to Shove: "what qualifies as a reliable, cost effective, worthwhile energy saving measure in one socio-cultural domain might count for nothing in another" (Shove, 1999:1109). Applying this perspective technology is formed and developed in networks in which actors meet and negotiate concerning various ideas and issues. The implementation of the PH concept can be expected to be wrapped up and shaped by social processes and built on knowledge, routines, institutions, methods established in networks. When technology is transferred methods and measures are seldom directly transferable, but can be picked up and "domesticated" in different spheres (Silverstone et al 1992, Lie & Sørensen 1996, Sørensen et al 2000). It is possible to identify and visualize new opportunities and new methods for different networks.

The existing networks in the building sector have been named Old Boy Network (Björklöf, 1986) and consist of earlier study and working friends. These networks are important for the spread of innovations, because they are used to solve upcoming problems and to strengthen social relations. The actors have easier to accept innovations presented by other actors in the network and usually innovations are spread by informal phone-calls within the networks. One reason for this is because of the time pressure in building projects and the result from this process is that colleagues act as "filters" that select and value innovations (Björklöf, 1986).

Case study methodology is about following a project in the real life context (Yin 1994) and has been the guiding principle for the empirical work of this research. Some researchers in methodology has emphasised the importance of finding the boundary between the project and the context in case study research (Merriam 1994), while others encourage inductively determining the scope of the research (Ragin 1992). Building processes, like the ones described in this paper, are complex projects with several organisations and different people involved in different parts of the project's timeline. This notion calls for an inductive approach which in this case has been applied using a social context inspired actor network analysis (se next chapter). The *case* can be described as *the implementation of Passive Houses in Sweden*.

In case studies so called thick descriptions are preferred (Geertz 1993). A thick description will not only include stakeholders' actions but the context as well. Firstly, to capture the network of actors involved in the project, information in documents from the building processes and from interviews with stakeholders were used. The documents were mainly collected from the Swedish council for building research, which co-funded the Lindås Park project. For the Bottnevägen and Oxtorget projects documents were provided by the developers (the housing companies owned by the municipalities in Göteborg and Värnamo). Also documents from the municipalities in Göteborg and Värnamo, about the spatial planning processes were used to describe the context of the case. For the later stages, minutes from the construction companies and articles in newspapers provided important information about how the projects proceeded. From the documents, key stakeholders were identified and interviewed about different aspects of the building processes. The purpose of the interviews was to gain more information about the context of the projects and especially learn about how and why decisions about different parts of the projects were made. The data was originally collected for a PhD project (c f Glad 2006). In this paper, the data from these case studies has been re-analysed by applying network theories focusing on the translation of passive houses in Sweden.

2 Lindås Park – A Passive House initiative in Sweden

The PH development in Sweden can be divided into different periods reflecting driving forces within different groups of stakeholders. The first period can be defined as a consequence of the oil crises in the 1970's when the need for low energy housing in Sweden was acknowledged both by the Swedish government and academia. Consequently, funds for experimenting and demonstrating low energy systems in buildings were provisioned by Swedish research councils. Also, techniques for low energy designs were taught at the universities. The Gothenburg University became an informal centre for low energy systems where Sweden's first professor of building services engineering Enno Abel encouraged students to adopt a holistic approach in their future professions (Abel & Elmroth 2007). Thus, the 20 terraced houses erected in Gothenburg in 2001 were not the first attempt to introduce houses with passive energy in Sweden. In the late 1970's and early 1980's, several experimental housing projects were carried through (Swedish Building Research Council 1991). But there were only a few follow-ups and no market introduction mainly because an excess of electricity supply due to the building of several nuclear power plants in the 1980's. The architect who initiated the Lindås Park project in the 1990's, Hans Eek, had been involved in some of the experimental low energy projects earlier, both in Sweden and in Germany, and thought this concept would have potential in Sweden (Glad 2006).

To suit the Nordic climate in Sweden, the German standard had to be adjusted to suit Swedish climate (Wall 2006). This required research on some of the technologies. For this purpose, three Swedish research institutes, the Faculty of engineering in Lund, Chalmers University of Technology and Swedish National Testing and Research Institute (SP), together with Hans Eek's, the architect's office EFEM, applied for funding from a Swedish research council. Similar to what Björklöf (1986) stated, the researchers involved in implementing this radical new concept knew each other before and had previously been engaged in different environmental projects together. In 1997 the group of researchers received funding for the development and improvement of building components, the ventilation system and the design of the building.(Glad 2006) This marks the start of a second period of PH development in Sweden, which is characterised by a sustainability context rising in the 1990's. Sustainable development became high priority in Sweden and research funding for environmentally sound energy systems was available. What attracted attention from the funding body was how the PH concept promised low energy housing without adding extra costs. This was offered something new to the industry and was the main reason for governmental funding.

The same year, the municipal owned housing company Göteborgs Egnahems AB, decided to get involved in the project and take on the role of building proprietor. Major developers on the Swedish market was approached by Eek but rejected the idea. The CEO of Göteborgs Egnahems AB was interested because he expected the company could learn a great deal from this project. Göteborgs Egnahems AB involved a construction company, PEAB, and different consultants at an early stage of the project since the idea was that practitioners and researcher with a more theoretical approach would develop a joint understanding of PHs in a Nordic climate (Glad 2006). The researchers made data simulations of different window areas and scenarios with different household sizes and time spent indoors (Wall 2006). They set the standards referring to a "normal" family as consisting of two adults and two children, all of whom spent a certain amount of time at home using different appliances, and the amount of electricity a normal household in Sweden is expected to use. Other parts of the energy concept included air-heat, which had been debated in Sweden since the 1980's and was partly forbidden in 1994. In 1999 the regulations around air-heat were loosened, but it was still controversial among experts in the energy sector (Harrysson 1999). In the Lindås Park project a reheater of 900 W was installed in the air-to-air heat exchanger to provide a back-up during cold periods, a method referred to as "the reinvention of air heating" (Feist et al 2005).

Hans Eek organised the building process around seminars where the PH concept were discussed and where different parts of the energy system in buildings were presented and debated. The seminars were organised mainly by and for researchers and funded by the research council. Parallel to these seminars were planning meetings and these were organised and funded by the construction company. Similar to the case Latour describes in *Science in Action* (1987) and what Lutzenhiser (1993) found in his studies of energy simulations and modelling, the assumed users were disconnected from the planning phase. At an early stage of the project it was planned to include expertise on residential behaviour and also dedicate one of the seminars to behavioural issues. When costs had to be cut, this expertise and seminar were cancelled (Glad 2006). Results from other research show how the involvement of end-users can influence projects in positive ways and minimising the risk of failure (Wynne 1988). Involving end-users, which would be the residents, was never an option in Lindås Park (Glad 2006).

When the model of *translation* is applied to this case, much of the content in the model can be verified. The concept, including the technologies and how the project was managed, was accepted by the participants. The architect formulated the problem and offered a solution in which he played an important part. The *problematisation* can be described as "we have a problem globally with excessive and unnecessary resource use and the construction industry in Sweden is not acting responsible and is too conservative – PHs is *the* solution" and the *obligatory passage point* being to accept this problem and its solution. A couple of years after the project finished, virtually every participant told the same story about what happened in the project (Glad 2006). The message was repeated within the group and when talking to outsiders, forming consensus about what the project was about. The exception being the construction company, which suffered a financial loss and dismissed the concept based on the financial aspect of the project. According to them, the concept did add extra costs to the project making it an expensive experience for everyone involved.

The domestication process described by Silverstone et al (1992) and Lie & Sørensen (1996) included elements of negotiation when bridges for implementing new technology are built. In the Lindås Park case several parts of the concept were negotiated during the seminars. One example is how the architect insisted of keeping the German PH standard of 15 kWh per square metre per year as a target. The figure was rejected by the construction company who demanded that the target was lowered. The researchers made new calculations and came up with a new figure of 39 kWh, but with a question mark attached to it. Still, the contractor did not accept the target and consensus about the concept were not reached during the planning phase (Glad 2006). At this point, the Swedish PH was an intangible concept described in documents from the seminars and planning meetings and an expression of the participants' ideas of the energy concept. Now, the energy concept had to be transferred to a new context, the building site. How could the concept be domesticated without being accepted by the construction company?

On the construction site, the construction company's representative and head of the project is the site manager. In Lindås Park the site manager was called Gunnar Tejlerdal and he became the missing link in the network for implementing the PHs. Eek and Tejlerdal connected and together they influenced how the rest of the project was carried out. The general ideas of the concept were accepted by the site manager and he was described as seriously dedicated to the project (Glad 2006). According to Guy and Shove (2000). when new technology is domesticated, established methods and the usual routines are challenged. Lindås Park was a project which differed from other projects and both the site manager and the hand-picked construction workers found it rewarding to work with a project which demanded more craftsmanship and meticulous work. However, in the construction process the energy concept would preferably not add any extra costs into the expensive building procedure. But the extra insulation and air-tightness demanded careful craftsmanship and more working hours for the contractor. This in turn resulted in that the construction company suffered a financial loss, and they stated in official reports that the financial aspect of the energy concept did not work. During the years of planning and building, the architect and project manager marketed the concept via mass media with the message that houses could function without a heating system, meaning little or no extra costs. The message was presented in the present tense as if the concept was already realised and worked as expected. In general, the project was presented in positive way and very little criticised (Glad 2006).

Guy and Shove stated that the "techno-economic view of energy efficiency" is predominant in our western societies (Guy and Shove 2000). According to this view decisions made by people to act energy efficiently is a result of having the right information, being aware of the benefits, the price is "right" and there are no conflicts of interests. An example of this view is the evaluation from SP Technical Research Institute of Sweden (Ruud & Lundin 2004). During two years, the energy consumption in Lindås Park was measured and the result showed the energy consumption being higher than expected, 69 kWh per square metre per year. This was explained partly by unexpected household behaviours, for example a demand for a higher indoor temperature and the use of extra heaters to keep the temperature up. According to the assessment, the residents did not have enough information and there was a conflict of interests between the desire to have a relatively high indoor temperature and save energy.

Projects like Lindås Park are sometimes referred to as "demonstration projects" and has since the 1970's been funded by governments and international bodies. However, knowledge from demonstration projects often fails to disseminate, since the knowledge available is usually "incomplete, un-reflected and not very trustworthy" (Femenías 2005:220). An explanation for this can partly be found in the fact that assessments are usually carried out by stakeholders involved in the projects who are usually biased. This was the case in the Lindås Park project since SP played an important part in developing the energy system for Lindås Park. A comprehensive analysis conducted by independent researchers shows that the operational and embodied energy for the Swedish PHs are close to half of a conventional comparable dwelling. The extra costs amounted to 20,000 Euro accourding to the Göteborgs Egnahems AB. These researchers stated that the pay-off period of 19,5 years was reasonable (Karlsson & Moshfegh 2007).

3 Bottnevägen low-energy houses

Conventional developments take time to plan for and build, and the PH is not an exception. On the contrary, PHs require more time for planning and building and more energy is used in this phase than normally. Energy is embodied in the material used and also in the work by builders on the construction site. In this case, the Lindås Park project was to be evaluated and the energy use was measured for two years. Other developers awaited the results from the evaluation but many showed interest in Lindås Park and during the years of measurement approximately 1500 visitors came to the site on study tours, including many developers (Glad 2006). The building proprietor of Lindås Park, Göteborgs Egnahems AB, stated they had positive experiences from Lindås Park, but still they decided not to build more PHs. Instead, they choose to change the concept and concentrate on a low-energy concept, implemented in the Bottnevägen project and without any targets for the energy demand, government funding and involvement of researchers or architect Eek. (Glad 2006) This could to be defined as the start of the third development period of PHs in Sweden constituted by the involvement of end users in the design process.

Ivory (2004) concluded that in construction projects architects are often the ones pushing innovations, and if end users are consulted they usually act rather conservative. In the Lindås Park project, architect Eek was an important driver for implementing the energy efficient innovative concept but the architects involved in the Bottnevägen project had chosen other innovative ideas as their trademark than energy efficient technology. The perception by the architects was that the PHs in Lindås Park were too dark because of the depth of the houses and they wanted to bring in more daylight into the new development. For the Bottnevägen project, the residents in Lindås Park influenced the energy concept based on the communication with Lindås Park residents, Göteborgs Egnahems AB concluded that a more flexible heating system was needed to satisfy the needs of the end users. Unlike Lindås Park, the goal for Bottnevägen was not to build a house with as low energy use as possible, but to satisfy the needs of end users. This could be achieved within the framework of a low energy concept, but not a PH concept. While the official statements from the architect and researchers were that most of the residents were satisfied and with minor improvements the PH concept could work even better (cf Eek 2002, Ruud & Lundin 2004, Isaksson 2005). But Göteborgs Egnahems AB dismissed the PH concept partly based on information collected from residents in Lindås Park and on their interpretation of the assessments. Another experience was that it is difficult to predict household behaviour and figures for heating demand could easily be miscalculated. Therefore it was decided from the start of the Bottnevägen project that the terraced and semidetached houses would have a heating system and no goals for low energy consumption were set. Some parts that were taken for granted in the former project, for example windows with extremely low-emittance glass or solar panels for hot water, were not implemented in Bottnevägen (Glad 2006). Not being part of any funding scheme or research project, a comprehensive assessment of this project is not likely to happen.

In the Bottnevägen project, the PH concept lost important parts of the network involved in the Lindås Park project. This third period of development involved end users but lost the more radical researchers and architects and thereby the original concept. The *problematisation* in this project was not about excessive energy use and the conservative construction industry but about how to get end user satisfaction within a low-energy house concept. The focus shifted from the professionals to lay people and their experience and knowledge about the PH concept in Lindås Park. This raises the question of whether the concept became more sustainable or if some important parts of sustainability were lost in the Bottnevägen project? It is possible to argue that some ecological sustainability was lost, since the Bottnevägen low energy house concept is likely to use more energy than the PH concept, but since experience from a new social group was included in the project and influenced the Bottnevägen concept, the concept became more socially sustainable.

The context in Gothenburg, the city where both the Lindås Park and Bottnevägen projects are found, is significant because of the presence of a particular urban regime called “the Spirit of Gothenburg” (Sydow 2004). In short this regime is characterized by a network of support in the city of Gothenburg including politicians, the industry, Chalmers University of Technology and University of Gothenburg. This network is enabling for innovations because it includes informal agreements about cooperation and flexibility in organising work and decision-making. The Lindås Park project was unusual development in Sweden since it was initiated by an architect (Green 2006). The way of organising the planning, design and building of Lindås Park was enabled by the urban regime since the locally based building proprietor Göteborgs Egnahems AB, owned by the Gothenburg municipality, accepted the unconventional process and an architect as project leader. In addition, researchers based in the city provided support for the project. In the Bottnevägen project the CEO of the group of companies to which Göteborgs Egnahems AB belongs put pressure to do a follow up, locking Göteborgs Egnahems AB in the leading position for the development of PHs in Sweden. All the local actors in Gothenburg were supportive of the projects and became enroled as spokespersons for the PH concept. The most prominent opponent to the concept was the construction company operating on the national level and not a part of the local urban regime. Similar to the case study on electrical vehicles as presented by Callon (1986a) the network of PH advocates failed to mobilise an important part of the industry and the question remains whether this will disable the transfer of the concept to other contexts? An analysis of the Oxtorget project might answer this question.

4 Oxtorget Passive Houses

In contrast to the Bottnevägen project, the municipal company Finnvedsbostäder in the town of Värnamo decided to embrace the PH concept and build four “zero-energy houses” with 40 flats. In addition, the Oxtorget project had the ambition to develop the concept and welcomed researchers and assessments (Glad 2006). In line with the theory of how technology is domesticated through networks of humans, artefacts, knowledge and institutions (Sørenson et al 2000), Finnvedsbostäder invited architect Eek and consultants involved in the former project to help with the concept plan and passive design features. As a result the network for the development and implementation of PHs in Sweden expanded.

From another perspective, the Oxtorget project can be described as an example of how environmental features can be used to negotiate with opponents to a development and building project. In 2002, the municipality in Värnamo made the decision to build dwellings on a site formerly used as a market place for cattle. After the site was abandoned by tradesmen, people from the neighbourhood used the green space as a recreation area and playground for children. When the decision to build on this site was announced, the neighbours dismissed the idea and made an appeal to the spatial planning bodies. In the same year, the managing director of Finnvedsbostäder became interested in the idea of Life Cycle Costs (LCC). Acccording to Finnvedsbostäder LCC could justify investments in more expensive technology if energy efficiency could be achieved during the technology life. Again in 2002, the Finnvedsbostäder yearly study tour went to Lindås Park to visit the PHs there. The managing director as well as the rest of the personnel and board members were all impressed by the concept. The conventional design was appealing to Finnvedsbostäder and even on this rather cold day in the autumn the houses were warm inside.

Parallel to the neighbours in Värnamo making appeals to higher courts, Finnvedsbostäder nourished the idea of LCC and PHs and came to the conclusion that the Oxtorget site would suit the concepts. When the neighbours’ appeal to the Supreme Administration Court was rejected, Finnvedsbostäder announced the idea of building PHs on Oxtorget. The opponents to the development did not object to this project although it would imply buildings on their green space. In addition, the local newspaper Värnamo Nyheter decided to publish a series of articles about the Oxtorget project. An analysis of these articles showed how they served as good PR for the project and being generally positive to Oxtorget (Glad 2006). To conclude, the Oxtorget project involved new stakeholders in the PH network. Massmedia was an important stakeholder already in the Lindås Park project, but the LCC concept was new and justified the PH concept as being financially responsible.

Problematisation in the Oxtorget project differs from the Lindås Park and Bottnevägen projects because dissimilarities in contexts. In Värnamo, the neighbours became part of the translation process and put pressure on the development for Oxtorget and forcing the building proprietor Finnvedsbostäder to think outside the square and expand the concept agreed on for the Oxtorget precinct. The problem was not defined at the global level, but at the local level where a green area was threatened. However, the PH concept offered a solution to both problems and the greening of the development proposed for Oxtorget made the project more acceptable for the neighbours and the local community represented by the Värnamo local news paper. I would propose that the Oxtorget project is an expansion of the network set up for the Lindås Park project. Virtually every part of the concept was copied and transferred to Värnamo and no parts were dismissed. Technologies used in Lindås Park were transferred to Oxtorget and actors involved in Lindås Park were consulted and influenced the final design of the buildings.

5 Conclusions and discussion

Network theory and the translation model offer important knowledge about how sustainable technology can be transferred between different contexts. The main purpose of using this approach is to reveal power relationships in the PH development in Sweden. The network for PHs in Sweden expanded between 1997 and 2005 and continues to expand as more actors embrace the idea. Recently a PH centre was established in the home town of the architect who initiated the Lindås Park project. In Sweden, the main opponents to PHs have been researchers specialising on the indoor climate and major national developers. Air heating is in general controversial in Sweden because bad experience in the past and the opposition from researchers can be framed within this debate and not against PHs as a concept. Since the innovativeness and sustainability efforts of major developers in Sweden had been heavily attacked in official reports from the government, statements from these companies were not credible and little notice was taken to the objections. These companies might have power in other contexts but their influence over the passive house development in Sweden has so far been limited. The Swedish government has in different ways supported the PH concept and governmental bodies have set up programmes to promote PHs and arranged seminars about low energy housing. It is a clever move to form liaisons with groups of stakeholders who will benefit from the PH concept, like building proprietors who will own the buildings and pay the energy bills in the future. Such building proprietors are for example housing companies owned by the municipality, which accounts for 22 percent of the total housing stock and comprise, as a group, the second largest owner of houses in Sweden. As long as the end-users are ignorant about how much it is possible to save on energy costs during the life-time of a building, and about the predictions of rising energy costs, the major developers are able to build conventional and resource consuming houses. The importance of municipal owned energy companies as driving forces for innovations on the energy area is part of the urban regime in Gothenburg and many other cities in Sweden which emphasise the importance of keeping the municipalities as actors on both the energy and housing market.

When the PH concept was implemented in Sweden, the technologies were translated by the initiating architect in order to engage other actors in fulfilling the goals of the project. Although driven by different incentives, the concept was the solution. A common denominator among several actors was the will to avoid unnecessary use of limited natural resources in housing. Many actors were representatives of public bodies, both on the national level with the research council offering financial support, and on the local level with the housing company owned by the municipality. Also researchers from universities and research institutes were funded by the research council and thereby representatives of public bodies. An overarching goal for public activities is sustainable development and all actors mentioned expressed concern about the environmental aspect of sustainability. The notion of environmental sustainability was transferred to other actors during the building process and the builders on site adopted the idea. The general idea of sustainability was translated into the work of the builders and became extraordinary craftsmanship including the goal to attain the densest building in the country. The three housing projects in this case study were located in attractive neighbourhoods adding an important value in the world of estate agents: location. This was a way for the building proprietors to hide extra costs for the PHs. Residents in Lindås Park stated they chose these houses because of their location and attractive design. The low energy concept added extra value to their dwelling but was not the primary reason for their decision to buy a PH. To conclude, the PH concept included many different parts which can be translated to meet different needs in the building sector which include other values than profit in the short run.

CHALLENGES FACING THE ADOPTION OF SUSTAINABLE BUILDING IN THE AUSTRALIAN COMMERCIAL SECTOR

Tara KOOLOOS [1]
Carolyn S HAYLES PhD[2]

1 Thinc Projects, Canberra, ACT, Australia
2 Queen's University, Belfast, UK

Keywords: Challenges, materials, technology, sustainability.

Summary

The building sector is being charged with the task of making changes to the way structures are commissioned and built; particularly in its approach to the use of energy and resources. This is apparent in Australia which is driving sustainable construction through the commissioning of buildings that meet Green Star environmental rating requirements. However there are a number of challenges facing the adoption of sustainable building. Construction professionals involved in the design and construction of sustainable buildings in Australia were interviewed as part of a qualitative based study undertaken in 2006. The major challenges they highlighted were: higher capital costs; cohesive knowledge sharing throughout the design and construction processes; and information on materials and technology including lack of research on performance. The principal challenge was therefore surrounding materials selection and justifying the decisions made. Insufficient product specifications and the availability of suitable local products at competitive prices were key issues identified by the interviewees. When a locally sourced material was chosen, it frequently had a higher capital cost and longer lead times; contributing to the higher first dollar costs and construction delays on projects. Aesthetic factors also meant that sometimes the most sustainable material choice was not always made.

1. Introduction

There is a general acceptance within the wider community that use of fossil fuels, consumption of non-renewable resources and greenhouse gas emissions are causing environmental harm. Climate change is 'likely to be the greatest destabilising force politically and socially of the next Century' (Edwards, 1998). The Construction Industry is recognised as a major contributor to the consumption of energy and thereby greenhouse gas emissions. The Organisation for Economic Cooperation and Development (OECD) advising that the building sector 'accounts for around 25-40% of final energy consumption in OECD countries' (OECD, 2006). With growing concerns for the environment and climate change, there has been a focus on the way new structures are commissioned and built; particularly in their use of energy and resources. There is an increasing recognition that buildings cannot be designed without consideration for their social impact on the environment (John et al., 2005). Further 'the impacts of construction and use of any built projects on the environment are at both local level, such as noise pollution, dust pollution, odour pollution; and global level, such as changes of climate and ecosystems' (Shen et al., 2006).

2. Sustainable construction

The issues highlighted above have been the driving force for more sustainable construction and the need to build 'green'. There are many terms for and interpretations of what constitutes sustainable building practice. Rather than providing a definition, the OECD sustainable building project identifies five objectives for sustainable buildings: resource efficiency; energy efficiency (including greenhouse gas emissions reduction); pollution prevention (including indoor air quality and noise abatement); harmonisation with environment; and integrated and systemic approaches (John et al., 2005). Sustainable construction is in effect 'a series of sustainable or 'best practice' decisions, which start well before construction (in the planning and design stages) and continue long after the construction team have left the site: a process that takes in the design, construction and on-going maintenance of what is being referred to as a 'green' building' (Hayles & Holdsworth, 2005).

2.1 Benefits of sustainable approaches to design and construction

According to Guidry (2004), there are three benefits associated with green building, namely: direct economic benefits; indirect social and psychological benefits; and environmental benefits. Cost benefits can be accrued as a result of sustainable building as 'integrating green principles into a building's planning and design process can generate 40% more savings and 40% better performance than simply adding green technologies to a traditionally planned and designed facility' (Lockwood, 2006). In addition, considering material sales and savings from avoiding landfill, deconstruction projects cost less than traditional demolition projects, whilst helping to preserve environmental resources at the same time (Green Leigh & Patterson, 2006).

Further, improving buildings' thermal properties will reduce consumption, the cost to the end user, and reduce CO_2 emissions (Reed & Wilkinson, 2005). The benefits attributed to green buildings include reduced energy costs, reduced employee health problems and increased productivity. These operate in conjunction with other less tangible benefits such as an enhanced company image for occupants of these buildings by demonstrating their corporate social responsibility, and potentially making them an employer of choice by providing a more attractive workplace (Edwards, 1998). Green building in the developed world is driven by a desire to reduce energy consumption and promoted as a financially-sound business decision.

2.2 Challenges to the adoption of sustainable building practices

The challenges facing the adoption of sustainable building described in the literature can be divided into five distinct categories, namely: cost; information; design processes; construction processes; and materials and technology.

2.2.1 Capital cost

The general industry view is that sustainable buildings come at a premium, with a minimal connection made between the up-front (capital) costs of construction and the operating costs, once the building is completed. Indeed, there is a widespread perception that sustainable buildings are higher in cost than the marketplace will pay for; even when they are not (Zerkin, 2006). This is believed to be due to the lack of accurate, thorough, and quantifiable information regarding the financial and economic impacts of high performance buildings (Suttell, 2006). McKee (1998) suggests that office buildings are not the best place to test new green technologies and designs, as developers and investors are not willing to carry the risk. The barriers to developers choosing high performance green buildings centre on the perception of higher first-dollar costs, and that the market is not willing to pay them, further there are not reliable cost models to assist developers to understand the true costs and benefits of high performance buildings. Developers also face a risk that the lending institutions may not understand high performance aspects and their value in the marketplace. Finally any new approaches are perceived as risky, and the developers are reliant on others' information and may not be able to determine who to trust (Zerkin, 2006). Economic barriers to sustainable design can include: lack of information about inherent long-term economic benefits of sustainable building; lack of integration among various incentive programs (rebates, loans, technical assistance, and recognition programs); reality that first cost is the overriding concern among financial institutions and investors; and the inherently conservative nature of the building industry (Townsend, 1997).

2.2.2 Information gathering

It is not always possible to predict whether a building will perform as predicted, whether the green costs are affordable or indeed whether the technology reliable (Edwards, 1998). There is concern that the complexity of some green designs (technological high performance) may bring about obsolescence earlier than conventional design (McKee, 1998). Further issues include a lack of consensus about what sustainable building actually means. There is also disagreement as to: what the minimum performance standards should be; which activities are considered to be environmentally stressful; what the economics are; and how to evaluate or measure sustainable building (Townsend, 1997). Attempts to integrate the vast amount of information currently available and effectively disseminate it have so far fallen short.

2.2.3 The design process

There appears to be limited understanding of available green options by design professionals. This includes: insufficient knowledge to produce specifications; a lack of available high performance materials; difficulties in gaining approval of new technologies for building codes; uncertainty about approvals; regulatory barriers to adoption of technologies and labour issues due to potential labour-saving measures; all providing further challenges to sustainable design (Zerkin, 2006). In order for sustainable building techniques and materials to be adopted they must be specified by the designer. However, there is no standard assessment criterion for products that allows them to be directly evaluated, and therefore design professionals must invest a lot of time in assessing potential materials and technology (Weber, 2005).

2.2.4 The construction process

Building on the issues described in the design process, the construction process can also be a difficult one. Issues include a lack of knowledge and consequently skilled labour to install and maintain new technologies (and minimal availability of training for the industry). There is limited infrastructure to handle and make available recycled material from deconstruction, thereby making costs prohibitive (Zerkin, 2006). The additional workers and time required also make deconstruction seem more costly than mechanical demolition (Green Leigh & Patterson, 2006). Furthermore time and financial pressures can have a negative impact on the effectiveness of environmental management systems on building sites (Shen et al, 2006).

2.2.5 Materials and technology

The challenges described above are all impacted on by materials and technology selection. Sustainable building practices can make a huge difference to global environmental sustainability, particularly through a drastic reduction in the use of natural resource consumption and energy intensive materials like cement, steel, aggregates and aluminum (du Plessis, 2001). The process of transporting materials via road, sea or air can leave a trail of pollution in its wake, making it more sustainable to use local products. Issues arise where, what is considered to be the most appropriate environmentally friendly product for a particular purpose is not available locally, thereby making materials selection extremely complex (Edwards, 1998). Most architects find it difficult to establish the life cycle costs of a particular product and consequently the environmental cost. For example, establishing a balance between harvesting practices, manufacturing processes, shipping, and the positive/negative impact a certain timber may have on indoor air quality once it is in situ (Weber, 2005) not to mention to disposal or re-use at the end of the buildings life, is extremely difficult. While the process of Life Cycle Analysis (LCA) exists to make this evaluation, a number of issues arise, such as the incentive for suppliers to perform this analysis on their products. This is likely to be consumer or industry demand driven, however if the results are not positive in environmental terms they are unlikely to be published (Graveline, 2005). Furthermore, LCA commonly needs to be completed from a whole of installation perspective, which involves obtaining LCA data for a number of components and therefore suppliers. Further, these suppliers often consider this information proprietary and are reluctant to release it into the public domain where competitors will be able to access it; making the information currently in the public domain limited and the process involved obviously expensive, meaning few clients are willing to pay the premium required (Graveline, 2005). How efficiently and environmentally the completed building operates is most commonly measured in terms of energy efficiency and productivity, detracting focus from the cost to the environment of the structure itself, which can often be unsustainable.

3 Australian Construction Sector Study

A research study was undertaken at RMIT University, Melbourne in 2006, which utilized semi-structured in-depth interviews conducted with three project managers to investigate their experiences and identify challenges facing the adoption of sustainable building in the Australian commercial sector. The interviewees had all been involved in projects rated under the GBCA's Green Star Program, in building refurbishment, office fit-out and as-built building. They were all assessed for a 5 or 6 star rating, 5 star being Australian Excellence and 6 star World Leadership (GBCA, 2006). Some of the buildings incorporated significant new technology, some receiving assistance from Sustainability Victoria's Commercial Office Building Energy Innovation Incentive (COBEII)[1]. All

[1] COBEII is a local government scheme which 'assists developers, property owners and tenants to demonstrate innovation in the design and application of sustainable energy' and provides some funding towards these initiatives (SV, 2006).

of the buildings incorporated sustainability criteria to some degree, including water conservation: daylighting: natural ventilation, VOC minimisation and energy conservation.

3.1 Interview Results

The interviews covered the five challenge areas identified in the literature review, namely: cost, information, design processes, construction processes, and materials and technology.

3.1.1 Capital Cost

Capital cost was a major consideration in each case, with all Managers all identifying this as an issue impeding the uptake of sustainable building. While the 'green' option was selected in each case, when queried, there was a vast difference in the Managers' views of cost issues and the reasoning behind cost decisions, these included:

- Preparation of budgets based upon conventional construction and technology alongside the use of green or sustainable construction methods and technology, versus the decision to incorporate sustainable initiatives almost as the construction was commencing.
- In all cases the green budget was more expensive with a premium ranging from approximately 1% to 30% depending on if the rating aspired to was 5 stars to 6 stars.
- In one case the payback period and energy savings from the sustainable initiatives made the project selection justifiable in economic terms. In the case of the other organizations the project selection was based upon less tangible perceived benefits, such as being an industry leader or innovator in these types of techniques or technologies, and demonstrating potential and skills to future investors or customers.
- The selection of the green option also allows these organisations to demonstrate a sense of corporate social responsibility towards both the environment and their employees.
- Industry ignorance creating a reluctance to invest, slowly being overcome by evidence that the buildings are working.
- Difficulty in getting a board or developer to agree to a significant premium to build a green building.
- The need to generate demand for green materials to provide economies of scale and reduce costs.

3.1.2 Information

Information on products, materials and benefits was a major consideration, with key issues raised by the Managers being:

- While there is significant information available from a European context, there is little by way of evidence in Australia.
- Lack of local companies running a scientific assessment of whether a particular project has contributed to reduced absenteeism or a higher health quotient for their employee base and the query of how scientific are any studies and do they have a strong basis for their argument.
- Due to the relative infancy of the sustainable building movement in Australia there is no long term information available.
- Heavy reliance on Green Star as a source of information and guidance, using it as a benchmark.
- Longer lead times on 'green' products causing program delays.
- Websites such as the Australian Green Procurement (AGP) database (AGP, 2006), could be used to source green products, however there was still a great deal of information that was not available on these websites.
- One organisation managed the sourcing of local products to some extent through a tender process, which effectively out-sourced many of these issues.
- A possible general lack of awareness in the Australian general population, with one Manager noting with more educational required.
- Industry level awareness greatly increasing, with high demand for knowledgeable professionals.
- The requirement to deal with complex information, such as volatile organic compounds and formaldehyde emissions, especially with regards to materials and finish selection.

3.1.3 Design Processes

The design process for the various buildings appeared to have run relatively smoothly due to the commitment of the organisations to green or sustainable features. The main issues being:

- Where new technology was utilised, extensive computer modeling was required to ensure that various technology types would work together (e.g. air flow through the building, or heating and cooling loads).
- One manager observed that for their building the planning authority and controlling body had set very high ESD guidelines to follow. These guidelines leading the organisation to the conclusion that as the planning requirements were so stringent that the building was required to be close to a five star building, the organisation should aim for the five star award.
- Organisations who received support from the COBEII scheme (SV, 2006) noted that this was extremely beneficial, allowing the organisations to investigate various alternatives for energy saving measures, and assisting with the design fees.
- This process was assisted by the various web based programs mentioned earlier, but similar to Weber's (2005) findings this was still a complicated part of the design process.

3.1.4 Construction Processes

The main issue for the construction process was the longer lead times required for some products, which had not been planned for and therefore caused some delays. Points being raised by the interviewees often related to items for the fit out of the premises:

- Due to the finish selection to achieve low VOC's, cabinetry had to be made, disassembled, treated, and then reassembled and brought to site, adding one to two months to a traditional joinery project.
- There was recognition of a change in the industry due to the market recognising that people want green star buildings, or people who want green star buildings want to go and buy products that achieve the criteria quite easily.
- New techniques and technologies did present some challenges, simply due to the organisations being first time adaptors, however this appeared to have been allowed for in some instances, and reportedly went quite smoothly.
- Access to skilled labor to implement new technologies did not cause great concern.
- In these cases environmental performance was a requirement of the organisations, who each also took the role of the client, and therefore, the cost of environmental performance was taken into account.
- The selection of environmentally favourable inputs for the construction did have time implications, as some of the projects were not completed on time, due in part to the difficulty in obtaining material.
- Lack of understanding as to what some of the challenges were in terms of sourcing some of the materials.
- Recycling is quite established in the industry with respect to products such as concrete and steel reinforcing mesh.

3.1.5 Materials and Technology

Materials and technology selection appears to cause some difficulty in an Australian context due to the limited number of suppliers of 'green' products, or where they are available, as noted previously they can be subject to long lead times and a cost premium. Key points raised were:

- While a requirement of the project in one case, a tender process eliminated the ability to note if the 95% Australian content was difficult to achieve or not. This requirement for 95% Australian content took the place of any LCA or assessment of the embodied energy of the products selected. In the case of the other organisations LCA and embodied energy were not studied, but rather the requirements outlined by Green Star in order to achieve points were utilised.
- The selection of materials is also driven by economics, many materials choices commercially driven, for example, more cost effective product imported from China would be selected over local products.
- The architectural or aesthetic factor was a strong influence, as buildings need to look attractive, and set the right image for the building owners' clients, or their tenants' clients, and in many cases in order to meet these aesthetic design elements, products were not available locally.

- The Green Star rating tool was valuable to the various Managers, and was much relied upon as a source of information, with the aim of the organisations being to achieve as many points as possible towards their Green Star rating.
- On some of the projects materials with an energy saving or recycled component were imported, however without an assessment of the transport energy used, resultant emissions and resources consumed, any benefit of these items may have been eliminated.

4. Discussion

Cost was a major challenge to the development of green buildings, with the interviewees' experiences noting a cost premium of up to 30% and the potential for investors to be reluctant to invest in a relatively new type of building with no proven returns. Indeed, investment in sustainable buildings was perceived by investors as a risk, with returns not yet considered to be proven within Australia. The cost of 'green' materials is a key factor in the cost premium.

Availability of appropriate information/specifications, especially when choosing appropriate 'green' materials is an issue. Whilst there are websites available regarding 'green' specifications and products, these are not yet sufficient. There is also considered to be a lack of evidence of the benefits of green building in a local context (due to the relative immaturity of the industry when compared to e.g. Europe). In addition, evidence of the whole of life benefits of sustainable building in Australia is not yet available, with no local studies completed.

The construction industry is seeking out more information on sustainable building and the level of expertise is increasing, however clients' knowledge is often very limited, making sustainable building less attractive if they do not understand what they are paying for (including higher capital costs).

Sustainable design and technology do not create difficulty with planning permissions and approvals in Australia. Information on new technologies and the ability of organisations to investigate them during the design process is assisted by schemes like COBEII (SV, 2006), and web-based sources such as the AGP database (AGP, 2006). Materials and technology selection is considered to be the most complex part of the design process. Likewise for the construction process, many of the issues relate to materials and technology selection and accurate, appropriate knowledge transfer. Some 'green' materials have longer lead times than their conventional equivalents which can cause delays. Recycling during the construction process does not cause undue difficulty in Australia, and is relatively well established.

Methods such as LCA and embodied energy calculations are not used to assess the suitability of materials in Australia. Based upon the responses of those interviewed, materials selection in sustainable building is subject to commercial viability as per conventional construction. Using imported products is quite common due to the relatively small market and range of local products available in Australia. Aesthetic considerations have been known to overrule the selection of local products which may be more environmentally friendly.

The availability of indigenous 'green' products and their capital cost are a major issue, which is also magnified by the often longer lead times to manufacture some of the more technical solutions. These long lead times can delay construction processes if the planner is not aware of them, and therefore has not factored them into the construction schedule. Furthermore, if a product is not available locally it is subject not only to longer production lead times, but also the vagaries of international shipping, which will bring into question whether it should be considered a sustainable solution at all.

5. Conclusions and Recommendations

The adoption of sustainable or green building in Australia shares a number of challenges with literature derived from the experiences of other nations in the developed world, including capital cost, and the need for developers to have a proven return on investment for green buildings before they are willing to take on the risk. Issues regarding access to or the availability of information (and knowledge) are also shared experiences, which impact directly on design and construction processes. Aside from capital cost the biggest challenge is the choice of materials and technology and their affordability; with a limited local selection of indigenous sustainable materials, supplied at higher prices and with long lead times.

A number of the challenges highlighted could be addressed by more appropriate approaches to green building including an integrated systems approach which would impact positively on the design and construction process as well rethinking what sustainable building practices aspire to; refocusing sustainability away from energy efficiency and highly technical solutions, to a more holistic examination of the impact of building on the environment. The challenge and the opportunity is cohesive decision making, and the harnessing of capacity and knowledge to ensure the most appropriate strategies are in place to deliver sustainable building solutions.

FOOD SECURITY AND THE DESIGN OF SUSTAINABLE BUILDINGS AND CITIES

Mark Gorgolewski, BSc, MSc, PhD, LEED AP [1]

[1] Department of Architectural Science, Ryerson University, Toronto, Canada, mgorgo@ryerson.ca

Keywords: urban agriculture, food security, sustainable cities, urban design

Summary

Despite the importance of the food sector in the functioning of cities, the link between sustainable built forms and food production, distribution and consumption is a new area of study. The emerging alternative food movement has barely engaged with the possible contributions that designers and the design process can make to develop an alternative to the food supply chain. This paper will discuss a series of projects that speculate about the potential for integrating food production into the design of cities. In particular, Toronto in Canada is used as a model to show ways to tackle agriculture and food issues as design challenges in urban locations. These examples of the connections between food issues and built form have the potential to transform not only food production and distribution; they can also underpin basic assumptions about the spaces and functions required in the design of buildings and urban spaces, and our understanding of the sustainable city.

1. Introduction

"The symbiotic relationship between a productive landscape and the human settlement system is as old as civilization. During the past 200 years, that millennium-old positive relationship deteriorated into a further and further separation of town and landscape." (Viljoen 2005)

Food is a key aspect of most cultures and has contributed to and inspired many creative aspects of our lives from local cuisine to urban form. Food is also among the most basic, primary needs of mankind. Over the millennia, the activity of satisfying this basic requirement has been one of the key ingredients in the formation and evolution of human settlements and cultures. At the same time it is at heart of current problems regarding the misuse of the natural environment, and is the topic of debate over the value of natural processes. Similarly, cities and urban developments are key aspects of human civilization, and now embrace half (and rising) of all humanity. Cities are also central to humanity's relationship with the natural world: they are both huge polluters and cause damage the natural landscape and environment, while on the other hand they offer perhaps the least damaging patterns of land use to enable the huge human populations that now exist on the earth to continue to thrive.

In the past, when transport options were limited and the technology of preserving food was less developed, there existed a very close link between the forms and patterns of cities and towns and their food supply systems which were largely regional. However, since the industrial revolution, growing fruit and vegetables within or close to urban areas has been largely eroded, particularly in western nations. A trip to the urban grocery store will produce a feast of vegetable, fruits and meats from thousands of miles away, made affordable by heavily subsidized transport and often underpaid third world labour. Large-scale industrialized agriculture has become a specialized rural activity, and the distances to market have become long and reliant on cheap transport and preservation techniques.

Now that we are struggling with the implications of building more sustainable and more compact cities, what are the implications of food production within the city on built forms and patterns?

2. Urban Food Production

Over recent years a growing consensus has formed that sustainability within an urban context should mean a more densely populated environment, moving away from suburban development and intensifying land use to accommodate more people, reduce transport and build multifunctional and well-integrated communities. At the same time, food security is becoming a central concern. Long-distance transport may no longer be possible due to diminishing oil supplies and the impact of climate change. There is also an increasing awareness of the health benefits of local fruits and vegetables that do not require artificial methods for preservation and ripening and the desire for more natural methods of food production.

Growing food within an urban or near urban rather than exclusively rural environment can reduce the need for industrialized production, packaging and transportation of foodstuffs to the consumers who dwell in the city. It can also act as a focus for urban community participation and engagement in a practical as well as cultural activity. Movements such as community agriculture, farmers' markets, the 100-mile diet and Slow Food put local food supply at the heart of urban sustainability. They encourage us to consider ourselves co-producers, not consumers, and in this way to engage in the many aspects of the food supply process.

Reconnecting cities to their food systems is now emerging as one of the core components of more sustainable urban settlements.

As the meaning of sustainability widens to embrace net-zero-impact living, the question of net-zero-impact food-supply chains for urban residents becomes directly relevant to the way we design and plan our built environment, so as to "make edible landscapes" (Batt & Kongshaug 2005). These pressures are likely to lead to a need for more locally produced food, including production within cities. So, how are we to reconcile increased urban populations and densities with land use for food production? How can we integrate food production into dense urban areas?

The link between the design and planning of the built environment and its food systems is an emerging area of study, reflecting a new awareness of the importance of food and the agriculture sector in the functioning of cities and communities. The alternative-food movement is just beginning to recognize the possible contributions that designers and the design process can make to the food supply chain; it has not yet tapped the potential that architects and planners can bring to the reintroduction of food systems into urban space. Recently, this subject has begun to attract significant attention and is gaining recognition among the world of architects and related professionals of the built environment, as well as within alternative food movements.

3. Toronto

A series of speculative design proposals in Toronto are described below to illustrate the potential for food production within the city. Toronto, with a population of 2.5 million has an ecological footprint about 200 times its actual land surface area, and almost a third of this is due to the food supply to the city, often from distant suppliers all over the world. Yet it has been estimated that about 22% of the land area, about 15,000 hectares, of the city could be used for food production (Wilcox *et al* 2007). These are vacant sites, underused waste land, roof tops, and yards. Also, Toronto's ravines offer possible agricultural land that could be put to productive use. This land could be used to feed over half of the city population, and could create a 1 billion dollar industry.

Proposals by Chris Hardwicke for Ravine City and Farm City (see Wilcox *et al* 200&) integrate visionary ideas for an urban ecosystem of collective housing that restores and enhances the ravine system of Toronto with a new kind of architecture that would enable the city to feed itself. The Toronto Ravine System is the defining natural feature of the city housing diverse ecosystems and running like fingers through the city. Ravine City creates housing development that runs along the top edge of the existing Toronto ravines, creating artificial ravines by connecting the terraced roof levels of the housing to create a continuous connected ecosystem. The artificial ravines function much like the natural ravines - controlling water flow and regeneration as well as cleaning the air, creating habitat and biomass. This new topographic infrastructure is connected to the natural ravine system and provides public open space. Farm City extends this concept to create agricultural areas integrated into new housing towers. By putting housing and farms in the same building, Farm City creates symbiotic relationships between energy, water and waste. Heat generated from the greenhouses is used to heat the housing units. Biomass from the greenhouses is used for energy. Solar energy is generated from the large glazed surface. Grey-water and compost generated from the housing is used in the greenhouses.

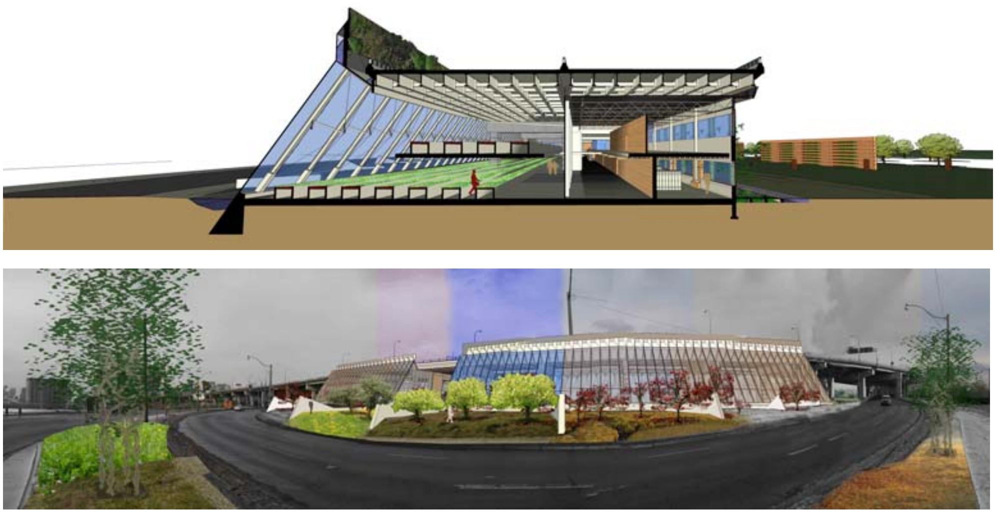

Figure 1: The Gardner Expressway Agriculture Centre

By creating living and growing space in a dense vertical format these proposals reduce the need for sprawling suburbs, reduce food travel distance and create a living architecture that is part of an urban ecosystem.

One fruitful area of research may be the use of undervalued or waste spaces in the city and its potential for community food production. The Gardiner Expressway, a highway overpass that slices through Toronto separating the city from Lake Ontario, includes a raised section. This provides the location for Andy Guiry's project (Figure 1), which investigates the possibility of situating productive greenhouse spaces below a raised highway, utilizing the side facing south to capture sunlight and the heavyweight structure of the highway for thermal mass to store the captured heat. Other features of the project include the reuse of wasteland adjacent to the highway for additional productive land, and the integration of educational facilities and a commercial space that sells garden supplies in addition to food and plants produced in the large greenhouse. Adding to the sustainable agenda for this project, small turbines were conceived for the median strip along the highway to generate electrical energy for the building through the wind from cars passing along the expressway. Materials proposed for the building were to be reused components from nearby wherever possible.

This concept has the potential to be implemented below many raised highway structures with unused, or underused land below.

Figure 2: Fort York community food centre

A second project, looking at underused land and waste material reuse, concentrates on how community development can be focused on food issues. Jordan Edmonds' community food center not only acts as a transitional bridge between housing and park space but also features reused existing structures and includes a farmers' market, community gathering spaces, bicycle paths, greenhouse structures for food production, and a community garden (Figure 2). His design is anchored in the history of the site, which was once a neighbourhood of icehouses and slaughterhouses and had a river running by (now buried). The project is a prototype for future urban landscapes that would be focused on creating a sense of community around the need for food production. It aims to enable the community to embrace food production through provision of growing spaces, both internal and external, preparation spaces, storage, sales space, all facilitating community participation and education in the processes.

The "Unzone" project by Nicholas Seed's takes some of the same ideas but integrates them into one structure. The project proposes the integration of cooperative housing, commercial, retail and community growing spaces all in one building. It is envisioned to be both a center of the local community, and co-op housing, combining adaptive reuse and new construction. The project site is a former office building in a residential area between the University of Toronto and the central business district. The proposals are for an outdoor farmers' market, an indoor market, garden plots, an orchard, mushroom growing in the basement, and rooftop green-roof gardens and greenhouses for multi-season food production serve the larger community.

Figure 3: Community food education centre

There is a need for projects of this kind to act as pedagogical tools, connecting urban Toronto dwellers with the food they eat, and providing educational opportunities for the community. A proposal by Victoria Dimitrieva proposes a teaching and a productive greenhouse/community space, strategically located near downtown Toronto in a neighbourhood of residential lofts and co-op apartments along a linear strip of green space that could provide for allotment garden plots across the street from the community building. The long southern exposure of the lot efficiently uses both vertical and horizontal growing surfaces, with specially designed cylindrical growing surfaces wrapped around structural columns as well as living walls. The north side has community rooms and offices. Solar panels provided energy for water distribution and filtration for the growing surfaces.

A project, by Brad Augustine, adopted a more conceptual approach to teach about the impact of food production on the environment. The goal of this proposal for a high-rise farm culminating in a penthouse restaurant was to demonstrate the size of building and resources needed to grow all the food consumed in the restaurant at the top of the tower. Feeding cattle to produce beef, for example, takes many times the space as producing vegetable. Restaurant patrons would travel in a glazed elevator through the floors of food production: cows, chickens, grain, vegetables, fruit trees, etc. into a restaurant where herbs are grown and the cooking is completely visible. This would provide an experience that was immediate, close, and informative on a very basic level, about the effort and resources involved in food production.

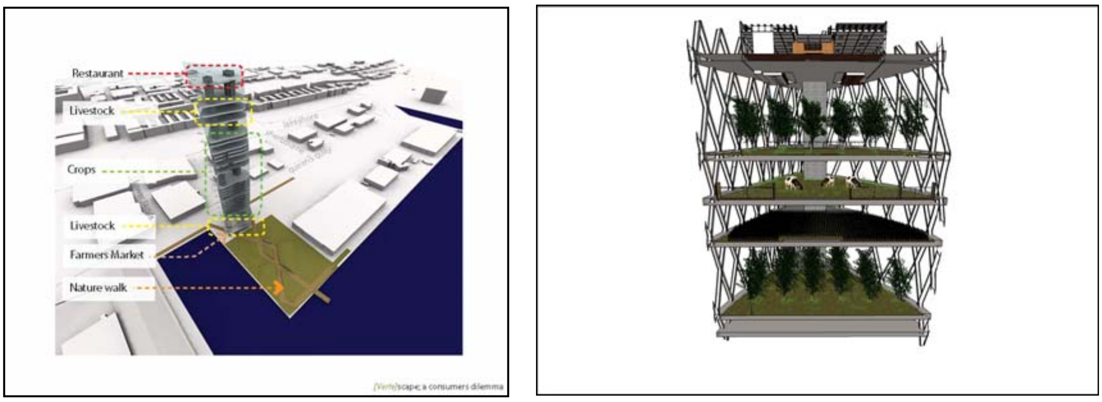

Figure 4: High-rise farm

4. Conclusions

The education of architects, planners and other professionals who impact the design of cities has long failed to address the implications of food supply on city design. As we begin to grapple with the issues of building a more sustainable way of living, food security is becoming a central concern. Food is part of the daily lives of every person in the world, and it is at the core of humanity's functional relationship with natural systems. Agriculture stands at the heart of current problems regarding the misuse of the natural environment; and is the topic of growing discussion over finding new relationships with natural processes.

A greater sophistication in the understanding of the meaning of sustainability and the scale of impacts that issues such as climate change and peak oil will have on food supply are beginning to demand attention. Questions about net-zero-impact food supply chains for urban residents are directly relevant to the way we design and plan our built environment, and therefore how we educate the designers of the future.

The projects discussed above illustrate the serious and diverse nature of possible responses to food supply issues in the city and the potential impact of these issues on the design of the city and its buildings. They start to shed some light on the types of networks of food services that are needed in the city and are the first step in generating ideas for the reintegration of values of community food production leading to change in socioeconomic values. These projects illustrate how providing for a basic human need of food may be possible in an urban context in a way that is socially, economically, and ecologically sound. The next level of thinking about food systems, above specific communities, requires the coordination of these services and segregated landscapes into what has been termed green infrastructure (Benedict 2006). Green infrastructure is essentially a connected network of landscapes within an urban context which is productive in providing for the needs of the people living in that environment. The specifics of how this network functions is dependant on the places that it serves, varying with size and shape of the spaces that are available, as well as the climate, topography, soils, and the needs of the community.

Keywords: renewable energy, efficiency, refurbishment, listed building, bricks, service-life.

Summary

The Leopold quarter of Brussels has been transformed from a prestigious late 19th century housing suburb into the 21st century administrative centre of the Capital of Europe. Within this area, we find the Renewable Energy House (REH). This 2800 m^2 office building houses eleven European renewable energy associations in a refurbished 140-year-old listed building. Not only is it one of the few remaining examples of this type of architecture that has been preserved in the area but it has been renovated with the latest technologies in order to meet the highest energy efficiency standards.

Experts believe that cost-effective technologies exist that could reduce the energy use in buildings by 22% in the European Union (EU). In order to produce an energy efficient and healthy building, one must use materials and products that effectively contribute to the energy performance of the building and its technical building system. This was the case with the REH, which manages a staggering energy saving of 50% and runs on 100% renewable energy. It was rightfully rewarded with a 2006 National Energy Globe Award.

1. Historical Background

After the revolution that erupted in Brussels in 1830, Belgium declared its independence and Leopold I became the first King of the Belgians. A civil Society was then created for the embellishment of Brussels, the capital of a new State. Its objective, to create the "Quartier Léopold", a suburb with new upper middle-class housing, gardens, public squares and horse-riding paths on 75 hectares of farm land. In 1865, Leopold II was crowned and under his reign Belgium became one of the leading industrial powers.

2. Architectural Developments

The "Quartier Léopold"- named after King Leopold I - was the first extension of the city outside its 14th century fortifications. The creation of such suburbs near historical centres is not specific to Brussels but was the consequence of the combined pressures of population growth, rural migration and industrial development. As Brussels had become the capital city, the democratic assemblies took over the prestigious buildings that surrounded the royal park. It is quite naturally that the servants of the new state should establish themselves on the adjoining plot of land just beyond the demolished city walls. "Quartier Léopold" was purposely built for them from 1837 onwards. The importance of this suburb can be proven by the fact that in 1838, only three years after the introduction of the railway in continental Europe, a railway station was built there and partially financed by the king himself.

Within these new quarters, one finds Arlon Street and the houses of numbers 63, 65 and 67. These were built between 1866 and 1868 from natural stone, clay bricks and roof tiles - materials commonly used in Brussels at the time. Such town mansions, most of which have since disappeared, tried to outdo each other in terms of beauty and prestige.

After the end of the Second World War, this residential suburb was gradually transformed into an administrative area and the arrival of the European institutions in the 1950s reinforced the trend. When the Treaty of Rome came into force in 1958, it brought together Germany, Belgium, France, Italy, Luxemburg and The Netherlands and Brussels became the seat of the European Economic Community (EEC). As the EEC established itself institutions tended to group themselves in and around the Leopold quarter because no single site had been chosen for the EEC and the area's grid street pattern facilitated the construction of large, multi-storey buildings (T. Demey 2007).

By 1965, more than 3000 EEC employees were spread across eight buildings in the Leopold quarter. Thus began a town-planning policy which experts agree lacked overall direction and so took its toll on the neighbourhood. In 1987, the demolition of the first railway station was even suggested as the European Parliament (EP) building project was developed. However, neighbourhood committees have endeavoured to ensure that this part of the city maintains and develops its diversity of functions and through their action the station is now a listed building and the EP building is known as the "folly of the gods". The Leopold Quarter is now the called European Quarter with some 30 520 EU officials occupying 77 buildings with a total surface of almost 1.5 million m^2 (T. Demey 2007).

3. The Renewable Energy House (REH)

Located in the European Quarter of Brussels, the REH is now a 2800 m^2 office building, which houses eleven European renewable energy associations.

Figure 1 The Renewable Energy House, Brussels (Belgium)

It was in 2005 that HRH Prince Laurent of Belgium suggested the refurbishment of the 140-year-old neo-classical listed building. His objective was to protect architectural heritage in a rapidly changing part of the capital, whilst integrating clean technologies in the restoration project. The renovation brought together partners from such various disciplines as energy efficiency, architecture and the construction products industry. The REH refurbishment project was completed in two phases. The buildings 63-65 Rue d'Arlon were first refurbished and inaugurated in March 2006. The third contiguous building was opened as an extension to the existing REH at the end of 2007.

3.1 The project

In the course of its life the building had been converted from a house into a shop and would now be transformed into energy efficient offices and accommodation. This called for the installation of a maximum number of renewable energy technologies and the implementation of the fire safety requirements whilst at the same time respecting the existing structure of a listed building in an urban environment.

With Brussels firmly established as the Capital of the European Union (EU), the objective was to bring together under a single roof the European associations representing the interests of the renewable energy industries grouped under the European Renewable Energy Council (EREC). More so, this building would become a showcase for these industries and be used for promotion and education purposes.

3.2 Modelling and Thermal Insulation

An encompassing energy concept was developed with the architect *Atelier d'Art Urbain* and energy consultant 3 E. The system is based on three core principles, i.e. limiting the thermal exchanges with the outside, heat recovery and the use of efficient renewable energy systems. The greatest opportunity in conserving energy is to reduce heat transfer through the building envelope and all the parameters were analysed with the TRNSYS model. The characteristics of such elements as the highly-efficient window frames (U=1.1 W/m^2 K g=0.6), the rear façade (8 cm of expanded polystyrene and rendering) or the roof insulation (20 cm of mineral wool) were determined according to the energy efficiency targets (global K=40).

3.3 Ventilation system with heat recovery

Heat recovery captures waste heat energy and reuses it by returning it to systems. It can give substantial long-term energy savings as it often reduces the need to generate heat in the first place.

The system uses a heat wheel with a heat recovery capacity of up to 85%. The process is based on indirect adiabatic cooling, i.e. air is humidified under adiabatic (evaporative) conditions. The advantage here is that energy is neither added nor removed as the required heat is taken from the air, which consequently cools.

In the summer, before being expelled, the air is cooled via a humidifier and then used to lower the temperature of the incoming air via a heat exchanger. In the winter, the expelled air is used to warm the incoming air and so providing a net temperature gain. Last but not least, to insure maximum efficiency, each room is fitted with a non-return valve, thermal probe and air quality sensor.

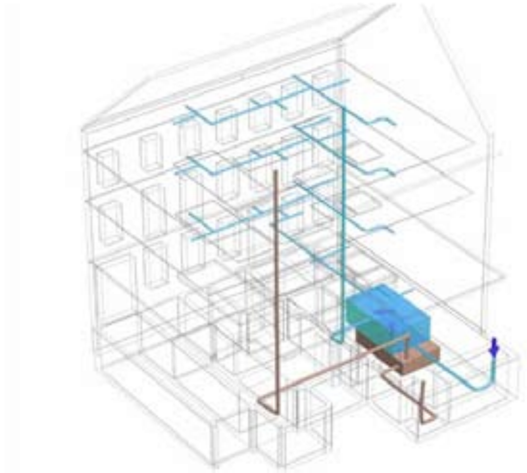

Figure 2 Double Flux Heat Recovery System

Two constraints had to be overcome, i.e. the space required for the machinery and the integration of the tubing.

3.4 Renewable Energy Systems

The Renewable Energy House obtains its complete heating and cooling requirements entirely from renewable energy sources.

Using a combination of solid biomass (wood pellets), solar thermal and geothermal energy, the heating, cooling and ventilation system generates high standards of comfort in the whole building throughout the year, with 21°C in the winter and a maximum of 25°C in the summer.

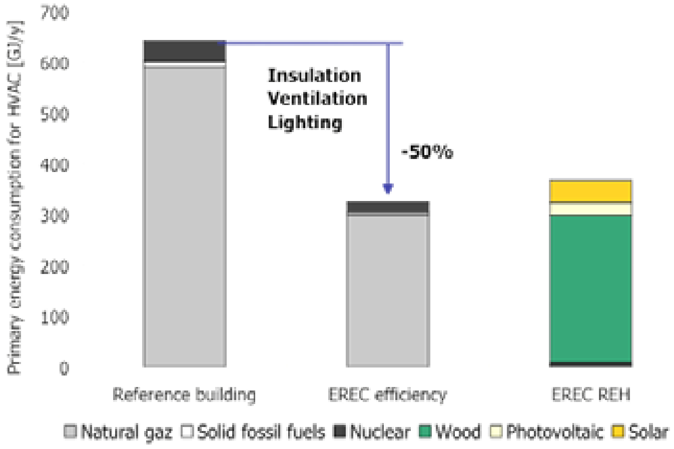

Figure 3 The REH Energy Consumption and Savings

In winter, the energy produced by the pellets boilers (85 kW + 15 kW) and the solar thermal collectors (30 m^2 flat plate collectors plus 30 m^2 evacuated tube collectors) is stored into two 2000 l water storage tanks, which supply both the radiator circuits and the ventilation system. The coal storage rooms were converted to store the wood pellets. Now, twice a year, 13 tons of pellets are blown from a tank truck into two interconnected rooms that are designed to automatically supply the boilers.

These combined solar and biomass energy sources are used to heat the three front buildings (2600 m^2). A ground coupled heat pump heats the back office buildings and conference rooms (200 m^2). This 25 kW heat pump coupled with four vertical heat exchangers (115 meters each) transforms energy from a temperature of 10-12°C into heat at a temperature of 35 to 45 °C. This energy is stored into a 400 l water storage tank which supplies the over-sized radiators circuit.

In the summer, a thermally driven cooling machine is used to refresh the whole building (main front buildings and back buildings). Here, the machine is driven by solar thermal energy with biomass as back-up. The hot water (80-85°C) feeds the absorption cycle to produce chilled water (7°- 9°C). This cold energy is stored into a 1000 l water storage tank and supplies the ventilation system. The waste heat (excess low-grade heat from the absorption cooling system) is released into the ground via the four borehole heat exchangers.

Three types of photovoltaic panels are in use, monocrystalline, multicrystalline and thin film. Semi-transparent cells are also integrated into the windows. The total 3 kW installed capacity is grid-connected and generates an annual production of 2550 kWh. It is foreseen to combine a stirling engine to the already operating 15 kW pellets boiler in order to further enhance the in-house electricity production capacity.

The implementation of energy efficient measures enables energy savings of 50 compared to a reference standard renovation project. On the supply side, 100 % of the building's heating and cooling demands are covered by the renewable energy technologies described above.

3.5 Renovation Costs

The standard renovation costs were estimated at € 984/m^2 (approximately $ 1550 US), whilst the insulation costs for roof and walls were € 23/m^2 (approximately $ 36 US) and the technical installations amounted to € 188/m^2 (approximately $ 296 US). This gave an extra 'sustainability' cost of € 211/m^2 (approximately $ 332 US) from which subsidies for restoring a listed building and for the potential energy saving were deducted. These amounted to € 76/m^2 (approximately $ 120 US) and this gave a total extra cost of approximately € 135/m^2 (approximately $ 212 US). This represents an 11% increase compared to a standard renovation project but of course this building was set up as a showcase of renewable energy technologies, which allowed for some extra solutions being included into the project.

4. Conclusions

In only seven months, a healthy and sustainable building was designed and implemented, having taken into account the existing structure and features, the interaction between building technologies, the technical building systems and the activities in the building. The Renewable Energy House is now characterised by a healthy and moisture safe indoor climate. This can be attributed to the original clay ceramic construction products which provide thermal inertia, efficient insulation, ventilation and a best available technology heating system. It must be added that such results can only be achieved through the use of well-established design procedures that take into account the construction system.

Brussels now has a truly spectacular sustainable energy showcase integrated in a monument-protected brick building and which is accessible to all those interested in sustainability. The Renewable Energy House demonstrates both a significant reduction of energy consumption for heating, lighting, cooling and ventilation through the application of energy efficiency measures, as well as providing as much renewable energy as possible. The tenants have access to a modern, healthy and prestigious office building. The success has been huge with more than 12 000 visitors and reports on more than 20 international TV channels in less than two years of operation.

The revision of the 2002 European Directive on energy performance of buildings (Directive 2002/91) is now underway and based on their own experience EREC and TBE will contribute to the debate. For now we know that the EC is planning to propose EU-wide minimum requirements for the energy performance of buildings. The options being considered include setting overall energy use limits expressed in kilowatt hours per m^2; the establishment of performance criteria for building components, e.g. the external wall; and last but not least, reducing the current 1000 m^2 threshold above which new and renovated buildings must meet minimum performance requirements.

As all countries have such old buildings making significant contribution to their cultural and historical heritage and as energy efficiency is a cornerstone of any sustainable energy policy, HRH Prince Laurent of Belgium established the Global Renewable Energy & Conservation Trust (GRECT) as a private foundation in 2006. More recently, New4Old, a European funded project within the Framework of the Intelligent Energy for Europe Programme (IEE), now aims at facilitating the integration of renewable energy and energy efficiency technologies into historic buildings and at the same time contributing to the protection of these buildings. New4Old is developing a network of REH. The expertise gained through the refurbishment of this historical building in Brussels can now be shared worldwide.

Keywords: housing, occupants, renovation, energy, comfort

Summary

In this research the problem of outdated low energy efficient housing built in the 1945-1975 period is discussed. Nowadays it can be observed that large quantities of these 40-60 year old houses are being demolished due to low general performance. The process of demolition generates enormous amounts of waste (over 120 tons per dwelling), and also generates the need for new material, energy and time for new housing. Occupants have to move and are often not able to return to their neighborhood due to increasing prices for new houses, a very unsustainable situation. After having analyzed the present situation and technical condition of the houses involved, possibilities for improving the energy performance have been studied; in this case the passive house approach has been analyzed. The combination of passive house elements applied to the outdated housing stock is modeled. Special attention is given to the comfort of the occupants of the houses during the proposed renovation process. In principle, a smooth renovation process is possible with limited hindrance for the occupants. Results show that technically a serious improvement of energy performance can be reached. However, a very important issue regarding energy performance after the renovation is the behavior of the occupants while living in the house.

Introduction

In the Netherlands some 7,000,000 houses exist for a population of 16,400,000 people. The average amount of newly built houses consists of 72,000 units per year. During the year 2006 many outdated dwellings have been demolished resulting is an annual net growth of only 52,000 houses. New houses are modern and energy efficient, existing houses often are outdated offering limited comfort and show high energy consumption. An entire building stock renewal will take more than 130 years. The situation of limited numbers of newly built houses and a yearly increasing amount of houses being demolished should be considered as an alarming situation [van der Flier, 2004]

Demolishing houses and subsequently building new houses cannot be considered as a sustainable practice. The demolition of estates will produce a lot of debris, involving many transportation movements. The demolished houses have to be replaced by new ones and this involves the production of new material and again related transportation.

If existing 40 to 50 year old neighborhoods are being demolished it also should be taken into account that not only technical infra structures will be lost but perhaps even more important also the social infrastructures will be demolished.

Demolition is a process that can be done in a relatively short time. Building new houses is a complex process with many parties involved and ensues huge bureaucracy. If things go well the building process can be realized in 2 or 3 years. But often delays occur and building realization times of over 8 years is rather the rule than the exception.

An approach consisting of a high level of renovation could prevent the loss of a social infrastructure and offers an almost endless life for social dwellings. After all, history has shown that building structures can perform endless if proper maintained and updated from time to time. In this research the updating of typical Dutch post World War II housing has been modeled into a computer program. First step is the modeling of the existing situation based on general characteristics. The second step consists of an array of possible actions for improvement. The differences in results will enable the designer to make choices for renovation based on the current situation and personal preferences. The third step is to develop an integrated model that will also calculate the consequences in terms of cost and appearance related to the possible choices.

Current situation

After World War II an enormous demand for houses existed, so many houses were built in a rush. Yearly production numbers of over 120,000 units were quite common back in the 1960's. Compared to today's building output of some 72,000 units per year quite an achievement for the 1960's! Of course technical standards in those days were not quite similar to the present. The 1973 oil crisis still was to come. Today, 25 years after the first oil crises the consumption of energy is an important issue in the building industry. Houses built around 1960 show characteristics like single pane windows, cavity walls without any thermal insulation, lots of thermal bridges and non insulated roofs. As a result the energy consumption only for heating will reach some 200 – 300 kWh/m2 per year.

The floor plan of a typical 1960 house shows limited surface. In general the ground floor consists of a footprint of some 40 m2 so the total available space for ground floor and first floor is only 80 m2. As building lots usually are some 150-200 m2 an extension would be a logical option, however in social housing every possibility must be used to ensure low rent, so in this research only an update of the existing house has been studied. A typical floor plan layout and section is given in fig 1.

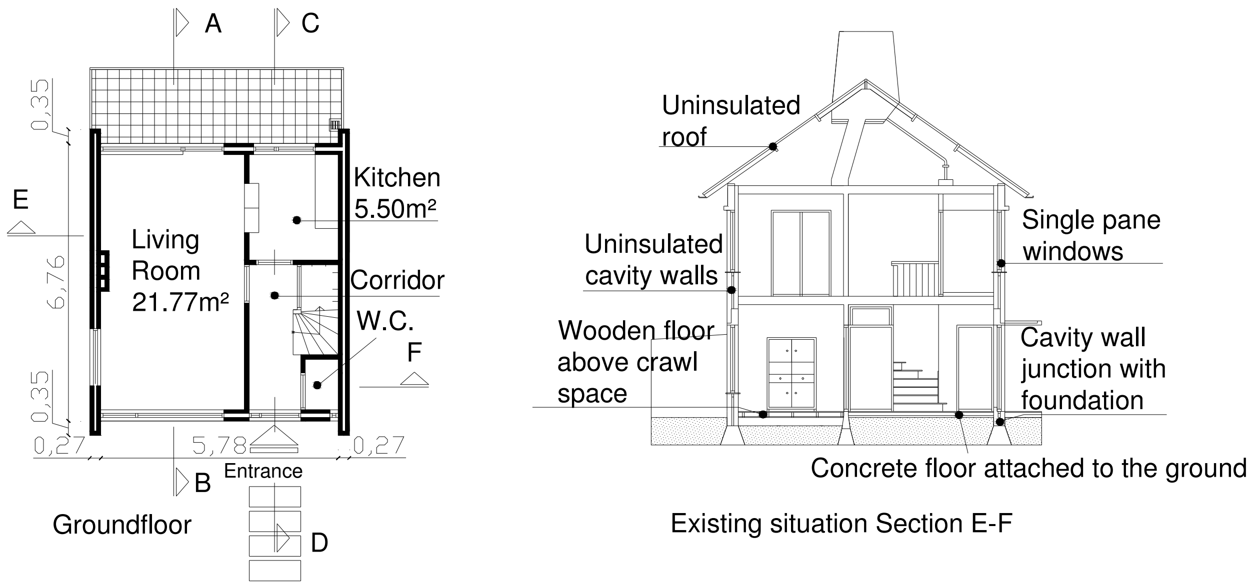

Figure 1 Typical floor plan and section of post World War II housing (1960)

Passive House characteristics

The general climate in Western Europe can be characterized by relatively moderate winters with average temperatures around 2ºC in January and cool summers with average temperatures around 17ºC in July. This means that a house should be heated during the winter period roughly from mid September till April. Cooling in summer generally is not needed. The passive House concept has been developed in Germany as early as 1992. The general idea of the passive house concept is to build a home that will keep the generated heat inside with as little as possible waste. This is achieved by applying thick thermal insulation some 300-400 mm, high performance windows, an airtight structure and a heat recovery ventilation system. Thick thermal insulation and high performance windows are just a matter of choosing the right material and the right products. An air tight construction is more difficult to realize. This can only be attained with dedicated and trained personnel and staff. During the renovation process at regular intervals tests must be done to ensure air tightness and corrections must be made if the required level is not attained. Details are to be designed in such a way that it is possible to realize an airtight result. Contractors must be aware that extra cost may arise. The heat recovery ventilation system is the most drastic change for the occupant. In Western Europe people have been used for ages to "natural" ventilation, simply consisting of using cracks and leaks for ventilation in combination with the opening of the windows. This has always been considered to be healthy. The passive house concept is the opposite of opening windows, in winter all windows need to be closed and ventilation is realized by a mechanical device called the heat recovery ventilation unit consisting of a heat exchanger and four pipes. The fist pipe is installed for the used exhaust air, this air is warm. This warm air passes a heat exchanger connected to the second pipe, the inlet of the outside cold air. The heat from the used exhaust air is transferred to the outside cold inlet air and pumped into the house by the third pipe. The used exhaust air is now cooled off and extracted by the fourth pipe to the outside as used cold air. An example of a heat recovery ventilation unit is given in figure 2. The crossing of the dotted line and the line is the place of the heat exchanger.

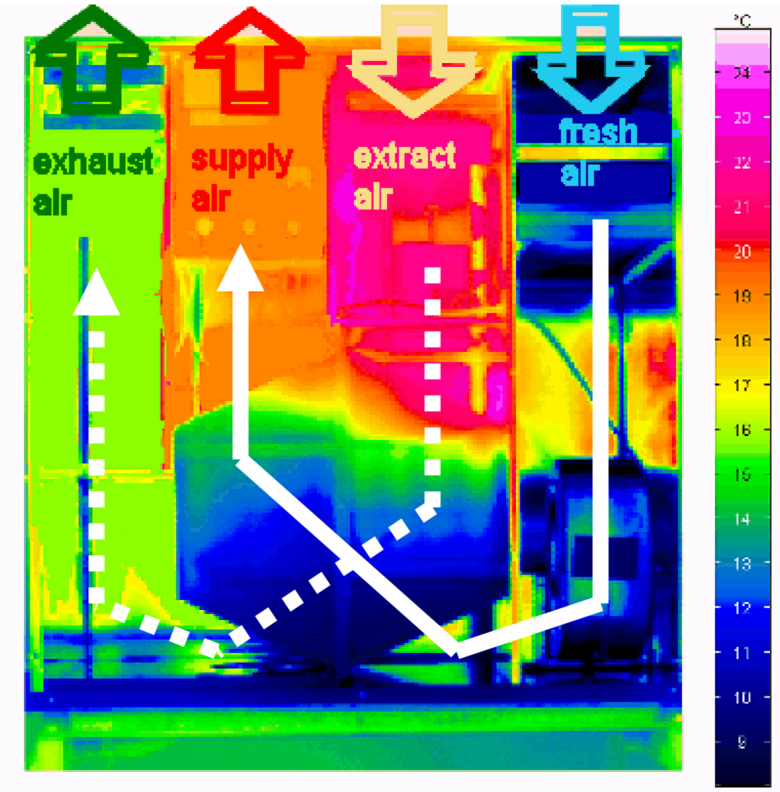

Figure 2. Example of Heat recovery ventilation Unit with 4 pipes.

A heat recovery ventilation unit can have an efficiency of some 80 – 85 % thus forming a significant contribution to the energy savings needed for reaching the passive house standard.

The air is transported mechanically so fans are needed. It is obvious that special attention must be given to noise levels as the thick thermal insulation in combination with the air tight structure and high performance windows will also contribute to the acoustical insulation of the dwelling to the outside noise. The inside noise levels (background noise) is so low that any other noise will stand out. It is even known that in a specific case the acoustical insulation from the outside was so good that an occupant of a passive house complained that she couldn't hear the children coming home from school, they suddenly appeared in the room. If air is forced through pipes obviously pollution is also forced in the system, so filters are needed to prevent pollution coming into the house. Once the filters are installed and are doing their work, they need to be changed from time to time, a task an occupant must get used to.

It can be concluded that passive house characteristics require a different and active approach for both the contractor building the house and the occupant living in the house in order to be successful.

Energy Efficient Renovation

The combination of an outdated dwelling and adding passive house elements is to be realized while occupants live in their house and at minimum cost. Applying outside thermal insulation is possible without any inconvenience, except for some drilling noise. It is important to place the piping for fresh inlet ventilation air also on the outside of the building and than cover the façade and piping with the required thermal insulation. Replacing the windows will cause disturbance as existing windows need to be removed. When using the existing window frame as a sub casing for the new window also in this respect inconvenience can be reduced. An example of this approach is shown in figure 3 (existing situation) and 4 (new situation).

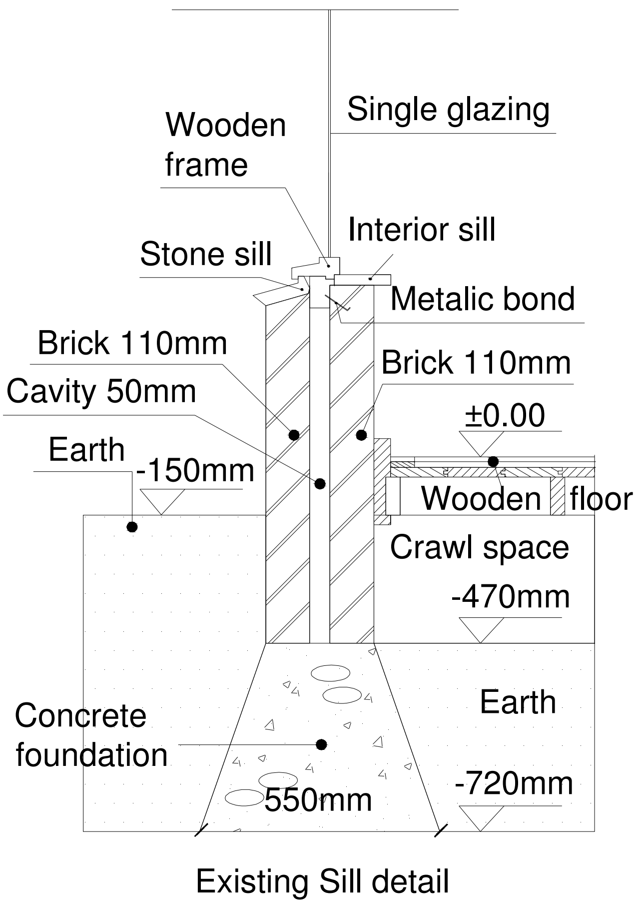

Figure 3. The existing window .

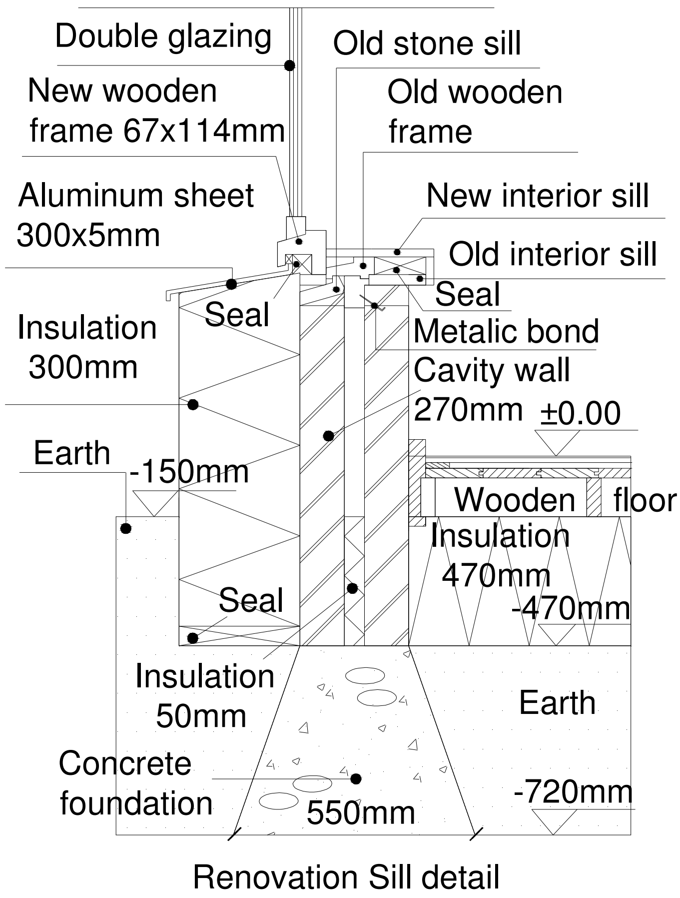

Figure 4. The new situation: the existing window used as a sub casing for the new window

Used air is to be extracted preferably at places where ducts already exist like e.g. in the kitchen, toilet and bathroom. Internal doors are to be adapted to allow fresh air to be blown in from the ducting on the façade to travel to the exhaust points located in toilet, bathroom and kitchen. Every specific situation is different and must be analyzed individually.

In the case of the project involved the energy consumption for heating only in the existing situation calculated according to the HAM base computer program is 240 kWh/m2 year. Under the current energy label according to the European standard EPBD this would mean class D, not very impressive at all, as expected.

Applying the four passive house characteristics (thermal insulation, high performance windows, airtight structure and heat recovery ventilation) the energy necessary for heating, calculated with the same computer program will be reduced to 35.6 kWh/m2 year. It can be concluded that the passive house standard will not be reached. This can be explained due to the influence of the existing ground floor and foundation. Thermal insulation is hard to mount in an existing foundation so thermal bridges will continue to exist.

The savings in energy are some 200 kWh/m2 year. With 90 m2 of surface the total fossil energy savings are 18,000 kWh. In The Netherlands due to vast natural gas resources, heating is usually realized by burning natural gas. 1 m3 of natural gas costs € 0.60 and will produce 10 kWh, so the energy savings will be some 1800 m3 of natural gas representing a cost of roughly € 1080.00

At present (March 2008): € 1.00 = US$ 1.60, € 0.60 = US $ 1.00, € 1,080.00 = US $ 1,728.00

The renovation to passive house standard will entail a significant reduction of fossil energy consumption, however the savings in money will be limited. According to German data [ILS NRW, 2006] the extra cost for additional thermal insulation, high performance windows, air tight structure and heat recovery ventilation system should be estimated to some € 15,000.00 (US $ 24,000.00) This means a payback time of over 15 years, not very attractive for the owner.

Conclusion

In order to reach a sustainable society with limited need for resources and limited fossil energy consumption the renovation of outdated building stock to the passive house level is technically feasible. Energy consumption for operating a house can be reduced seriously. In preserving existing buildings enormous amounts of waste will be avoided, the need for new material is limited, and numerous transport movements of material and people will not be necessary thus contributing to a sustainable society. Demolition of 40-60 year old houses can be avoided thus continuing existing social infra structures.

The direct cost for energy efficient housing renovation is high and the benefits in terms of saved money as a result of the energy savings are limited. Pure economically speaking this leads to a very long payback time of over 15 years. The question is however what society considers important, cheap housing and the well being of the people or new and expensive up to date housing. In the future the price of fossil energy will continue to fluctuate, today it is expected that prices will go up anyway, so an investment in energy efficient housing may be profitable on shorter notice than expected today.

Keywords: ecotourism, certification tools, regenerative tourism, sustainability

Summary

This paper will explore EcoTourism tools and their role in supporting the uptake in sustainability in tourism activities. In a world looking to minimise its ecological footprint, will travelling to far flung corners of the world to have the 'eco' experience be justifiable, and can tools help with this? Will the EcoTourism offerings need to adapt and offer more than access to pristine mature and minimal impact. With this in mind the benefits and short comings of EcoTourism certification tools are explored with a view of looking towards future development opportunities. This is done in the context of the lessons learned by green building tools such as LEED, BREEAM and GreenStar. Finally this paper asks the question about the ability of rating tools to lead to a sustainable future and makes the argument that a shift to regenerative tourism will provide both a new framework for the rating tools and an offering that justifies our ecological investment.

Introduction - ecotourism and certification

Tourism is a sector of the economy that is both large and has a large impact. Ecotourism is a concept from the 1980s that came from an awareness of this impact and the need to protect fast disappearing ecologically sensitive areas. By the early 1990s it was starting to be seen as the fastest growing sector of the travel and tourism industry, Honey and Stewart (2002a:2) describe Ecotourism as:

> *"… a multifaceted concept that involves travel to fragile, pristine and usually protected areas. It strives to be low impact and usually small scale; helps to educate the traveller, provides funds for conservation, directly impacts economic development and political empowerment of the local communities; and fosters respect for different cultures and human rights."*

Yet within this potential many researchers have found a miss-use or miss-understanding of the concept of ecotourism (Buckely 2001b, Preece et al. 1995, Fennel 2003, Caldicott and Fuller 2005), some even pointing to deliberate greenwash (Honey 1999, Weaver 2001, Wright 1993, Synergy 2000, Font 2001b). This drove the need for certification of these types of initiatives, resulting in the proliferation of labels, rating tools, certification schemes and guidelines. The World Tourism Organisation (WTO) in 2002, reported some 500 voluntary certification initiatives of which 59 were regarded as "comprehensive" schemes (Pina 2005a).

Rating tools, certification and labelling

Rating, certification and labelling tools are terms often used interchangeably, a *rating tool* rates a project based on the achievement of certain criteria; examples are Green Star, LEED, energy ratings on appliances and so forth. These tools are widely used for housing, commercial buildings, appliances and products, but tend not to be used for Ecotourism facilities. A *certification tool* assesses a project based on set criteria which may be a demonstration of intent or performance. Based on this the project either passes and gets certified or does not. This is the type of tool most favoured in the Ecotourism industry. *Labels* can be used with both types of tools; with a rating tool the label shows stars or some other mark indicating a level of achievement, where as the certification label will just show that that certification has been achieved. There has also been some merging of the certification and rating tools, for example Green Globe (a certification tool) now has a bronze, silver and gold label to signify the level of commitment and action taken. However, this still does not identify actual performance.

Volumes have been written on the ecotourism certification, labelling and rating tools[1]. The aim of this paper is to briefly outline certification tool types, as these are most used and discuss whether they are indeed helping the consumer to reduce their ecological footprint.

From the literature, the consumers and users of the certification and labelling tools require:

---

[1] For further reading on specific tools see Font and Buckley 2001, Honey 2002, Buckley 2003 and Schianetz et al 2007 for a review on tool approaches

- transparency and public accessibility to information;
- global relevance but local implementation;
- auditing – real and relevant categories, targets, performance etc.;
- technical detail and diversity – scale, types, locations, etc.;
- both guts and teeth – rigor in the assessment and methodology and consequences for not meeting requirements – for example procedures that ensure labels are awarded when levels are achieved and taken away if performance decreases, potentially with penalties;
- maturity and penetration – they are used by the majority of the industry and have acceptance within the market as demonstrating a level of environmental responsibility;
- a tiered structure – from an easy accessible level of certification through to world's best practice;
- simple yet thorough frameworks with clear threshold requirements; and,
- third party verification, auditing and certification.

Lessons from other certification and labelling tools

In the building industry there are some very successful rating tools, rather than certification tools, that have begun to create a market shift to more sustainable buildings. These tools have built up the credibility and integrity to be taken up by industry, and though voluntary, are used by government and industry as a measure for requiring a specific standard of design and potential performance. The tools, though developed around a similar timeline as the Ecotourism certification tools, seem to be more mature. For this reason this paper briefly touches on these tools and the ways in which they are expected to develop in the future as a potential input to the development of ecotourism certification tools.

It is clear that the building rating tools, such as LEED, Green Star and BREEAM, have been effective at one level, which is to raise awareness, create a language and a market for green rated buildings. This is demonstrated by the fact that recent US Green Building Council figures show a tenfold increase in membership since 2000, and have over 3,500 registered buildings. On another level though, rating tools seem to be only partly effective, achieving varying levels of incremental improvement in energy use, as well as addressing limited social and indoor environment improvements and providing some financial benefits (Hes 2007, Hes and Syndercombe 2008). Yet, in creating awareness they are an important part of the increased uptake of sustainability in our built environment.

The lessons that could be taken up from these tools are (Hes 2007, Hes and Syndercombe 2008):

- reducing cost and time needed for carrying out rating;
- streamlining the assessment process;
- working towards a performance based tool;
- working towards and international standard with regional variations; and
- improvement of indicators.

Issues related to ecotourism certification tools

Certification programs tend to have either process or performance requirements and lately some have been incorporating both (Honey and Stewart, 2002b). The process approach requires the development of an environmental management system, such as ISO 14000, that guides the way a facility is run. The performance programs require that certain targets be set and reported against. Depending on the program these can be based on internal benchmarking or targets set at the certifier level. Both can include environmental, social and economic sustainability criteria.

Research conducted by Honey and Stewart (2002b:59 quoting Synergy 2000) concluded that the combined approach is the most successful because it: "*encourages business to establish comprehensive environmental management systems that deliver systematic and continuous improvements, include performance targets and also encourage business to invest in technologies that deliver the greatest economic and environmental benefits within a specific region*".

Many of the current certification programs are still based in the process framework; for example Green Globe, Green Flag for Green Hotels, ECOTUR in Spain and Green Key in Denmark (Font 2001a, Font and Buckley 2001, Honey and Steward 2002b:54). The reasons for staying away from performance certification are that it is difficult to have verified and accessible criteria that are relevant across the multitude of ecotourism products and regions. This presents a problem in that many of these programs end up with more of a commitment to improve practice and do so against their own benchmarks, rather than providing concrete improvements based on standard performance levels. This leads to some scepticism on the part of the consumer (Synergy 2000).

The large numbers of tools that are available are another well documented problem influencing the effectiveness of the tools in attracting consumer uptake (Honey 2003, Kahlenborn and Domine 2001, Schianetz et al. 2007, Butler 1998, Buckley 2001a, Pina 2005a, Font 2001a).

> *"The tourists who are the targets of ecolabels are often more put off than attracted by the vast number of schemes available to them. Not knowing which scheme to trust, a large number of them probably ignore these schemes all together." (Kahlenborn and Domine 2001:247)*

Also tools need maturity and penetration, this means that consumers need to understand the consequences of an ecotourism facility not having a label as clearly as if it had one. Further, maturity is achieved by continual re-evaluation and a re-certification over time as technology and knowledge advances (Buckley, 2001a).

There is a call, therefore, for tools to be integrated and for greater consistency and collaboration between them, their organisations and their countries (Font 2003, Honey 2003, Schianetz et al. 2007, Butler 1998, Pforr 2004). Yet complete integration is not possible. The research of Schianetz and colleagues (2007:381-5) found that certification tools not only differ between process or performance, but also by being retrospective or prospective; have global or site specific assessment criteria; be based in the technosphere or ecosphere; and, can focus on different effects (triple bottom line, cumulative, dynamic etc.). They conclude that there is no single tool that brings together all these elements and that the final scheme should ideally combine a variety of these tools to ensure a comprehensive assessment and path to sustainability. This research then did not provide what this 'final scheme' could be as they concluded that the choice of mix of tools needs to be project dependent.

The critique of the effectiveness of the certification tools are summarised by Buckley (2001a:259):

> *"Criticisms of tourism ecolabels are that they are expensive, they require time, usually they focus on hotels or ecotourism providers, the ecolabel organiser has limited marketing power, and the criteria focus on environmental management, not environmental performance."*

The above all suggest that the tools may not be as effective as hoped in moving the industry to sustainability. Further, when looking specifically at whether these tools have actually led to a decrease on ecological impacts, even just carbon footprint, the literature is strangely silent. In part this is because many of the schemes have not required public reporting. More telling though is the research by Sasidharam and Font (2001:105) that concludes:

> *"Despite the potential benefits from ecolabels, to date no conclusive evidence exists to support their assertive claims that ecolabels improve the environment…Social science research suggests that environmental education of consumers does not stimulate environmentally responsive purchasing behaviour."*

One of the main reasons provided as to why the education of the consumer through certification has such limited impact, if at all, is the small percentage of the decision making process that is influenced by ecological consciousness. Location, cost, value for money, availability, convenience, and so forth have a much higher priority (Font 2001a). This may have changed with the swell of environmental consciousness created in the wake of Al Gore's crusade on Climate Change and the Stern report, but no literature has been found at the writing of this paper to counteract the above claims.

Buckley (2001c:195) describes the Nordic Ecolabel for Hotels as having the greatest potential of delivering assured results. In summary he concludes this is because it grew out of a mature, high penetration labelling scheme called the Nordic Swan and it has "*quantitative environmental performance criteria, e.g. for energy consumption per capita, wastewater quality etc which apply uniformly across the entire schemes*". This gives assurance and leads to consumer trust which results in the label being well accepted and 'thriving'. Yet Buckley also shows that the label has low penetration and thus its ability to lead to a reduction in impact is similarly limited.

From the review carried out it can be concluded that certification of ecotourism cannot be said to have a significant impact on the ecological impact of its users (Synergy 2000, Pina 200a/b, Sasidharam and Font 2001, Buckley 2001b, Font 2001a).

> *"Most ecolabels mention the protection of environmental resources as their objective, yet little evidence is available on whether these objectives are met. Advocates of tourism ecolabels will emphasise that these minimise the damage, a more realistic aim than avoiding it, yet critics say that the certification of tourism products is endorsing the use of fragile natural resources". (Font 2001a:14)*

The problem may lie in the fact that we are trying to solve a problem – our 'unsustainability' – within the framework of what has created the problem in the first place. We are using labels and certification that will only work while they present a benefit to the user as they differentiate them within the market (Pina 2005 a and b). Most of the schemes are trying to make the process as simple and implementable as possible without real public reporting and responsibility (Synergy 2000). Further, due to the costs of certification often the few who choose to pay extra for the piece of mind of a 'responsible' holiday are subsidising those who do not (Buckley 2001b)

Moreover, if sustainability is about more than the competitive advantage, if it is about sustainment, reduction of impact or even net benefit then it should be something embraced by all tourism offerings in contradiction to the fundamentals of certification. For this reason Pina and others (Pforr 2004, Pina 2005a and b, Griffin 2002, Buckley 2001b, Wright 1998) argue that the standard environmental and sustainable performance of tourism should be regulated:

> *"…whereas some erosion and pollution of resources is caused by great numbers of visitors, most environmental damage is caused by lack of plans, policies, and action …Tourism cannot be blamed for environmental deterioration caused by bad decisions rather than real visitor impacts". (Wright 1998:75)*

Though labelling may have a small influence on buyer behaviour, it results in piecemeal and incremental improvement rather than sustainability (Pina 2005b). Pforr (2004) agrees with Pina that sustainability is a key public policy driver and that fundamental reforms of the tourism industry need to be led by the public sector because of current ecotourism certification shortcomings are: "*its highly fragmented and little co-ordinated nature, a lack in information exchange and often unclear responsibilities*". Pforr (2004:85) adds though, that the traditional machinery of government may not be able to deal effectively with the complex and dynamic agenda of sustainability and tourism. Something in-between is needed and he argues that this may be rethinking tourism and redirecting it based on the concept of sustainable development. As argued in this paper, due to the contested nature of sustainable development and to a certain extent its subversion into efficiency rather than improvement, this change in placement of the industry might achieve more for the long term if set within a regenerative tourism framework (Owen 2007).

Regenerative tourism framework

So how far has this approach to sustainability lead us? It is around 45 years since Rachel Carson's "Silent Spring" was published, warning of the chemicals we were using. Kenneth Boulding's "Spaceship Earth" came out in 1966 reminding us that we only have one planet, yet currently we seem to be happy with the fact we are using more chemicals and the equivalent of over four earths in resources (in Australia's case). In 1972 the Club of Rome published "Limits to Growth" (Meadows et al. 1972). The Brundtland Commission "Our Common Future" came out fifteen years later (WCED, 1987); 1992, Agenda 21 was presented at the Earth Summit in Rio (UNCED, 1992). A more worrying demonstration of our current way of thinking's failure to deal with these problems is that over 100 year ago Svante Arrhenius (1896) calculated that increasing carbon dioxide emissions from human activities will lead to global warming, sixty-eight years since Guy Callendar (1938) warned that global warming is already underway. It is 17 years since the first report from the Inter-governmental Panel on Climate Change (1990) came out, yet our greenhouse gas emissions have gone up. In fact, the recent Millennium Ecosystem Assessment report concluded that: *"…the results of human activity are putting such a strain on the natural functions of Earth that the ability of the planet's ecosystems to sustain future generations can no longer be taken for granted"* (Millennium Ecosystem Assessment, 2005:2). They showed that nearly two-thirds of the essential services provided to us by nature – air, water, resources, etc. are in such decline that collapse is likely.

With increased awareness of ecological issues and the use of certification and rating tools, why are we still depleting our resources at such a great rate? One of the reasons is based in the Cartesian logic that places humans outside of nature, in opposition to it; the reductionist approach to sustainability and the attempt to solve problems within the same framework that has created them. There is a need for a paradigm shift away from this type of thinking, a need echoed by many researchers and commentators for example Schumacher, 1974; Naess, 1995; Sachs, 1995; Devereux, 1996; Capra, 1996 and 2002; Bossel, 1998; AtKisson, 1999; Kumar, 2002; du Plessis 2006.

The regenerative framework stems from the above call for change and by the fact that even with these more mature tools (LEED etc.) are we really on a path to reducing out ecological footprint? These tools seem to be a good start but are they sufficient in scope or tempo of take up to achieve a move to the more sustainable world before we reach a critical tipping point? Is this incremental slow rate of improvement a result of trying to find solutions within the same framework that created the problem? If they are, should we be looking at doing things differently and what could this look like?

To understand how we could approach 'sustainability' differently, regeneratively, we need to understand what we currently mean by the term. Sustainability, depending on who you speak to, is about sustaining. Most of us approach it with a view to keeping things as they are – or not letting them get worse. The problem, and the cause of its contestability lies in what people are trying to sustain - the use, misuse and consequent renegotiation of this term has resulted in a reduction of its potency. In particular, its connection with the conceptually divergent goals of economic growth and production under the popularised Brundtland definition of 'sustainable development' has led to scepticism of the value and meaning of this term. Furthermore, the framework of minimising impacts, or perhaps even more problematically offsetting impacts, is seen as both ineffective and presumptuous since it continues to grant indulgences on behalf of the planet.

This paradigm shift to regenerative development, starts by looking at things as a whole, as a set of interconnected and interdependent relationships. Solutions cannot be linear and cannot be simple, and this new thinking is being supported by current scientific development in quantum physics, complexity theory and complex adaptive systems, and the science of ecology. This means moving away from our Cartesian way of thinking of humans as apart from and in competition with nature. Called the 'ecological paradigm' by Du Plessis (2006:12) this "*requires that our definition of development shifts from the successful domination of nature, forcing it to follow ideas of order that ignore its inherent systemic properties, to embracing nature and participating in and co-evolving through its processes (Lyle, 1994; Eisenberg and Reed, 2003).*"

The second requirement in this shift is a move away from seeing humans as takers. Rather linked to the above point, tourists become not only partakers but also adders of value. This is the key and the pivotal point for this change. Tourists can become a regenerative force in the system, seeing how each activity can add value, leaving the earth better than when arriving. The premise is simple – that our actions should result in net benefits to our ecological and social environments. The application is more complicated, but it is based on what William Reed has described as building capacity rather than things.

This is becoming known as Regenerative Development and for the purpose of tourism, Regenerative Tourism (Owen 2007). This is not a new concept with many leading thinkers also approaching this problem and providing concepts such as regenerative design (Lyle 1994), interdependence (McDonough, 1998), resilience, symbiosis and positive development (Bikeland, 2007). Moving beyond Ecotourism to Regenerative Tourism, does not mean that ecotourism need abandon those aspects that support sustainability principles such as energy and water efficiency. It means for the purposes of this paper:

1 – Adding value - The first point of differentiation between ecotourism and the concept of regenerative tourism is the key issue that is universally shared amongst all proponents of regenerative development. It looks at whether it is possible to develop positively, adding capacity and capital rather than taking and diminishing our resources (Birkeland 2007).

2 – Working with nature as a partner of equal value - Regenerative tourism looks for inspiration in the complexity and symbiosis of nature. Regenerative tourism should move to reconcile the historically constructed division between humans and nature. That is to start looking at issues as a whole, as a set of interconnected and interdependent relationships.

3 – Socio-political aspects inclusion - Much of the Cartesian problem is based in the need to quantify and control. However, there are so many things for which science cannot account. In particular, the socio-political dimension requires value judgements which can never be quantified. Ecotourism does not exclude the socio-political dimension, but it defines it as a distinct realm; one of the four 'pillars' or three 'legs' depending on how the pie is sliced. Conversely, regenerative tourism is concerned with the complex web of relationships that form an integrated whole that cannot so easily be dissected. This is an aspiration rather than a reality and unfortunately social relationships are too readily glossed over or presented as universal and homogenous. One notable point of difference is Steven Moore's work on regenerative design, through an analysis of the Laredo Blueprint Farm in Texas, in which he explores the inter-relationships between the success of environmental initiatives and the politics of ownership, production and education (Moore 2004).

Regenerative tourism and tools

Having discussed what the issues are with current ecotourism certification tools, and having looked at the need to move to a regenerative tourism framework, this section briefly looks at the consequence this may have for how tools develop in the future.

1 – Adding value - There are two aspects to supporting this, the first relates to the opportunity for the tourists to add value, the second is for the facility itself to add capital. Certification tools need to support visitors and stakeholders within the facility to be able to contribute actively. This might be through active promotion of the voluntourism aspects of the area, or through the design and planning of the tourism experience to allow active engagement with the context of the facility. Meanwhile, following Birkeland's concepts of positive development, ensuring that the facility actively contributes through its design; for example, using passive techniques, ensuring that green roves, solar panels, water collection, waste recycling and reuse are all part of the operations of the building. Particularly ensuring that there is no taking of the capital, and where possible adding to it through adding to fresh air, native flora and fauna habitat and food production.

2 – Working with nature as a partner of equal value - Tools can move towards instilling a partnership with nature by highlighting the interconnectedness of all aspects of a tourism facility. Firstly, this needs to be reflected in an ability to see all parts of the certification as important and not trading off say water efficiency with energy efficiency. Secondly, it is about providing educational and experiential opportunities for the tourist to be able to engage with nature and as such gain a richer appreciation and connectedness with the place they are visiting.

3 – Socio-political aspects inclusion - This aspect is the most difficult to put into concrete actions that could be taken by certifying tools as this is centred on equality for all participants. A tool could represent this by ensuring education, participation and ownership is addressed among all stakeholders. Educational opportunities for the local inhabitants as well as education of other stakeholders of the traditional inhabitants

could form one of the measures. Participation in decision making on the facility by all stakeholders through consultation and real representation of their voices could be another measure. Finally, instilling a sense of pride and ownership in the ideals of the facility is a third potential measure, this ownership is not intended in the financial sense, though this may be how value is attributed, but in a ability to identify and understand the ecotourism facility.

Future work is needs to be done on how these can inform tool evolution, as shown by the building rating tools they need to be simple, easy to implement, internationally relevant, using representative indicators and a verifiable communication mechanism for those looking to travel responsibly. This is still required in the short to medium term. The hope is that in the long term the concept of regeneration will become part of the practice of tourism. A practice where no activity is carried out that does not add value to its context, working with nature and the community. Not only an elimination of the ecological footprint of the experience but actually productively adding capacity.

Conclusion

This paper has shown how ecotourism certification and labelling tools have been effective in raising awareness but that they have many flaws; both in the rate of uptake and influence and their ability to support sustainability. This paper also argued that the development of these tools within the framework that created the problems in the first place will not lead to their solutions. Further, this paper introduces the concept of regenerative development and regenerative tourism. It gives a brief outline of the principles and how these differ from the current way of thinking about.

The roles of the tools at present seem to be as a marketing and awareness program, but as argued this does not really result in a decrease in a tourist's impact on the environment nor lead to sustainability. In the future these tools could be developed to support a regenerative frame of thinking, but ultimately this will not lead to certification or a label, but a benchmark which will be fundamental to all tourism facilities.

[2] Institute of Technology, Shimizu Corp., 3-4-17 Etchujima, Koto-ku, 135-8530, Tokyo, Japan, michiya@shimz.co.jp

Keywords: daylighting, energy saving control system

Summary

The authors have developed a “Gradation Blind”, a venetian blind with slats having different angles vertically. The blind reflects more effectively the direct sunlight to the ceiling of a room than ordinary blinds, because the slats of the blind are controlled these angles depending on solar position. Thus the blind increases the brightness of the room and reduces the lighting energy. According to the intimate calculation that the authors made, the lighting energy of the room that was installed “Gradation Blind” in window was lower in 24% than the room that was installed nothing. On the other hand, it is possible that the “Gradation Blind” increases the cooling load as a result of the increased introduction of the solar radiation. So, the authors propose a system to control the blind the best condition to minimize the sum of the lighting energy and the air-conditioning energy. And we proved this control system was available for saving the total energy consumption of the building.

1. Introduction

Because from one-fourth to one-third of building operation energy is from the lighting and the office equipment, it is necessary to reduce this energy in the building. The daylight use technique leads to the reduction in the lighting energy by effectively using the natural energy of sunlight. As for this daylight use technique, various methods are examined, and have been introduced. The authors have developed a “Gradation Blind”, whose lighting performance is higher than a past window shade by having the slats different angles vertically. This paper shows a basic feature of the “Gradation Blind”. On the other hand, it is possible that the “Gradation Blind” increases the cooling load as a result of the increased introduction of the solar radiation. So, the authors propose a system to control the blind the best condition to minimize the sum of the lighting energy and the air-conditioning energy. This paper shows the outline of the new control system of “Gradation Blind”, and the result of verifying the effect of the control system.

2. The outline of “Gradation Blind”

2.1 Control Principle of “Gradation Blind”

“Gradation Blind” is a daylight introduction device that makes the room brighter by reflecting direct sunlight to the room ceiling by changing the interval of the slat on a window side and the indoor side as shown in figure1. The angle of the slat is controlled by the solar position. And each of slats reflects the direct sunshine to the ceiling in the room optimally.

The angle of the slat located on the top of the blind is controlled so that the slat reflects the direct sunshine to the ceiling in the room whose position is farthest away from windows. The angle of the slat at such time becomes like the formula in figure 4, and this angle is assumed to be “ β_1 ”. If the angle of the slat located on the top of the blind is inclined to the angle that is calculated by the formula, the change attaches to the angle of the slat of each height, and direct sunshine is taken in the room as shown in figure 2.

However, direct sunlight might be irradiated directly to the floor in the room when controlled at a specific angle calculated by the formula in figure 4. So the slat angle when direct sunshine is not irradiated just directly to the floor in the room should be calculated at the same time, and it becomes the formula in figure5.

If the angle of the slat that located on the top of blind is inclined to that angle, direct sunshine never leaks between the slat and the slat because the angle of the slat that is under of the top of the blind becomes smaller than the angle of the slat of the top. And this angle is assumed to be "β_2".

If the value of β_1 is smaller than that of β_2, the angle of the slat that located on the top of blind becomes β_1. And if the value of β_1 is bigger than that of β_2, when the direct sunshine irradiate directly at the floor, the slat angle becomes β_2. The method of operating the blind as mentioned above becomes flow as shown in figure 6.

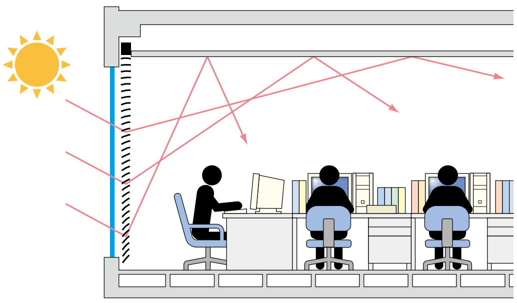

Figure 2. The direction of reflected sunlight in the case of Gradation Blind

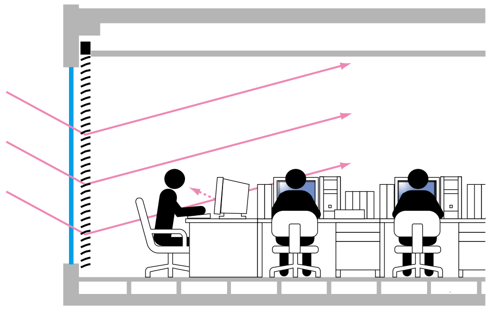

Figure 3. The direction of reflected sunlight in the case of conventional blind

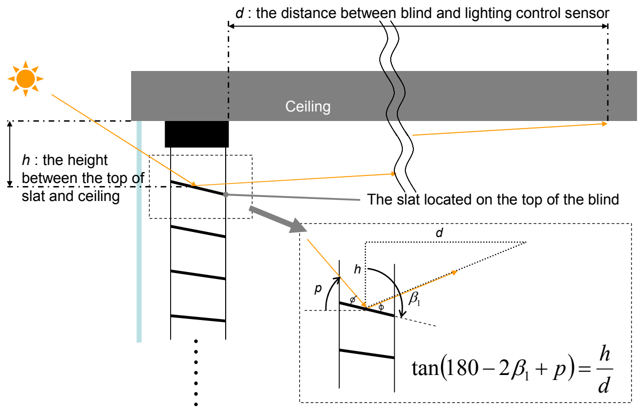

Figure 4. Calculation diagram of slat angle β_1

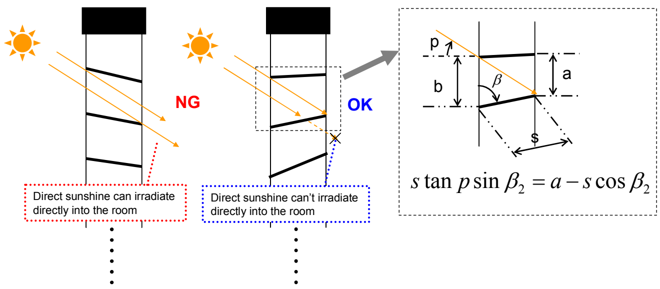

Figure 5. Calculation diagram of slat angle β_2

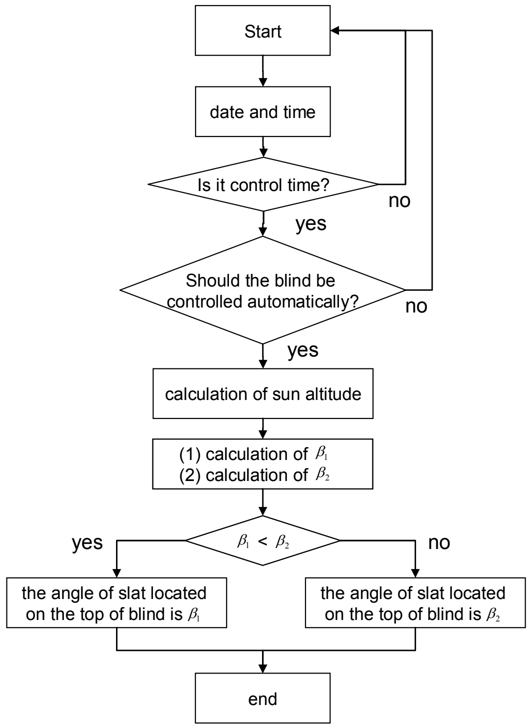

Figure 6. Operating flow of "Gradation Blind"

1.2. The effect of "Gradation Blind"

The following effects can be expected by introducing "Gradation Blind".

(1) Reduction in lighting energy
A further effect of the lighting energy saving is achieved by combining the fluorescent lights with a dimmer switch and "Gradation Blind". (Figure 7 shows that the difference of the brightness in the room between "Gradation Blind" and conventional blind. The room with "Gradation Blind" is brighter than that of conventional blind.)

(2) Securing of effect of shading and view
The view can be secured with the effect of the solar shading by introducing the "Gradation Blind" as shown in figure.

(3) Introduction of daylight into place away from window
The blind reflects more effectively the direct sunlight to the ceiling of a room than conventional blinds, because the slats of the blind are controlled these angles depending on solar position.

(4) Decrease of glare of fenestration
The distance from the fenestration that reflected light from the slat reaches person's eyes directly shortens more than conventional blind, and, therefore, feeling the glare decreases, as shown in the figure 2 and 3.

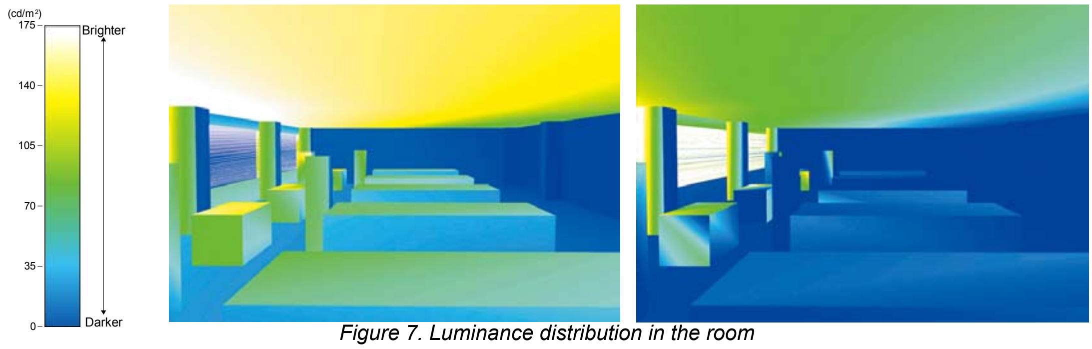

Figure 7. Luminance distribution in the room
The difference between "Gradation Blind" (left) and conventional blind (right)

Figure 8. Ability to view outside
The difference between "Gradation Blind" (left) and conventional blind (right)

2. Case study result in effect of energy saving by "Gradation Blind" introduction

2.1 Condition of model

(1) Shape of the model: shown in figure 9

(2) Condition of pane: float glass of thickness of 6mm

(3) Shape of fenestration: multiple window of 1.6m height as shown in figure 9

(4) Direction of building façade: south, north, east, west

(5) Window shade: Gradation Blind

(6) Range of lighting control: 6m from fenestration

(7) Design illuminance in the room: 750lx

(8) Date and time: 365days, 8:00-18:00 (using Japanese standard weather data at Tokyo)

(9) Lighting fixture: The electric energy is 98W per one lighting fixture. The lighting fixture can dim 25% of luminance flux at the lowest. The amount of power consumption when 100% lighting is 98W, and the amount of power consumption when 25% lighting is 37W. In the relation between the lighting control ratio and power consumption, from 25 to 100% in the lighting control ratio is the relations of linear, and the amount of power consumption is 37W at 25% or less. (Shown in figure 10)

Each of equipment was arranged as shown in figure and lighting fixture was controlled so that the illuminance on the desk in the room may become 750lx. The lighting consumption energy was calculated during year on the above-mentioned condition.

2.2 Calculation method

(1) Method of calculating the indoor illuminance with "Gradation Blind"

The illuminance in the room where "Gradation Blind" was set up was calculated with visual environment simulation software INSPIRER. 8 conditions of Gradation Blind, when the solar profile angle is 10, 20, 30, 40, 50, 60, and 70, 80 degrees, were calculated. And daylight factor was calculated.

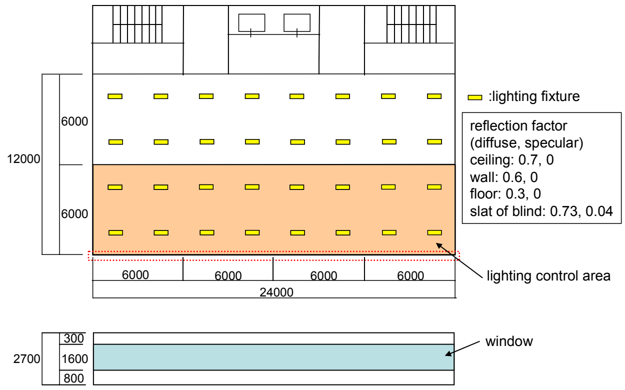

Figure 9. Calculation model (above: plan, below: elevation of façade)

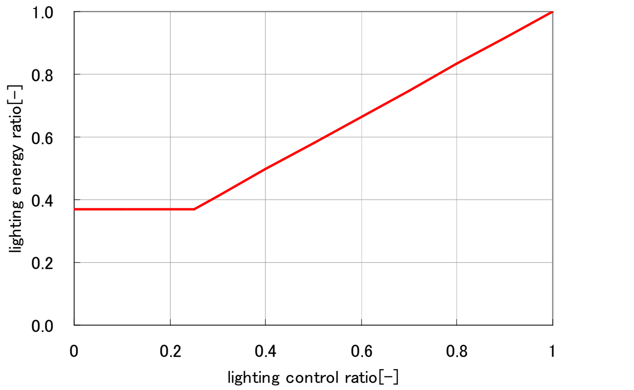

Figure 10. The relationship of lighting control ratio and energy ratio

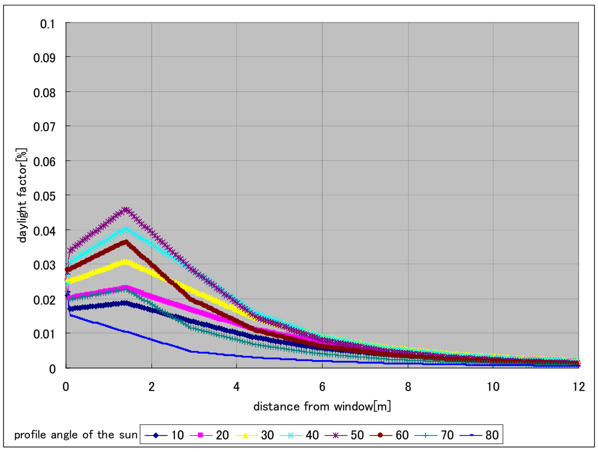

Figure 11. Daylight factor for direct sunlight

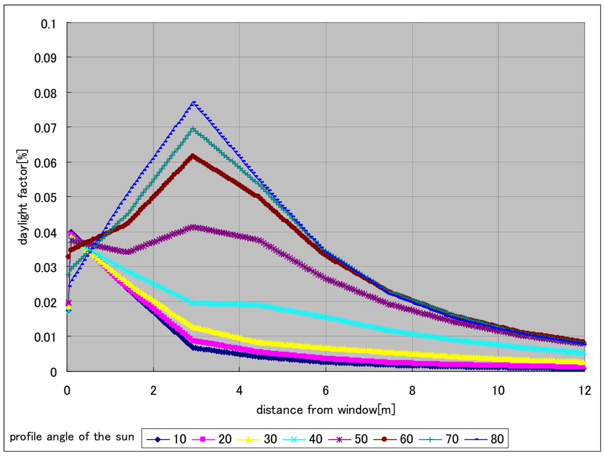

Figure 12. Daylight factor for diffused sunlight

The figure 11 shows the daylight factor when only the direct sunlight is irradiated outside the room at the condition of “Gradation Blind” when the sun’s profile angle is 10, 20, 30, 40, 50, 60, and 70, 80 degrees. The figure 12 shows the daylight factor when only the diffused sunlight is irradiated outside the room at the same condition. It seems that the illuminance in the room depend on solar altitude, because the Gradation blind is the lighting equipment that positively takes direct sunlight in the room. So the daylight factor was divided in the daylight factor of direct sunlight and the daylight factor of diffused sunlight. The daylight factor is calculated as a function concerning the distance from the window, and indoor illuminance is calculated by the following formulas.

$$E_N(x) = D_D(x)E_D + D_S(x)E_S$$

($E_N(x)$:illuminance in the room at the point x m away from window, $D_D(x)$:daylight factor for direct sunlight, $D_S(x)$: daylight factor for diffused sunlight, E_D: illuminance of direct sunlight, E_S: illuminance of diffused sunlight)

(2) Method of calculating lighting energy

The position of the sun of per hour is calculated during year, and the condition of the Gradation blind is judged. The annual indoor illuminance per hour is calculated by substituting the annual outdoor illuminance per hour for the above-mentioned formulas. The annual outdoor illuminance per hour is calculated by Japanese standard weather data. Because light is supplemented to reach the design illuminance by lighting fixture, illuminance by lighting fixture is calculated by decreasing the indoor illuminance by the daylight to the design illuminance. And lighting rate was calculated and lighting energy per hour during year, and then annual lighting energy was calculated.

2.3 Results and consideration

The results are shown in Figure 13 to 20.

(1) Difference by season of energy reduction rate

The energy reduction rate has risen for summer when the outdoor illuminance is large.

(2) Difference by azimuth in window of energy reduction rate

The energy reduction rate has risen more than facing north as for look souths when the north is compared with the south. This is because there is a lot of time that the look south takes light of firing directly than facing north, and the effect of Gradation Blind that can take light of firing directly is frankly shown.

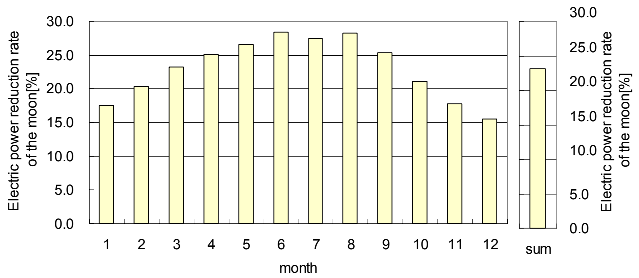

Figure 20. Electric power reduction rate (West façade)

3. New control system of the Gradation Blind

3.1 Outline of the system

Although it becomes a reduction in lighting energy when the daylight is introduced into the room, it is possible that the cooling load in summer increases by introducing a solar radiation. When the Gradation blind is introduced in the building, the same thing can be possible. Then the calculation function of the air-conditioning energy and lighting energy is given to the above-mentioned Gradation blind’s control logic. The air-conditioning energy and lighting energy are calculated from solar radiation and outside temperature. So this system needs the solar radiation sensor and outside temperature sensor. The figure shows that the system configuration.

The blind is controlled to introduce the daylight or prevent the solar radiation. The state of introducing the daylight is that the slat of blind is controlled according to solar position, and this state is assumed to be “daylight using state”. The state of preventing the solar radiation is that blind is all closed, and this state is assumed to be “closed state”. In the control system, sum of air conditioning energy and lighting energy at both stages is calculated. The system compares the two values, and decides which state is optimistic. If sum of air-conditioning energy and lighting energy at "daylight using state" (it assumed to be "E1") is smaller than sum of air-conditioning energy and lighting energy at "closed state"(it assumed to be "E2"), the blind is controlled to be a "daylight using state". On the other hand, E1 is bigger than E2, the blind is controlled to be a "closed state". As a result, the control that synchronizes with air-conditioning can be done, and a further effect of the energy reduction can be expected. The figure 22 shows the flow of control logic.

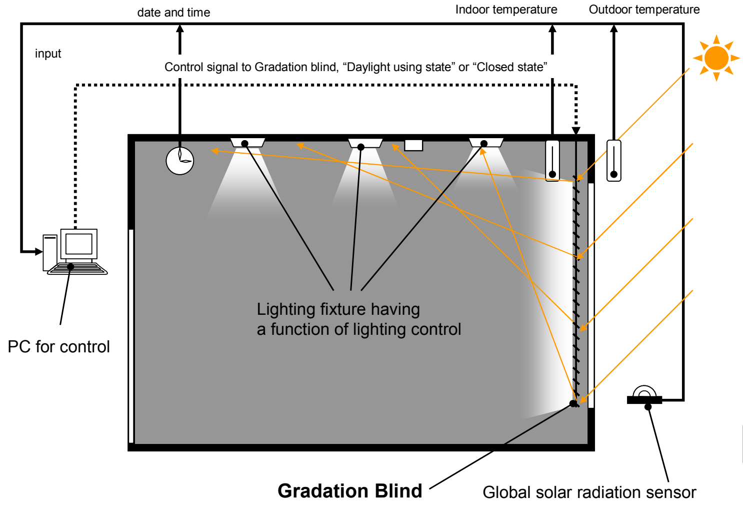

Figure 21. System configuration of new control system

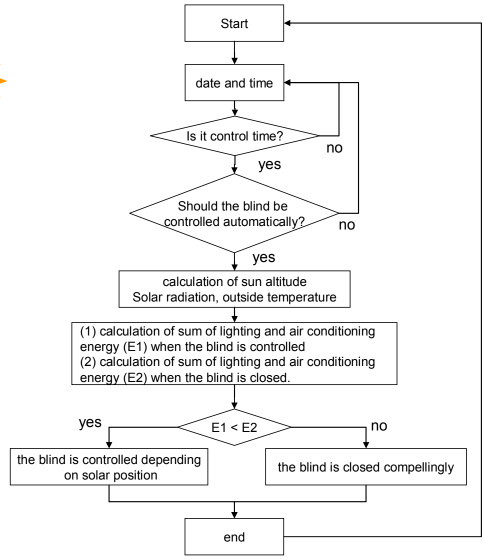

Figure 22. Operating flow of new control system

3.2 Method of calculating air conditioning and energy

Figure 23 shows the calculation flow of the air-conditioning energy and the lighting energy.

(1) The solar position is calculated by location data (altitude and longitude of the site), date and time.

(2) The flux of diffused solar radiation and the flux of direct solar radiation are calculated by solar position and flux of global radiation from the sensor.

(3) The air-conditioning load due to diffused solar radiation is calculated by multiplying the shading coefficient in each state of the blind and the flux of diffused solar radiation, and the load due to direct solar radiation is calculated by multiplying the shading coefficient and flux of direct solar radiation.

(4) The heat of transmission load is calculated by the outside temperature and the room temperature.

(5) The flux of solar radiation is converted into the outdoor illuminance, and lighting energy is calculated by the method where it describes in 2.2.

(6) The air-conditioning energy is calculated by dividing the sum of the air-conditioning load due to solar radiation, the heat of transmission load, and the lighting load (= lighting energy) with coefficient of performance (COP).

(7) Therefore, the sum of air-conditioning energy and lighting energy is calculated.

The solar shading coefficient is different with "daylight using state" and "closed state", and generally the former one is larger than later one. So the effect of preventing the solar radiation is considered. The lighting control is done when the blind is "closed state" because the lighting fixture has the lighting control function, so indoor illuminance was calculated by the daylight factor at the "closed state".

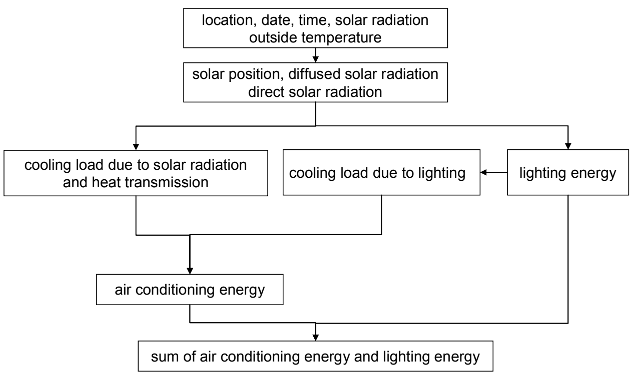

Figure 23. Flow of calculating the air-conditioning and lighting energy

4. Case study result in effect of energy saving by new control system introduction

4.1 Condition of model and calculation method

(1) Shape of the model: shown in figure 9

(2) Condition of pane: float glass of thickness of 6mm,

(3) Shape of fenestration: multiple window of 1.6m height as shown in figure 9

(4) Direction of building façade: south

(5) Window shade: Gradation Blind

(6) Range of lighting control: 6m from fenestration

(7) Design illuminance in the room: 750lx

(8) Date and time: August 30th 8:00-18:00 (using Japanese standard weather data)

(9) Lighting fixture: similar to 2.1

(10) Set point temperature: 26^{o}C

(11) Volume of outdoor air intake: 5m^3/h/m^2

(12) cooling load from lighting: 11W/m^2

(13) cooling load from office equipment: 18 W/m^2

(14) cooling load from occupancy: 12 W/m^2

(15) Coefficient of performance of the heat source: 1.8

(16) Control systems of Gradation blind and lighting: (system 1) Gradation blind is controlled to be "daylight using state" all time, and there is lighting control. (system 2) Gradation blind is closed all time and there is lighting control. (system 3) Gradation blind is closed all time and there is no lighting control. (system 4) Gradation blind is controlled by new control system and there is lighting control.

The conditions of calculation are basically similar to 2.1. The air-conditioning load is calculated by individually calculating each of the loads from the flux of solar radiation, occupancy, lighting, equipment, and the dehumidification load. Then air-conditioning energy is calculated by dividing the load with COP. The method of calculating lighting energy is similar to the method referred in 2.2. About the air conditioning and lighting energy consumed by "system 4", the energy consumed by system1 and the energy consumed by system 2 are compared at each time, and smaller one is adopted as a result of the energy consumed by system 4.

4.2 Results and consideration

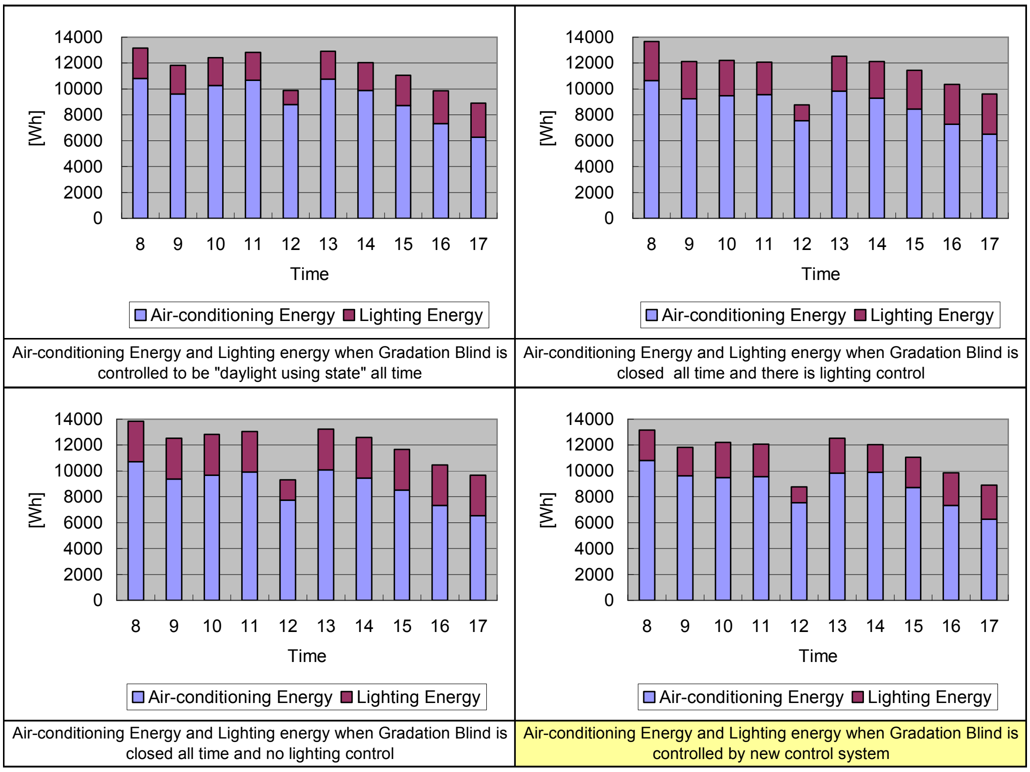
The Gradation blind is controlled to be "closed state" at 10:00, 11:00, 12:00 and 13:00. Because the air conditioning loads from solar radiation at these times are larger than other time, the differences between air-conditioning energy consumed by "system1" and that of "system2" at these times are bigger than the difference of lighting energy, then it becomes such result.

As for other time zones, air conditioning energy consumed by "system1" is larger than that of "system2". But the difference is small, because air-conditioning load from lighting consumed by "system1" is smaller than that of "system2". As a result, the Gradation blind is controlled to be "daylight using state".

As for the energy of the day multiplication, comparing the total energy (the sum of air-conditioning energy and lighting energy) consumed by "system 3" and that of "system 1", the effect of energy reduction of "system 1" is about 4%. Comparing the total energy consumed by "system 3" and that of "system 4", the effect of energy reduction of "system 4" is about 6%. Then, the improvement of the effect of the energy reduction of 2% was able to be achieved from a past control system by a new control system.

Table 1.Calculation results Air-conditioning and Lighting energy
: The total energy during 8/30

	Blind: closed no lighting control (system 3)	Blind: daylight using state light: controlled (system 1)	Blind: depends on the calculation of the energy Light: controlled (system 4)
Air-conditioning Energy	89352	93178 (1.04)	89080 (1.00)
Lighting Energy	29792	21720 (0.73)	23358 (0.78)
Sum of two kind of energy	119144	114898 (0.96)	112438 (0.94)



Air-conditioning Energy and Lighting energy when Gradation Blind is controlled to be "daylight using state" all time

Air-conditioning Energy and Lighting energy when Gradation Blind is closed all time and there is lighting control

Air-conditioning Energy and Lighting energy when Gradation Blind is closed all time and no lighting control

Air-conditioning Energy and Lighting energy when Gradation Blind is controlled by new control system

Figure24. Calculation results, Air-conditioning and Lighting energy: The change in a day

5. Conclusion

This paper shows a basic feature of the “Gradation Blind” and the system to control the blind the best condition to minimize the sum of lighting and the air-conditioning energy. Then the following conclusions are obtained.

(1) The lighting energy of the room that was installed Gradation Blind in window was lower in 24% than the room that was no lighting control.

(2) The sum of the air-conditioning energy and the lighting energy of the room that was installed Gradation Blind with ordinary control system was lower in 4% than the room that was installed no lighting control system and whose blinds are always closed, for a typical day of summer.

(3) The sum of the air-conditioning energy and the lighting energy of the room that was installed Gradation Blind with new control system was lower in 6% than the room that was installed no lighting control system and whose blinds are always closed, for a typical day of summer. And it is proved that the new control system of Gradation Blind was available for saving the total energy consumption of the building.

Acknowledgement

I got big cooperation at the stage of development from Mr. Kuwana and Mr. Wada (Yokota Co., Ltd). We would like to note the gratitude to their cooperation.

Keywords: Energy, Whole Building, Design

ABSTRACT:
Sustainability; physically and economically is to a large extent manifest in the habitat built form, it is the scientific temper that will lend a design methodology and process, in order to render Architecture sustainable. To achieve this; A ' Energy, Resource Flow – Ecological Foot Print' model is suggested which can help optimize input out-put parameters and their relationship. This leads to a process of design and various actual projects in response to critical issues. Thus suggesting **A New Language of Architecture**.

1.0 Preamble

Globally accepted definition of sustainable development is **"development that meets the needs of the present without compromising the ability of future generations to meet their own needs" (Brundtland Commission Report 1987).**

The beautiful blue planet that we co-habit with 70 million other species, our Mother Earth - is habitat for every species on the planet. While it is a dynamic Eco-system, it is finite: An eco-system that is driven by Sun, a regenerative resource

1.1 The Challenge:

Therefore the challenge for contemporary design is to use the regenerative solar spectrum and design a sustainable habitat within the capacity of the finite eco-system that is our Mother Earth.

Sustainable design must integrate consideration of resource and energy efficiency, healthy buildings and materials, ecologically and socially sensitive land use and an aesthetic sensitivity that inspires, affirms and ennobles, to achieve a culturally appropriate eco-settlement.

2.0 ENERGY, RESOURCE FLOW - ECOLOGICAL FOOT PRINT MODEL:

Human habitat a physical manifestation of socio-economic ecological context is the major consumer and generator of energy and natural, man-made resource. Energy-Resource Flow Model and presented below, illustrates the input-output relationships.

**This input-output intrinsic relationship determines the ecological foot-print: the community, city or the region / country – the ultimate determinant of sustainability.
Yet, central to this entire flow model is the habitat / building (refer figure- 2.1). It is both in the construction and operation of this habitat / building that energy-resource flow can be optimised.**

Outlining the criticality of planning and design of the habitat / building. Wherein, Climate-Responsive Architectural design and Ecological Planning become the determinants of energy-resource flow and offer a powerful tool for optimisation.

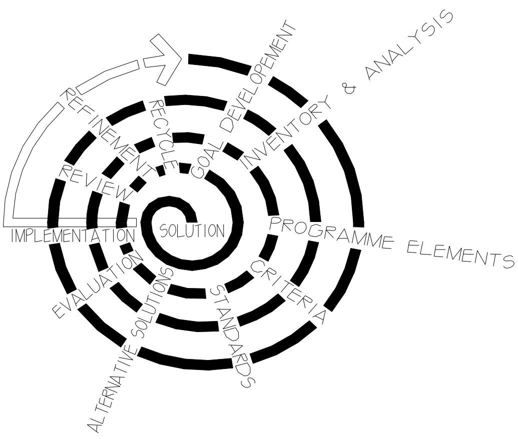
3. CLIMATE RESPONSIVE ARCHITECTURE - THE TOOL AND THE PROCESS:

This leads to defining a process of architectural design that is scientific and developed on an ecological basis.



Graphical Representation of Process

Process of architectural design is a complex exercise, involving interactive relationships between parameters of diverse nature and varying magnitude. Yet, it is the prime generator of architecture as we see and experience.
Various ideas have dominated architectural thought from time to time. Yet, the fundamental issue of energy as an embodiment of Sun, Wind and Light – the ecological context - have not been a basic paradigm of design..

The idea of climatically responsive design is to modulate the conditions such that they are always within or as close as possible to the band of appropriate ecological design.

Ecological Process of Design:
Based on this premise, a design decision making knowledge based expert system has been developed by the author and published in C*limate Responsive Architecture – A design handbook* [1] *(Tata McGraw Hill, New Delhi 2001)*

4.0 SOME CONTEMPORARY SOLUTIONS:

One single parameter that embodies the state and use of natural resources in their various forms is energy. Author presents some contemporary solutions that optimize energy use / consumption through architectural design.

- Design principles elicited from analysis of indigenous architecture and the scientific process of design have been translated into design of following modern buildings at various locations in the country with diverse ecological context.

4.1 What Possible Architectural Responses Can Be Evolved For A Composite Climate And The Context Of Urbanity Of Chandigarh, India ?

4.1.2 PEDA Office complex, Chandigarh, India

Located at Chandigarh, on a flat practically square site with no major topographical variations. Chandigarh as a city lies on the planes at the foot of ‘Lower Himalayas’, in a ‘Composite climate context’.

- With climate swings over the year i.e. very hot and dry period of almost two and a half months (Max. DBT 44 °C) and a quite cold period of shorter duration (Min. DBT 3 °C). The hot dry period is followed by a hot humid monsoon period (Max DBT 38 °C and Max R.H.90 %) of about two months with intervening periods of milder climate.

- Equally important, for Chandigarh is the context in space and time. Chandigarh, a bold experiment in city planning and architecture, was based on the professed ethos of design: ‘build with climate’.

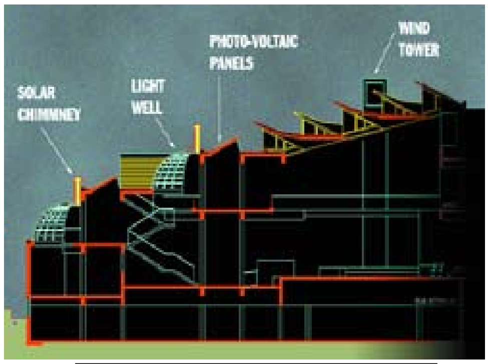


Fig.4.1.1 : Section

Fig. 4.1.2. OVERALL INTERNAL VIEW

- Building configuration has been generated in response to solar geometry, a unique built form thus generated in response to summer and winter requirements. Building form follows solar geometry, it does not follow any pre-conceived notion of design.

- **A holistic office design has been developed wherein the floor plates float in a large volume of air, and the building envelope interacts with the external conditions rather than the conventional stacking of floor plates one on top of the other where each floor plate is segregated.**

Fig. 4.1.3. SOLAR SHELLS DURING CONSTRUCTION AND ON COMPLETION

- **Fenestration design has been innovated as spherical 'solar Shells' in response to solar geometry.**
- A natural movement of air is achieved through a down draft wind tower coupled with vertical cut outs running through various floors with solar chimneys integerated with Solar shells allowing good movement of air.
- A well designed water-body in the center of the building provides a cooling element and restful environment.
- Atrium roof designed as Hyperbolic pre-fabricated units in response to solar geometry allows winter solar access and cuts of summer penetration. Allowing a very good day light distribution.

- ➢ Very good day-light distribution is achieved, thereby optimizing consumption of electrical energy.
- ➢ Architectural design strategies have resulted in fascinating architecture in response to solar geometry.
- ➢ Integeration of renewable energy systems. Building integrates Photovoltaic panels as an element of roof design, thereby generating its own energy.

4.2 Can We Evolve A New Language Of Ecological Architecture For An Innovative Institute?

Sardar Swaran Singh – National Institute of Renewable Energy, Ministry of Non-Conventional Energy sources, Government of India

Author was invited to participate in a limited competition for the above project. **An innovative architectural design evolving a language of ecological architecture presented by the author was selected by the jury for implementation of the project.**

4.2.1 Strategies for Planning and Design:

- Control of micro-climate of the site by generating a water-body drawn off the canal on rear boundary of site and by forestation of the site.
- Entire complex and each building designed as a climate responsive – solar passive building coupled with wind-towers and earth tunnels to maximize geothermal conditioning.
- Architectural design: the primary generator / tool for developing a low energy building design.
- Maximize environmental control through naturally conditioned laboratories and spaces.
- Maximize use of day light to minimize electricity consumption in day time.
- Couple evaporative cooling from water-body with building design.

Ecological Architectural Design of R&D Wings:

- R & D wing has therefore been designed to couple the naturally conditioned laboratories and spaces to the water-body through **Wind towers coupled with earth-tunnels to the laboratory and building spaces.**
- Domical light vault designed for adequate day-light distribution integrated with Solar chimney on domical vault coupled to wind towers.

Fig. 4.2.1: SECTIONAL PERSPECTIVE

4.2.2 Roof System:

- Roof forms the critical element of the building design since it attracts the maximum solar heat gain and can be used as an element to generate efficient day-light distribution.
- Hyperbolic Paraboloid used as the structural element for the roof to: Optimize on structural design and generate a form that responds to solar geometry i.e cut off summer radiative heat gai and allow winter heat gain.
- Double curved surface responds naturally to solar geometry cutting of solar heat gain due to summer sum and allowing penetration solar heat gain for winters.

4.2.3 Integration of Renewable Energy Systems:

- Solar chimneys integrated with building design for natural ventilation
- Photovoltaic panels sandwiched in translucent panels on the south facing central spaces for generating electricity and allowing penetration of diffused day light.
- Water management system to be coupled with entire building complex for recycling of water and waste management.

5.0Conclusion:

TO MY MIND DESIGN IS A VERY POWERFUL TOOL TO ACHIEVE BALANCE BETWEEN MAN AND NATURE

THE ONLY LIMIT TO WHAT ONE CAN DO IS ONES OWN IMAGINATION

SUSTAINABILITY AND THE BRITISH BRICK INDUSTRY

Michael Stuart DRIVER MA DipArch RIBA

Director, Brick Development Association Ltd, Woodside House, Windsor UK michaeldriver@brick.org.uk

Keywords: Brick, building, regulations, emissions, sustainability, construction.

Summary

During the 1990s it was clear that Sustainability would become an important issue for the Brick Industry. The case study will show how the Industry faced the challenge of proving its sustainability credentials and will look at the threats and opportunities that the current situation poses in the United Kingdom.

The study will discuss how the current regulatory regime in the UK has developed, investigating the inter-relationship of Government aspirations, research results, and manufacturing reality. It will report on how sustainability is being reduced to considerations of environmental assessment in the Code for Sustainable Homes published by the UK Government in 2007.

The study will conclude with an indication of the likely impact of the Code for Sustainable Homes on the design of dwellings and the knock-on effect on the Construction Products Industry in general and the Brick Industry in particular.

1. The UK Brick Industry

The United Kingdom brick industry produces 2.5 billion bricks per year from nearly 90 plants. It employs around 4,500 people and has a turnover approaching 550 million GBP. It is a well-established industry with many of the plants in rural locations where they are often the major employer in the area. Brick is a popular material, well liked by the public and appreciated by designers. 60% of the output is used in housing, 25% in repair and maintenance and the remainder in public projects, education, health and commerce.

Ten years ago "sustainability" was a word that was hardly part of the brick-maker's vocabulary but the growing awareness of sustainability in the industry and the impact that the introduction of sustainability assessment methods has had on the industry makes an interesting case study.

2. Sustainable Construction

The Building Research Establishment (BRE) at Watford made one of the earliest moves towards sustainable construction in the UK in the 1990s. The BRE assembled a set of elemental specifications for walls, roofs, floors and building components and then provided the relative environmental impacts of each one. In order to make the environmental assessment BRE created a database of the environmental profiles of the materials involved measuring each one against a range of impacts such as climate change, toxicity, fossil fuel and ozone depletion, levels of emission of pollutants and material for water extraction.

The brick industry was party to this operation and cooperated with the BRE in the production of a generic environmental profile for brick. The results of the study were published in the Green Guide and they became fundamental to the schemes for the environmental assessment of buildings produced by BRE.

3. The Brick Industry's Early Involvement with Sustainability

There is no doubt that this involvement with the BRE prompted the brick industry to take an interest in sustainability and in 2000 a Sustainability Working Group was set up. The Group was tasked with investigating ways that the industry could respond to the challenge of proving sustainability for the product to ensure that it did not suffer unduly in the market place. It was also to consider how the industry should respond to the challenge issued by the Government in its Sustainable Development Strategy of 1999 in which Trade Associations were invited to develop sector sustainability strategies that would provide a framework for sectors to assess their economic, environmental and social performance; identify areas for improvement in the light of future opportunities and threats; set targets and implement action plans to bring about their improvement and then to report back on the process to stakeholders.

In order to progress this the Government set up a Pioneers Group in which a number of Trade Associations were given the opportunity to develop a sustainability strategy for their own sector in conjunction with other associations. The Brick Industry accepted the offer and embarked on the Sustainability Trail – a journey that has already had twists and turns and certainly shows no sign of finishing.

The Government was clear that Sustainable Development was about delivering a better quality of life for everyone now, and for generations to come. The four key objectives of social progress, protection of the environment, prudent use of natural resources and maintenance of high and stable levels of economic growth and employment were seen as central to the enterprise. The brick industry refined the definition of sustainability into "the responsible use of resources be they human, physical, or financial". A number of measurable objectives were to be declared and responsibility shown by the willingness to report annually on progress towards the objective. These Key Performance Indicators were also to be reviewed annually so the activity of the industry was kept under scrutiny.

The industry declared 17 objectives; 4 under social progress, 4 under effective protection of the environment, 5 under the prudent use of natural resources, and 3 under the maintenance of high unstable levels of economic growth and employment. The spread across the 4 fields is important as it demonstrates that all aspects of sustainability are measured. As the story develops this broad spread is gradually focused into a narrow band that is concerned primarily with environmental aspects. One reason for this must be that this is where BRE started. Once you have developed a technique for producing an environmental profile and are using it as part of an assessment process then there is a temptation to continue working in that way. Another reason is that the UK Government has made commitments to reduce carbon emissions and inevitably efforts are intensified to achieve those targets. If they can be under the heading of "Sustainability" so much the better, even if it is in a restricted area of the concept.

However, the brick industry made its case across all aspects of sustainability. Probably the strongest point is that manufacturing is dispersed around the UK in factories located near the clay deposits. Hence it is possible to specify a material that is made locally reinforcing the aesthetic impact of buildings by using local materials and reducing delivery costs. The manufacturing process has received massive investment since 1990. The industry was well aware of the need to reduce energy costs long before sustainability became fashionable. Alternative sources of energy have been investigated and there are now factories fuelled by the methane gas taken off the land-fill that has been encased in exhausted clay pits. Although the industry is cited as an "intensive energy user" the reality is that the industry only consumes 1.5% of the total energy consumed by the UK manufacturing industry. The UK Government, working with the EU, now issues increasingly stringent targets for the reduction of energy use for individual industries. The brick industry has always met the targets imposed.

Beyond the factory gate brick contributes to the sustainability of the structure of which it is a part. It is extremely durable with little maintenance and will provide an attractive façade to a building almost indefinitely. It fulfils a variety of roles in building technology in providing physical support, security, protection from sound and fire, weather resistance and an appearance that is enhanced by age. Buildings built in masonry are easy to alter and adapt. We have examples of brick buildings entering a third or fourth life because they have been altered to accommodate new functions; the ability to change means that the initial investment is enhanced many times over.

Looking ahead, and considering the threat of global warming, it has been shown that as temperatures rise the heavy masonry structure with its high thermal mass will be able to moderate the effects of high temperature without recourse to air-conditioning. This is likely to be an important asset when the "future-proofing" of buildings is considered.

The Sustainability Strategy produced by the Brick Industry rehearsed the arguments outlined above. It was one of the first strategies to be produced by a sector working with the Pioneers Group but the context in which it had been produced was changing – something those of us concerned with sustainability are learning to get used to.

4. UK Building Regulations

Building Regulations in the United Kingdom have a long history that can be traced back to 1666 and the aftermath of the Great Fire of London. More recently the Government has used the Regulations to control all aspects of building, and especially the insulation of buildings through "Part L" of the Regulations. The idea being that if you increase the insulation in a building you reduce the amount of energy required to heat it. This simple idea had been refined by the introduction of SAP or Standard Assessment Procedure. This is a method of analysis that looks at not only the insulation of a building but also at solar gain, heat production, siting and orientation to achieve a better understanding of how each aspect contributed to the thermal efficiency of the building. It was a cumbersome tool but it was significant because it was the first time that the Regulations had acknowledged that there are many inter-dependent factors that contribute to the performance of the building. Basic insulation standards under Part L were also raised but as far as brick was concerned the insulation material could still be accommodated in the 75 – 100 mm cavity brick / cavity block wall or within the framing of a lightweight frame with brick as an external skin.

However, when Part L values were reviewed in 2001 it was made clear by the construction industry that the regular increase in performance standards was difficult to handle. What was required was a longer-term prediction of how values might move with a number of milestones along the way that gave a programme for implementation. This suggestion was to become part of the strategy behind the Code for Sustainable Homes.

5. The Building Industry and the Drive for Improved Efficiency

The efficiency of the building industry had been addressed in a number of reports that had been compiled in the 1990s. The Latham Report 1994 and the Egan Report 1998 proposed a number of measures to improve the situation but a common theme was that by removing construction from the site into the factory there would be worthwhile benefits. It was claimed that factory production would give greater accuracy, guarantee performance standards, and reduce construction waste. Site assembly rather than site production would give faster build times with predictable performance and fewer defects. This halcyon vision had been a reality in the 1960s when, in an effort to solve the housing crisis, the Government had backed the introduction of factory-produced site-assembled building systems. The point that we are still paying the price of this venture was ignored. There was faith that a more experienced industry would be able to make it work the second time around.

The prospect of “modern methods of construction” was seen as an opportunity not only to increase the number of dwellings built per year but also to ensure that they were technically superior to any mass housing produced previously. This was good news for the Government who were anxious to increase the rate of build from around 180,000 to 250,00 per year and also to ensure these homes were technically sophisticated.

6. The Code for Sustainable Homes

The upshot of all this activity was the publication in December 2006 of the “Code for Sustainable Homes”. This document claimed to herald a step change in sustainable home-building practice. Based on the proposition that in 2004 more than a quarter of the Uk’s carbon dioxide emissions came from the energy used to heat, light, and run our homes it concluded that it is vital to ensure that homes are built in a way that reduces the use of energy and harmful emissions. In addition to the reduction of CO_2 the Code also suggested standards for the use of water within the home and the collection of surface water, the promotion of health and well-being and the reduction of waste and pollution from materials as well as the sustainability of the materials themselves. Code compliance is voluntary but it is likely that assessment under the Code standards will be mandatory in the future. The key point is that the Code sets out six levels of performance so that industry is able to understand how the standards will change with time. These code levels each show an improvement in “carbon performance” when compared with the Target Emission Rate (TER) defined by the 2006 Building Regulations Standards.

- Level 1 shows a 10% improvement over 2006 TER
- Level 2 shows an 18% improvement over 2006 TER
- Level 3 shows a 25% improvement over 2006 TER
- Level 4 shows a 44% improvement over 2006 TER
- Level 5 shows a 100% improvement over 2006 TER
- Level 6 shows a “zero carbon” improvement over 2006 TER

When the “carbon performance” for a building is determined a number of credits are assigned to the building. Credits are also scored for:

- The environmental profile of materials used
- The predicted water consumption per person per day
- Means of controlling surface water run-off
- Facilities provided for minimising waste during construction and recycling / composting waste during habitation
- The limitation of the global warming potential of insulants and emissions of nitrous oxide from space and water heating systems
- The standard of daylight and sound insulation
- The quality of a management system for the building itself and the ecology around it

Each of the headings has a number of sub-headings that are also potential credit earners. The credits are converted to points by a multiplier that is different for each category and the code level is determined by the number of points achieved.

This system has much to commend it. It provides industry with a clear development path, it is flexible in that there is no one way of achieving a particular level, it considers the whole house and the way in which it is used, it is voluntary and therefore housing developers are able to gain market advantage by complying with higher code levels. It has stimulated debate and activity in an industry that has realised if the Government is to stick to its intention of requiring all new private sector homes to be Code level 3 by 2010, Code level 4 by 2013, and Code level 6 – zero carbon by 2016 there is no time to be lost.

Now that the dust has settled it has become clear that level 3 can be achieved by improving current standards, level 4 will require some innovation, especially with regard to renewable energy, and level 5 and 6 require some major shifts in the way energy is supplied to, and used, in the house. It appears that once the fabric of the house is able to achieve level 4, the higher levels will be achieved through other means.

7. Implications of the Code

A number of “demonstration” homes have been constructed at the BRE’s Innovation Park. Initially it was considered that conventional brick and block construction would not be able to provide the air-tightness required by the higher levels of the Code but this perception has proved false and it is the framed structures that are struggling to achieve the standards.

The debate about standards and methods of construction is vitally important to the masonry industry in general and the brick industry in particular. If there is wholehearted acceptance that the only way to solve the problems of constructing these homes is by lightweight frameworks manufactured off-site then its likely the designer will use alternative material on the external face. There is a temptation to go down that road, especially as it seems to offer the easy “quick-fix” solution.

However, there are also strong arguments, not just for the use of a brick / block solution, but also for a serious research programme to investigate the development of what is called “traditional” construction.

There are 180,000 homes built each year in England, Wales and N. Ireland. Of these some 15% are made from lightweight framing – so “traditional” construction is providing the bulk of homes. What is needed is a thorough examination of the “traditional package “. Greater efficiency could be achieved by rationalising the dimensions of brickwork and components, investigating ways of incorporating standard units, such as pre-fabricated floors and service pods, the use of wiring looms and prefabricated plumbing. There is also room for the development of alternative methods of insulation. Currently the solution to increasing the ‘U’ value of a wall is seen as making it wider to allow more insulation to be inserted. There is potential in vacuum insulation panels that would satisfy the most stringent code level in a thickness of 30mm. It would be a neat trick if the insulation became a positive element around which the building is built, rather than a void that is simply filled.

The assembly of brick and block will also need to be carefully considered. There are sufficient bricklayers to cope with the predicted increase in the provision of homes but the higher standards of air-tightness will demand that the work is carried out with greater care and attention to detail. There are also new techniques for providing brick / block walls. The “Hanson House” on the BRE Innovation Park has cavity walls assembled in a factory using glued mortar and delivered to site in large panels 2,400 x 5,000 mm. Thus combining the timeless qualities of brick with off-site techniques.

When the brick industry produced the original Sustainability Strategy, no one imagined that within a few years we would be involved in a project like the Code for Sustainable Homes. The irony is that in the Code the only aspect of sustainability that is considered in the material section is that of “Environmental Sustainability”. However, lurking in the Code is the possibility of points for Responsible Sourcing of Materials. Current thinking between BRE and the Trade Associations is that this is an area where credit will be obtained for an all-round approach to sustainability. Once more we will have the opportunity to demonstrate that the brick industry promotes “the responsible use of resources be they human, physical or financial”.

INTELLIGENT CONTROL FOR OPTIMIZING OCCUPANT COMFORT AND ENERGY CONSUMPTION IN BUILDING ROOM

Mir-Nasiri Nazim PhD

Swinburne University of Technology (Sarawak Campus), Sarawak, Malaysia, nnasiri@swinburne.edy.my

Keywords: fuzzy logic, energy saving, occupant comfort, intelligent blinds

Summary

The paper introduces the intelligent way of controlling light and cooling sources in the office to provide comfort for the room occupant using fuzzy control theory. The system is particular useful for the hot climate countries, such as Malaysia. The system under the control consists of motorized window blinds to monitor and control the amount of light and heat admitted into the room, the split air-conditioning unit to control the low temperature source inside of the room, and dimming device to control brightness of electrical bulb. The joint intelligent control of all three subsystems provides two goals simultaneously, comfort for the room occupant as well as minimum energy required for operation of internal light and cooling devices. The paper for the first time analyses and offers a solution for the problem of energy savings through optimizing simultaneously the energy consumption by electric light and air-conditioning devices. In the mean time the system autonomously provides comfort for the room occupant by offering an appropriate level of light and temperature.

1. Introduction

The fenestration system of a commercial building drives much of the building's energy consumption for heating, ventilating, air-conditioning and lighting. When exterior shading is inadequate, building occupants must rely on interior shading devices such as venetian blinds and shades for controlling the amount of light and heat that enters their offices. Even though such devices can make conditions more comfortable for building occupants, previous research has shown that venetian blinds are adjusted infrequently as indicated by Rubin (1978), Rea (1984), IESNA (2000), and that blinds and shades are usually set for worse-case conditions as indicated by IESNA (1999), Bordass (2001). When used correctly, shading devices can greatly reduce the amount of direct sunlight admitted into office space, substitute light with daylight, and thus reduce energy consumption. In order to achieve such energy-saving benefits from daylight, many fenestration systems with automated components integrated with daylight dimming systems have been developed. Most studies in building control were written by the architectural and natural environment community, such as Foster et al. (2001), Guillemin (2003), Lee et al. (1998) the primary focus was on energy- efficiency while user comfort was only subsidiary constrain in finding the optimal device states. Guillemin, for example, uses fuzzy rules to incorporate expert knowledge. Adaptation to user wishes is provided through tuning the fuzzy membership function by a genetic algorithm. Guillemin showed that energy savings of up to 20% compared to a manual system could be achieved. Hagras et al. (2003) focuses primarily on user-comfort. They also use fuzzy logic, but adaptation is done through automatic generation rules. They use a supervised learning algorithm that gets its input by interaction with the user, called *machine-user dialog,* but do not describe it explicitly. Rutishauser et al (2004) took a similar approach. The difference is that they use an unsupervised learning algorithm that does not require a special user interface. The training of the controller is done through normal interaction with building devices.

Al-Sudani et al. (2005) has used a simple approach to build the automated window blind system. They use several light dependent resistors to detect whether it is day or night and detect the position of the sun.

These resistors then send respective signals to the microprocessor and it, in turn, operate the servomotors to close, open or adjust the angle of blinds. The system also activates a dimmer to reduce the used internal light to save the energy. This method does not consider variation of internal temperature due to the blinds rotation. In more extensive research Trobec et al. (2005) have developed a system for managing the movable roller blind which is based on the alternative control approach. It contains two basic control loops for thermal and for lighting regulation. Each loop contains a cascade control with a fuzzy and conventional PID controller to provide a user set values of light and temperature. However these loops work independently .and the illumination control loop is given a priority. The roller blind is managed with illumination loop first and when the desired internal illumination level is achieved, the thermal loop takes over the control of the roller positioning. Within the illumination tolerance range (2 %) the thermal loop pushes the blinds as much as possible to follow the set-point temperature profile. Thus there is an error between the set-point temperature and actual temperature as well. This work does not consider the possibility of variation of internal temperature by adjusting the air-conditioning unit. The Center for Building Performance and Diagnosis (CBPD) Khee Poh et al. (2005) has developed intelligent workspace tools for the entire building data management. The center has also developed some strategies to support individual control over personal work space environment. The system is complex and expensive. It may be effective if implemented at earlier stages of building construction and utilities installation.

Present paper describes one goal approach, i.e. the monitoring internal temperature and the lighting in the separate office space through one single fuzzy controller which is able not only to control the blinds opening angle for light admission but also adjust the cooling power of split air-conditioning unit to achieve an acceptable level of temperature for occupants comfort.

2. System Modeling and Components Setup

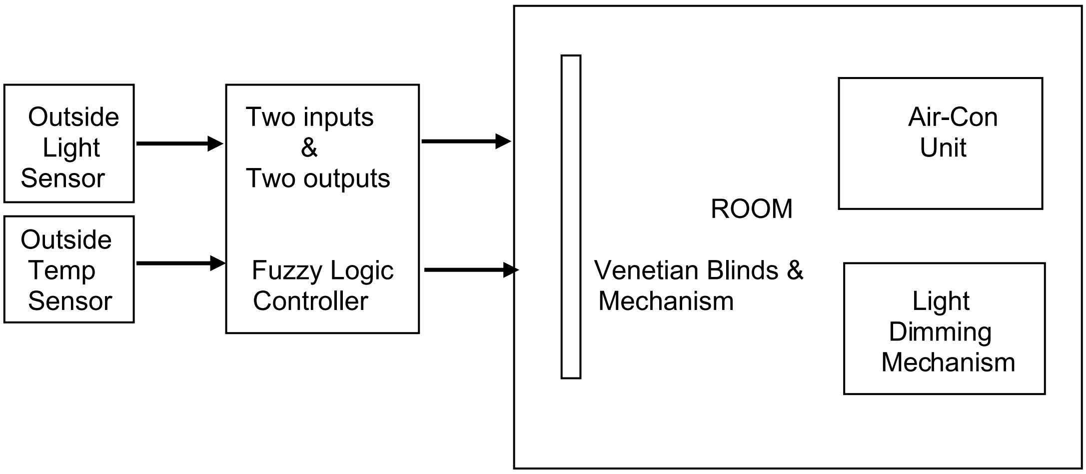

Figure 1 System Setup

This work is based on simulation of office room conditions and some assumptions are made. Figure 1 shows basic system components and their connections. The core of the system is fuzzy controller which receives real time analog data from two different sensors located outside of the room: one measures the amount of daylight and signals about night; the second provides outdoor temperature values. The fuzzy controller intelligently estimates the amount of light and temperature right outside of the room and outputs two simultaneous driving signals: one to the motors of the venetian blinds and light dimming mechanism; the second to the air conditioning unit. The comfort of the room occupant is provided by the fuzzy controller and expressed in the form of fuzzy sets and membership functions of input values as well as fuzzy logic rules of fuzzy inference system that forms the required outputs. This approach does not maintain approximately user selected values for the internal temperature or light as it was described by Trobec et al. (2005). Instead the system suggests by itself the range of acceptable room temperatures during the day by intelligently manipulating power of the air-conditioner and closing of the blinds. It also compensates for light shortage in the room due to the blinds closing by reducing the dimming of internal light in proportion to the blinds closing. To simulate the entire light and temperature management system and define the anticipated internal temperature as a function of a specific set of input variables a simplified mathematical model of heat conduction through the window glass and blinds material as well as heat convection form the window to the air conditioning unit, low temperature source, has been developed.

2.1 Mathematical Model of Room Temperature Distribution

A simplified model of heat transfer from the source of high temperature outside of the room down to the source of low temperature inside of the room can be represented in three different modes of operation:

1. Blinds are fully opened
2. Blinds are fully closed
3. Blinds are partially closed

In the first mode of operation, as shown in Figure 2a, the heat transfer and temperature distribution is due to conduction via the window glass and heat convection inside of the room. In the second mode of operation, as shown in Figure 2b, the heat transfer and temperature distribution is due to conduction through the window glass and blinds and then heat convection inside of the room. In the third mode of operation, as shown in Figure 2c, the heat transfer is combination of two conduction processes: the first conduction is through the glass only for uncovered areas of window and the second conduction is through both, the glass and blinds covering the glass. It generates the zone of mixed temperatures right after the blinds. The thermal system under the consideration is assumed to be a static one in which heat capacity of the materials involved into the process is not considered as well as time of the process is long enough to ignore the rate of change of temperature with time.

For the first mode of operation (Figure 2a) the equation of static temperature distribution can be derived by equating the heat flow through the glass and the convection through the air [13], i.e.

$$\frac{k_g \cdot A}{L_g}(T_{out} - T_g) = h \cdot A(T_g - T_a) \tag{1}$$

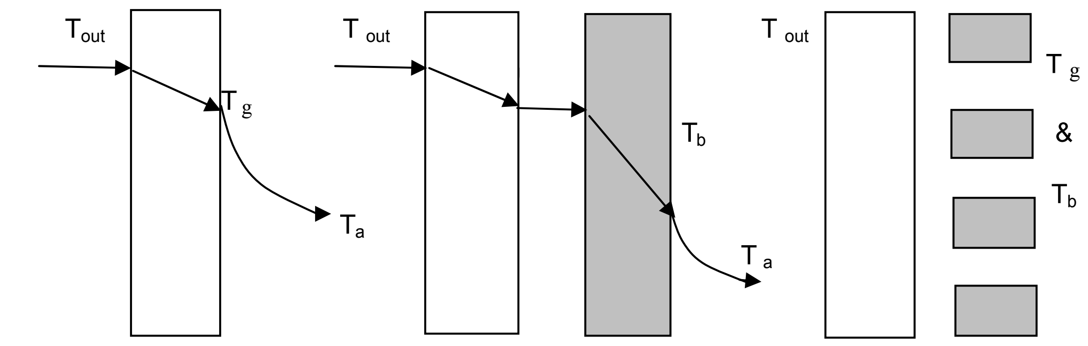
where: k_g is the thermal conductivity of glass , 0.81 W/(m· °K)
h is the free air convection coefficient, 18.0 W/(m^2· °C)
A is the active areas of widow glass
L_g is the thickness of the glass, 6· 10^{-3} m
T_{out} is the outer surface temperature on the glass
T_g is the inner surface temperature on the glass
T_a is the temperature of the free stream air at some distance away from the glass surface (temperature at air-conditioning unit at the other end of the room)

The equation (1) yields the following expression for the maximum possible inner surface temperature on the glass in case the blinds are fully opened:

$$T_{\max} = \frac{T_{out}(k_g / L_g) + T_a \cdot h}{(k_g / L_g + h)} \tag{2}$$

Substituting the numerical values of k_g, h, and L_g suggested for the simulation studies the equation (2) reduces to:

$$T_{\max} = \frac{T_{out}(15) + T_a(2)}{17} \tag{3}$$



a) Glass

b) Glass and Blinds

c) Glass and partially closed blinds

Figure 2 Heat losses through the window glass and blinds

For the second mode of operation (Figure 2b) the equation of static temperature distribution can be derived by equating, firstly, heat flow through the glass and fully closed blinds and, secondly, the heat flow through the blinds and the convection through the air [13] i.e.

$$\frac{k_g \cdot A}{L_g}(T_{out} - T_g) = \frac{k_b \cdot A}{L_b} \cdot (T_g - T_b) \tag{4}$$

$$\frac{k_b \cdot A}{L_b}(T_g - T_b) = h \cdot A(T_b - T_a) \tag{5}$$

where: k_b is the thermal conductivity of blind material (linoleum) , 0.081 W/(m· °K)
A is the active areas of widow glass and the blinds
L_b is the thickness of the glass, 6· 10^{-3} m
T_{out} is the outer surface temperature on the glass
T_g is the inner surface temperature on the glass
T_b is the inner surface temperature on the blinds
T_a is the temperature of the free stream air at some distance away from the blinds surface (temperature at air-conditioning unit)

Excluding T_g from two equations (4) and (5) yields the following expression for the minimum possible inner surface temperature on the blinds when the they are fully closed:

$$T_{\min} = \frac{T_{out}\left(\frac{K_g \cdot K_b}{L_g \cdot L_b}\right) + T_a\left(\frac{K_g}{L_b} + \frac{K_b}{L_b}\right) \cdot h}{\frac{K_g \cdot K_b}{L_g \cdot L_b} + \left(\frac{K_g}{L_g} + \frac{K_b}{L_b}\right) \cdot h} \tag{6}$$

Substituting the numerical values of k_g, k_b, h, L_g, and L_b suggested for the simulation studies the equation (2) reduces to:

$$T_{\min} = \frac{T_{out}(7.5) + T_a(11)}{18.5} \quad (7)$$

In the third mode of operation (Figure 2c) the temperature on the inner surface of the widow is assumed to be somewhere between two extreme temperatures, T_{min} and T_{maz}. If P is the percentage of blinds opening then the actual temperature at the inner window surface can be approximated as a composition of two extreme temperatures and can be represented by the following expression:

$$T_w = T_{min} + P \cdot (T_{max} - T_{min}) \quad (8)$$

In the expression (8) P can vary from 0 (fully closed blinds to 1 (fully opened blinds). It means that T_w is directly proportional to the percentage of blinds opening.

For the purpose of temperature and light controller simulation the check point for temperature control is selected somewhat away from the inner window surface where the room occupant is assumed to be physically located. The temperature at this point should be somewhere between T_w and T_a due to further losses of heat in the room itself. Actual drop of temperature is a non-linear function of distance from the window. To simplify the analysis the drop of temperature is assumed to be a linear function of distance from the window and to minimize the error we assume only 20 % of drop of temperature from T_w down to T_a, i.e. consider a point of interest to be closer to the window (T_w) rather than to the air-conditioning unit at the end of the room (T_a). The following expression takes into the account the temperature calculation for the point of interest T_p and it is used as output temperature for the process simulation:

$$T_p = T_w - 0.2 \cdot (T_w - T_a) \quad (9)$$

2.2 Fuzzy Logic Controller Design

The fuzzy controller receives light and temperature signals, estimates them carefully based on selected fuzzy sets and membership functions of two inputs, passes it through fuzzy inference system where the process of mapping from a given input to an output takes place, and finally by aggregating and defuzzifying all outputs the controller generates two appropriate signals to control indoor devices. The occupant comfort, i.e. acceptable level of internal light and heat is controlled by the controller's fuzzy logic rules. General components of the designed fuzzy logic controller are shown in Figure 3.

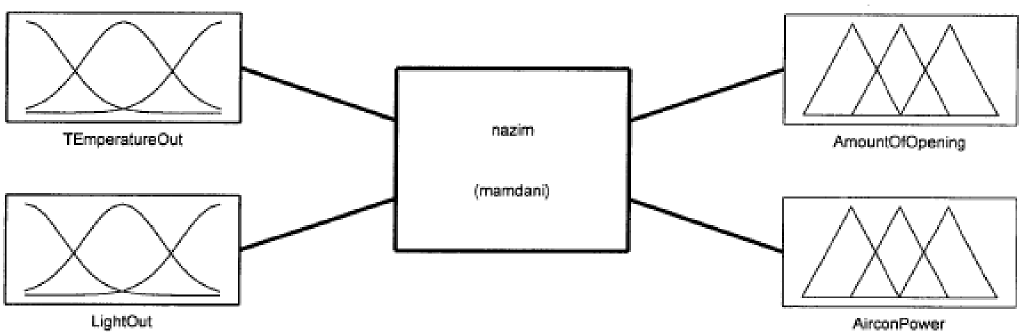


Figure 3 Components of Fuzzy Controller

The fuzzy sets and membership functions of the input 'Temperature Out' is shown in Figure 4. The range for the output temperature has been selected to be from 20°C to 50°C Similarly membership functions for the input 'Light Out' and two outputs 'Amount of Opening' and 'Air-Con Power' have been selected to be either trapezoidal or triangular shapes. The 'Air-Con Power' is set to vary temperature from 10°C (high power) to 25°C (lower power) in the fuzzy controller.

Fuzzy inference system of the designed fuzzy controller, i.e. the process of formulating the mapping from a given input to an output using fuzzy logic is based on Mamdani method. In general, it consists of fuzzifying current inputs by determining the degree to which they belong to each of the appropriate fuzzy sets via membership functions; applying fuzzy operator AND for each rule to obtain one number that represents the result for that rule; applying implication method for each rule to obtain an appropriate output fuzzy set reshaped according to the number generated by previous step; aggregate all outputs from all the rules, i.e. to obtain the list of truncated output functions and their single aggregate fuzzy set; applying defuzzification process to extract a single number as an output from the aggregate fuzzy set . The single number is the location of centroid of area under the aggregate fuzzy set shape. The fuzzy logic rules forms a basis for the designed fuzzy inference system and defines linguistically the degree of human perception between the outside light and heat on one hand and the necessary amount of blinds opening and air-con power control on the other hand

The three-dimensional surface that shows the interrelation between the two inputs and one of the outputs is shown in Figure 5. It shows that the higher percentage of blinds opening (close to 0) falls on the regions where the outside light is relatively high (close to 1) and the outside temperature is relatively low (close to 20 °C).

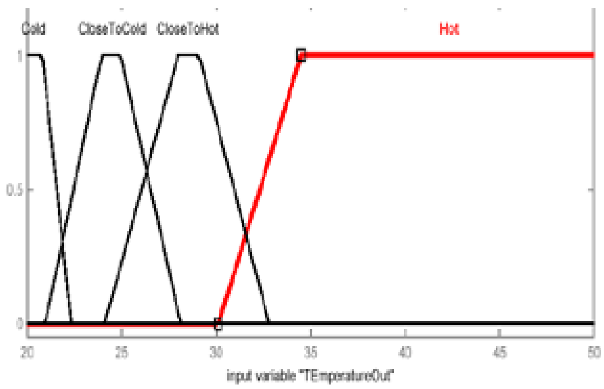

Figure 4 Membership functions of the input Temperature Out

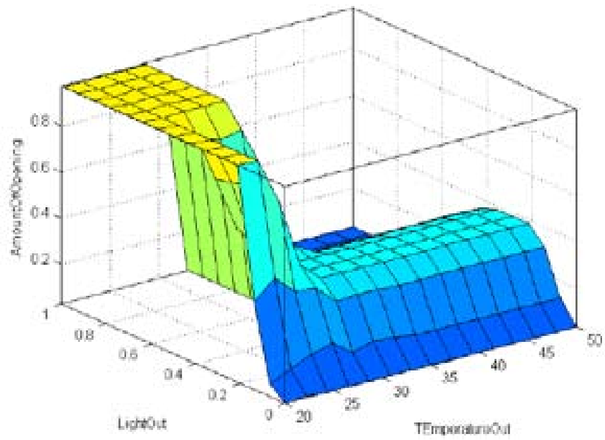

Figure 5 Fuzzy surface

3. System simulation using MATLAB Simulink

The entire block-diagram of the simulation is shown in Figure 7. The two inputs to the fuzzy controller 'Temperature Out' and 'Light Out' (Figure 6) are presented by trapezoidal function to approximate the change of outside temperature and light conditions during the day time. The ascending portion of the trapezoidal signal represents the rise of the light and temperature values from early morning till afternoon, and the descending portion of the signal represents the fall of that from late afternoon till full night. In the middle of the day both signals from outside of the room remain constant and high in values. The simulation is conducted for the duration equivalent to 12 hours of day time. The output signals generated by the controller, i.e. fraction of blinds opening and required temperature at the air conditioning unit, are entered to the thermal processing potion in the simulation block diagram. This potion of block diagram simply executes all necessary thermal calculations using formulas (3), (7), (8), and (9). There are two types of outputs from this simulated system. The 'Tem Window Adjusted' output controls variation of temperature value at the point of interest in the room during the day. The 'Bulb Brightness' output controls variation of bulb power during the day from 0 to 1, where 0 means the bulb is off and 1 meant the bulb is at its maximum brightness. The increase in the bulb power is inversely proportional to the blinds opening. The simulation was conducted for two distinct weather conditions:

i) Sunny day, when the temperature rises in the simulation experiment from 20°C (night) to 50°C (noon) and the brightness of daylight rises from 0 (night) to 1 (noon)
ii) Cloudy day, when the temperature rises in the simulation experiment form 20°C (night) to 32°C (noon) and the brightness of daylight rises from 0 (night) to 0.75 (noon)

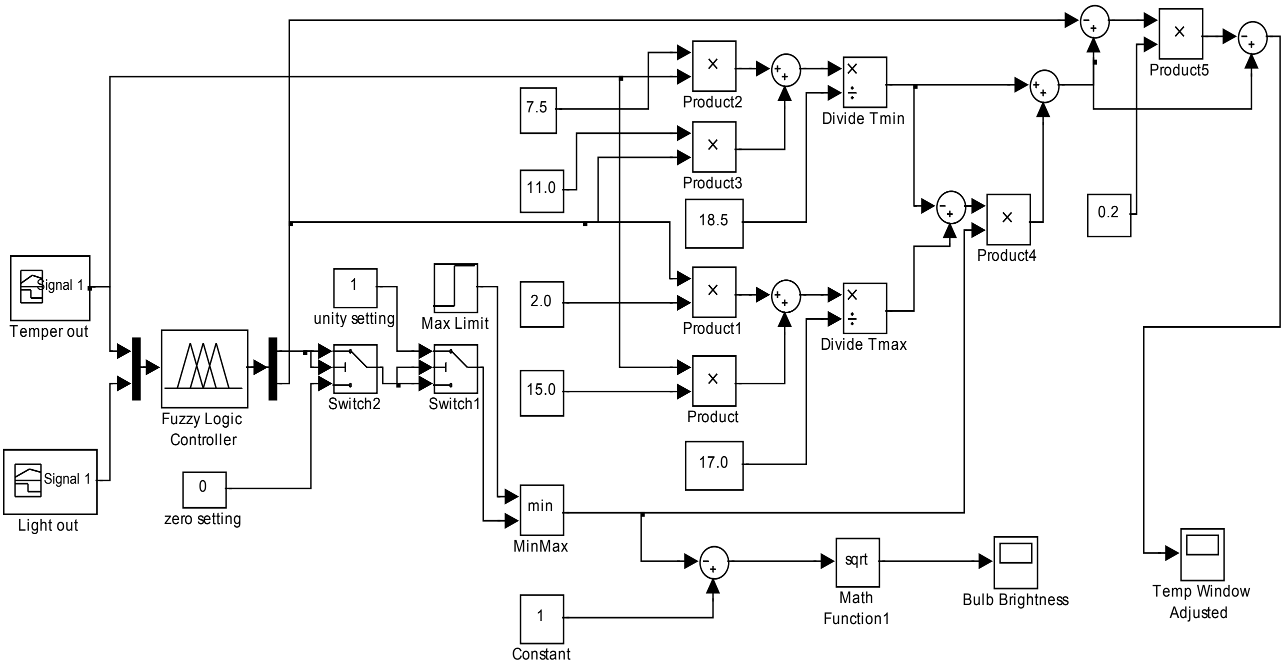

Figure 6 Simulink block diagram

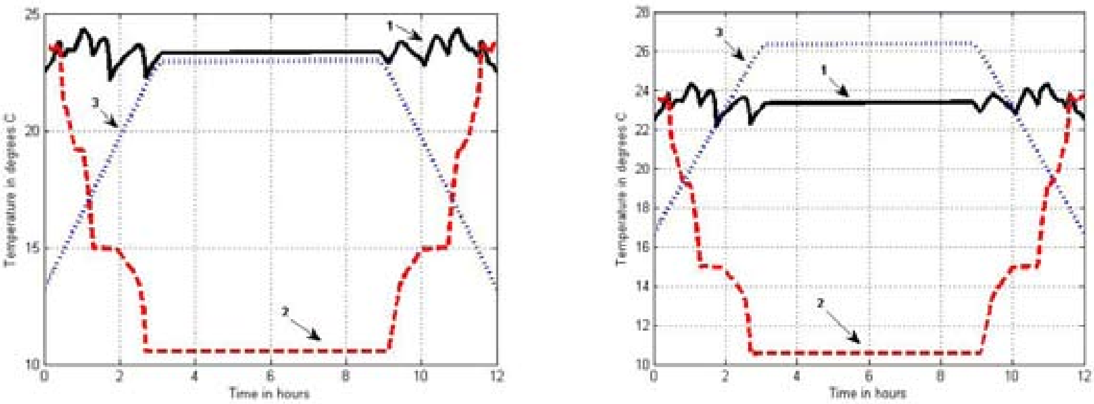

(a) (b)

Figure 7 Results of temperature control simulation for hot day

For the first weather condition the temperature simulation results are shown in Figures 7a and 7b. The first curve in both graphs demonstrates the variation of temperature at the point of interest due to the controller action. The second curve demonstrates the variation of temperature at the air-conditioning unit due to the controller action during the day. The third curve is used to compare it with the first curve. It demonstrates possible variation of temperature at the point of interest in case the controller is disabled, the blinds are fully closed and the air-conditioning unit set to produce one temperature of 10°C in Figure 7a and 15°C in Figure 7b. The controller demonstrates its advantage by maintaining one single value of the temperature (around 23°C) regardless of temperature variation outside of the room. In contrast, in case of room without the controller the temperature during morning and late afternoon time is much lower than comfort level (between 14°C and 22°C) as shown in Figure 7a and it rises above the comfort level (26.5°C) during the noon time as shown in Figure 7b. The second curve in both figures shows the energy savings due to variation of air-conditioning unit temperature by the controller especially during morning and late afternoon periods. Similar results have been obtained for the cloudy day simulation, i.e. in the second case, as is shown in Figure 8. The third curve in both figures demonstrates possible variation of temperature at the point of interest for the case when the controller is disabled, the blinds are fully closed and the air-conditioning unit set to constant temperature of 10°C (first figure) and 15°C (second figure). These figures indicate that in case of temperature control mode the room temperature still remains stable and it is about the same value of 23°C. However, for the uncontrolled conditions the room temperature drops significantly below the comfort level (curve 3).

Figure 9 shows the variation of power consumption by the light bulb in the room during the simulated sunny and cloudy days. The controller successfully manages to admit day light into the room not only during the morning and late afternoon periods for hot and sunny day (Fig. 9a) but during the noon time for cloudy day (Fig. 9b). In both conditions the temperature automatically sustained at the occupant's comfort level.

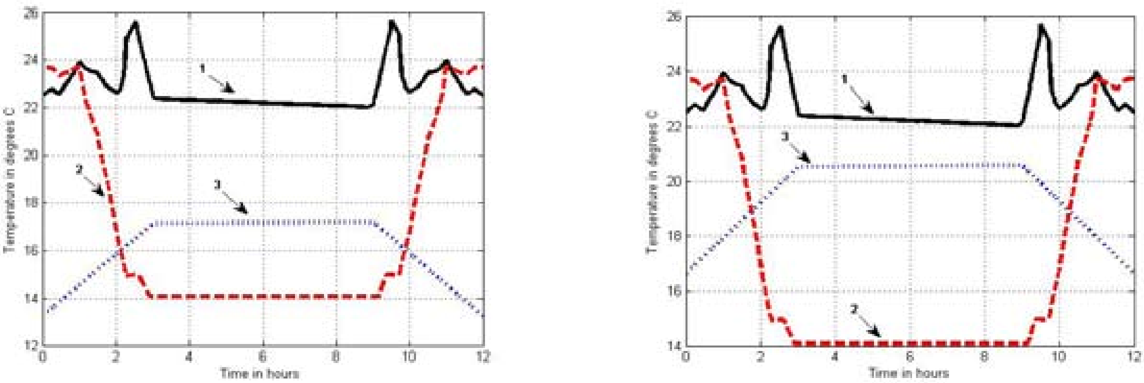

Figure 8 Results of temperature control simulation for cloudy day

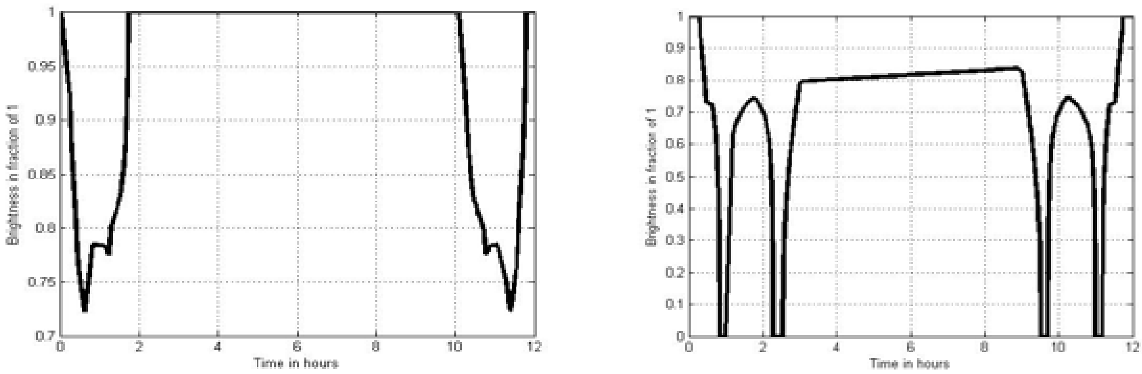

(a) (b)

Figure 9 Results of bulb control simulation for hot and cloudy days

Finally, Figure 10 demonstrates the ability of the system to manage internal temperature and light for changing weather conditions during the day. The temperature variation outside is similar to the third curve in Figure 10. That means the system was tested against sunny day at the beginning and end of the day and against cloudy condition in the middle of the day when the intensity of light and heat has been diminished by the clouds. As the figure shows the system could maintain the temperature at about the same level inside of the room and in the meantime has reduced the use of bulb light by opening the blinds during the midday.

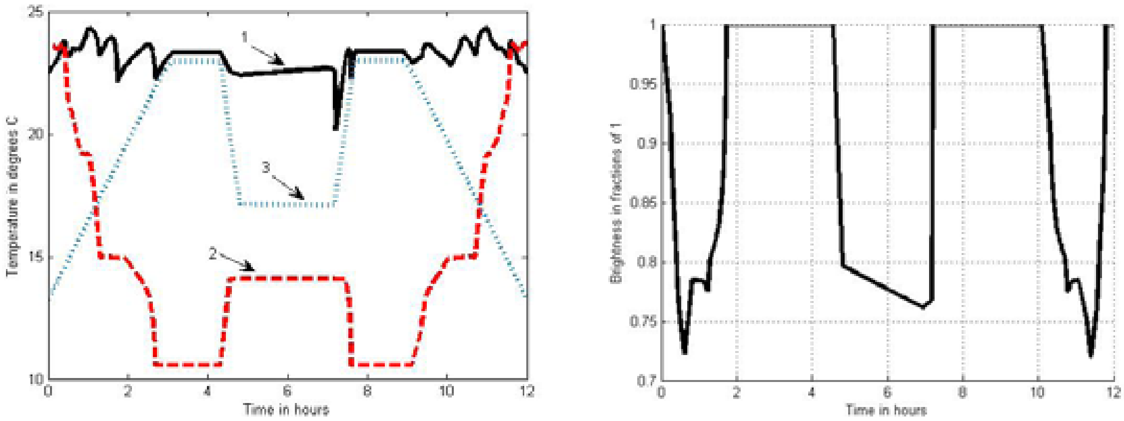

Figure 10 Results of temperature and bulb control simulations for combined hot and cloudy day

4. Conclusion

The paper describes the new concept of temperature and light control in a room. It is able to provide temperature and light comfort for the occupant as well as energy savings for the optimal building energy management. The core of the system is a fuzzy controller that provides comfort and energy savings through properly selected fuzzy rules in the fuzzy inference system. This system by itself generates and successfully maintains the acceptable levels of temperature and light in the room by manipulating with window blinds, light dimming mechanism, and temperature of the air-conditioning unit in response to changing weather conditions outside of the room. The mathematical simulation of the system in a hypothetical room for two distinct weather conditions (sunny and cloudy) obviously demonstrates advantage of the designed system as compared to non-controlled or manually controlled room conditions. Energy savings are accumulated from the intelligent variation of energy consumption by the air-conditioning unit and the light bulb during the day.

Keywords: moisture buffering, passive control, numerical simulation, indoor air quality, energy consumption

Summary

Taiwan is located in a sub-tropical climatic region. The hot and humid climate in Taiwan provides a fertile environment for microbe contamination sources such as fungi and mold, and leads to significant microbial pollution. A moisture buffering effect that provides passive moisture control by using interior materials with large internal surface area was proposed as an effective way to alleviate such dampness problems and improve IAQ (Indoor Air Quality). In this paper, numerical simulations including heat/moisture transportation inside the interior materials are carried out to evaluate the adsorption/desorption phenomenon quantitatively. Indoor air temperature, humidity and energy consumption analysis are carried out to study the moisture buffering effect and energy impact of interior materials in three major Taiwanese cities.

1. Introduction

Many indoor air pollutants have been extensively studied during the past decade. In recent years, issues concerning health problems related to dampness in buildings have been widely reported in Europe and America. Taiwan is in a sub-tropical climatic region. The mean annual relative humidity is over 75% in Taipei, Taichung and Kaohsiung, three major cities in Taiwan, with monthly average values for each month exceeding 70% (Central Weather Bureau of Taiwan). Dampness in buildings can lead to significant respiratory symptoms and damage to buildings. Indoor humidity can affect a building¡s energy consumption and its structure, as well as the occupants¡ comfort and health (Andrade, C. et al. 1999 and Bornehag, C.G. et al. 2004). In some related studies, a moisture buffer effect that provides passive moisture control (reductions in peak humidity levels outside the humidity comfort zone) using interior materials was proposed as an effective way to alleviate such dampness problems in humid climates (Hameury, S. 2005 and Osanyintola, O.F. et al. 2006). In this paper, numerical simulations including heat/moisture transportation inside the interior materials were carried out to evaluate the adsorption/desorption phenomenon quantitatively. Indoor air temperature, humidity and energy consumption analysis were carried to study the moisture buffering effect and energy impact of interior materials in the three main cities in Taiwan.

2. The Simulation Model and Boundary Conditions

2.1 The Simulation Object and Method

In this paper, a single room in a residential building was used as the simulation object. The room dimensions were 3.30 x 5.70 x 2.40 (meters) [L×W×H] (area: 18.81 m^2; volume: 45.144 m^3). Outdoor temperature and humidity were defined by typical annual weather data (typical meteorological years) for Taipei, Taichung and Kaohsiung cities in Taiwan (Lin, H.T. et al. 2005). Table 1 shows the boundary conditions and physical properties of the interior materials. The room was assumed to be occupied only at night (20:00 ~ 08:00), heat and moisture generated indoors were set as 203 W and 160 g/h, which included sensible and latent heat generated from two occupants and a sensible heat load for lighting. During the day (08:00 ~ 20:00), the

Table 1 Boundary Conditions and Physical Properties of Interior Materials

Boundary Conditions			
Room dimensions	L 3.30m × W 5.70m × H 2.40m (Area: 18.81m^2, Volume: 45.144m^3)		
Ventilation conditions	Daytime (08:00~20:00): 22.57m^3/h (ACH=0.5 times/h) Nighttime (20:00~08:00): (ACH=3 times/h)		
Mesh division	20 equal portions (Material thickness: 20 mm)		
Heat transfer coefficient of surface	9.3 W/m^2/K	Difference scheme	Crank-Nicolson
Mass transfer coefficient of surface	1.26 x 10^{-2} kg/m^2/s/(kg/kg)	Time step	1 second
Air-conditioning system	No heating. Cooling room air to 26°C when room temperature exceeds 26°C at night.		

Physical Properties of Interior Materials		
Material	Plywood	Gypsum Board
Net density (kg/m^3)	600	680
Specific heat (J/kg/K)	1,300	870
Thermal conductivity (W/m/K)	0.15	0.24
Porosity (m^3/m^3)	0.57	0.68
Vapor conductivity (kg/m/s/(kg/kg))	4.355 x 10^{-6}	1.03 x 10^{-5}
κ (kg/m^3)	Curve approximation (Figure)	
v (kg/m^3/K)	3.56	0.618

room was assumed to be unoccupied, thus no heat or moisture were generated indoors. An air-exchange rate of 3 (times/h) is used at night, and 0.5 (times/h) during the day.

A program written by the authors based on Finite Difference Method (FDM) was used, and the validity of the program was verified in a benchmark test performed by the Architectural Institute of Japan (AIJ). In the simulation, both gypsum and plywood with a thickness of 20 mm and area of 18.81 m^2 were considered as the interior material. The simulation cases carried out are shown in Table 2, which includes weather data for the three cities and three kinds of interior surface (without material, gypsum board and plywood).

Note that in this paper, the main issue is to study the affect of the interior materials, thus heat transmission via the outer walls was not taken into account at this stage. Therefore, the wall surface of the room was defined as completely insulated in terms of heat and humidity except for the adsorption/desorption of the material surface.

2.2 Diffusive and Adsorptive Transportation in Material

Heat and vapor transportation inside the material was described using Matsumoto¡s model (Matsumoto, M. et al. 1990/91). This model assumes humidity under hygroscopic conditions. That means transportation of free or capillary water in the material can be ignored, and only vapor transfer and bound or hygroscopic water are taken into account. In the model, temperature T (K) and absolute humidity X have been chosen as the heat and vapor transport potentials. The governing equation for unsteady-state isothermal vapor transfer through a porous material is given as Fick¡s second law and the mass transfer caused by adsorption/desorption, as shown in Equation 1 in one dimension.

$$\Phi\rho_{air}\frac{\partial X}{\partial t}=\frac{\partial}{\partial x}\left(\lambda'_X\frac{\partial X}{\partial x}\right)-\left(\rho_{mat}\frac{\partial\theta}{\partial t}\right) \tag{1}$$

Where Φ (m^3/m^3) is the porosity of the material, λ'_X (kg/m/s/(kg/kg)) is the mass conductivity of vapor, ρ_{mat} (kg/m^3) is the net density of the material, and θ (kg/kg) is the liquid water content of the material.

The governing equation for heat transfer through a porous material layer is assumed to follow the second law of Fourier and the latent heat caused by adsorption/desorption, as shown in Equation 2.

$$C_{mat}\rho_{mat}\frac{\partial T}{\partial t}=\frac{\partial}{\partial x}\left(\lambda\frac{\partial T}{\partial x}\right)+r\left(\rho_{mat}\frac{\partial\theta}{\partial t}\right) \tag{2}$$

Where $Cmat$ (J/kg/K) is the specific heat of the material, λ (kW/m/K) is the thermal conductivity of the material, and r (kJ/kg) is the latent heat of vapor.

To close the moisture transfer system of equations, the phase equilibrium equation for the material has to be given. According to the assumption that the rate of adsorption becomes equal to the rate of desorption and thus an equilibrium is achieved in the material, the relationship can be described by Equation 3,

$$\rho_{mat}\frac{\partial\theta}{\partial t}=\kappa\frac{\partial X}{\partial t}-\nu\frac{\partial T}{\partial t}\quad,(\kappa=\rho_{mat}\frac{\partial\theta}{\partial X},\nu=-\rho_{mat}\frac{\partial\theta}{\partial T}) \tag{3}$$

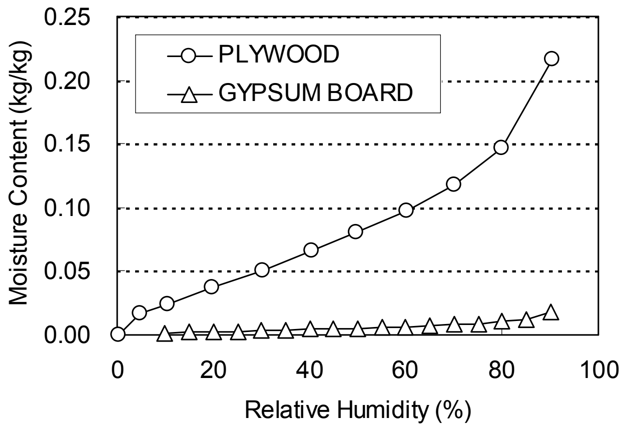

Figure 1 Equilibrium moisture content of materials at 23°C

Table 2 Setting of Simulation Cases

Case	Weather	Interior Material
Case TP0	Taipei City	None
Case TP1		Plywood
Case TP2		Gypsum Board
Case TC0	Taichung City	None
Case TC1		Plywood
Case TC2		Gypsum Board
Case KH0	Kaohsiung City	None
Case KH1		Plywood
Case KH2		Gypsum Board

and the term of adsorption/desorption can be given by the equilibrium moisture content at various temperatures and relative humidities (sorption isothermals) as shown in Figure 1. The equilibrium moisture content of gypsum board was measured by Kato et al. (2005), and that of plywood was determined from documentation (International Energy Agency, 2001).

2.3 Simulation of Room Temperature and Humidity

For room air simulation, a well-mixed indoor air (complete diffusion) is assumed to simplify the calculation. The heat and moisture transfer equations based on the law of conservation of enthalpy and mass for indoor air are written as:

$$VC_{air}\rho_{air}\frac{\partial T_{in}}{\partial t}=\sum_i \alpha^i A^i\left(T_S^i-T_{in}\right)+q_{OA}C_{air}\rho_{air}\left(T_{OA}-T_{in}\right)+q_{SA}C_{air}\rho_{air}\left(T_{SA}-T_{in}\right)+G_H \tag{4}$$

$$V\rho_{air}\frac{\partial X_{in}}{\partial t}=\sum_i \alpha'^i A^i\left(X_S^i-X_{in}\right)+q_{OA}\rho_{air}\left(X_{OA}-X_{in}\right)+q_{SA}\rho_{air}\left(X_{SA}-X_{in}\right)+G_X \tag{5}$$

Where V (m^3) is the room volume, C_{air} (J/kg/K) is the specific heat of the room air, ρ_{air} (kg/m^3) is the density of the room air, T_{in} (K) is the room temperature, α (W/m^2/K) is the heat transfer coefficient of the material surface, A (m^2) is the area of the interior material, q (m^3/s) is the ventilation rate, G_H (W) is the heat generation rate, X_{in} (kg/kg) is the room absolute humidity, α' (W/m^2) is the vapor transfer coefficient of the material surface, G_X (kg/s) is the vapor generation rate, subscript i indicates a different inner surface, S indicates the material surface, OA indicates outdoor air, and SA indicates supply air from the air-conditioning system. The vapor and heat transfer between the surface of the material layer and ambient air is governed by the boundary conditions shown as

$$\lambda\frac{\partial T_{mat}}{\partial x}=\alpha\left(T_{in}-T_S\right) \tag{8}$$

$$\lambda'_X\frac{\partial X_{mat}}{\partial x}=\alpha'\left(X_{in}-X_S\right) \tag{9}$$

2.4 Simulation Model for Air-Conditioning System

Consider the behavior of the inhabitants of Taiwan, heating does not need to be considered in the air-conditioning model, and only cooling power is taken into account. The room is cooled to 26°C when occupied if the room temperature exceeds 26°C. If the temperature of the supply air drops below the dew point, resulting in condensation within the air-conditioning system, the relative humidity of the supply air is 100%, and moisture dehumidified is calculated from the difference of absolute humidity between inlet and outlet of air-conditioning system. A formula, (6-7), to calculate the dew point was brought forward in the work by Barenbrug (1974).

$$T_d=\frac{b\cdot f\left(T_C,RH\right)}{a-f\left(T_C,RH\right)} \tag{6}$$

Where $f\left(T_C,RH\right)=\dfrac{a\cdot T}{b+T}+\ln\left(RH\right)$ (7)

and a=17.27, b=237.7°C. T_C (°C) is temperature in degrees Celsius, RH is relative humidity, T_d (°C) is dew point temperature.

3. Simulation Results and Discussion

3.1 Moisture Buffering Effect

Figure 2-7 shows the variation in indoor temperature and relative humidity during Jun. 23~27. Compared with cases with no interior material, the relative humidity shows smaller variation range in cases using interior materials, and plywood shows better moisture buffering than gypsum board. On the other hand, those cases with interior materials show lower indoor air temperature and higher relative humidity than those without materials during the day. This is due to the sensible heat loss via the room air moisture desorption phenomenon, and the influence of the specific heat capacity of the materials.

3.2 Indoor Air Quality

Some studies indicated that fungi, mould and mites multiply more quickly in conditions of high relative humidity, and respiratory health problems increase in areas with high relative humidity (Ezeonu, I.M. et al. 1994, Lacey and J. et al. 1994). Figures 8~10 show the cumulative ratio of relative humidities of indoor air. The cumulative time is the sum of the calculation time. The cumulative ratio is calculated by the sum of the time (hours) when the indoor relative humidity is over 70%, 80% and 90%, divided by the sum of the simulation time (8,760 hours). Compared with those cases without interior materials, the cumulative ratio of relative humidities over 90% were reduced in cases with interior materials, but the cumulative ratio of relative humidities over 70% was higher in Taichung and Kaohsiung cities. This is also evidence of the adsorption and desorption process of the interior material.

3.3 Energy Impacts of Moisture Buffering

Some studies (Osanyintola, O.F. et al. 2006) have evaluated the energy impacts of moisture buffering in cold climates, but the effect in hot and humid climates has not been studied to the same degree. Figures 11~13 show the total heat removed by air-conditioning systems (heat load) in all cases. When using plywood as the interior material, the heat load is higher than that with no materials. On the other hand, the heat load is higher in Taipei, and lower in Taichung and Kaohsiung when using gypsum board as the interior material. Note that the energy impacts of hygrothermal materials are influenced by many parameters such as the air exchange rate and heat/moisture generation rate, and the effect requires further study for precise evaluation.

4. Conclusions

In this paper, the moisture buffering effect and energy impacts are studied by numerical simulation under hot and humid climates for three major cities in Taiwan. The conclusions are as follows:

(1) Compared to cases with no interior materials, the relative humidity demonstrates a smaller variation range in cases using interior materials, and plywood shows better moisture buffering than gypsum board.

(2) Compared to cases without interior material, the cumulative ratio of relative humidities over 90% were reduced in cases with interior material, but the cumulative ratio of relative humidities over 70% were higher in Taichung and Kaohsiung cities.

(3) When using plywood as the interior material, the heat load is higher than that with no materials. On the other hand, the heat load is higher in Taipei, and lower in Taichung and Kaohsiung when using gypsum board as the interior material.

Keywords: detached wooden houses, measurement survey, CO_2 emission, $LCCO_2$, construction materials, construction waste, energy consumption, inhabitants' daily schedule

Summary

CO_2 emissions from the construction and use of houses have been increasing. In order to promote the reduction of CO_2, it is necessary to know the exact amount of CO_2 emissions from houses. First, the authors measured the exact weight of the construction materials and waste. Next, the authors researched the inhabitants' daily schedule and measured the energy consumption from the daily use of the house. The following results were obtained: 1) the weight per floor of construction materials and waste was 1.03×10^3kg/m^2 and 12.9kg/m^2, respectively 2) the amount of CO_2 emissions per floor of construction materials and waste was 0.319×10^3kg-CO_2/m^2 and 13.1kg-CO_2/m^2, respectively 3) the amount of electricity consumed was 30.6GJ/year for the first year and 28.9GJ/year for the second year 4) the amount of CO_2 emissions from both the construction and two years use of the house was 389.07kg-CO_2/m^2.

1. Introduction

CO_2 emissions from the construction and use of houses in 1990 were about 18% of the total CO_2 emissions in Japan, and the total amount of emissions from the construction and use of houses has been increasing. In order to promote the reduction of CO_2, it is necessary to know the exact amounts of CO_2 emissions from houses.

Well-insulated and airtight houses are constructed from various materials, some of which result in a lot of CO_2 emissions during their factory production. The authors measured the exact weight of the construction materials and waste to determine their environmental impact. Since most researchers in Japan calculate CO_2 emissions using construction material measurements from housing blueprints, the values are not accurate. The reason for the inaccuracies is the difficulty in calculating the weight of the construction materials and waste over the long construction period. This leads to a difference between the weight based on actual measurements and the estimated weight based on calculations. From our measurements, the exact weight of construction materials and waste was determined and the amount of CO_2 emissions was calculated.

CO_2 emissions from energy consumption in a household after construction are an important design factor. For the houses whose construction materials and waste were measured, the amount of electricity and water consumed was recorded. The hot water supply system, cooking system and air conditioner use electricity in this house. The amount of CO_2 emissions due to energy consumption from 2005 to 2007 was calculated from a measurement survey.

Methods to reduce CO_2 emissions related to construction materials were considered. Here, the use of materials with lower emissions is proposed as one CO_2 reduction method.

2. Outline of Target House

Figure 1 shows the floor plan of the second floor and figure 2 shows the floor plan of the third floor. Figure 3 shows the elevation plan of the south side of the house. The house that we measured was constructed in Nagano Prefecture, Japan. The house had three floors. The first floor was constructed with reinforced concrete. The second and third floors were constructed with wood and by conventional methods. The total floor area is 162.0m^2. The house was insulated with glass wool. The thickness of the ceiling's insulation is 200mm and the insulation for each wall is 100mm. The insulation for the floor is 80mm. The density of the ceiling's insulation is 10kg/m^3, with each wall at 16 kg/m^3 and the floor at 32 kg/m^3. Each window has a sash made from plastic and aluminum with double glazing. The exterior is made with a ceramic material which has a thickness of 13mm. The roof uses a coated sheet steel which has a thickness of 0.4mm. The interior decorations consist of wallpaper made from vinyl. The flooring material uses an adhesion bond. The thickness of the flooring materials is 12mm.

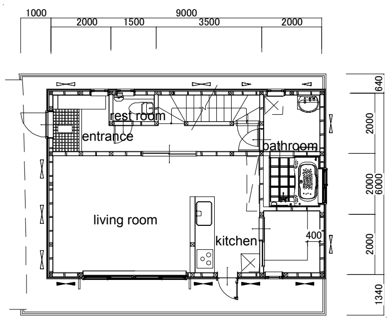

Figure 1 : Floor plan of second floor

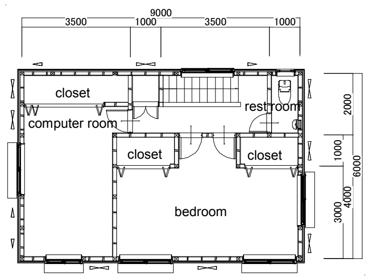

Figure 2 : Floor plan of third floor

Figure 3 : Elevation plan of the south side of the house

3. Attribution of Inhabitants and Outline of Facilities

The inhabitants are a husband and wife and two children. The husband and wife are in their 30's. The two children are under 5 years of age. The husband is a company employee. The wife is a full-time housewife. The hot water supply system, cooking system and air conditioner are run by electricity. There are two air conditioners, one located in the living room and the other located in the bedroom. The PTC (positive temperature coefficient) floor heating system was put in the living room. The inhabitants used the PTC floor heating system for the first year. They used an electrical carpet for the second year instead of the PTC floor heating system. The halogen heater was put in the computer room. The hot water supply system consists of a heat pump using CO_2 as the heating medium. The cooking device is an induction heater. The rating power consumption for the air conditioner is 585W (heating), 645W (cooling). The power consumption of the PTC floor heating system is 2,070W. The power consumption of the halogen heater is 800W. The power consumption of the electrical carpet is 606W. The power consumption of the induction heater is 4,000W.

4. Weight of the Construction Materials and Waste

4.1 Outline of Measurement Survey

The authors measured construction materials using a scale whenever these materials were brought to the construction site. The authors pooled together all of the construction waste, again measuring this with a scale. Each type of material was recorded. The authors calculated the weight of the materials that could not be measured by scale, such as concrete and wood, using a standard density. The authors figured out the weight of rebar by weight per unit length. The weight of the hot water supply system and the air conditioner was calculated through data obtained from the manufacturer.

4.2 Result of Measurement Survey

Figure 4 shows the weight of construction materials. We classified the construction materials into the eleven following categories: wood, metals, plastics, soils and stones, paper, glass, chemical products, rubber, cloths and threads, cables, and combined materials (material made from more than two materials).

The total weight of construction materials was 166 x10^{3}kg. The top three categories in terms of weight are soils and stones, wood, and metals. The breakdown of these three largest categories is as follows: soils and stones - 89.7% (149 x10^{3}kg), wood - 6.0% (9.95 x10^{3}kg), metal - 3.1% (5.08 x10^{3}kg). Soils and stones have the highest weight because the house's first floor was constructed with reinforced concrete.

The main materials that make up the eleven kinds of construction materials are as follows: 1) wood: laminated wood, lumber, plywood, etc. 2) metals: rebar, structural metal, nails, etc. 3) plastics: wallpaper, airtight sheet, PVC pipe, etc. 4) soils and stones: concrete, broken stone, plaster board, etc. 5) paper: base sheet of roof 6) glass: window, glass wool, mirror 7) chemical products: adhesion bond, paint, repellent for ants, etc. 8) rubber: urethane foam, sealant, etc. 9) cloths and threads: curtains 10) cables: electrical wiring, antifreeze heater for pipe, etc. 11) combined materials: home electric appliances, etc..

Figure 5 shows the weight of construction waste. The total weight of construction waste was 2,090 kg. The top three categories in terms of weight of construction waste are soils and stones, wood, and paper. The breakdown of these three largest categories is as follows: soils and stones - 41.2% (859kg), wood - 34.4% (718kg), and paper - 12.9% (268kg).

The main materials that make up construction waste is as follows: 1) wood: mill ends of lumber and plywood and flooring material, etc. 2) metals: mill ends of coated sheet steel, nails used for formwork, etc. 3) plastics: polypropylene band, buffer material, etc. 4) soils and stones: mill ends of plaster board and exterior, etc. 5) paper: cardboard, center core of airtight sheet 6) glass: mill ends of glass wool, etc. 7) chemical products: remover for formwork, etc. 8) rubber: mill ends of electrical wiring, etc. 9) combined materials: case of adhesion bond and sealant, etc..

Table 1 shows the disaggregated data of construction waste. Excluding mill ends, construction waste consisted almost entirely of packaging material. Soils and stones, glass and cables were only mill ends. Excluding mill ends, paper and chemical products were mostly construction waste.

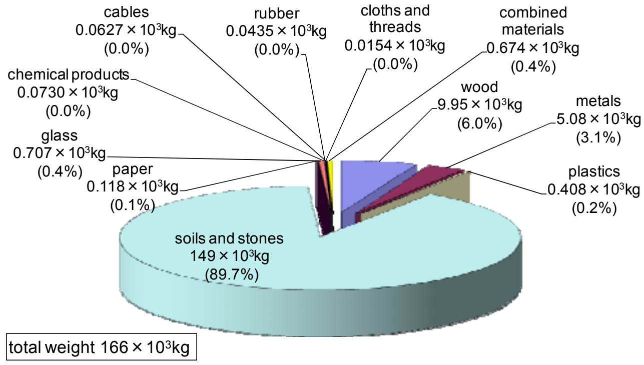

Figure 4 : Weight of construction materials

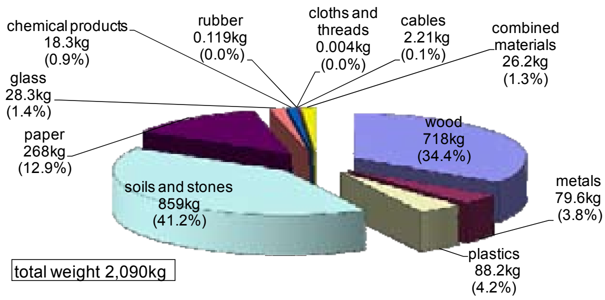

Figure 5 : Weight of construction waste

Table 1 : Disaggregated data of construction waste

Materials	Weight of mill ends(kg)	Weight of construction waste excluding for mill ends(kg)
wood	704	14.2
metals	56.9	22.7
plastics	42.7	45.5
soils and stones	859	-
paper	1.40	267
glass	28.3	-
chemical products	0.794	17.5
rubber	0.053	0.066
cloths and threads	-	0.004
cables	2.21	-
combined materials	12.4	13.8
total	1,708	381

5. CO_2 Emissions

5.1 Method for Estimation of CO_2 Emissions

We measured the exact weight of construction materials and waste. We multiplied the weight of construction materials and waste by a basic unit. This basic unit was calculated based on an input-output analysis. The Architectural Institute of Japan officially announces the basic units.

5.2 Amount of CO_2 Emissions of Construction Materials and Waste

Figure 6 shows the amount of CO_2 emissions from construction materials. The total amount of CO_2 emissions from construction materials was 51.7 x10^3kg-CO_2. The top three categories in terms of the amount of CO_2 emissions from construction materials are soils and stones, wood, and metals. The breakdown of these largest categories is as follows: soils and stones - 60.8% (31.4 x10^3kg-CO_2), metals - 12.4% (6.42 x10^3kg-CO_2), wood - 12.4% (6.42 x10^3kg-CO_2).

Figure 7 shows the amount of CO_2 emissions from construction waste. The CO_2 emissions from construction waste emerged during production. The total amount of CO_2 emissions from construction waste was 2,120kg-CO_2. The top three categories in terms of the amount of CO_2 emissions from construction waste are soils and stones, wood, and paper. The breakdown of these largest categories is as follows: soils and stones - 26.6% (562kg-CO_2), wood - 25.0% (529kg-CO_2), paper - 24.7% (523 kg-CO_2).

6. Improvement of Index of Environmental Load

We recalculated the data obtained thus far into a per floor unit of measurement in order to compare it with other data taken from housing blue prints. The target house's first floor is constructed with reinforced

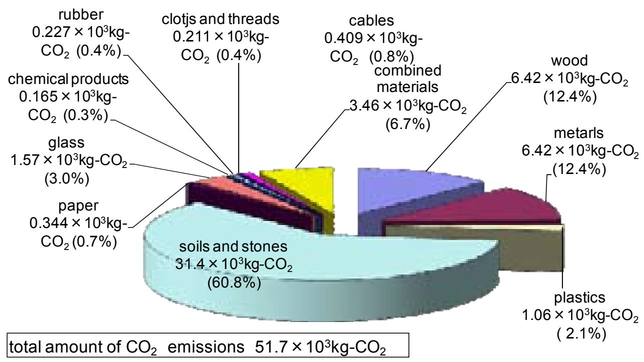

Figure 6 : Amount of CO_2 emissions from construction materials

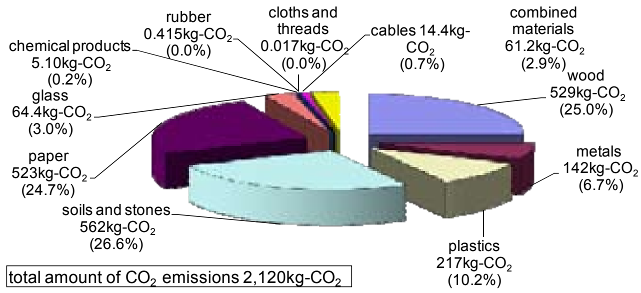

Figure 7 : Amount of CO_2 emissions from construction waste

concrete, so it uses larger amounts of concrete than normal houses. We calculated the data from the groundsill up and arranged this data into a per floor measurement (second and third floor:108m^2). Table 2 shows the weight per floor of construction materials and the amount of CO_2 emissions per floor from construction materials. Table 3 shows the weight per floor of construction waste and the amount of CO_2 emissions per floor from construction waste. The weight per floor of construction materials and waste was 1.03×10^3kg/m^2 and 12.9kg/m^2, respectively. The amount of CO_2 emissions per floor of construction materials and waste was 0.319×10^3kg-CO_2/m^2 and 13.1kg-CO_2/m^2, respectively.

Table 2 : Weight per floor of construction materials and the amount of CO_2 emissions per floor from construction materials

Materials	Weight of construction materials		Amount of CO_2 emissions	
	weight per floor(kg/m^2)	weight per second and third floor(kg/m^2)	amount of CO_2 emissions per floor(kg-CO_2/m^2)	amount of CO_2 emissions per second and third floor(kg/m^2)

7. Research of the Inhabitants' Daily Schedule

The authors researched the inhabitants' daily schedule in order to discover its relationship to the amount of energy consumed. The research targeted only the husband and wife. The research periods were as follows: fall (November 14-20, 2005), winter (February 13-17, 25-26, 2006), spring (May 15-21, 2006), and summer

(August 28-September 3, 2006). The research periods included all five weekdays, and Saturday and Sunday. The inhabitants reported their actions and whereabouts every 15 minutes.

Figures 8-11 show the weekday results for the times the inhabitants were inside the house and awake (the percentage of stay and awake). Figure 8 is the husband's winter results. Figure 9 is the husband's summer results. Figure 10 is the wife's winter results. Figure 11 is the wife's summer results. The graphs below (Figures 8-11) also include the results of an NHK (Japan Broadcasting Corporation) research project in order to compare our findings.

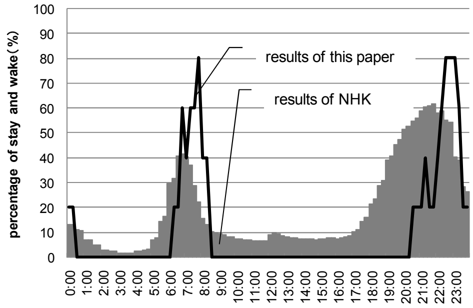

Figure 8 : The weekday results of the husband (winter)

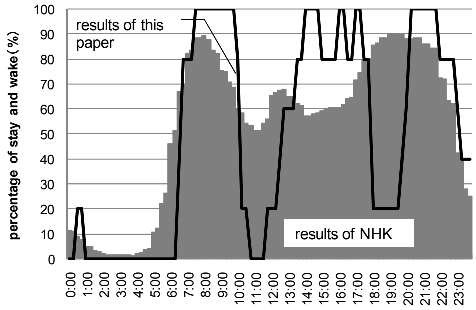

Figure 10 : The weekday results of the wife (winter)

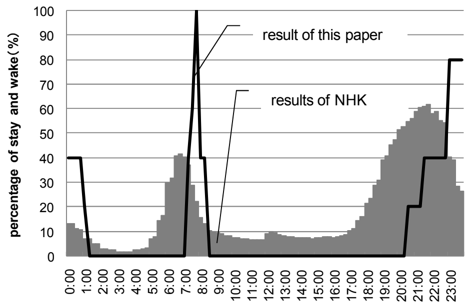

Figure 9 : The weekday results of the husband (summer)

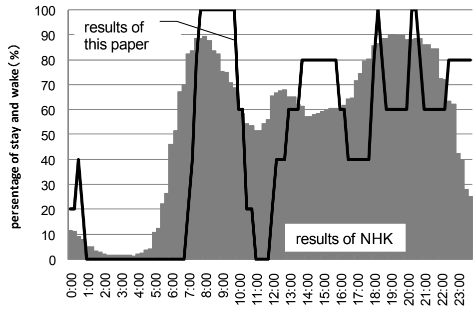

Figure 11 : The weekday results of the wife (summer)

8. Room Temperature

The authors measured the room temperature every 10 minutes. The target rooms were living room, bedroom and computer room. Figure 12 shows the room temperatures during the winter for the weekdays. Figure 13 shows the room temperatures during the summer for the weekdays. During our research of the inhabitants' daily schedule, the average winter room temperature for three target rooms were as follows: the living room was 18.3℃, the computer room was 13.9℃, and the bedroom was 16.5℃. The average summer room temperatures for the living room and the bedroom were 26.9℃, and 27.4℃, respectively. The summer room temperatures for the computer room had incomplete data. The authors infer from the data obtained that the inhabitants rarely use the air conditioner during the summer.

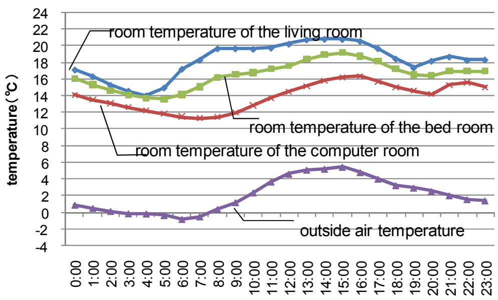

Figure 12 : Room temperatures in winter

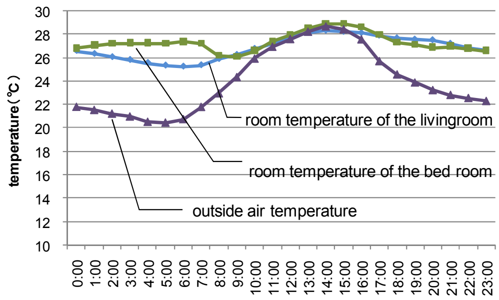

Figure 13 : Room temperatures in summer

9. Energy Consumption

9.1 Outline of Measurement Survey

For the houses whose construction materials and waste were measured, the amount of electricity and water consumed was recorded. The electricity consumed was recorded every minute. The electricity consumed for the total use of the house, except for the hot water supply system, was recorded. The amount of electricity consumed by the hot water supply system, the air conditioner, the electric carpet and the halogen heater was recorded. The measuring period for the hot water supply system and total use of the house, except for the hot water supply system, was from September 9, 2005 to October 11, 2007. The measuring period for the second floor air conditioner was from August 19, 2006 to October 11, 2007. The measuring period for the third floor air conditioner, the electric carpet and the halogen heater was from December 1, 2006 to November 11, 2007. The total consumption for electricity and water was confirmed using the utility companies' billing system.

9.2 Electric Power Consumption

Figure 14 shows the electric power consumption per month. The amount of electricity consumed was 30.6GJ/year for the first year and 28.9GJ/year for the second year. There was no significant difference between the amount of electricity consumed during the first year and second year. For the second year in winter, heating accounted for 20.2% in December, 20.0% in January, and 10.9% in February of the total consumption. The hot water supply system accounted for 36.9% in December, 38.6% in January, 43.1% in February of the total consumption. For the second year in summer, the air conditioner accounted for 5.9% of the total consumption and the hot water supply system accounted for 11.3% of the total consumption.

Figure 15 shows per hour consumption of electricity in winter. The data is the average of a typical day for February (February 19-23, 2007). The times when the heating was in use coincide with the times when the inhabitants were at home and active. Figure 16 shows per hour consumption of electricity in summer. The data is average of a typical day for August (August 6-10, 2007). The times when the cooling was in use coincide with the times when the wife was at home and active.

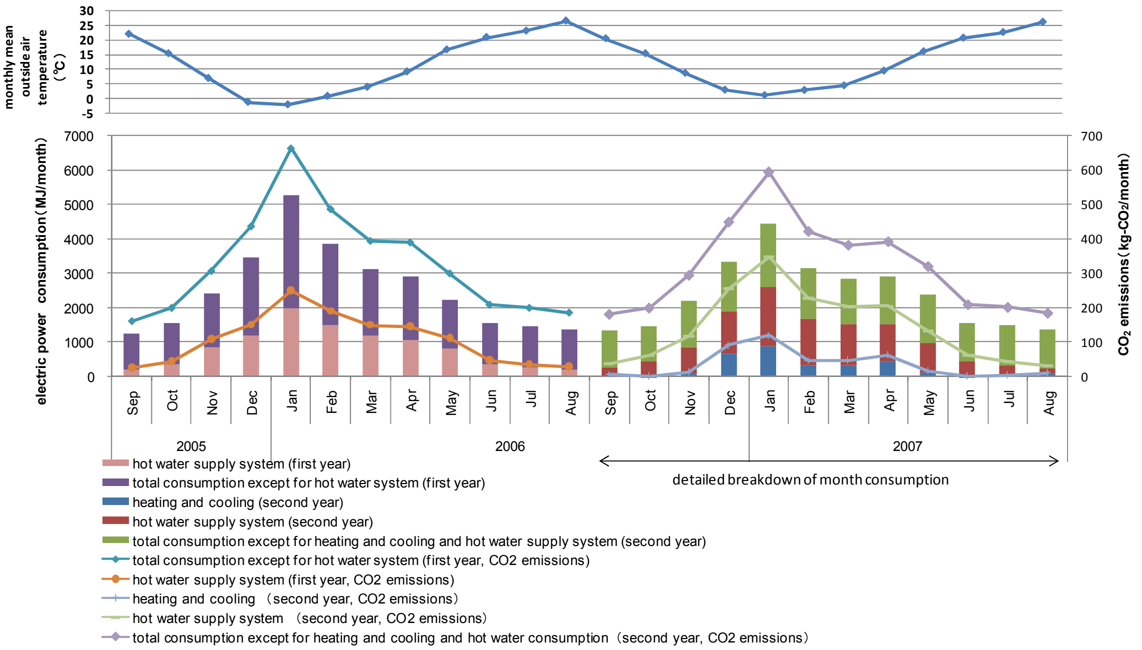

Figure 14: Electric power consumption per month

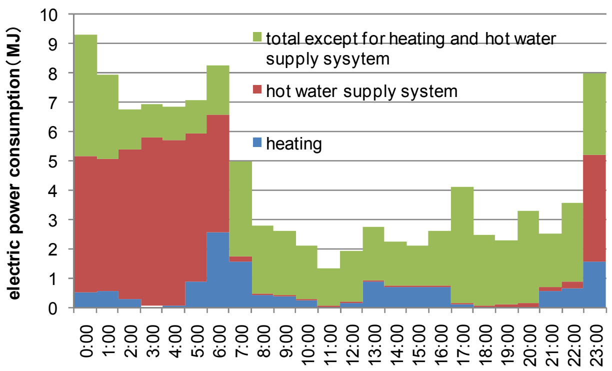

Figure 15 : Per hour consumption of electricity in winter

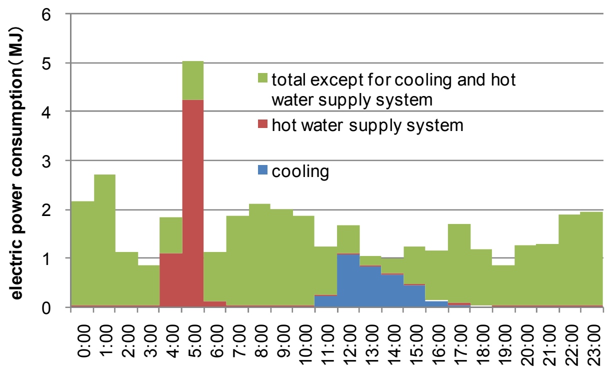

Figure 16 : Per hour consumption of electricity in summer

9.3 Water Consumption

Figure 17 shows the water consumption per two months. (Note: The first year's data for September and October also includes the amount of consumption for August.) Total water consumption was 170m^3/year for the first year and 191m^3/year for the second year.

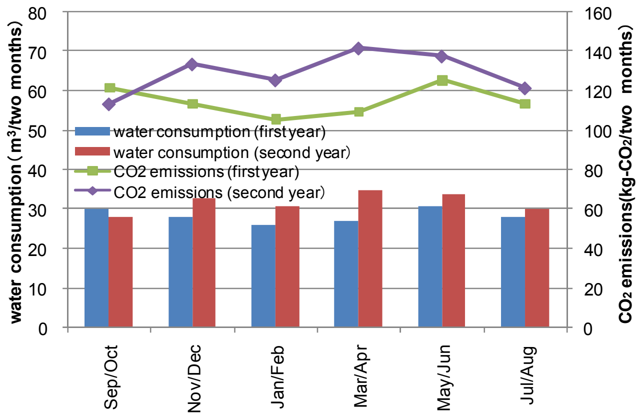

Figure 17 : Water consumption per two months

10. Value of $LCCO_2$ Based on Measurement Survey

Figure 14 shows the amount of CO_2 emissions from electric power consumption. Figure 17 shows the amount of CO_2 emissions from water consumption. The amount of CO_2 emissions from electric power consumption was 3,918 kg-CO_2/year for the first year and 3,816 kg-CO_2/year for the second year. The amount of CO_2 emissions from water consumption was 689.0 kg-CO_2/year for the first year and 774.1 kg-CO_2/year for the second year.

Table 4 shows the amount of CO_2 emissions from both the construction and two years' use of the house. The amount of CO_2 emissions from both the construction and two years' use of the house was 389.07kg-CO_2/m^2.

Table 4 : The amount of CO_2 emissions from both the construction and two years' use of the house

The amount of CO_2 emissions from construction(kg-CO_2/m^2)	Construction materials	319.21
	Construction waste	13.08
The amount of CO_2 emissions from electric power consumption of heating and cooling(kg-CO_2/m^2)	First year	-
	Second year	2.55
The amount of CO_2 emissions from electric power consumption of hot water supply system(kg-CO_2/m^2)	First year	7.94
	Second year	8.10
The amount of CO_2 emissions from total electric power consumption except for heating and cooling and hot water supply system(kg-CO_2/m^2)	First year	16.25※
	Second year	12.91
The amount of CO_2 emissions from water consumption(kg-CO_2/m^2)	First year	4.25
	Second year	4.78

※includes the amount of CO_2 emissions from electric power consumption of heating and cooling

11. Method to Reduce CO_2 Emissions

11.1 Change the Structure of the Groundwork and Take Away the First Floor

The first floor of the target house was constructed with reinforced concrete. The amount of concrete and rebar used was greater than what is found in other detached wooden houses constructed by conventional methods. The authors made an improved plan that took away the first floor and changed the structure of the groundwork. The authors calculated the weight of construction materials for the improved plan. Table 5 shows the weight of the construction materials that we had reported and the amount of CO_2 emissions from these materials (only the altered materials). The total weight of construction materials was reduced by 73.4×

10^3kg, with soils and stones accounting for 70.9×10^3kg, and metals accounting for 2.52×10^3kg. The reduction of CO_2 emissions was 15.7×10^3kg-CO_2.

Table 5 : Weight of construction materials and the amount of CO_2 emissions from construction materials (only the altered materials)

Materials	Weight of construction materials(kg)		Amount of CO_2 emissions(kg-CO_2)	
	actual plan	improved plan	actual plan	improved plan
metals	5,078.1	2,559.7	6,420.6	4,013.3
plastics	407.7	402.9	1,064.2	1,053.0
soils and stones	149,282.1	78,358.4	31,421.0	18,136.0
total (only the altered materials)	154,767.8	8,1321.0	38,905.8	23,202.3

11.2 Change the Interior Decorations

The authors planned to use interior decorations which emitted less CO_2 during their factory production. The interior decorations, excluding the kitchen, consist of natural wood instead of wallpaper made from vinyl and plasterboard. The interior decorations for the kitchen consist of wallpaper made from vinyl and plasterboard to protect against fire. The flooring material uses natural wood instead of materials that use adhesion bond. Table 6 shows the weight of materials and the amount of CO_2 emissions from construction materials (only the altered materials). The amount of CO_2 emitted by interior decorations with lower CO_2 emissions during their factory production was 1.48×10^3kg-CO_2. The new interior decorations reduced CO_2 emissions by 5.13 ×10^3kg-CO_2.

By changing the structure of the groundwork and taking away the first floor and by using interior decorations with lower CO_2 emissions during their factory production, the total amount of CO_2 emissions was 30.9× 10^3kg-CO_2. The countermeasures that the authors described in their improved plan reduced CO_2 emissions by 20.8×10^3kg-CO_2. The improved plan reduced CO_2 emissions by 40.3%.

Table 6 The weight of materials and the amount of CO_2 emissions (only the altered materials)

	Actual plan			Improved plan		
	material	weight ［kg］	CO_2 emissions ［kg-CO_2］	material	weight ［kg］	CO_2 emissions ［kg-CO_2］
floor	flooring material	482.8	614.1	Japanese oak	691.0	220.4
wall and ceiling	plaster board	4,005.5	5,603.7	Japanese oak	2,910.1	928.3
				plaster board	211.4	295.7
	wallpaper made from vinyl	86.8	213.2	wallpaper made from vinyl	8.2	20.0
	adhesion bond, etc.	79.8	175.6	adhesion bond, etc.	2.2	15.2
total (only the altered materials)		4,654.9	6,606.6		3,822.9	1,479.8

12. Conclusion

The authors measured the exact weight of construction materials and waste. Next, the authors calculated the amount of CO_2 emissions based on exact weight. Then, the authors measured the energy consumption from using the houses. The authors calculated the amount of CO_2 emissions from both construction and two years' use of the houses. The authors' plans to reduce CO_2 emissions in constructing houses were centered on using materials with lower CO_2 emissions.

The authors need to continuously measure energy consumption.

Keywords: Integrated, Design, Process, Living, Breathing, Building, Sustainable

Summary

We are witnessing a global retreat to architectural rhetoric and 'fundamentalist' beliefs, relating to the role of architecture in the 'sustainable development' of the planet. Architects from around the world continue to create mechanistically based 'solutions' to address climate change, without questioning fundamental assumptions around measuring criteria. Globally, programs like LEED® have created an artificial system of measurement that implies that our new and renovated buildings can move towards a 'net zero' impact. Meanwhile, we continue to rapidly increase the total net building stock of the earth without guilt. To quote Dr. David Suzuki, the Canadian scientist and environmentalist: "Our personal consumer choices have ecological, social, and spiritual consequences and it's time to re-examine some of our deeply held notions that underlie our lifestyles." In our practice, we never assume that what we do with architecture has a predictable effect on the global climate; we believe that we don't yet have the predictive tools to measure even the local impact of our designs. We prefer to work within the Integrated Design Process (IDP) (Figure 2), a concept we introduced at the 1998 Green Building Challenge conference in Vancouver. This enables us to address issues that we can measure, without creating a corresponding belief system around the 'sustainability' value of our work.

1. Mechanistic Thinking and the Rise of Fundamentalism in Architecture

"There are those metaphysical moments in the life of empires when their sheer size and their overwhelming power become the reason for their loss of purpose, direction, and flexibility." The way in which we approach building design is always subject to the philosophical paradigm of our epoch. Currently we are in a transitional phase. We are leaving the 'mechanistic' paradigm of Newtonian Mechanics and the calculus he invented to describe it, and we are moving towards a 'natural systems' based paradigm reflected in concepts like bio-mimicry, systems theory, fractal geometry, chaos theory and non linear algebra. Our current building stock and our approach to it is very much embedded in the mechanistic paradigm, while our climate change modelling and our building performance modelling rests solidly in the realm of fractal geometry and 'fuzzy logic'. I believe that this is the reason why so many experts in the field of development and climate change analysis struggle with the complexity of this problem and continually revert to an overly simplified solution based on individual components rather than dynamic systems. Addressing the dynamic would force us to design holistically, measuring the consequences of our developments at different and far more complex scales.

The reality of our age is that we have become too comfortable measuring our buildings by literally breaking them apart into structural, mechanical, electrical and landscape elements. We have been forced to work in 'disciplines' and we look for comfort and reassurance that, as specialist professionals, we have done 'our' job correctly. As a result, our mechanistically based 'solutions' to climate change issues fail to question fundamental assumptions around the measuring criteria. Programs like LEED® are 'discipline' based and reflect the mechanistic paradigm at their core.

At the present time, a really interesting phenomenon is occurring in architecture. Buildings have moved away from highly mechanised boxes to robotic edifices mimicking the natural form, which is in fact a higher form of mechanised evolution. For example, the acclaimed architect Santiago Calatrava celebrates the *City of Arts & Sciences in Valencia* with a robotic eye (Figure 1). While beautiful, I believe that this form of building is the dark side of bio-mimicry. It remains endlessly fascinating to us because we are still fundamentally vested in the art and science of the mechanistic paradigm. There is far less embodied energy and far more durability in a simple 'non building', that uses biomass and natural systems, than in a complex engineered building embracing multiple mechanical systems within a complex skin.

Figure 1. City of Arts & Science in Valencia

It is clear to me that we are currently witnessing a global retreat to architectural rhetoric and fundamentalist beliefs, directly related to the role of architecture in the 'sustainable development' (oxymoron) of the planet. The original environmental concerns of the 1980's came out of the energy crisis, when fuel costs rose at an alarming rate. At this time, studies conducted by the Rocky Mountain Institute and the R-2000 program in Canada were developed strictly to reduce the energy consumption of homes and buildings. For example, the R-2000 program was created as a partnership between the Canadian Home Builders' Association and Natural Resources Canada. "It began with a research project in the Prairies to develop ways of building homes that were comfortable and healthy to live in during the frigid winters, but used much less energy than conventional homes." The assumption at that time was that buildings that used less energy would do less harm. Now we see a transition where 'net zero' is rapidly moving away from 'net zero footprint' to 'net zero carbon'. We need to understand why James Rust, a Southern Sierra Miwok elder, believes that, "The white man sure ruined this country. It's turned back to wilderness." Native generations stewarded the land harmoniously with natural principals and served their own needs for grains and meats in perpetuity. They radically transformed the landscape, but their alterations were not destructive. Ours are.

Fundamentalism occurs at the point where knowledge systems transition into belief systems. Currently, we believe, for instance, that green roofs are 'good'. Yet, there is in fact a body of knowledge that suggests that green roofs are not viable as functioning ecosystems and will continually fail. Green roof design has been based on engineered facilities, to address storm water management and temporarily detain water. These remain structures based on an open, flow through, piped designed criteria. We need to rethink roof design as functional landscape elements – lift the vegetated ground and slide a building underneath. Green roof design must be part of an economic benefit both of the building, (Corpus), and the landscape, (ecosystem). We need to adopt closed-loop natural design principles using a decentralized 'fit-for-purpose' approach for water management, rather than the present 'potable water' for every use from a thirst quencher to making concrete, flushing toilets to bathing. In short, we must first understand how our landscapes functioned before we altered their structure and established non-sustainable functional processes and attributes. Yet, in an era where it is felt that we must do something to reverse climate change, thoughtful or constructive questioning of sustainable building practices is perceived as unhelpful.

Renewable energy systems like wind, methane and PV energy generators are made from non-renewable materials like aluminum and glass in systems with limited life spans and dubious performance. If a 'net zero' footprint truly is the goal, I maintain that it is far too early in the sustainable development practice for us to solidify our knowledge system into a codified set of rules. Now is the time for us to step back from prescriptive doctrines in order to understand what positive co-evolution could mean for the future of this planet.

2. Artificially Restricted Measures

If we look at the most commonly used sustainable design systems of measurement in use today, we find that although systems vary, they all measure energy 'in' and 'out'. This presupposes that energy is the only component worth considering when evaluating the environmental impact of buildings. The fact is there is an equally pressing need for us to assess the human impact on our atmosphere, our land and our oceans at a global level. We can then use this understanding as a reference for the evaluation of our human development impact. Specifically there are three known human effects on the atmosphere:

1. The emission of CO2e or GHG's
2. The generation of particulates from fossil fuel burning
3. An increase in the albedo of the planet due to rice paddies and urban development

There are also three natural mechanisms that influence climate. These are changes in the sun, changes in the amount of volcanic dust in the atmosphere and the internal variability of the coupled atmosphere-ocean system. All of these processes can add heat to the atmosphere. Even with the Kyoto targets in place, there will be an average temperature rise of two degrees by 2030, wherein the expansion of the warm zone top layer of the ocean will have exceeded coral reef temperature tolerance in eighty percent of the world's oceans.

There are two even more critical impacts on the land and its ecosystems that are, in many ways, independent of the three effects stated above. They result from our agriculture, aquaculture and urbanization.

4. The disruption of ecosystem corridors
5. The disruption of transpiration of water across the earth's surface

Our disruption of ecosystems is due mainly to our interference with natural passageways including avian corridors, coastlines, rivers and forest corridors.

It is a principal of nature that, "Islands are a dead-end road; islands are where species go to die". When we create a Roman block urban landscape, each block is an island and is not ecologically viable. Additionally, when we break up our landscape with hard surface roadways, we disrupt the eco corridors creating forest islands that eventually will also fail, unless they too are of a sufficient size.

Our dealings with water are also misguided. We mistakenly believe that we should return clear run-off to the 'groundwater' and we will 'recharge the aquifers'. Actually, what biology teaches us, is that the first principal of nature is to keep water on the land as long as possible, where it is available for plants, birds, animals and insects. Water evaporating from our oceans is condensed as rain over coastal areas and there begins a series of evapo-transpiration micor-cycles of water across the land through the biomass and soils. Our cities therefore are functioning, in natural terms, as irrigated deserts.

When we examine the five major human impacts on the earth, it is evident that our current sustainable design system of measurement addresses only the first two effects (i.e., GHG's and particulates). For instance, the systems that we use at present do not assess the impact of the albedo effect. A dark surface can be a forest that photosynthesises the sun's energy, or an asphalt parking lot that demands more and more fossil fuel for its maintenance. Yet currently we apply the same albedo factor to them. Our current systems also fail to examine the city-block based urban planning effects on ecosystem corridors. Perhaps most importantly, these sustainable design measuring systems actively encourage the return of water through porous paving and drainage systems to the groundwater, without considering the needs of plants, birds, animals and insects which require access to water on the surface. When you think about it therefore, it should not be possible for an aluminum-clad building, located on acres of land in a city block environment, containing a huge mass of embodied energy and a wealth of mechanised systems, to earn a platinum or gold award. Yet it is done every day! Our current systems of measurement are helping us rationalise high impact development without questioning basic fundamental assumptions. By codifying things so quickly and so early on in terms of our understanding, we are stealthily moving away from true zero footprint or impact to zero CO2 impact. In this way we may, in fact, increasingly be doing more harm than good.

3. The Integrated Design Process and the move towards Living Breathing Buildings™

In his book "Happier", Harvard professor Dr. Tal Ben-Shahar evaluates the ever-elusive state of happiness. He suggests that, "The accumulation of wealth would often determine whether we would survive the next drought or the next cold winter (…) the accumulation of wealth is no longer a means towards survival, but an end in itself. We no longer accumulate to live; we live to accumulate." His views are supported by the writer and academic Thomas Homer-Dixon in "The Upside of Down: Catastrophe, Creativity and the Ruin of Civilization". He concludes that, "The average income in poor countries won't fully catch up to that in rich countries until the year 2291 – almost three centuries from now – at the staggering level of $27.7 million a person a year". In short, this means that, "The more people perceive that today's globalized capitalism is making the already rich vastly richer while simultaneously leaving the world's population behind, the lower will be its moral standing as a set of principles for ordering people's social and economic lives".

In our desire to understand what 'drives the drive' to overbuild our cities and our communities, my practice worked with the National Research Council of Canada to develop the Commercial Buildings Incentive Program. Out of this was born our original Integrated Design Process, a formal eight step procedure that enables any team anywhere to achieve a superior level of high performance building construction and sustainable development.

All of the architects in our practice still use the IDP today to successfully create millions of square feet of environmentally sustainable commercial and institutional work. Indeed we now have more square feet of LEED® NC Gold-certified projects than any other architectural firm in North America. In our experience, the Integrated Design Process reduces the need for complex building solutions and almost completely eliminates most mechanical systems. The Integrated Design Process lets architecture do the work for us as a form of global bio-mimicry, wherein the buildings themselves ultimately become the energy producers, working to protect and preserve the ecosystems around them. In short, the Integrated Design Process has enabled us to move away from the machines that have come to dominate architectural design. We address each project and its unique issues without reference to any codified program and actively promote a dynamic questioning atmosphere in the project development team. In such an atmosphere creative solutions abound and the points based measure or certification program is only brought in at the end as a sort of complimentary cross check. It no longer acts as a definitive guide. Many of the strategies that come out of the IDP will not, in fact, earn points on something like

LEED®. Conversely, we have found that by using the IDP we are able to raise the ultimate number of points we can get in LEED®.

Experience has taught us that the first step of the Integrated Design Process, known as *Orientation and Massing*, is perhaps the most crucial as it creates the foundation for all future building performance. We make effective use of the north light to maximize daylight potential and prevent overheating and examine opportunities to enhance neighbouring communities with connections to green-spaces, public amenities and urban pedestrian links.

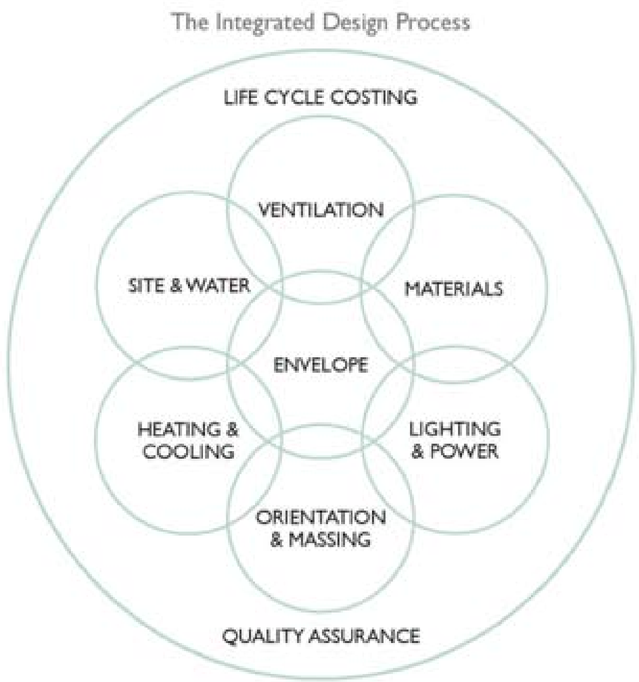

Figure 2. The Integrated Design Process

In our second step, *Site and Water*, we actively look for the natural features of the site to create and maintain ecosystems and water sources. "Climate has used different weapons to bring down the mighty. Most of the time it is drought that upsets the balance of power. (…) 'Through history it has been changes in precipitation, not temperature, that has brought down civilizations'." We take particular care to complement the mass of the building with defined site strategies, thereby enhancing both building performance and site ecosystems. This may mean planting trees, or creating a green parking facility around the building. We specifically look for opportunities to creatively define the site within revised boundaries or, alternatively, we set aside part of the location as a protected green space. This ensures that the site becomes an integral part of the building and can connect to other eco-corridors.

Once we reach the third step of our Integrated Design Process, we focus on developing the *Envelope*. This is almost the reverse of the normal design process in which the outside of the building is initially developed as an image. In our interpretation of the envelope stage, we define the area of windows to be used on each face for day-lighting and specify the types of windows and skylights. We detail the insulation values of the walls and the construction type, developing the shading and transmission values of the glazing. This helps us to create a balanced energy model effect around the building as the glass on each face is rarely the same and the insulation values of the walls can also vary. In particular, we give careful consideration to the roof. We develop light-wells down into the space below and ventilation chimneys or louvers may be added to exhaust warm air out. Options for surfaces, including a green roof or use of other innovations, ensures that the building remains warm in winter and cool in summer.

Our next consideration, and the fourth step, is to develop an exceptional *Ventilation* strategy. Except in horrifically polluted areas, we target ‘natural’ ventilation. This means we draw a clear line firstly between natural and mechanical ventilation systems and secondly for the air used for the heating and cooling of the space. We always look at the most effective way to get fresh air into the building, and to its occupants.

Our fifth step is *Day-Lighting Design*. We consider each face of the building separately and set a target for optimizing the use of natural daylight without attracting solar gain or glare. We do not approach this in a traditional architectural way. Instead, we work with the landscape architects to use trees to screen the building. We also work closely with electrical engineers to develop light wells through the spaces and with energy engineers to refine the openings on the building, making sure we are not creating peak load zones with overlit areas.

It is only at this point that we truly consider the building mechanical conditioning systems after refining the base building to passively condition itself as much as possible. We develop the energy model for the building form and the building envelope, and then see what is left to condition with mechanical systems. This ideally means a very small or nominal heating load and no cooling load at all. It is in this, our sixth IDP step, that we look at renewable H*eating and Cooling System Design.* This could include ‘geothermal’ heating through radiant piping embedded in the mass of the building, or ‘photovoltaics’ linked to fuel cells, or methane gas converters, or wind turbines.

Our seventh IDP step is connected to the *Materials* we select for the building. Our prime concern here is to ensure the health and safety of the building occupants. We select materials that do not off-gas, harbour mould or mildew, or breakdown resulting in particulate contamination. Where possible, we select local materials that are durable but do not have a high embodied energy factor. We work as a team to reduce the materials in the building, using recycled or reused materials wherever possible.

Finally, our eighth and most critical step is to develop a Q*uality Assurance* protocol to ensure the building can be understood and looked after long after the first generation of maintenance staff has left. This is a key step; innovations in buildings can quickly be rendered ineffectual if they are inadvertently compromised. Detailed operational manuals are produced to take the building through into the future.

In “*The Living Building Challenge”,* the Cascadia Region Green Building Council, (Cascadia), invites us to, “Imagine buildings that are built to operate as elegantly and efficiently as a flower. (…) It is time to move beyond Platinum to the Level of the Living Building”. As architects and designers, we must not limit our thinking to our immediate project boundary, because the impact of our work is cumulative and the effects are global.
In order to achieve this, we must first recognise the first three human effects on the atmosphere that must be mitigated in order to achieve true “zero footprint” buildings. Firstly, with regard to GHG emissions, (or CO_2e), we need to begin to think outside the box. For instance, we need to target the waste our buildings produce at source for heat energy. One molecule of methane is equal to 28 molecules of CO_2 and our cities could theoretically substantially heat themselves with the methane gas produced through energy produced from solid/liquid resource streams. Secondly, with regard to particulates as they are emitted into the atmosphere, we need to absolutely stop the burning of fossil fuel for operating energy, transportation of materials to building sites and manufacture of building materials. This means that we need to consider renewable energy systems. In our practice we emphasize the use of locally produced materials in the design and creation of our buildings.

Finally, we also need to be aware of the albedo effect of our developments and move towards greenspace photosynthesizing solar energy, rather than high albedo surfaces reflecting it back into the atmosphere.

As we begin to imagine new forms, we look at the macro level of impact where we must begin to identify eco-system corridors and preserve and protect them. Forest corridors must be reconnected to restore their vitality and along with avian flyways must be marked on every map as 'no go' development zones. Water courses must be understood and protected. Instead of developing an urban form based on the Roman city block system that is convenient for cars and other forms of mechanised transport, we must eliminate the 'city block islands' in our urban planning and create greenbelts instead of asphalt deadzones. In short, we have to allow nature to restore itself through accelerated adoption of bio and eco-mimicry, using the fundamental patterns that underlie life on earth. This can be summarised as the Six Pillars of Biological Wisdom:

1. Nutrition (by allowing water to remain at the surface)
2. Respiration, by creating eco-corridors which will lead to,
3. Growth and
4. Homeostasis (the steady state of a healthy eco system)

This supports:

5. Procreation/reproduction
6. Adaption (which will lead to natural evolutionary processes).

Nature cannot develop and evolve unless we feed it.

Our human impact must be understood as an historical change in nutritional mode and the adaptation of a sedentary lifestyle based on the co-evolutionary, eco-system deforming technologies of agriculture and civilisation, for both agriculture/aquaculture and civilisation/urban development. We have co-evolved with our earth. Stewardship of the planet does not mean a return to wilderness, but rather development informed by a complete understanding of these "Six Pillars of Biological Wisdom". As a practice, Bunting Coady Architects focuses on Creating Living Breathing Buildings® that are ecosystems in their own right.

It is my belief that we can never truly create a Living Breathing Building™ unless we integrate completely with our culture. We know that on every level we are failing to connect to the human condition. Our fast paced culture is creating junk food, disposable clothes and transient buildings, all of which cause great harm and never truly satisfy the spirit. Our buildings used to be inspirational and one of the highest forms of human expression. We must bring the art and craft back into buildings as a reflection of the human condition so that our buildings, once again, have meaning for us. This, in turn, will allow us to give them the time, care and attention to commensurate with their impact on the environment. Ironically, part of responding to the climate change challenge will be to bring the art back into architecture. If we don't value what we create, we will destroy it. If we want our buildings to last, they have to be symbolic and beautiful and connected to our lives on every level.

Summary

A combined Life Cycle Assessment (LCA) / Life Cycle Costing (LCC) Study for a 40-storey standard HKHA (Hong Kong Housing Authority) public rental housing block - New Harmony Block (Option 2) (NHB) was completed in 2004. The study was conducted by a consortium comprising of the University of Hong Kong, Department of Architecture, Davis Langdon & Seah Management Ltd., and the Business Environment Council. The objective of the study quantitatively measured the following ten environmental impacts generated and the life cycle costs from the NHB block from the whole building life-cycle perspective, including (1) raw material extraction; (2) building material manufacturing; (3) transportation stage; (4) construction; (5) building operation; (6) repair and maintenance, and (7) disposal stage:

Energy (MJ)
Resource depletion (kg Sb eq.)
Water consumption (m^3)
Waste (kg)
Climate change (kg CO_2 eq.)
Acid rain(kg SO_2 eq.)
Photochemical smog (kg C_2H_4 eq.)
Ozone depletion (kg CFC-11 eq.)
Toxicity to humans (kg toxic eq.)
Toxicity to ecosystems (kg toxic eq.)

From 2004 to 2007, the combined LCA and LCC study has been extended to other building archetypes in Pearl River Delta, including office, carpark, retail, and hotel buildings. This paper will report the LCA results for each building archetype in the region.

1. Introduction

Thegreenroom, The University of Hong Kong, Davis Langdon & Seah Management Ltd (DLSM), and Business Environmental Council (BEC) completed a combined Life Cycle Assessment (LCA) and Life Cycle Costing (LCC) decision-support tool in 2004. The tool is capable of measuring the following ten environmental impacts and determines the following three financial implications of buildings from the whole life cycle perspective, including (1) raw-material extraction, (2) building material manufacturing, (3) transportation, (4) construction, (5) building operation, (6) repair and maintenance, and (7) disposal stages (Wong et al., 2005):

1. Energy (MJ)
2. Resource depletion (kg)
3. Water consumption (m^3)
4. Waste (kg)
5. Climate change (kg CO_2 eq.)
6. Acid rain(kg SO_2 eq.)
7. Photochemical smog (kg C_2H_4 eq.)
8. Ozone depletion (kg CFC-11 eq.)
9. Toxicity to humans (kg toxic eq.)
10. Toxicity to ecosystems (kg toxic eq.)

A. Capital cost (HK$)
B. Recurring cost (HK$) (operational, repair and maintenance cost)
C. Disposal cost (HK$)

The building in assessment was the New Harmony Block (Option 2) (NHB), a 40-storey concrete-framed residential building for public-rental that accommodates a total of 3,196 individuals. (Fig. 1)

 

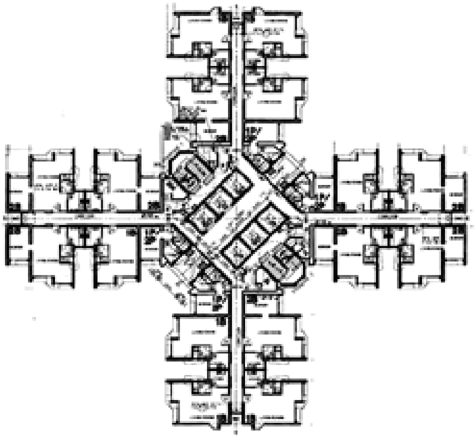

Figure 1 Typical floor plan (left) and the appearance (right) of the New Harmony Block (Option 2)

From 2004 to 2007, thegreenroom, The University of Hong Kong and DLSM conducted a combined LCA and LCC assessment for the following building archetypes in Pearl River Delta:

- A 40-storey concrete-framed office tower in Pearl River Delta
- A 28-storey concrete-framed hotel tower in Pearl River Delta
- A 4-storey concrete –framed shopping arcade in Pearl River Delta
- A 4-storey underground carpark in Pearl River Delta

To measure the environmental impacts of buildings in Pearl River Delta, a unique material-impact database was set up for 200 building materials. The resultant database is relevant for the Southern China/ HK production, energy mix and transportation profile. To accurately assess both LCA and LCC implications, the decision-making tool relied on the following quantum data for the assessment:

- The quantities of building materials used were sourced from the bills of quantity or the cost plan of these building archetypes.
- The repair and maintenance frequency of building component were sourced from the repair record of building archetypes in-use.
- Water, electricity and gas consumption were sourced from real electricity, gas and water bill of building archetypes in-use.

Based on the above quantum data and regionalised material-impact database, the tool characterizes[1], normalizes[2] and weights environmental impacts of buildings into a notional HK environ-point (HK E-pt) which was equivalent to the ten environmental impacts generated by one HK citizen annually (Amato 2006). Alternatively, the tool can measure the building in terms of individual impacts, such as the global warming potency in kg CO_2 equivalent. This decision-making tool could assist accurate carbon footprint reporting in sustainability report of the building assets.

[1] HOWARD N. et. al., (1999) described characterization as: "For each category of impact, characterization will be taken to define the contribution of an environmental burden (intervention) to the impact. The purpose of this is to translate different inventory inputs into directly comparable impact indicators. For example, characterization would provide an estimate of the relative human toxicity between lead and zinc. One burden which makes a contribution which is considered to have a contribution to that impact, or 'potency', of 1. Other burdens are considered with a potency factor relative to that. Alternatively, the burden can be characterized by measuring it in a particular unit, such as cubic meters of water. The characterization process follows international practices in the characterization of inventory data for their potency with the different impact categories."

[2] HOWARD N. et. al., (1999) described normalisation as: "The characterized impact will then be normalized. The purpose is to express impact indicator data in a way that can be compared among impact categories. The procedures normalized the characterized results by dividing by selected reference values, which can be:

- *The total emissions or resource use for region that may be local, regional or global*
- *The total emissions or resource use for an area on a per capita basis"*

2. THE LCA PATTERN OF THE BUILDING ARCHETYPES

Fig. 1 shows total whole life HK E-points of the assessed building archetypes. Fig. 2 shows the whole life HK E-points/ CFA. Fig. 3 shows the whole life HK E-points per inhabitants of the assessed building archetypes.

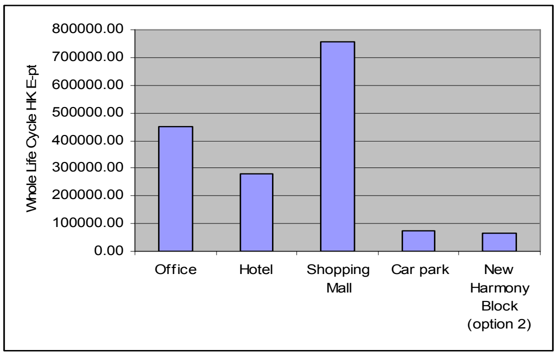

Figure 2 Total HK E-pt of the assessed building archetypes

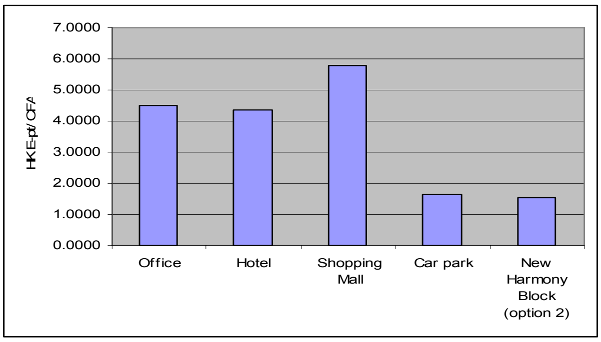

Figure 2 HK E-pt/ CFA of the assess building archetypes

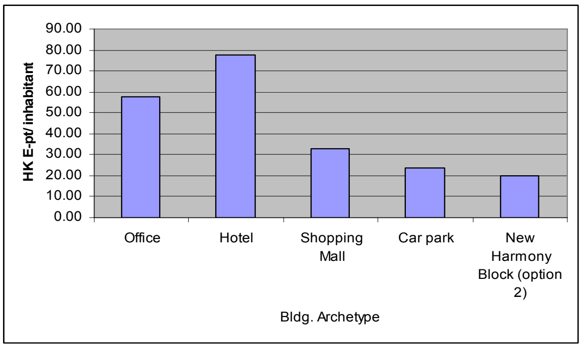

Figure 3 HK E-pt/ inhabitant of the assessed building archetypes

It shows that NHB in HK has the best LCA performance in respect of the three types of indicators. This is because NHB have the lowest energy consumption at operation stage and building-material consumption at initial stage. Underground carpark has the 2nd best LCA performance. 90% of the electricity fuel mix in Pearl River Delta was sourced from coal mix. It increased the environmental impacts of underground carpark in operational stage.

Shopping mall has the worst LCA performance for the HK E-pt/ building and HK E-pt/ CFA indicators. However, in respect of the HK E-pt/ inhabitant, it has the third best LCA performance archetypes. The long operating hours which consumes huge amount of energy that shoot up the whole life E-pt and HK E-pt/ CFA. However, in respect of the HK E-pt/ inhabitant, the figure is lowered down due to the large amount of users. The social attraction in staying at a comfortable shopping mall improve the sustainability performance of these building archetype in view of HK E-pt/ inhabitant indicator.

Office and hotel have the second and third worst LCA performance in view of HK E-pt/ building and HK E-pt/CFA. This is because the office and hotel have higher operating energy demand from office, guestroom and conferences rooms. Office and hotel also have high repair impacts as they have high churn rate. In respect of HK E-pt/inhabitant, office has better performance than hotel due to higher population density in office archetypes. Conclusively, office and hotel can have better performance in view of HK E-pt/inhabitant indicator if population density can be optimised through re-layout or major renovation.

Fig. 5 shows the distribution of HK E-pt across the whole life-cycle for each building archetype. Different building archetypes have differences on distribution of environmental impacts across the whole life cycle. Office and hotel have higher proportion of repair and maintenance impact (27%, 17%) because of the high churn rate and high maintenance frequency, respectively. The significance of repair impacts encourages careful selection of duration building materials at design stage for office and hotel building archetypes. Retail and carpark archetypes have a higher proportion of operation impacts (82%, 76%) because of the longer daily operation period on lighting, cooling, ventilation and other small power loadings. Designers should choose more energy-efficient equipments and renewable energy source to reduce the operational impacts.

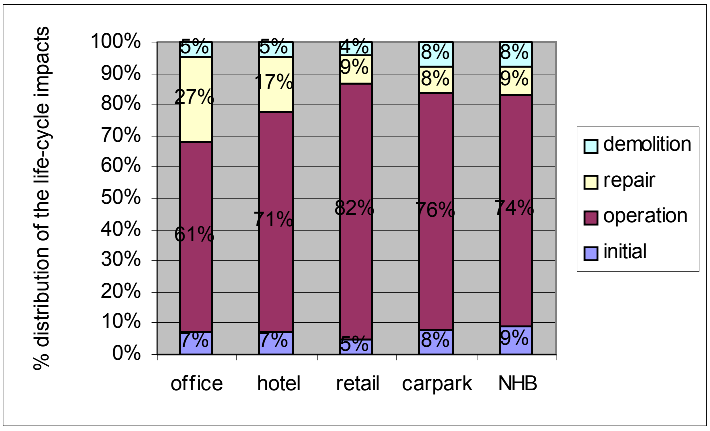

Figure 5 HK E-pt distribution of building archetypes in the life cycle

3. Conclusion

In all assessed building archetypes, New Harmony Block (option 2) has the best performance in the total HK E-pt, HK E-pt/CFA and HK E-pt/ user or inhabitant indicator. This is because NHB have the lowest energy consumption at operation stage and building-material consumption at initial stage. On the other hand, hotel archetype has the poorest performance in HK E-pt/ user indicator. This is because hotel has higher operating energy demand from guestroom and conferences rooms and low population density. From the comparative LCA assessment, each building archetypes has its own pattern of environmental impacts across the whole life-cycle. For example, the hot-spot life cycle stage focus of shopping mall was operational stage. The second hot-spot stage for office was repair & maintenance stage. Designer should select the strategy, such as optimising material or energy efficient strategy, to reduce the environmental impacts of each building archetype across the whole life cycle in order to improve the overall sustainability of the buildings. To strive the sustainability for the whole Pearl River Delta, a combined LCA and LCC study for all building archetypes can help the decision maker to identify alternative way to optimise the overall environmental impacts of buildings in the region.

ACKNOWLEDGEMENT

The authors gratefully acknowledge Hong Kong Housing Authority (HKHA) and Davis Langdon & Seah Ltd (DLS) for the support on the above LCA and LCC projects.

Keywords: urban quality, urban sustainability, indicators, participation

Summary

The quality of living is a complex concept that includes different meanings. In this paper, quality of living was assumed as a mix of qualitative and quantitative aspects with reference to urban built environment.

The paper describes the results of a Preliminary Study for the Plan of Quality of Living (PSPQL) of a town in the hinterland of Milan, conducted by an interdisciplinary group of researchers, involving also facilitators, town councillors, administrators, technicians and citizens. Main aim of the work is identifying the most sustainable actions to be taken for improving conditions of living. A bottom-up and participative approach has been followed. A deep analysis has been carried out, elaborating a set of 33 indicators, defined with the help of the town councillors, administrators and technicians. Indicators investigated 6 different systems: environment, territory, mobility, society, economy and health. Results of different indicators have been represented and communicated by graphs, images and maps, with the help of GIS-based model. On the basis of the results of the indicators, fields of intervention for each topic have been indicated, in order to improve built environment performances and quality of living within different time steps. This study can be considered as a promising, interdisciplinary and experimental start for developing actions for the sustainable development of communities.

1. Introduction

Target setting is extremely important in the searching for sustainability process because it aims at a desired quality of life. Targets are generally a compromise or trade off between what is envisioned and what is feasible.

The evaluation of sustainability and quality of life at the local level has been identified as a strategic goal during the Rio Summit in 1992[1]. In 1994, Aalborg Charter underlines these needs, by committing the signatory local authorities to the use of indicators as an on-going supporting tool for long-term policy-making. Responding to these calls, a lot of initiatives in Europe tried to measure and monitor the level of sustainability and quality of life of local communities by different set of indicators with reference to environmental, social and economic issues.

This paper describes the outcomes of a Preliminary Study for the Plan of Quality of Living (PSPQL) of Senago, a town of about 20.000 inhabitants, located in the hinterland of Milan, in Lombardy Region (North of Italy).

[1] The quality of life issue has been studied for a long time, even if its measurement is a more recent matter (Iezzi, 2006). It's possible to distinguish two main approaches: the first one, depending on which the quality of life corresponds to the social wellbeing and it can be measured objectively (Bauer,1996; Oecd, 2001; Osberg, 2004); the second one, that emphasizes the perceptive dimension of quality of life, such as needs, feelings and aspirations (Andrews, Whitney,1976; Campbell et al., 1976).

The PSPQL has been defined in the framework before described and follows a bottom-up approach. According to the complexity of the meaning of quality of life, in this paper this concept was assumed as a mix of qualitative and quantitative aspects with reference to urban built environment[2].

The study started in summer 2005 and ended in spring 2006, with a short addition in summer 2007, but his concept has been developed during many years, in which, the governance try to focus his interests and resources on the improvement of urban sustainability. The study has been commissioned by the municipality and has been carried out by an interdisciplinary group of young researchers (architects and engineers), involving also facilitators, town councillors, administrators, technicians and citizens. A participatory approach requires that Local Governments shift their understanding of governing and define their role primarily as important partner for local sustainable development. As a matter of fact, agreement on targets by all relevant stakeholders and actors will develop ownership of the process and responsibility to implement respective measures.

The most important aim of this study is to give a multidimensional vision of the town, investigating the actual conditions of living with reference to all the citizens (children, teenagers, young people, adults and old people) and prioritizing the needs emerging from the previous analytical steps, in order to define actions with different term: short, mid and long. Furthermore, there is the intention of putting on trial a new tool, finalized to create a clear base of common knowledge, an interchange platform supporting actors involved in urban planning and management in taking actions in order to promote sustainable development.

2. Methodology

The concept of the study has been promoted and discussed during several occasions of interaction among researchers, councillors and technicians. The study was challenged starting from the concept that not only what is mandatory has to be done, but also what is actually feasible in order to improve living conditions. In fact, the so called Plan of Quality of Living is not a defined or mandatory plan; it is an optional plan, not defined before in any other town planning experiences. For this reason, since the beginning, it was very important to define the methodology of the study, including different phases, aims, contents, sources, dissemination tools and scheduling. The requirements emerging from this first discussions and shared between all participants were the followings: give an overall picture of quality of life topics at the local level; support sustainable community strategies with the aim to set local priorities and goals; monitor progress by assessing changes over time; promote comparisons of performance between different communities; increase public awareness. In order to meet all of these demands, a set of performance indicators was developed.

2.1 Definition of the set of indicators

Many efforts were made in order to define an effective set of indicators for giving a picture of the present situation, but also for simulating and predicting effects of different choices on living conditions in the future. The set has been established by specifying a number of selected issues identified according to local priorities and strategies, with the help of the town councillors, administrators and technicians. After that, a deep analysis has been carried out, elaborating a set of 27 indicators. Most of them relies on existing indicators (i.e. European Common Indicators, National and Local Planning Strategies); others, called *User Defined* (UD), have been defined “ad hoc” and elaborated for the first time for Senago. Afterwards the Municipality of Senago required to develop more in deeply the cultural issues. So were added 6 new indicators (from 28 to 33) in order to better measure this topic.

Indicators investigated 6 different systems: environment, territory, mobility, society, economy and health (see Figure 1). More specifically the indicators selected, ordered by systems, are:

- Environment: 1. air quality, 2. energy consumption, 3. waste production, 4. waste collection, 5. waste management and disposal, 6. environmental accounting
- Territory: 7. proportion of woodland, 8. sustainable land use, 9. availability of local public open areas and services
- Mobility: 10. availability of pedestrian street, 11. local mobility, 12. children’s journeys to and from school
- Society: 13. citizens' satisfaction with the local community, 14. education degree of population, 15. proportion of 19 year olds with secondary school qualifications, 16. availability of childcare places, 17.

[2] American researchers prefer to maintain a clear distinction between the two concepts of Quality of Life, the European ones often suggest an integrated approach (Zajczyk, 1997).

cultural services-associations, 18. crimes committed, 19. proportion of strangers, 20. computer knowledge, 28. public libraries system: supply, 29. public libraries system: staff paid, 30. public libraries system: opening hours, 31.leisure and cultural services, 32. sportsman, enrolled and sports association, 33. sports services

- Economy: 21. affordable housing, 22. proportion of people of working age in employment, 23. poverty rate, 24. local businesses e jobs
- Health: 25. death rate by cause, 26. people with disabilities and demand for social assistance services, 27. public health services.

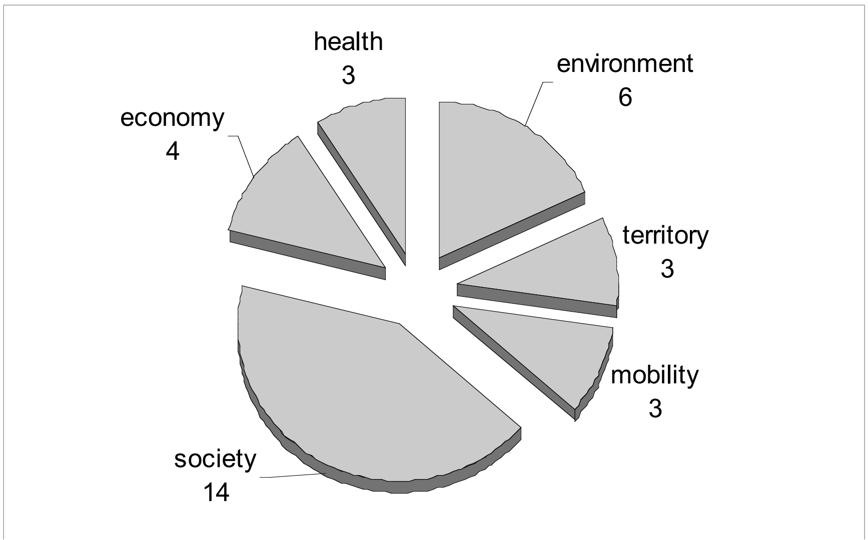

Figure 1 Repartition of the 33 indicators in the 6 systems.

Each indicator is identified by a code and is supplemented by a methodological sheet that specifies object of measurement, data collecting and elaborating methodology, data sources, references and typology of outputs. This sheet is useful not only to make the decision making process clear, but also to support the assessment of the local sustainability level in the future.

The collection and analysis of the available information about urban environment was one of the most important step of the work. Some difficulties were encountered because of the different data base supports and reference offices. Furthermore, data were often not homogeneous, because were referred to different years. It was very hard to collect updated local plans and programs and to interpret them for having an overall view of the territory, considering it as a system and not as the sum of different parts. Firstly, data was ordered by theme: environment, including energy, waste management and water cycle; territory, including contaminated soils; mobility, including availability of pedestrian paths and accessibility of services; utilities, including library, nurseries, schools, green areas, sport facilities, other services for handicapped and old people; economy; society and health. Because some information about territory and environment were lacking or out of time, several survey “in situ” have been carried out for rendering the actual living conditions and for checking the reliability of existing plans and programs. After that, measures, observations and remarks were transferred from papers to information support, based on Geographic Information System (GIS). The improvement in quality and availability of information has allowed to build-on a cross-sectoral vision and the use of GIS technology have also made easier communication between different sectors by integrating spatial and statistical data in the same format, structure and map (see Figures 2 and 3).

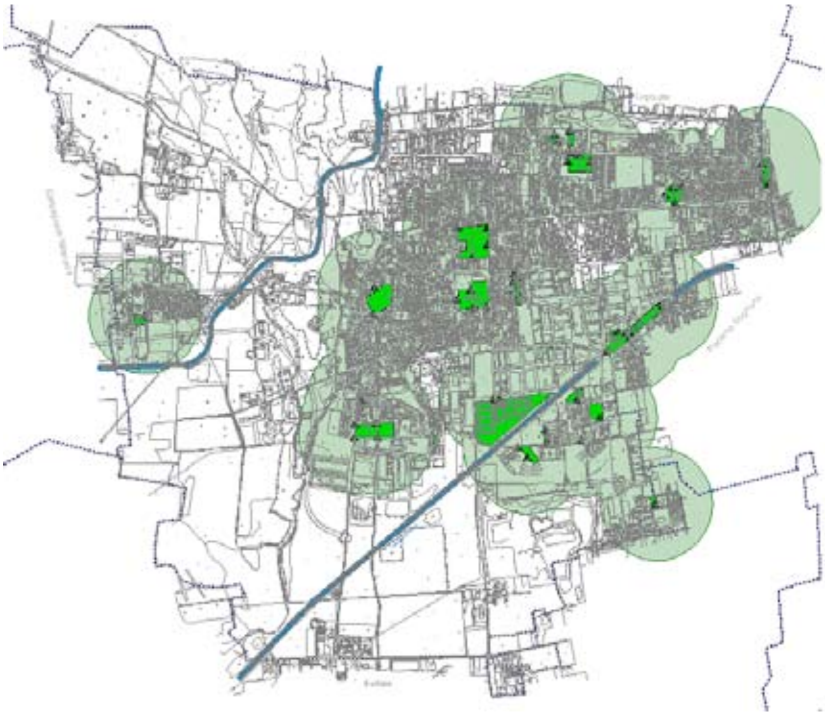

Figure 2 Map of the availability and accessibility of local green areas

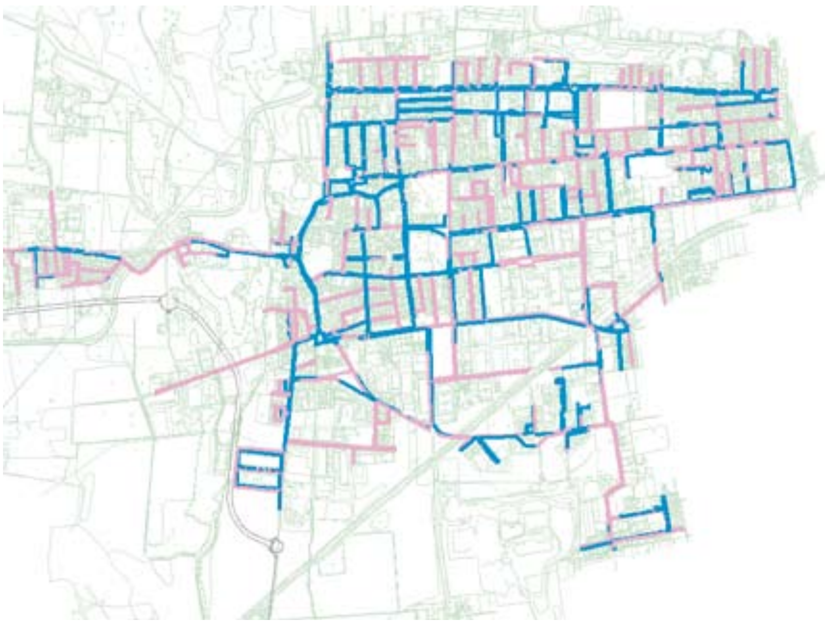

Figure 3 Map of availability of pedestrian paths. Different colours are used to point out the outcomes of the evaluation of these path with reference to the following aspects: width, lighting, flooring and the presence of barriers for users

The overall analysis permitted to investigate, discuss and underline the strong and weak points of living standards and to study in depth the actual meaning of the uninspired numbers, usually called standards of living in plans and programs.

2.2 Calculation of the indicators, results and considerations

Despite the lacks of data and the non homogeneity of them, the 33 indicators (previously described) were calculated. Full information about procedure of calculation, proxy indicators used and quantitative results are reported in the official deliverables. Results of different indicators have been represented and communicated with graphs, images and maps. An overall and qualitative view of the results is available in the following table. In order to briefly describe the complex picture emerging from the analysis carried out in the previous steps, has been assigned a qualitative score to each indicator. The judgment has been scaled in three different levels: bad, medium, good. This kind of assessment means losing the quantitative information and the critical interpretations developed for all the indicators. Even so it can contribute to promote understanding and communication about the territory between government, stakeholders and citizens.

Table 1: overview of the evaluation through indicators; results were translated in a qualitative score (*: bad; **: medium; ***: good; user defined – UD – indicators in bold)

indic.	score	indic.	score	indic.	score	indic.	score	indic.	score	indic.	score
1.		6.	**	**11.**	*	**16.**	**	**21.**	**	**26.**	**
2.	*	7.	**	12.	*	**17.**	***	22.	**	**27.**	**
3.	***	8.	*	13.	***	18.	***	**23.**	**	28	**
4.	***	9.	***	**14.**	*	19.	***	**24.**	*	29.	**
5.	**	**10.**	*	**15.**	*	20.	***	25.	**	30.	**
31.	*	**32.**	***	**33.**	***						

Furthermore, this overview underlines the more critical topics, that needs interventions in order to improve the urban quality. The most crucial topics are built environment (action: to improve rehabilitation interventions), territory (action: to promote conservation and protection of natural resources), mobility (action: to optimize services in order to minimize the use of private cars), economy (action: to encourage sustainable and high technology productive assets).

3. Energy Performance of Built Environment

The calculation of the 33 indicators pointed out important results about the built environment (i.e. buildings performance and energy consumption in buildings and transportation). For calculating indicator “2. Energy consumption” (one of the six indicators of system ENVIRONMENT), a rough survey of energy performance of existing buildings has been carried out. On the basis of the collected data, it is possible to state that main residential conditions are quite suitable and the availability of spaces is quite good (see Table 2).

Table 2: statistical data about built environment of Senago (year 2001)

Num. of families	7238	Aver. residential surface per person	32 m^2
Average num. of person per family	2.6	Average num. units per buildings	3.9
Average surface of residential units	84 m^2	Average num. rooms/Unit	3.6

But, looking at the actual characteristics of built environment and buildings system, it is possible to find out that a scheduled and adequate program for refurbishment is needed. In fact, more than 50% of buildings were built more than 30 years ago and the most part of them were built during years 1946–1961, period in which no performance requirements were considered nor fixed by law (see figure 2, on the left, in which reported data represent a situation that is very popular in Italy). Looking at the shape of buildings and considering surface/volume ratio (S/V), it is possible to suppose a bad thermal behaviour of buildings and high thermal losses (see figure 2, on the right).

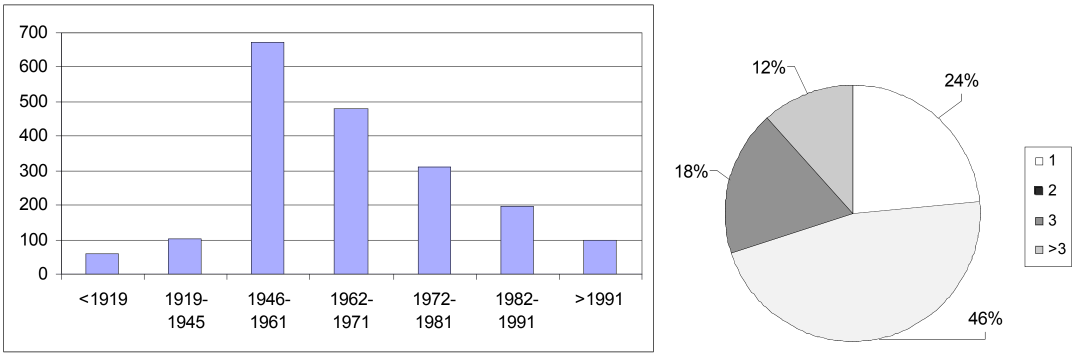

Figure 4 Number of buildings ordered by age (left) and percentage of buildings with 1, 2, 3 or more than 3 floor above the ground (right)

All these considerations are confirmed by data about energy consumption in buildings for heating, cooling and appliances. It was very difficult to find homogeneous and correct data about natural gas (most used source for heating) and electricity and to define the reference built surface and lived space, but at the end it is possible to assert following data:

- natural gas consumption in buildings (all, public and private): about 750 m^3/inhabitant, otherwise more than 200 kWh/m^2 per year, in term of primary energy; analogous results were obtained considering natural gas consumption in public buildings that represent about 3-4% of total consumption; worst performance in term of natural gas consumption was observed in a nursery
- electricity consumption in buildings (all, public and private): about 26 kWh/m^2 per year
- electricity consumption in public buildings: about 40 kWh/m^2 per year.

On the basis of a rough analysis carried out in few public building, these high consumptions do not correspond to good comfort conditions. Further, considering results of a campaign for monitoring air pollution in 2004, it is possible to find out that heating systems and plants contribute for half of the total CO_2 and NO_x emissions. Therefore, despite final result of indicator “2. Energy consumption” represents an average situation if compare with the national Italian one, a wide potential for reducing energy consumptions and, as consequence, CO_2-eq emissions has been pointed; and this information is more important if considered in the framework of new European Directive on Energy Performance in Buildings and following national and local laws and regulations.

4. Participative Approach

Local involvement in planning and management of the environment allows strategies to be tested and refined before adoption, ensuring built environment that satisfy both individual and community needs. Nowadays, there is a growing range of methods that has been developed in different experiences from many countries. They include different ways of listening to what local people have to say about their surroundings referring to different level of participation.

The approach adopted in this study rises from the principles of Local Agenda 21 processes and includes, in particular, three different stages of community involvement: surveying citizens’ satisfaction with the municipality as a place to live and work and the modes of transport of children travelling between home and school, according to European Common Indicators recommendations; inquiring visitors of the local trade exhibition about quality of public spaces by interactive displays; awakening people to environmental issues by public conferences and graphic materials shown during the same exhibition to capture the views of a large number of citizens.

Even if this kind of participatory approach has been applied only ex-ante, because of the term of the assignment, local authority was requested to consider identifying communities’ needs as an ongoing action: before to planning strategies, this gives an idea of how to improve their surroundings; during implementation of actions, it makes sure that you are on target in order to get the maximum impact from the resources spent; after the actions has been carried out, the review of outcomes and outputs is useful to further the development of a community initiative.

5. Developments and Conclusions

In order to improve built environment performances and quality of living by the action plan according to different targets and time steps (short-, middle- and long-term targets), on the basis of the indicators for each topic have been indicated the fields of intervention. More in deeply, has been defined procedures for maintaining and refurbishing existing buildings, for providing low energy and renewable in new buildings, promoting public transportation system and use of bicycles, improving public lighting efficiency, developing environmental protection and monitoring campaigns.

Identifying clearly the targets with the aim to outline an action plan is a very difficult step and needs to carry out deep analysis about available resources, simulation/modelling of interventions, forecasting of outcomes and impacts, in order to optimize them. It will be useful to set up a Planning Office, with the task to check the development of the action plan by updating indicators and to promote communication between local government and communities.

After all, because one of the aims of the PSPQL was to give an overview and to put in communication existing plans and programs for optimizing their effects and evolution, relationships among PQL and the most important defined by law plans and programs have been underlined, as development of the study. For all these reasons, the study can be considered as a promising, interdisciplinary and experimental start for developing actions for the sustainable development of communities.

Furthermore, in this way all decision-makers involved in the process are accountable to citizens, as well as to institutional stakeholders. Transparency is built on the free and accessible flow of information. The process built-up since now has tried to serve all stakeholders by producing results that meet needs while making the best use of resources. Partner relationships are encouraged among authorities and also the creation of networks of cooperation and knowledge transfer which can go beyond the local context.

The model simulation of the architectural micro-physical outdoors environment

Chiag Che-Ming, **De-En Lin** , Po-Cheng Chou and Yen-Yi Li
Archilife research foundation, Taipei, Taiwan , archilif@ms35.hinet.net

Keywords：WRF model、micro-physical environment、weather forecast system

Summary

To pursue higher security, better healthy, and more comfort for dweller, it is very important to study the correlation about outdoor and indoor atmosphere status and the sensitive information of micro-climate meteorology which the building provided. Through the latest meso-scale model "WRF" to process numerical emulation about the Archilife research living center, it could make up the space and time resolution deficiency in traditional weather observed tools, then in accordance with the model emulation results to retrieve information back to the background data of indoor micro climate and weather station, so it could provide more scientific evidence to clarify the relation between indoor, outdoor physical environment and buildings.

The research results reveal that the ability of WRF model emulating the micro climate and weather status is well generally, as for the problem of higher weather factors magnitude in model simulated result than real observed one, especially in wind field, this maybe caused by terrain characteristic and geographical features over there, that could be fixed by improving the terrain parameter and tuning the boundary condition of model in the future.

1.Introduction

The main function of the modern buildings, in addition to provide the residents a secure living environment, the ability of pursuing the quality of life and offering comfortable living is also more and more subjected by people as time goes by. Perceiving the characteristics of weather system and environment around buildings thoroughly, and controlling the period and frequency of variety by the way of following tendency, turning resistance into assistance, and adverse status into fortunate status, the life property will be advanced more effectively and the restriction produced by natural environment will also be reduced. To retrieve the environmental static data into reality generation, then identify the relation between various weather systems owning different scales, and find out the optimum experiment scheme, the scientific significance will be acquired and extracted more legitimately.

2.Research method

The research method is applying the WRF meso-scale model to process numerical emulation about the Archilife research living center. The latest WRF model (Weather Research Forecasting model) adopts the sigma coordinate in vertical plane and Arakawa B cross grid in horizontal plane, and the multi-nest grid scheme could simulate the interaction between various weather owning different scales effectively. For the complex meso-scale weather system, WRF model could make up the space and time resolution deficiency in traditional weather observed tools. Recently, because of improved boundary layer condition, cumulus parameter, and Four-Dimension Assimilation, the WRF model had been used to study and emulate the meso-scale weather system extensively by scientist so far.

There are two level in model grid nested scheme, the procedure is so-called "two-way interactive" method, which could retrieve the fine grid data back to coarse grid data. In order to raise the time and space resolution of model, the grid interval is set from 0.5 to 1.5 km (Fig.1 and Fig.2 shows model coarse and fine grid integral region, respectively) and time interval is set 1 hr to emulate the characteristics of meso- and small-scale weather systems. For model fine grid region, the maximum terrain height in Taiwan area is about 3731 meter, cumulus parameter is set Kain-Fritsch Scheme（Kain and Fritsch, 1993）, then boundary layer is set Yonsei University scheme（YSU, Hong, and Pan,1996）, and micro physics parameter is set WRF Single-Moment 5-class scheme（WSM5, Hong et al., 2004）. The total model integral time is 48 hr, and apply the NCEP（National Center for Environmental Prediction）GFS AVN model data to be model initial data.

3. Verification and examination

For the purpose of understanding the ability of WRF model emulating various weather system more clearly, we choose weather systems occurred from Oct 2006 to Jan 2007 (there are 20 weather systems cases, 80 samples during four month totally), in which including a variety of weather systems (e.g. front, front pass through Taiwan northern ocean, northeastern monsoon in the winter season, cyclone flow near and outside typhoon, cold surge, continental high pressure, and continental high pressure backflow etc.) and weather phenomenon (e.g. low temperature, small rain, rain, rain shower, sunny, and cloudy etc.), we try to investigate the long-term weather characteristics and organization around and near the Archilife research living center in favor of following verifying and examining the simulated capability of WRF model.

Real observed data was adopted from two micro climate observation stations, one constructed at and another constructed near the Archilife research living center, above two stations data was compared each other to get the optimum observed data. Observed data time is 02, 08, 14, and 20 o'clock local time, and observed weather factors include temperature, pressure, humidity, precipitation, and wind field etc, beside verifying and examining WRF model, the model initial time is set 12hr early than the observed data time to avoid the problem of model “spin up”.

Table 1 shows the evolution and variation of temperature factor in this research, in which, the blue line represents the real data recorded by micro climate and weather station, called ”observation-1”, the red line represents the high-resolution WRF model simulated data, called ”simulation-1”, and the brown one represents the low-resolution WRF model simulated data, called ”simulation-2”. The research result reveals that the high resolution model data is more sensitive, exact, and much similar to real atmosphere status then low resolution one, no matter in variation magnitude, profile, and amplitude of temperature factor. For simulation-2, on the other hand, appears excess magnitude and exists some phase shift (displacement) then observation-1, especially in sample from 46 to 52 and from 61 to 67. In general, in simulation-1 and simulation-2, there are more or less excess magnitudes temperature factor (but there are some magnitude shortage samples in simulation-2, that maybe generated by the stable characteristic of wave), especially in simulation-2. As for relative humidity, pressure, and precipitation, the variation tendency of model emulated results are very similar to observed data (figure not shown), that also can illustrate the great ability of WRF model simulated the meso-scale weather system in local area.

4.Simulational results

For the purpose of displaying the excellent ability of WRF model simulated the meso-scale weather system around and near the Archilife research living center and providing residents the latest model data in time to satisfy their living needs, so select the cold surge case occurred during 16^{th} to 17^{th} Dec 2006.

Severe continental high pressure moved southward and northeastern monsoon penetrated directly during 16^{th} to 17^{th} Dec 2006, because the specific location of the Archilife research living center (windward side for northeastern monsoon), there would be obvious variation in various atmospheric weather factors in this period. Fig.3 shows the variation of temperature factor in all Dec month, there were two low temperature phenomenon appeared in 16^{th} and17^{th} Dec which was the minimum temperature value in all Dec month(14℃ in 16^{th} and 13.5℃ in 17^{th} Dec, respectively), followed by cold surge weaken and temperature raised. If consider the pressure variation simultaneously, then the transformation and development procedure of cold surge moving southward can be described expressly. The Severe continental high pressure started to move southward in 14^{th} Dec, then the strength of continental high pressure arrived strongest in 16^{th} and 17^{th} Dec, the center pressure magnitude of continental high pressure is about 1017-1018hPa during this period, followed by strength weaken produced by the characteristic distinction between continent and ocean and far from away the formatted source area of high pressure. The wind field pattern, in which reveals when severe continental high pressure moved southward, accompanied by strong wind field, speed from 8 to 10 m/s in average and sustained 36 to 48 (or above) hr. Clearly, this is a traditional severe cold surge case in winter season because of the obvious variation in temperature, pressure, and wind field factors. For precipitation, on the other hand, there was no obvious magnitude observed by research weather station, this maybe caused by a little amount of water vapor in atmosphere and the track of continental high pressure moved southward.

The model simulated weather factors were a little bit great than observed one in magnitude, the temperature factor was 13-14℃ in 16^{th} and 12-13℃ in 17^{th} Dec in average, this was very similar to real observed data, but there was much variation in wind field, speed about 12.5-15m/s in 16^{th}, and 15-17.5m/s in 17^{th} which maybe caused by the simulated continental high pressure burst southward suddenly. Although the simulated wind field was higher than reality data in magnitude, but the variation tendency is very similar each other (Fig.5 shows the relation of temperature factor between model simulated result and observed data, in which, the correlation coefficient is 0.8667), this maybe formed by terrain characteristics and geographical features over there, so this problem could be fixed by improving the terrain parameter and tuning the boundary condition of model in the future.

5.Discussion and Conclusion

In general, through verified and examined the model simulated results, the ability of WRF model emulated the micro climate and weather system well can be identified, so the simulated results can be retrieved back to the basic information of micro climate and weather data, then provide the more scientific information to clarify the relation between buildings and indoor, outdoor environments, and supply the important parameters of designing and selecting the material of buildings to fit the needs of residents. As for the problem of model simulated weather factors is excess than real observed data in magnitude, especially in wind field, this maybe caused by terrain characteristics and geographical features over there, and that could be fixed by improving the terrain parameter and tuning the boundary condition of model in the future.

Design and Development of Natural Ventilation Products and Associated Improvement of Indoor Environment Quality.

Associate Professor S .T. K. West[1]

[1]Head of Building and Construction Management, University of Canberra, Australia
shane.west@canberra.edu.au

Keywords: Natural ventilation, wind ventilators, Skylight vent

Summary

The Australian / New Zealand Standard, 4740 (2000) *Natural Ventilators- Classification and Performance,* is discussed in this paper. It has provided an ideal platform to standardise and make accurate comparative analysis of natural ventilators exhaust flow rates.

Experiments with various manufacturers' ventilators were undertaken, comparing them to, the relative performance of an unimpeded 300mm diameter opening; the methodology employed and the results of this testing are disclosed in this paper.

New advanced ventilation designs and test procedures are also described in this paper, such as the long volume turbines and improved wind directional vanes, with increased exhaust flow rates.

Product innovation and improved performance and test results utilising the test facility developed for the Australian / NZ ventilation standard has led to the commercialisation of new products such as the Wind Directional Skylight Ventilator and the roof siphon that utilises the hot air in the roof space to further drive the natural ventilation process.

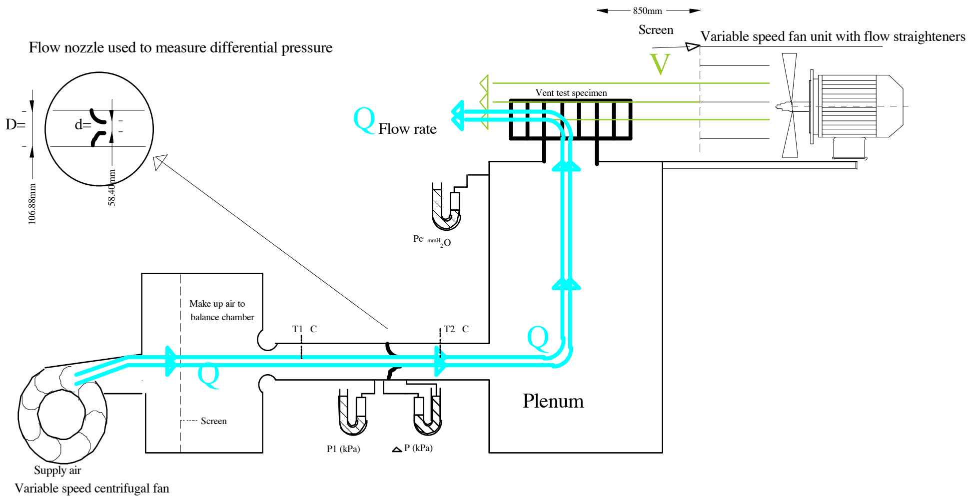
The paper concludes with discussion on the detailed product design of the unique Wind Directional Skylight Ventilator, its measured exhaust flow rates, ability to reduce condensation and improve indoor environmental air quality via natural ventilation and daylight.

1. Introduction

An initial approach by the Australian Consumers' Association (CHOICE) and a leading ventilator manufacturing company to see if low wind speed testing was achievable at the University of Technology, Sydney aerodynamics laboratory, developed into a very successful industry and cross Faculty collaboration. The research outcomes have significantly advanced the understanding of wind driven turbine ventilators and natural ventilation in general.

Following exhaustive trials, a suitable test rig was developed, (please refer to figure No.1.) and a comparative analysis undertaken of most of the ventilators on the Australian market supported by the Australian Consumers' Association.

Following the results of the testing and comments submitted to Standards Australia/New Zealand regarding a draft Standard on Natural Ventilators, the author was invited to join the Standards Committee on Natural Ventilators
This work has resulted in the Australian/New Zealand Standard AS/NZ 4740 2000 Natural ventilators- Classification and performance.



UTS pressure differential ventilation test rig

Figure No.1. The UTS pressure differential ventilation test rig later adopted as the test method for Australian / New Zealand Standard AS 4740.

Several wind siphonage test configurations were evaluated at the UTS aerodynamics laboratory, with reference to results achieved by other testing facilities and to manufacturers published performance. From these attempts at finding the best test methodology to employ, an appropriate testing standard was sought.

No official standard was available so, guidelines were established following trials including variables such as:

Air flow to be measured using a flow metering device as described in AS 2360.1.1 1993 *Measurement of fluid flow in closed conduits.*

A controlled airconditioned environment was considered essential to allow for consistent result which would have otherwise been affected by pressure and temperature differentials, as each ventilator would be required to be mounted on a stack and the pressure and temperature needed to be controlled within the stack, to allow for consistent results, as a decrease or increase in temperature will affect density and subsequent flow rate measurements.

It was assessed that a variable wind speed would be required to be applied as Free Field (unbounded fluid flow field) instead of a closed test station such as a wind tunnel, which would lead to blockage effects. And subsequently each ventilator should be mounted on a stack / plenum chamber and the pressure and temperature controlled within the plenum chamber

It was a requirement to make the testing procedure as realistic as possible to field applications so the results obtained from these tests would establish the relative performance of several ventilators measured to the control- (300mm diameter open pipe 200mm high) as depicted in Figure No.1.

2. Methodology

To test ventilators performance a comparative analysis was undertaken, utilising the developed pressure differential facility. A suitable fan produced the required wind velocity over the ventilator, opening or wind directional vane, giving rise to suction, drafting air out of the plenum chamber. Air pressure is balanced by an input supply fan to achieve ambient air pressure and this in turn is measured applying Bernoulli's principle across a flow metering nozzle as shown in Figure.1 and mathematically expressed, to derive the appropriate flow rate formula:

3. Results

3.1 Comparative analysis of ventilators performance

Ventilators tested were those that are sold commonly in the Sydney market and experimental designs aimed at increasing performance. A fair analysis was sought to compare the ventilators performance at Sydney's average wind speed of 12km/hr.

Ventilators on the market had a range of manufacturers performance and options such as fans (refer to figure No 2.) stated as improving exhaust performance. In fact throat restrictions in the case of some fans actually impeded performance.

Figure No 2. 380mmm throat vent with fan blade fitted.

A significant result of the comparative performance was the effect that throat area had on the flow rate. Comparing a 250mm throat diameter to a 300mm throat diameter,(0.049m^2 and 0.071m^2 respectively) showed a 30% increase in throat area but there is not a proportional association i.e. as the throat increases in diameter the flow rate does not increase proportionally, but increases by an extra15% over the 30% throat increase giving a 45%

increase in flow rate. In experimental designs the limitation of throat diameter was recognised and the ability to increase the blade height was also assessed as being a possible variable affecting exhaust flow. In other words the throat area remains constant but the vent lengthens in blade height to increase its volume, hence the term, long volume turbines (refer to figure No.3).

Figure No. 3. Variable blade height / Long Volume Turbines (LVT's)

In this experiment, keeping the uniform 300mm throat and allowing only the blade height as a variable showed the poor performance of the 170mm blade height model, which only had half the exhaust performance of the 340mm blade height model, which also corresponded to a 25% increase in the blade height over the normal 250mm model and correspondingly increased the exhaust flow by 15%.

The 50% blade height was not manufactured correctly and a 50% increase on the standard 250 should have been 375mm not 340mm, however the hypothesis was proven correct and results were scientifically unique. Blade separation, shape and reduced bearing drag were other factors that were shown to contribute to exhaust efficiencies.

4. New Product development-Wind Directional Skylight Vent

With the on going energy reduction / greenhouse emission campaigns and in line with ESD principles the relevance of stack effect and wind siphonage to provide energy neutral effective ventilation is now gaining the attention of building designers around the world.

Experimentation and extensive CFD analysis with new designs resulted in a unique omni directional aerodynamic foil that ventilates by rotating into the wind and generating negative pressure to extract efficiently and at the same time provides daylight as a vertical light pipe. The Wind Directional Skylight Vent (WDSV) was a product designed to incorporate cost efficient componentry and was laboratory tested to the Australian/New Zealand Standard AS/NZ 4740 2000 requirements. The product is a clear aerofoil skylight that ventilates by turning as an omni directional vane into the wind, giving rise to increased air extraction flow rates, (as seen in Figure No 4 below)

Figure No 4. 300mmm throat Wind Directional Skylight Vent.

The WDSV product will be particularly useful in New Zealand, which has condensation problems. The WDSV has been demonstrated to ventilate at twice the air changes per hour (ACH) compared to the 250mm rotary vent. Another useful feature for local conditions is the purported benefits of daylight into attic spaces discouraging possums and vermin that being nocturnal like to sleep during the day, in the darkened roof space.

Another major benefit of the vent is the ability to locate it over sources of moisture to remove hot and moist air at ceiling height via a tube to the outside (please refer to Figure No.7). As inside temperatures rise, the ability for air to hold moisture rises, which is usually exasperated by warm humid sources such as showers, kitchen sink, clothes dryers etc.

Above the point of the moisture source is an ideal location to have a ceiling vent that will via light tube and WDSV, extract the humid air to the outside environment saving potential dew / condensation forming inside the house as would be the case if warm humid air touches cool windows or walls and results in mould issues leading to asthma and material decay.

The results shown in figure No 5 were all tested at the UTS aerodynamics laboratory, under AS/NZ 4740 requirements, those in yellow by the author on the 20.7.05 and those in red by (Low 2006).

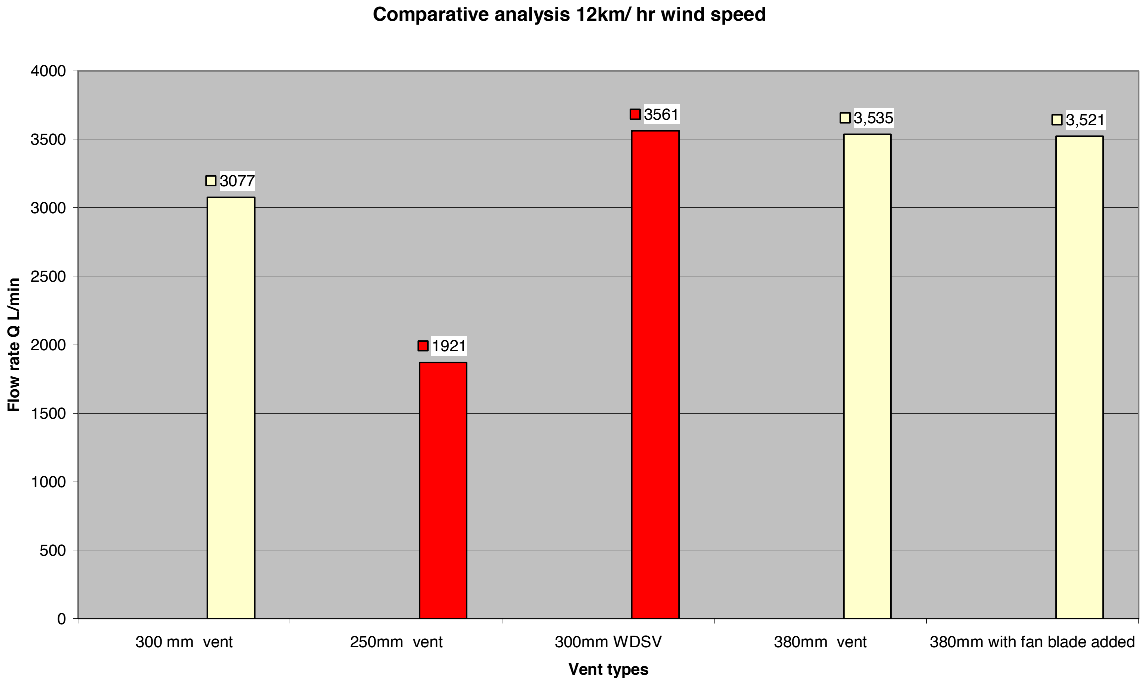


Figure No. 5 Vents tested, 300 mm throat, 250mm throat, WDSV 300mm throat, 380mm throat with and without fan.

The efficiency of the WDSV having a smaller throat size than the 380 mm throat vent but better performance is a notable experimental result as is the slight reduction in flow rate caused by blockage to the throat of the 380mmm throat fitted with a fan blade compared to the relative performance of the same vent with the fan removed.

5. Condensation- IAQ Health Issues

Indoor Air Quality is well known and growing concern and reports have consistently shown that indoor air pollution may be twice or up to five times worse than outside air (Hess-Kosa, 2002). Breathing trapped polluted air, is one definition that could be used to describe the indoor air quality that occupants may be subjected to in some buildings. Even in airconditioned buildings, contrary to the name "conditioned", implying improved air quality; the internal air may have poor filtration and have less than 15% fresh air intake, (Australian Standard 1668 Pt 2 1991, recommends offices to have a ventilation rate of 10 litres per second per person.) leaving the internal air space full of contaminants.

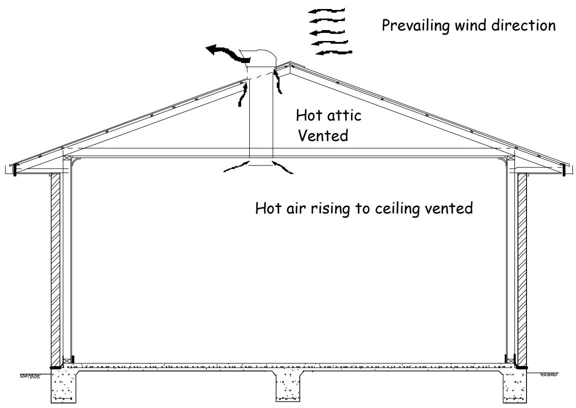
The value of increased ventilation and desired removal at ceiling levels above sources has been identified in several studies such as (Li & Delsante 1997) where range hoods and direct bathroom exhaust ceiling extractor efficiencies were measured. This study showed the efficiency and ability to reduce the spread of moisture and contaminants were best achieved at source before dispersal throughout the building.

The need to further increase and induce air movement in bathrooms and kitchens of Malaysian houses was expressed by (Zain –Ahmed Et al 2005).

Many mould issues associated with bathrooms and carpets having high moisture content have also been shown to have higher dust mite concentrations. In New Zealand studies have suggested that higher ventilation rates are required to overcome the situation of tighter houses requiring greater drying ventilation to reduce moisture content. (Cunningham et al 2001) suggested the need to alter bio climatic conditions and reduce humidity levels to reduce mould growth and associated micro organism proliferation.

The WDSV's ability of reducing moisture laden air at its source over shower recesses is combined with an energy free operation that allows for ventilation to continue unabated and provide a suitable outlet that is required for tight buildings that operate with roof ventilation supply systems that push drier air from the roof attic space or outside into the house, relying on the moist inside air finding seepage out of the building via ill fitting doors etc..

The effectiveness of reducing the moisture at the source, providing daylight to further reduce mould growth and the ability to ventilate at ceiling level are the features incorporated with the WDSV operation that enhances the anti condensation pressure systems by providing a flow path of air to the outside that is capable of greater exhaust than a rotating cowl by also utilising attic pressure, better wind siphonage, and internal stack pressures as shown in figure No 6.



This system has three way extraction: Stack effect, wind assisted, attic siphonage

This arrangement ventilates the room space and the attic space, whilst providing daylight to both the room and attic space.

Roof Siphon

Figure No 6. The Wind Directional Skylight Vent operating as a ceiling daylight and vent combination.

6. Conclusion

The testing procedure developed at UTS and incorporated into the Australian / New Zealand Standard 4740 has provided an ideal platform to standardise and make accurate comparative analysis of natural ventilators exhaust flow rates.

The need to provide ventilation, reduce or dissipate heat and moisture levels inside buildings to improve health and comfort conditions and hence productivity is desirable. However, the costs associated with redesigning, air conditioning and insulation may be prohibitive and simple cost effective natural ventilation methods are now being considered as more sustainable options.

In the experiments conducted, advanced aerodynamic designs have been shown to have increased exhaust flow rates and improved ventilation rates for stack flow and wind siphonage. The increased flow rate will in turn provide reduce heat load and moisture by increasing the air exchange rate. The WDSV's application into ceiling fixtures in conjunction with attic exhaust will assist in reducing mould growth conditions associated with bathrooms and laundries, by exhausting warm moisture laden air to the outside of the building envelope, helping in turn to improve IAQ.

Further to these advances, the development of WDSV technology described in this paper will make another contribution to improving energy efficient building operations, cleaner / healthier internal environments by providing a cost efficiency saving in the product design. Cost efficiency (economic sustainability) needs to be considered in sustainably designed products, in the case of the WDSV by simplifying and reducing the need for expensive mechanical ventilation, and reducing artificial lighting it is a straight forward design that does the role currently of two or three products associated with higher energy demand.

Summary

The aim of this study is to understand the influence of energy efficient design on energy consumption and indoor environment. For this reason, an environmental house was built in Dec. 2005 in the north of Sendai city, northwest of Honshu Island of Japan. It is a three-story house, including a basement, a first floor and a second floor under the pitched roof. The first and second floors were constructed in wood, while basement was built by concrete. The total floor area is about 240m^2.

Many sustainable design components were included for the house. For example, it is well insulated and airtight. The heating transmission rate and equivalent leakage value is 0.86 W/m^2·K and 0.94cm^2/m^2 respectively. It equipped with a 5.64kW solar panel on the roof for electric generation, a solar hot water system is placed in the garden. First floor is heated by thermal storage floor heater using midnight power and cooled by air-conditioner, according to the seasonal conditions. A number of low or no VOC building materials are used, including less polluting paints, wood product, etc. As it is an experimental house, it is only occupied twice a year, a week each in summer and winter. In order to predict the energy consumption and indoor environment of the investigated house in line with the actual state of inhabited residence, simulation was carried out with the condition of 4-person dwelt in the house.

1. Outline of Investigated House

The experimental house (Fig.1.) is a three-story house, including a basement, a first floor and a second floor under a pitched roof. The floor plans of the said house are given in Figure 2. It is an electrified and detached house completed in Dec. 2005. The house is located in the north of Sendai city which is in the northeast area of Honshu Island in Japan. The first and second floors were constructed in wood, while the basement was built by concrete. The total floor area is about 240m^2 and it is well insulated and airtight. The heating transmission rate and equivalent leakage value is 0.86 W/m^2·K and 0.94cm^2/m^2 respectively. Air tightness was measured by the pressurization method. It is equipped with a 5.64kW solar panel on the roof for electric generation, a solar hot water system is placed in the garden. First floor is heated by thermal storage floor heater using midnight power and cooled by air-conditioner, according to the season. The guest room in the basement and the child's room on the second floor are heated and cooled by air-conditioner. As it is an experimental house, it is only occupied twice a year, a week each in summer and winter.

Figure 1 Exterior of experimental house

2. Measurement

2.1 Outline of measurement

Measurement items included energy consumption, indoor temperature & humidity, wall temperature, indoor air quality and airflow rate of the ventilation system. Measuring points of temperature & humidity are shown in Fig.2. The measurement intervals of energy consumption, electric generation and indoor temperature were 1 minute and 15 minutes, respectively. The measurement was carried out from Jan.1 2006 to Oct.31 2007.

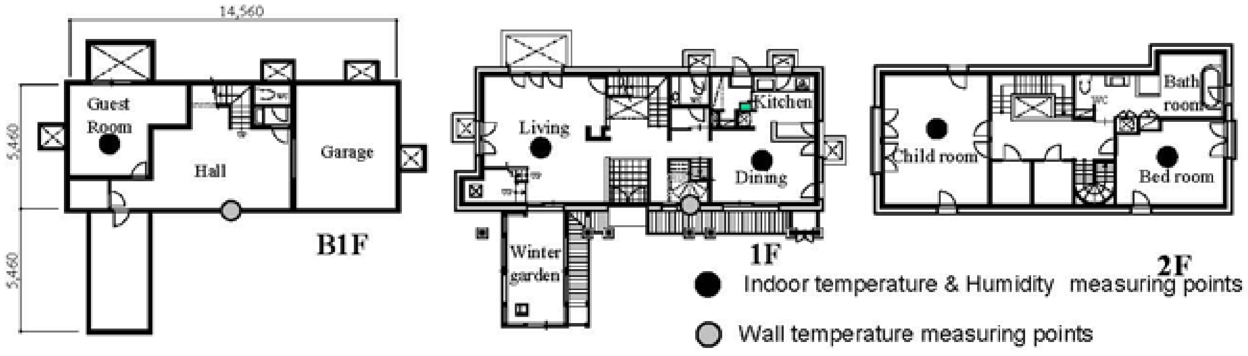

Figure 2 Floor plans of experimental house

2.2 Profile of daily energy consumption and mean temperature

The profiles of daily amount of energy consumption and electric generation by PV, daily mean temperature of the experimental house over the measurement period, Jan. 2006 to Oct. 2007, are shown in Fig.3. In the lower graph under Figure 3, plus and minus signs of y-axis are the amount of energy consumption and electric generation respectively. Hot water supply means the consumption of electric-heated hot water, which does not include the usage of the solar hot water system.

In the beginning of January, indoor temperatures gradually rose from 12~13°C to 20°C. During this period, the heat began to be stored in the building frame. Since the end of January, indoor temperature was maintained constantly at about 20°C. In summer, the temperature on the second floor was generally higher compared to outdoor temperature, while that of the basement was constantly at 20°C due to the ground cooling effect. The operation of floor heater began at the end of November. Since then, the fluctuation of indoor temperature became bigger because of frequent changes of heating set point.

Space heating constitutes a large portion of the overall energy consumption, while electric generation varied between 0 and 34kWh/day. Nevertheless, it is expected that the energy consumption for other end uses would be higher, if the house was occupied.

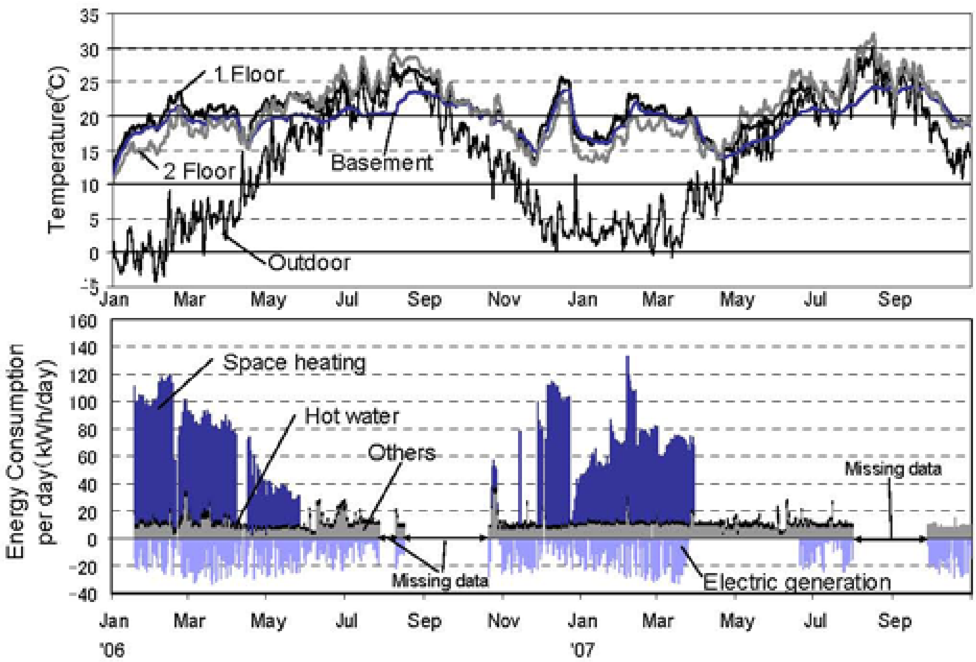

Figure 3 One year profiles of daily mean temperature, energy consumption and electric generation

2.3 Temperature and energy consumption profiles during occupancy periods

For the purpose of this study, 4 persons were living in the experimental house a week each in summer and winter for a week. The temperature and energy consumption profile during the selected three days within the occupancy periods are shown in Fig.4. The per day energy consumption and electric generation are shown in Fig.5.

2.3.1 Winter

Although outdoor temperature varied from -1.0°C to 11.8°C, the temperatures of the first floor and basement were maintained constant at 22°C and 20°C respectively. The energy was mainly consumed from 1 am to 6 am everyday by using mid-night electricity for space heating and hot water supply, while energy consumption was small during other times. In this three-day time, energy consumption for space heating constitutes about 73% of the total energy consumption, while the ratio of electric generation against energy consumption was 17%.

2.3.2 Summer

The fluctuation of indoor temperature was more stable compared to outdoor temperature which varied between 18°C and 32°C. It must be noted that the temperature of the basement floor was maintained constantly at 20°C due to the ground cooling effect.

With respect to energy consumption, there were some peaks of about 3.5kW during cooking hours. The total energy consumption was 0.3 times lower compared to that in winter, while the ratio of electric generation to total energy consumption was 80%.

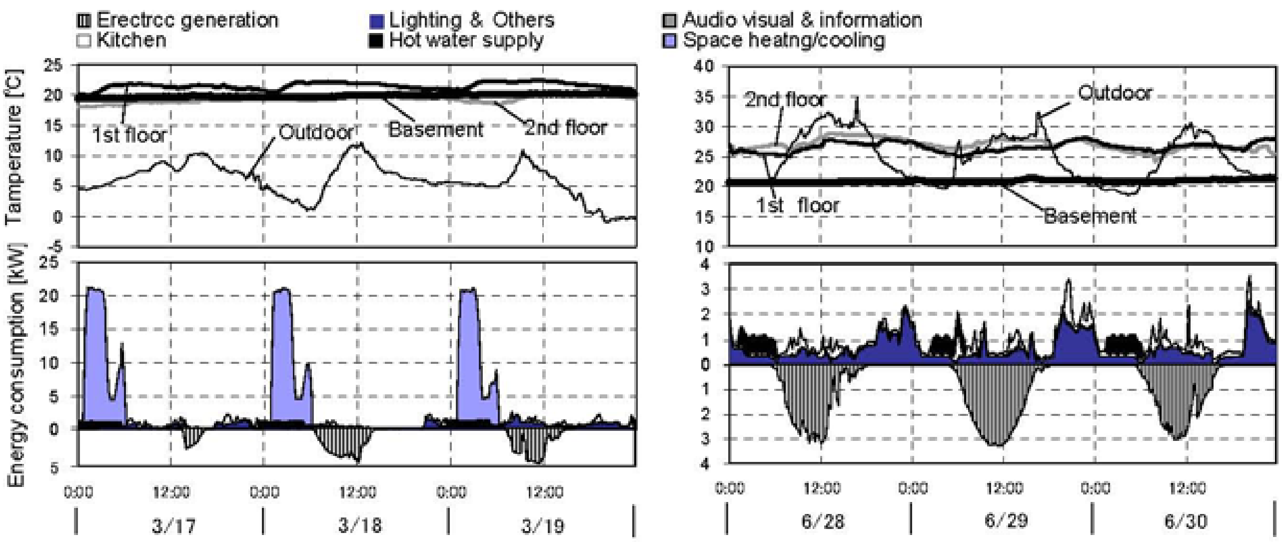

Figure 4 Profiles of temperature and energy consumption during the 3-day occupied period

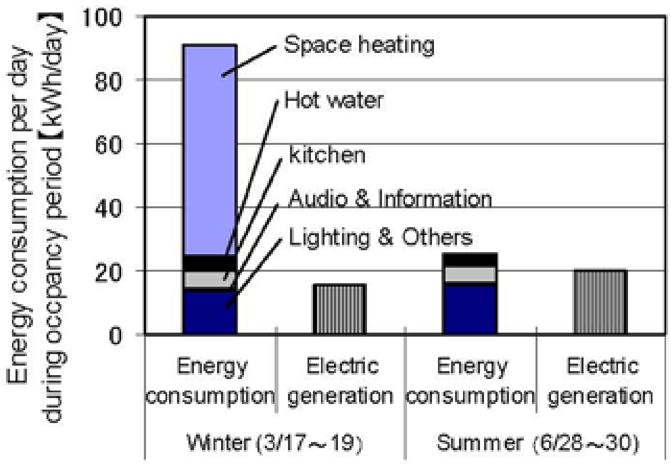

Figure 5 Energy consumption by end use per day of occupancy period

2.4 Indoor air quality

Investigations of indoor air quality were carried out in summer and winter. The results showed that the concentration of formaldehyde was higher than the guideline value (0,08ppm) in summer. In addition, the generation of α - pinene from the woods resulted in that the concentrations of TVOC were much higher than the guideline value both in summer and winter.

3. Calculation

3.1 Outline of Calculation

In order to predict the energy consumption and indoor environment of the investigated house in line with the actual state of inhabited residence, simulation was carried out with the condition of four persons living in the house. Energy consumptions for appliances, lighting and hot water supply were calculated using the program of SHEDULE Ver.2 (SHASE House Energy Simulation Subcommittee (2000). Electric generation by PV was calculated from Sakai's predicted relation (Sakai et al. 2004). Heating/cooking load was calculated, and the data of internal heat generation, building and climate were input into the TRNSYS program (Solar Energy Laboratory University of Wisconsin-Madison. 1996). In the simulation, climate data was the typical climate data in Sendai. A family of two adults and two children was assumed to be living in the experimental house. The set points for heating and cooling were 20°C and 27°C respectively.

3.2 Verification of the simulation model

In order to verify the simulation model, calculated results were compared with the measurements during the occupancy periods, which are shown in Fig.6. (Left: Winter; Right: Summer). The results obtained from calculation for summer and winter show good agreement with the measurements. Thus, the said simulation model can be used to predict the annual energy consumption in a typical family.

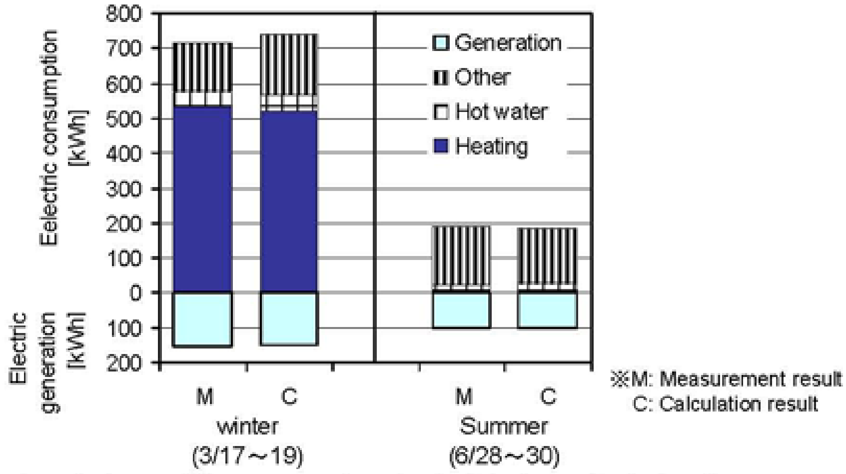

Figure 6 Comparison between Measurement and calculated results during the occupancy periods

3.3 Results of monthly energy consumption and electric generation

The calculated results of monthly energy consumption and electric generation are shown in Fig.7. Monthly energy consumption varied between 2.1 and 9.0 GJ/month. Energy consumption was large in winter due to floor heating, with the maximum value approximately 9.0GJ/month in January. Monthly amount of electric

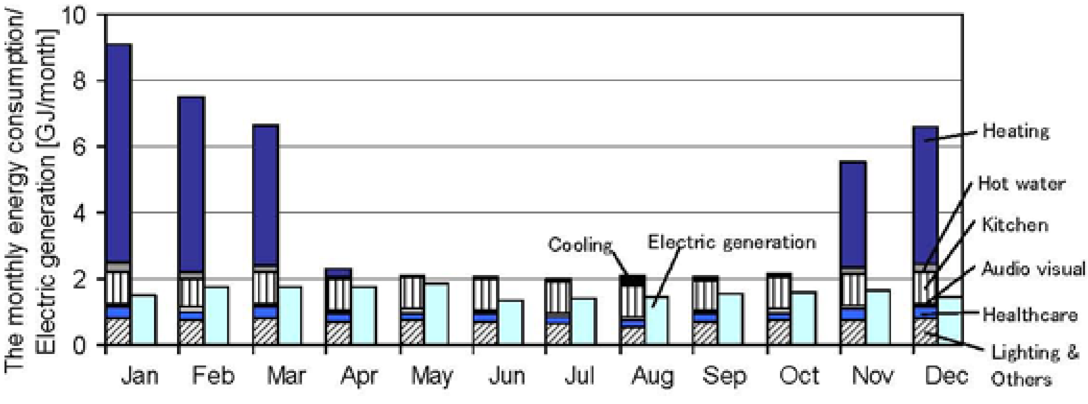

Figure 7 Calculation results of monthly energy consumption and electric generation

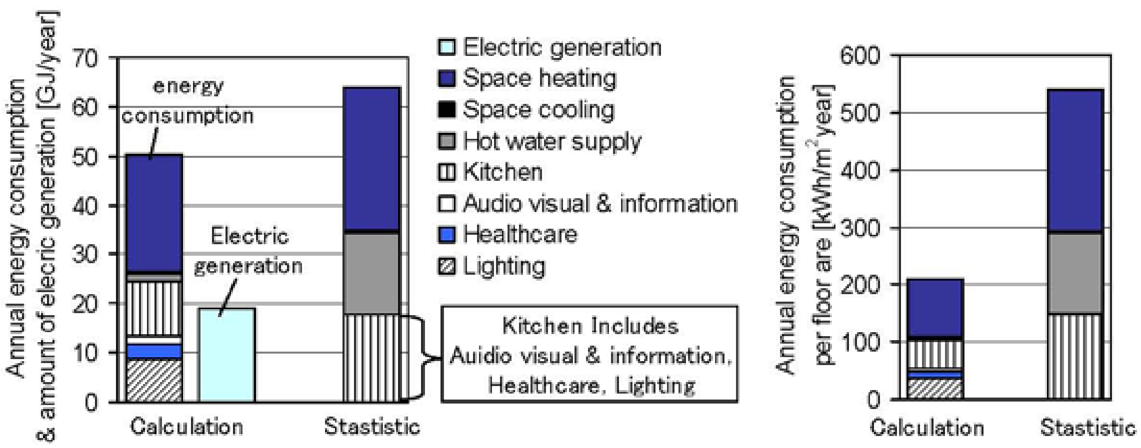
generation varied between 1.4 and 1.9 GJ/month. Although electric generation varied according to season, it was less than energy consumption throughout the year. January and May have the minimum and maximum ratios of electric generation against energy consumption i.e. 15% and 88% respectively.

3.4 Annual energy consumption and amount of electric generation

Fig.8. shows the annual energy consumption and electric generation in comparison with the statistical values in the northern region of Japan (Jyukankyo Research Institute Inc. 2004). As shown in Fig.8. (a), the total energy consumption in the modeled house was 50.1GJ/year. The amount of electric generation is 19GJ/year and its ratio against the total energy consumption was 37.1%. The percentage of energy consumption for space heating and hot water supply was 47% and 3% respectively. Hot water supply shared smaller percentage compared to the statistical value due to the usage of high efficiency water heater and solar hot water system.

Fig.8. (b) presents the energy consumption by end use per floor area. The results show that the total energy consumption per floor area was less than 50% of the statistical value in Tohoku region. The reduction rate of energy consumption for space heating was 40% due to high insulation and air-tightness.



(a) Annual total (b) Annual total per floor area

3. Trial of Assessment with Japan's comprehensive Assessment System for Building Environmental Efficiency (CASBEE)

In CASBEE, sub-items are classified into two assessment categories, which are building environmental quality and performance (Q) and reduction of environmental loadings (LR). Table.1 shows the contents of each sub-item. BEE (Building Environmental Efficiency) which indicates the final assessment results is defined by

$$BEE = \frac{Q}{L} = \frac{25 \times (SQ - 1)}{25 \times (5 - SLR)} \qquad (1)$$

In CASBEE, a five-level scoring system is used; SQ and SLR in the above-mentioned definition represent the scores of Q and LR respectively.

Fig.9. shows the final assessment results of the investigated house obtained by CASBEE. The scores of each sub-item are shown on the left hand side while BEE value is shown on the right.

Table 1 The contents of each sub- items

	No.	content
Q	Q1	Indoor Environment
	Q2	Quality of Service
	Q3	Outdoor Environment on Site
L	LR1	Energy
	LR2	Resources& Materials
	LR3	Off-site Environment

Scores of the six sub-items excluding Q3 are above the score of level 3 ("Average"), among them the score of Q2 is the highest (SQ2=4.4) due to the utilization of materials which have long life span (e.g. the life of the building frame is more than 100 years). In addition, the scores of Q1 and LR1 are also very high due to the installation of high performance insulator and renewable energy systems, such as installation of solar panels and solar hot water systems, etc. On the other hand, however, since the investigated house was an experimental house which was not built inside any usual residential area, there were some difficulties in evaluating the outdoor environment on site and off site. Thus, in this assessment, the items concern with the surroundings in Q3 and LR3 were given the scores of Level 3 ("Average").

The calculated BEE value of this investigated house is 3.1 while it is only 1.0 of the general houses only 1.0.

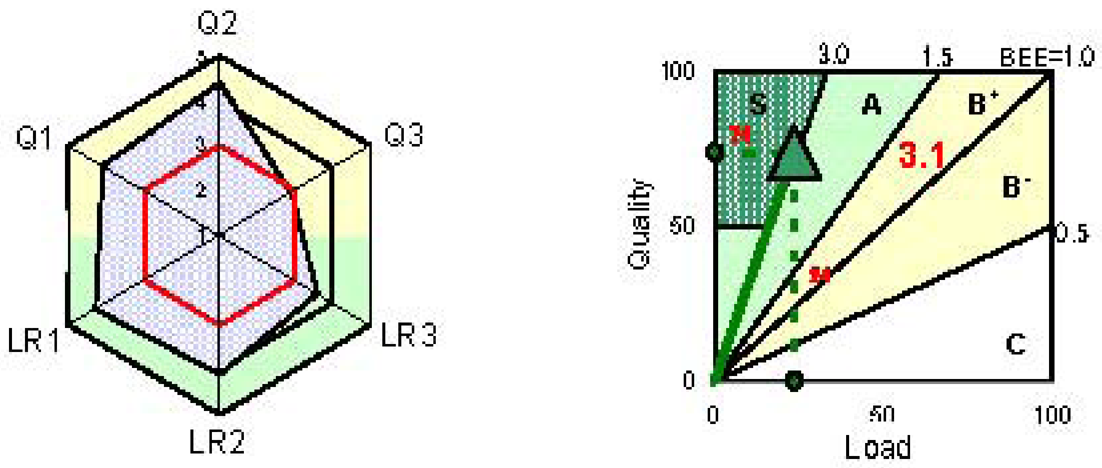

Figure 9 Final assessment results of the investigated house obtained by CASBEE

4. Conclusion

This paper provided a detailed description of the indoor environment and energy consumption of the experimental house in Tohoku district of Japan.

Measurement

(1)The temperatures of the first floor and basement were maintained constantly at 22°C and 20°C, respectively, during the occupancy period of winter. In summer, the temperature of the basement was stable at 20°C due to the ground cooling effect.

Calculation

(1)Energy consumption ranged from 2.1 to 9.0 GJ/month. The ratio of electric generation to energy consumption was maximum in May i.e. 88%, and minimum in January i.e. 15%.

(2)In term of annual energy consumption, the energy consumptions for space heating and hot water supply constituted 47% and 3% respectively of the overall energy consumption. The ratio of electric generation against energy consumption was 37%.

(3)The annual energy consumption per floor area was 0.4 times lower than statistical value for Tohoku region.

(4)The calculated BEE value of this investigated house is 3.1.

LIDERA - AN ASSESSMENT SYSTEM TO SUPPORT ENVIRONMENTAL MANAGEMENT – FACTORIAL APPROACH

Manuel Duarte Pinheiro, Ph.D. Environmental Engineering, Professor[1]

[1] Department of Civil Engineering and Architecture, IST, TULisbon, Lisbon, Portugal, manuel.pinheiro@civil.ist.utl.pt

Keywords: sustainable construction assessment, environmental management system, factorial analysis, regenerative sustainable construction

Summary

LiderA is a Portuguese voluntary assessment system, developed by the author at the Civil Engineering and Architecture Department in IST/TULisbon, and it is in place since 2006 (www.lidera.info). The system has a new component methodology, trying to support the challenge of identifying the opportunities to improve the performance like factor 2, 4 or 10, involving new measures, ways of use and environmental management of the building, its components and the main stakeholders involved. The factorial approach involve: (1) environmental aspects identification, (2) factorial improvement analysis to the project and/or to the users, (3) the LiderA criteria environmental improvement performance is compared with major life cycle cost and other viable analysis in order to (4) support design decision, user mode or management. The results of the analysis applied to the certification cases show important variables of control, influence and management and also new possibilities to the project, renovation or management. This paper presents this new factorial analysis approach, major cases results and implications to project design and environmental management in the building.

1. LiderA – What is it?

LiderA is a Portuguese voluntary building assessment system, developed at TULisbon (Pinheiro e Nunes, 2005). It has a global approach that in the limit could have 50 assessment criteria organized in: Site and integration, resources consumption efficiency, load impacts, indoor environment and functional aspects (durability, accessibility, environmental management and innovation).

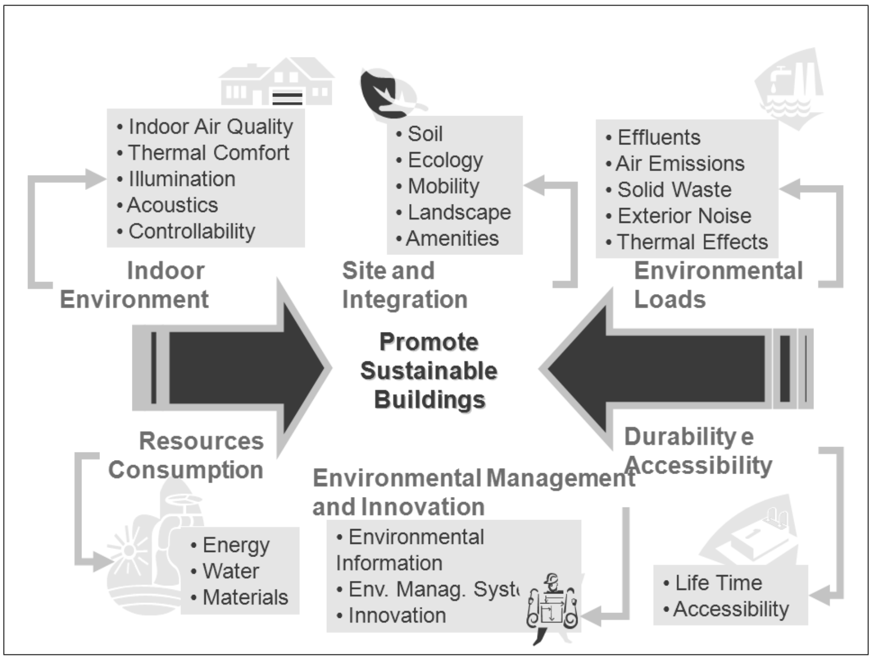

Figure 1 LiderA main areas and aspects

Each of the criteria has environmental performance levels from the point of view of sustainability that can be compared with different performance levels, which should be better than existing practices, supplying a final evaluation of the building and built environment. The system allows the assessment of the building's life cycle development in all phases and is applied to different typologies.

The LiderA system performed in 2007 five certifications with class A, and is estimated that in 2008 will certify 27 others. The first five Portuguese certifications in 2007 show an important environmental performance improvement of the different buildings in the standard use mode that, in average, represent an increasing of 50%, that is a A class in LiderA.

Figure 2 First five LiderA certifications (Class A)

Nevertheless the search of sustainable level, challenge the building design, the users and managers in order to get a structural improvement of the environmental performance, in energy, water, materials, loads, interior environment, and other functional areas. The main questions lie in knowing how it can be build a performance level that lead to sustainable construction not only in a design phase but also in the use and management of buildings and infra-structures.

2. Sustainable construction and performance level?

The sustainable construction definition has a broad variation and aspect (Cole, 2003; Kibert 2005). But in general that include a better environmental performance improvement (that must support future balance), social benefits, that in some ways of thinking at least do not create a strong increase of economic construction costs to other, although that is acceptable to others, even if in the framework of the whole cost cycle, it will lead to equal or even smaller costs.

In each of the approach one of the fundamental questions is to know **what are the levels to be pursued in order to achieve sustainable construction and promoting the changing process**? Looking, for example, to Portuguese data, there is strong evidence (Figure 3) that construction works and its products impacts (Pinheiro, 2006) are of huge importance and in some cases, like energy and water, this impact is growing.

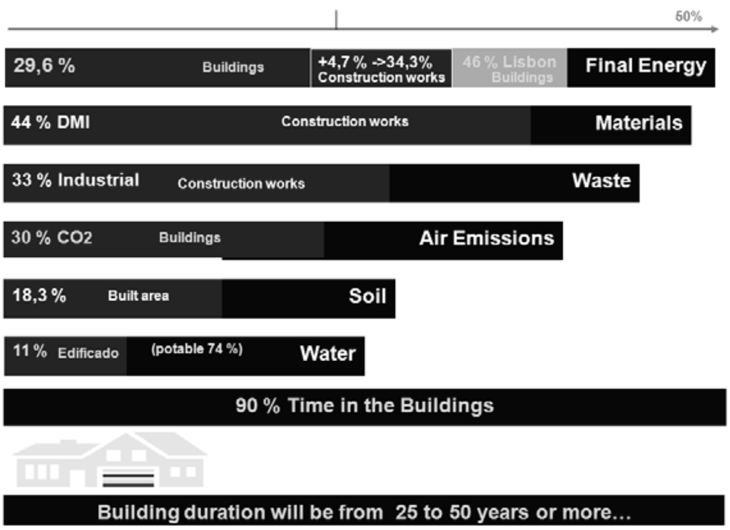

Figure 3 Portuguese construction environmental impact profiles

If the new buildings or the refurbishment of older will lead to increase performance when compared with the existing, for example by 25% or 37.5% or 50 % that is an important achieve and is a progress towards sustainable construction. In LiderA system that levels will mean a class C, B or A.

The international certification is begin to show that costs can be reduced (Landgon, 2004), that value can be create (RICS, 2005) and that it is possible and economically viable, as the LiderA practice in the first certification constructions in 2007 (class A) show it is possible to achieve those levels with good practice and to be economically viable.

The results and costs depend of measures taken, but the mainly important aspect is that, from the beginning, one should try to include a holistic approach that try to assure the main ecological local characteristics, a bioclimatic approach and to include solutions that allow the reduction of water consumption and comfort improvement.

When we look to ecological footprint (pointing out that Portugal need two more areas equivalent as available, direct material inputs (DMI), with 17 tons per capita per year) and to the actual impact level and trend, it is a point of the major importance to change the actual trend in increase of consumption and environmental impact changes, in order to begin to reduce those impacts.

So, if society wishes to achieve sustainable levels, the performance level must be done in the framework of the buildings and construction project life time that is 25 to 50 years. In that time period performance must be greater than 50 %, for example in Portugal must be at least a factor four improvement. In some cases, like materials, we can speak about a factor 10 (Schmidt-Bleeck, 1993) or even a factor 20 (Ryan, 1998).

Is there that variation in the environmental building performance? If you look to possible environmental performance in buildings we find that the potential performance variation, when compared with the practice, could be larger that a 50 % increasing, for example in energy, from 1-10 until to 1-20 (Ratti *et. al*, 2005), and that also happens in others areas like water and natural habitats (Pinheiro, 2008).

In some specific and more precise areas it is possible to have solutions that could improve to factor 4 with viable solutions, for example after assure natural illumination in energy illumination the classic lamps could be replaced by CFL (compact fluorescent lamps) that represent a factor 4 improvement with economic viability and in the future the led lamp can be a viable factor 10 solution. Nevertheless, actually there is no substantial evidence that some of these levels could be economically viable in several areas.

Even there is strong beliefs that an holistic approach, as bioclimatic solutions, can have synergetic results when performance improves and can pass the cost barrier and even achieve levels in which the result could be not necessarily a zero level, but a positive net balance in terms of energy, water and ecosystems, what can be defined as regenerative solutions (Reed, 2006).

These new levels factor 10 or regenerative can be define as the level that truly assures sustainability since it inverts the negative impacts not only to a low level but in order of a positive impact. In LiderA factor 4 is an A+ class, Factor 10 or regenerative is an A++ Class and further get an A+++ Class.

3. Factorial approach

The system has a new component methodology trying to support that challenge and to identify the opportunities to improve the performance, like factor 2 or 4 or 10, involving new measures, ways of use and environmental management of the building and its components. The factorial approach involve: (1) environmental aspects identification and what is the performance position in that criteria, (2) factorial improvement analysis to the project and/or to the users, (3) the LiderA criteria environmental improvement performance is compared with major life cycle cost and other viable analysis in order to (4) support design decision, user mode or management and identifications of the opportunities to improve the performance.

3.1 Performance position

The first step in the analysis involve the understanding of what is the environmental performance level, namely if it is equal to usual practice or if is better by a factor 2 (A), 4 (A+), 10 (A++) or other. In that logic the solutions must be assess in a global level in order to obtain what is the factorial improvement in relation with the usual practice.

The performance position must at least be defined in a standard building use, for example if it is an hotel there will be an average annual use of the system during an average day, concerning for example the energy systems (it could be illumination during six hours, computer working during one hour, cooling or heating during six hours and several support systems during twelve hours).

The first five Portuguese certifications show the important environmental performance of the different buildings in the standard use mode and in four of them the results in real use. As it can be seen, in Figure 4, in these five buildings most of the criteria's (50 x 5) are better than practice, including 83 criteria classified as factor 2, that means 33,2% (50 criteria x 5 cases =250 criteria), 21 criteria achieved factor 4 (8,4%) and 14 criteria reached the 10 factor (5,6 %).

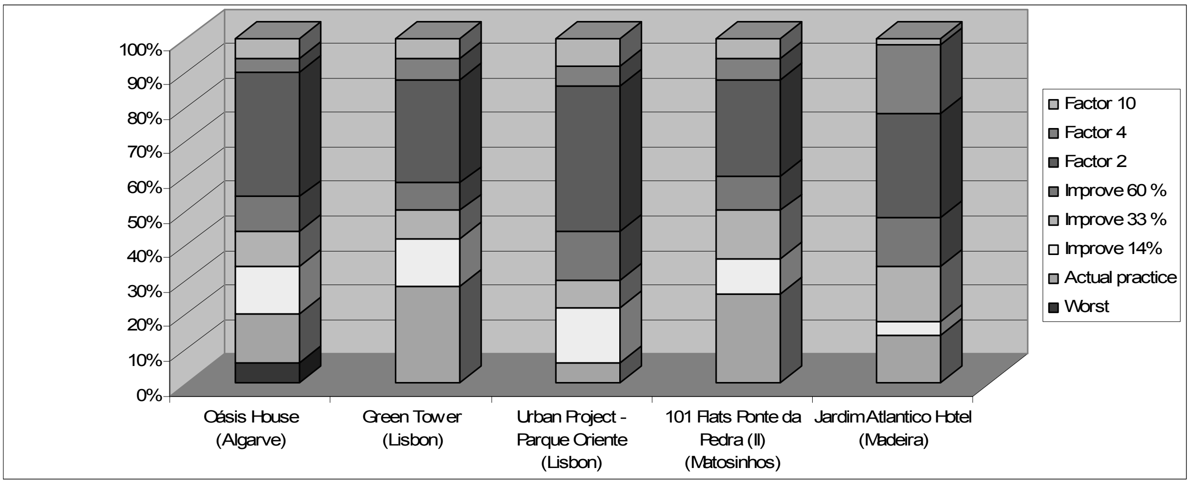

Figure 4 Actual factorial levels of the five first LiderA certifications cases

3.2 Potential Factorial Improvement

Nevertheless the search of sustainable level, challenges the building design, the users and the managers, in order to get a structural improvement of environmental performance, in energy, water, materials, loads, interior environment, and other functional areas.

So, one of the potential analysis is to see what kind of solution or measures will improve the performance, according to two perspectives, one from the project (new or refurbishment) and another from the operation actors, like user, maintenance or management.

There are several studies about what are the different components contributions, like building project, equipment systems, users and environmental conditions; for example Ratti (*et al.*, 2005) found a variation of 1 to 20 in energy consumption in offices, and pointed out (Figure 5) that it explains 2.5 by options of project design, 2 by the type of system, 2 by the environmental context (climatic and urban) and 2 by the user contributions.

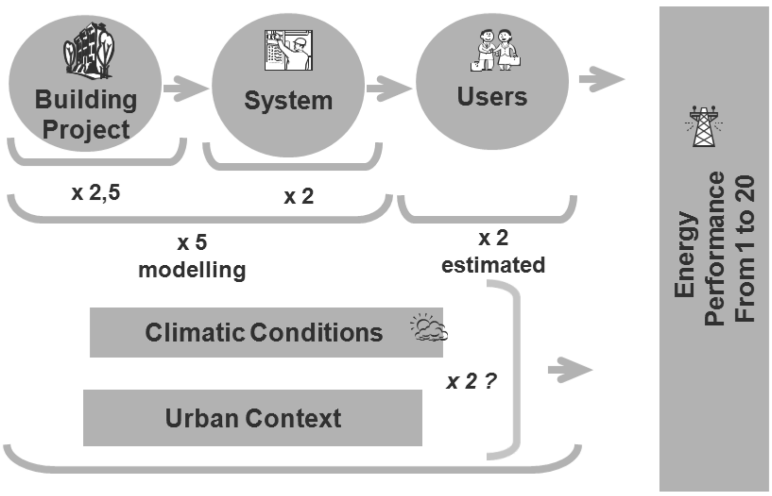

Figure 5 Example of different component contributions in case energy operation offices (Ratti, et al., 2005)

The importance of each component can be different, but in general the contributions result from one side from design, that includes project and equipments and also a response to context (as bioclimatic architecture) and from the other side are related to the users. In specific studies it has been shown (Pinheiro, 2008) that the user can have a contribution of 2 and in some areas, like water, the users and management can achieve a contribution up to 10 times.

The main aspects to factorial improve performance must look to solutions to be include in the building and also to the users. In order to see the approach it is presented the analysis of one of the LiderA certificated buildings, namely the Hotel Jardim Atlântico.

Even with an environmental performance that, in average, is 50% better than other similar hotels, the LiderA factorial module application at Jardim Atlântico Hotel found opportunities for improvement, both in refurbishing of the buildings as well as in use and management of energy and water, among other aspects.

For example, the hotel applies several measures that significantly contribute to water use reduction. One of them is a roof drainage system for collection of rainwater (C19). However, this system isn't working because there is not an appropriate storage and pump system. If a storage tank and a small pump were installed, the rainwater could be reused in the pool and for other purposes (toilets, floor cleaning). With this solution the hotel could achieve an additional consumption reduction in water from public supply of nearly 25%. Together with better use of wastewater, which could be treated to irrigate green areas, it can be achieved a final water consumption of less than 25% of the usual practice in hotels, which is factor 4.

The energetic field was targeted with several measures and special attention was given to the main goal, which was to reduce the electricity consumption (C11). At a mid term, the increasing of the equipment efficiency and wind energy and photovoltaic integrated façade will allow to achieve at least factor 4 in electricity consumption and electricity from renewable sources.

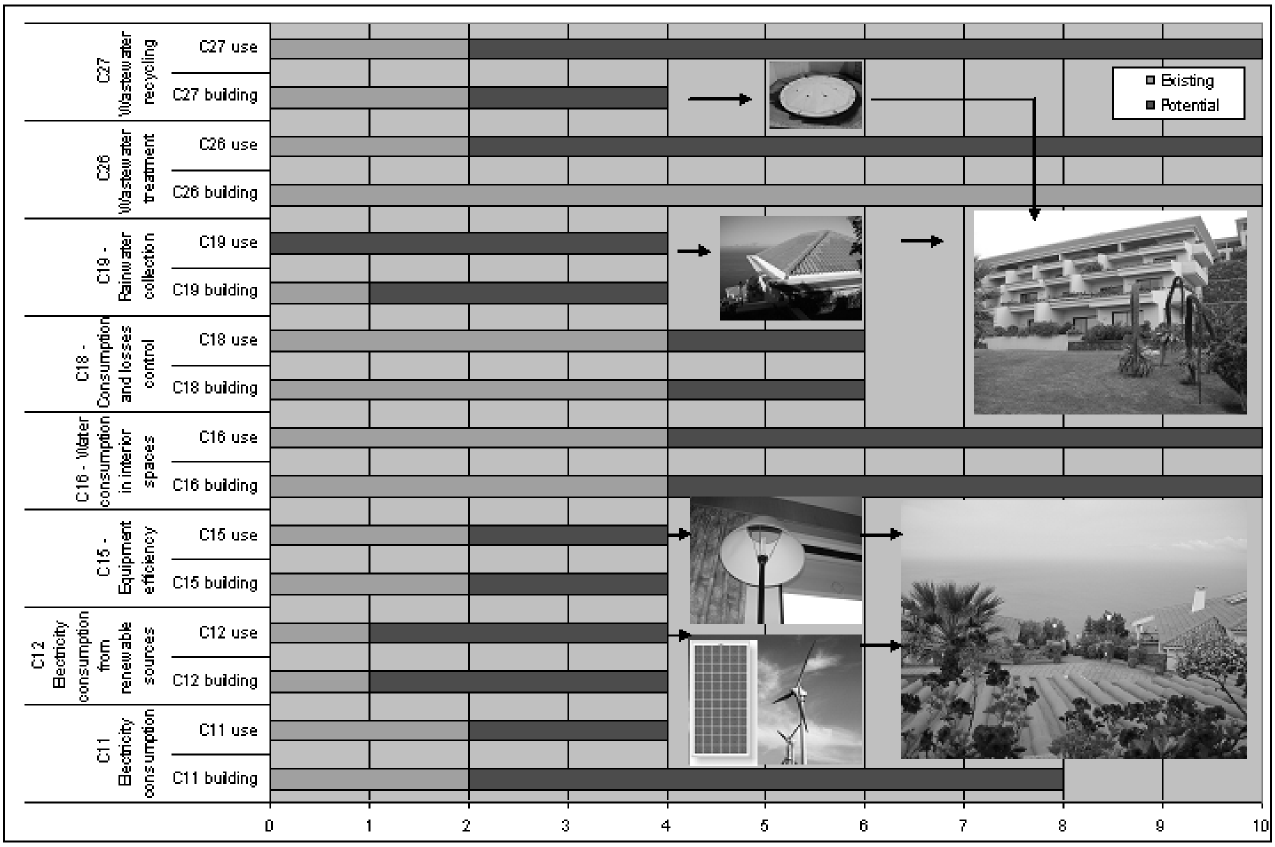

Figure 6 Profile examples of some possible environmental measures to be applied to Jardim Atlântico Hotel (Pinheiro, 2007)

Naturally each solution proposal can have a direct and secondary impact, for example when CFL is used, this reduces the thermal loads from lamps and have an indirect impact in the need of cooling, or when new taps with lowers flow are introduced that will also lead to reduce the effluent flow and wastewater treatment requirements.

So, after the definition of solutions to be considered, there must be a global analysis in order to obtain the global result from the measures including the direct and indirect impact, decreasing or increasing of the performance level. That analysis will give the new building proposal level in a standard use, allowing to know what will roughly be the energy consumption, like electricity (C11), water consumption (C16) and the other LiderA criteria's.

Another important point is that the real performance will result from these building characteristics (solutions and system present) but also, not from a standard use, but from the real use in practice in a day and day base. So the factorial analysis also considers what kind of information and actions can be done in order to have a better conduct by the manager and the users.

For example, it is available in Jardim Atlântico Hotel a system that collects rain water (C19 building) but this system is not actually in use to irrigate green areas, because that is not a practice and requires further collect system, which means that even if that will be a possible use there will be the need to give training in order to have a new practice (C19 use).

So the potential factorial improvement analysis consider not only the possible changes in building measures and its factorial progress but also the potential actions, practices and procedures to management and other users. So that analysis will allow reaching an enhanced in factorial real improvement.

3.3 Viability Analysis and support to decision and management

In the next step of this factorial analysis it is assessed the life cycle cost of the proposed measures, including payback time and environmental improvement resulting from its applications. In the analysis it will be seen what aspects must be changed, in order to fulfill the performance of the measures.

Based in this information the decision is made by the responsible and that can be: (a) to implement the measures, for example in the renovations of the buildings, including a meter to monitor the water losses (C18 building) or a training program to the workers to reduce water losses (C18 use); (b) prepare the building organization to progressive changes in order to get a timeline to be applied, this is the case of photovoltaic solutions (C12 building) or the use of pluvial waters (C19 building) or (c) solutions to support better management, for example introducing a mechanism allowing the use of recycled wastewater in different green areas (C27 use).

From this analysis solutions were identified, in order to be included in the building design as measures to be taken in the environmental management, both applied to workers and suppliers, in a base of command and control or awareness, and also to the users as influence logic.

4. An approach that support environmental management

In most of the cases there is an informal environmental management, and in other more structural approach the environmental management is done in a formal way with the most common environmental management system (ISO 14001).

Nevertheless the ISO 14001 system is not a guarantee of achievement of a good environmental performance or of the promotion of a sustainable management in general areas including sustainable construction (Pinheiro, 2008). Because the ISO 14001 standard allows choosing the targets and goals to achieve, it does not have a specific focus in sustainable issues.

Sustainable construction is challenging the environmental management in order to have the appropriate requirements. To support sustainable construction through environment, LiderA approach propose a supplementary requirement to the most common environmental management system (ISO 14001) in order to achieve sustainable construction.

The main lines include an environmental performance assessment process with factorial increasing level (as previous defined) and an organization process that adjusts formal requires together with control and influence management.

LiderA system have a standard performance use in the different areas defined, for example electricity consumption (C11 building) and that level can be compared with the real electricity consumption (C11 real) allowing management to understand how well is the real performance and if there are opportunities to do actions in order to get a reduction in real consumption.

These actions can involve the working forces (in the case of offices, hotels or other) with orders, indications, or influential actions, but also the users, in this case concerning mainly to influential actions. Since we have also measures to the users, managers and other agents in factorial analysis (C11 use) this can lead and support management in that actions.

For example in Hotel Jardim Atlântico there is in place an ISO 14001 environmental system that control environmental aspects and involve workers and other parts in the search of a better environmental performance, but also have an extensive and appellative information to the users explaining the measures and what can be done in order to have a better environmental performance.

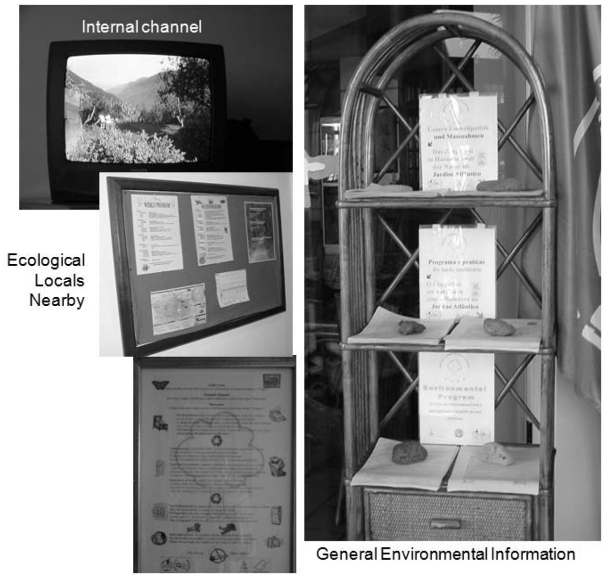

Figure 7 Environmental information's to the users (in Portuguese, English and German) in Jardim Atlântico Hotel

In another case, known as green tower in Lisbon, there is a guide (Manual) to the users and building administration that explain how to use bioclimatic system like Trombe wall and other specifications in order to improve performance and also assure how, when and what must be done to have the system function, including maintenance.

Even if there is no ISO 14001 system in Green Tower, besides the Manual, there is an intranet where it is presented the month consumption and costs that allow each user to understand the environmental performance and react if he wishes so. Until now this is not available but LiderA give recommendations in order to have also a list of good practices.

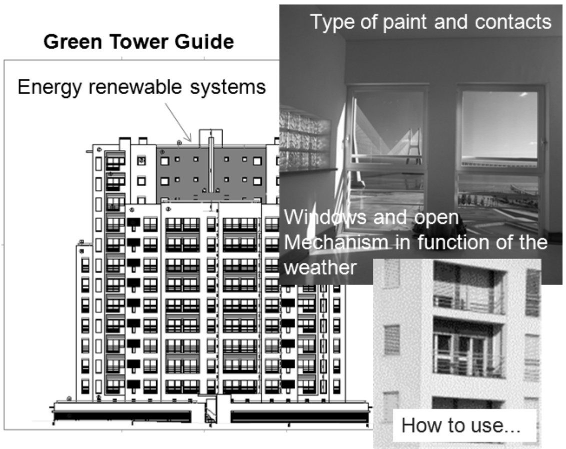

Figure 8 Example of Green Tower Guide

The five study cases above designated show the approach application in phases like design, operation and support to construction phase, to different uses as residential, tourist and others. The results point out the potential effectiveness and efficiency in the sustainable search with improvement opportunities in design and also in supporting the management.

5. Performance level will lead to regenerative environmental management?

The application of factorial analysis to construction using LiderA shows the actual performance level, Class A, that is a factor 2. The approach allows, even in the preliminary design, to know where you are in environmental performance and which steps must be taken in order to structurally improve environmental performance; for example the global measures that includes others than the present in Figure 6, can allow Hotel Jardim Atlantico achieve a performance near factor 4 (Class A+) in the next five years.

Results of the analysis applied to the certification cases, show that, even besides the performance, they still have important variables of control, influence and management and also new possibilities to the project, renovation or management.

Also the promoters, designer or owner that achieved an A class, begin to question what they can do to get a higher performance class, and, when they achieve a level, what can be done if they want to get better results (in the base of their viability). So this can create a new dynamic and *momentum* that can lead to a performance that might be regenerative and in that point, possibly will be understand as strong sustainable.

6. Concluding

The use of LiderA approach allows, even in the preliminary design, to know where you are concerning environmental performance and which steps must be taken to improve environmental performance, in a factorial order given a timeline to medium and long term search.

The results of the analysis applied to the certification cases show important variables of control, influence and management and also new possibilities to the project, renovation or management. This paper presents this new factorial analysis approach, major cases results and its implications to project design and environmental management in the building.

The first five Portuguese certifications show the important environmental performance of the different buildings in the standard use mode and in four of them the results in real use. Nevertheless, the search for a sustainable level, challenge the building design, the users and the managers in order to structural improve the environmental performance, in energy, water, materials, loads, interior environment, and other functional areas.

So, this analysis allows a search of important solutions to design, to manage, and also how to use and maintain, identify and promoting structural environmental performance, in a factorial order, that support design and environmental management in the way of sustainable construction.

This approach opens new methodological possibilities, new needs and further applications in sustainable construction. The method described is one the first steps to other potential holistic approach involving design, maintenance and the users in order to achieve sustainable buildings and also to support management to walk in the direction of sustainable communities.

Keywords: Symbiotic relationship, Indigenous wild vegetable planting method, Healthy food supply system

Summary:

To create a sustainable building our objective held that the focus could not be on just the infrastructure of the building itself, but had to integrate the symbiotic relationship of human and the other be chosen organisms.

Based on the premise that food cannot be replaced in our daily lives but can be modified, we turned to experimenting with indigenous edible plants. A very important step is taken toward sustainability by increasing the recycling efficiency of the food materials and decreasing the food material input. A vertical planting system was integrated onto our experimental sustainable building. We developed an ecological symbiotic planting method dependent on the growth and various seasonal characteristics of the wild vegetables. Most of these wild species have special physiological functions according to Chinese medical theory. The subsequent development of eleven different functional diet types provided along with guidelines and recipes in a manual help not only to alleviate various symptoms of disease, but guard against malnutrition and climate changes.

The project has been successfully operational for the past four years and presently provides abundant nutrients for the residents in the twenty-four existing units. Minimum maintenance is required as the selected vegetables have a strong propensity for growth and self-propagation.

This viable regenerative food supply results in a green web-like cover for the experimental sustainable building. It has an additional effect of regulating internal temperature and reducing overall carbon emission.

1. Introduction

To create a sustainable building our objective held that the focus could not be on just the infrastructure of the building itself, but had to integrate the symbiotic relationship of human and the other be chosen organisms. It becomes more important than before that because of the pressure of climate change.

Global food supply deficiency will happen in climate impact that had been proved by many scientists. A very important step is taken toward sustainability by increasing the recycling efficiency of the food materials and decreasing the food material input in our daily life. Based on the premise that food cannot be replaced but can be modified, we turned to experimenting with indigenous edible plants.

Indigenous wild vegetables are the most important symbiotic species to human being in our system. There are many sustainable factors to grow wild vegetables becoming human being's foods, including no pesticide and without chemical fertilizer, containing special nutrition and with medicinal purpose, and friendly to surrounding environment.

A vertical planting system was integrated onto our experimental sustainable building. We developed an ecological symbiotic planting method dependent on the growth and various seasonal characteristics of the wild vegetables. Most of these wild species have special physiological functions according to Chinese medicinal theory. Following these functions, we developed a series of healthy food supply system.

The result is the Symbiosphere Center 1 (SBC-1) with its unique eco-cycle of material recycling; planting; composting; and food supply.

2. Material

Wild vegetables, Map, Tools for wild vegetables collection, Vertical planting system, Plant taxonomic textbook, Chinese medicinal textbook

3. Method

For understanding the resources of wild vegetables to set up the ecological symbiotic planting method and healthy food supply system, we investigated the species of vascular plants within the radius of five kilometers around SBC-1. Some wild vegetables were collected and chosen to be planted on the vertical planting system in SBC-1.

The planting strategy is mix planting by cultivated different varieties together. The cultivated vegetables and wild species were mix planted with equal ratio. Following the characteristics of plants, a stable symbiotic ecosystem was built by this way.

Most of the wild vegetable varieties can be planted and grown together very well except for some intruder species. Following the characteristics of these indigenous edible plants, several good mix planting models were identified and set up.

Under severe climate impact, the relationships of environment, body constitution, and wild vegetables were very important for health regulation. For this reason, we focused on studying the features of wild edible plants, medicinal plants and the relationships with health regulations.

4. Results

4.1 Investigated Indigenous Wild Vegetables for Ecological Symbiotic Planting Method

Wild vegetables are the key point to develop the ecological symbiotic planting method. These indigenous plants can be cultivating very easily and becoming good foods, environmental controllers, and healthy resources. It is very friendly to environment and saving energy and resources to cultivate wild vegetables in our planting system.

For introducing these wild plants into SBC-1, we investigated the plant resources within five kilometers radius around the building（Figure 1, Figure 2）. In our investigation, we found 564 species of vascular plants. There are 132 species of wild vegetables in these varieties of vascular plants（Table 1）. Some of these varieties had been introduced to SBC-1. There were 51 varieties of wild vegetables had been transferred and recorded their growth conditions in the first year.

Figure 1.　Within the radius of five kilometers around SBC-1.

Figure 2. Investigated the plant resources and collected wild vegetables

Table 1 Number of plant resources

Item	Number of vascular plant species	Number of vascular plants with medicinal purpose	Number of wild vegetable species	Number of wild vegetables with medicinal purpose
Pteridophyta	34	21	6	4
Gymnospermae	6	3	0	0
Angiospermae	488	173	126	107
Dicotyledones	418	152	105	87
Monocotyledons	70	21	21	20
Total	564	197	132	111

4.2 Introduced Wild Edible Plants into Symbiotic Center 1

In the second year, we transferred and bred 71 kinds of plants from SBC-1 nearby again, and planted them on the vertical planting system（Figure 3, 4）.The planting strategy was mix planting to let different wild edible plants were cultivated together. We cultivated vegetables and wild vegetables with equal ratio and mixed planting them. A stable symbiotic ecosystem was built by this way.

We found this system need one or two months to become a stable ecosystem. The wild vegetables, insects, microbes, environment, mankind reached a dynamic balance. Through the season changed, their relationships changed. Some wild vegetables replaced by the other species, and attracted different insects. Wild vegetables were the main stable factors that reduced cultivated difficulties and let this system work easily.

This strategy let plants growth very well, abundant and harmony. Mix planting wild vegetables and cultivars reduced the pest and pathogen. By way of observation about four years, we found this system still can work very well. Most of wild vegetables can propagate their descendants by themselves, the new generation of plants appeared on the vertical planting system. This is a very new system to plant vegetables easily, and supply healthy foods providing abundant life.

Fig 4 Mix planting

4.3 Studied on the characteristics of symbiotic wild vegetables

It is a good way to approach the sustainable building from combining the wild vegetables and buildings. Based on the premise that food cannot be replaced in our daily lives but can be modified, we chose indigenous edible plants as the foods and medicines of residents.

Most of these wild species have special physiological functions according to Chinese medicinal theory. In total 564 species of vascular plants near by SBC-1 were including 197species of medicinal purposes. On the other hand, in all of 132 species wild edible plants, there are 111 species with medicinal functions. All of the medicinal functions are including 11 types: body constitution regulation-45 species trend to cold and cool, 10 species trend to hot and warm; 16 species related to satiation; 32 species for improving immune system. Related to gastrointestine system, there are 14 species help antidiarrhea, 12 species advantage egest; 16 species related to bone and skin; 10 species improve eyesight; 22 species related to circulation; 55 species related to metabolism. There are 61 species for hemostasis (stop bleeding) and detumescence (reduction of swelling); 9 species for reproduction adjustment; 47 species salve symptom of cold. Then we compiled the medicinal functions manual of wild edible plants for residents to maintain or improve health.

4.4 Healthy Symbiotic Wild Vegetable Diets

Under the global climate change, healthy wild vegetable diets must be considered about the interaction of human, wild vegetables and environment to bring this system into full play. In order to check the healthy food supply system from Chinese medicinal theory, we developed series diets by indigenous wild vegetables to enrich the living of habitants in SBC-1. In our study, wild vegetables were recombined to become salad or other style foods to neutralize the effect of body and weather interaction. Four types wild vegetable diets were classified：Dry materials, raw, cooked, and reproduced products（Figure 5, Table 2）.

We focused on studying 5 parts of diets including salad, sauce, oil, fresh tea or soup, and spirits. The typical sauce is combined with oil, vinegar and protein. We suggested using the light sauce for spring and using thick sauce for winter. The oil in the sauce can use non-saturated fatty acid from wild vegetable seeds.

On the other hand, we made the wild vegetable sauce bases especially for sauce with different flavors easily. For example, we chose Ailanthus or Tarragon for summer, and Chinese mahogany, perilla and basil for spring.

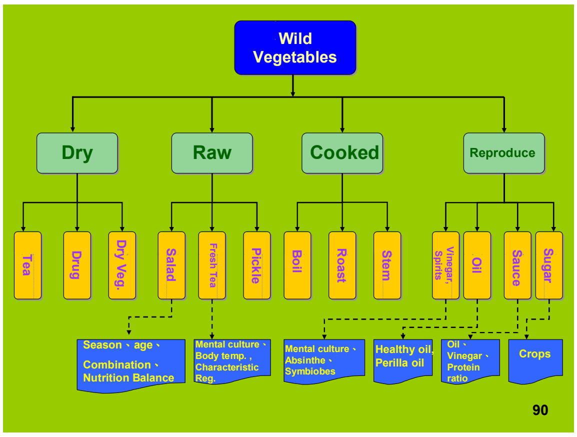

Fig 5 Four types wild vegetable diets

Table 2 Principles for Wild Vegetable Recipes by Seasons

	Spring（2,3）	Summer（4,5,6,7,8,9,10）	Autumn（11,12）	Winter（1）
Wild Vegetable Salad	Cold 5% Cool 30% Neutral 30% Warm 30% Hot 5%	Cold 20% Cool 50% Neutral 20% Warm 5% Hot 5%	Cold 5% Cool 20% Neutral 30% Warm 40% Hot 5%	Cold 0% Cool20% Neutral 20% Warm 50% Hot 10%
Sauce	Light Oil	Light Oil	Thick Oil	Thick Oil
Vinegar	High Ratio	High Ratio	Low Ratio	Low Ratio
Soup	Major Light Soup	Major Light Soup	Major Thick Soup	Major Thick Soup
Tea or Spirits	Herbal Tea	Cool Wild Vegetable Tea	Herbal Tea	Herbal Spirits Herbal warm Tea

We found there are two potential oils can join our symbiotic wild vegetable diets. One is perilla seed oil, the other one is Oil tea camellia oil. Perilla seed oil contains most of the α-linoleic acid in all of known plants. The α-linoleic acid is the precursor of EPA and DHA. We chose the traditional way to produce perilla seed oil by hand made, including four steps: fried, crash, steam, make shape, and press. Finally, we got the perilla seed oil with light yellow color. The other important component in sauce is vinegar, it comes from wild vegetables interact with symbiotic microbes. The wild tarragon is the best material to produce high-class vinegar.

On the other hand, soup can change the body's feeling about warm or cold very fast in our daily food. We suggested to prepare light soup for summer; thick soup for winter.

The other choice when we finish abundant salad is the soft drink. We suggested to prepare the cold wild vegetable tea or herbal tea for summer; hot wild vegetable tea, herbal tea, herbal spirits or herbal wine for winter.

4.5 Confront Future Climate Change and Impact

For the future climate change, it is very important to make the recipes of wild vegetable diets by seasons. The principles to set up the recipes of seasonal wild vegetable diets are using the properties of wild vegetables to balance the weather effect(Figure 6). For example, in summer, people can eat more wild vegetables with cool or cold properties, in winter, is opposite. In spring and autumn, we suggested tending to neutral and more flexibility about diets because of the weather change quickly（Figure 7）.

Figure 6 Spring healthy salad

Figure 7 Summer cool meal

The habitants lived in SBC-1 had a health checkup per season in Taipei Medical University. The average results of biochemical and physiology test, including the index of uric acid and anemia, were better than the data of urban habitants.

The subsequent development of eleven different functional diet types provided along with guidelines and recipes in a manual help not only to alleviate various symptoms of disease, but guard against malnutrition and climate changes.

5. Conclusions

The project has been successfully operational for the past four years and presently provides abundant nutrients for the residents in the twenty-four existing units. Minimum maintenance is required as the selected vegetables have a strong propensity for growth and self-propagation.

This viable regenerative food supply results in a green web-like cover（Figure 8）for the experimental sustainable building. It has an additional effect of regulating internal temperature and reducing overall carbon emission.

Summary

The housing market finds itself facing an emergency due to the difference between supply and demand, in particular in the social housing market. Faced with a demand for cheap social housing, that runs the risk of creating new situations of poverty and profound social marginalisation, the residential buildings market is proposing, at the medium and high end, to turn to the private market and a set of requirements and questions that are more easy to resolve.

At the dawning of a new era in social housing, the quantity requirements have to be viewed alongside research that privileges many aspects of environmental and technological quality, characterised by both interactivity and its relationship with the natural environment.

The reflections on the technological aspects of the building organism are reflected in the transformations it aims to assist: the new materials introduced on to the market are joined to conventional technology, the new and elevated performance levels required have to face up to the behaviour patterns and functional schemes of contemporary life.

In this context, we consider the experience of the Municipality of Rome, an experience that marks a very important step in an initial stage of innovation and sensitivity to the new mode of conceiving and managing building elements.

1. New actions for social housing

1.1 Actual urban planning: the new Zone Plans (PdZ) in Rome

In the last twenty years, the City of Rome, like all other administrative bodies of big European metropolitan areas, has had to confront, at various times, the housing crisis, in other words, the problem of a strong demand for social housing in response to the housing needs of many parts of the population in marginal social or economic conditions.

The City of Rome confronted these questions by drawing up the Plans for Popular and Economic Buildings (Piani per l'Edilizia Economica e Populare – PEEP) that were used from time to time to determine the quantity of buildings to be constructed; in particular, the 2nd PEEP, proposed in 1985, was redefined and refinanced many times until 2005. At this point, the City, due to the requirements of regulations aimed at alleviating the "housing problem" (Law 8, February 2001, n 21), passed a new series of measures to launch a truly valid Plan to deal with the Housing Crisis.

Under this plan, the City identified various initiatives, including the promotion of the transformation of 36 areas within its territory. In these territories it promoted detailed town planning, local urban planning, Zone Plans (Piani di Zona - PdZ) which are prerequisites for the operative planning of the building and infrastructure interventions that are necessary for the creation of new residential installations and their services. In this case, an in-depth study of quality definitions for the interventions to be carried in the territory was carried out, in such a way as to supply the citizen with a services and housing offer that doesn't merely satisfy a need for quantity, but also satisfies the aspects of housing relating to greater environmental quality.

In order to achieve this, the administration proposed accompanying the traditional structure of actual urban planning with a "code of practice", as a set of guidelines for the planning of future installations to be built; the code will gather together and place at the disposition of the planners and promoters of future installations all of the indicators and tools for the definition of an integrated planning strategy, to control the overall quality of the interventions. In this way, alongside the traditional indications of technical regulations relating to the construction of residential buildings it is possible to place a system of best practices, of innovative guidelines about environmental quality of constructions, about energy and environmental management systems for sites and buildings, about the knowledgeable use of technological solutions aimed at the overall improvement of the performance of the building and the urban complex.

1.2 The need for quantity and the demand for quality: the qualification of the project

Despite the housing market always reporting an emergency due to the gap between housing supply and demand, in particular in the social housing market, faced with a need for low-cost social housing, that runs the risk of creating new situations of poverty and profound social marginalisation, the residential buildings market is proposing, at the medium and high end, to turn to the private market and a set of requirements and questions that are more easy to resolve.

In both the social requirement for quantity and the private demand for quality, the market responds in a uniform and unimaginative way, using very traditional technological definitions and typological solutions, blocked partly due to current regulations, offering as an added value only extra space or fittings. Faced with this picture of the relationship between housing supply and demand in the market, it is possible to state that the need for quantity springs from the perception of the inadequate quantity of the existing housing stock, while the demand for quality springs from the knowledge of the necessity to establish a new relationship with the surrounding neighbourhood, on the scale of the building and the urban complex.

Quality is not an objective characteristic, it's not the qualifying characteristic of a product; instead it is the response to the expression of a need. Therefore, a new demand for quality presupposes a dissatisfaction among the users of current building stock; when speaking of the quality of an architectural or urban project, its level of quality must be discussed, the degree to which it responded to the need that generated it.

It is possible to acknowledge at least two different levels of quality in a project: the intended quality and the end quality.

The Municipality intends to go precisely in this direction with the planning process for the interventions included in the new Zone Plans, by supplying guidelines to improve the intended quality of a project to improve its end quality, thanks to this more finely tuned and more complex control tool relating to expected performance. In this instance, all of the planning indicators in force today can be applied in an organic way by the city with single measures and the new regulations of the General Regulatory Plan regarding environmental sustainability of building interventions, overcoming at the same time a certain traditional rigidity in these same urban instruments.

The code of practice is conceived as a support tool and pointer for the realisation and control of sustainability in constructions, in particular social housing, that proposes a highly integrated approach to planning. The code looks again at housing requirements in terms of economic, social, functional, environmental and energy sustainability; these proposals for innovative functional "add-ons" to the creation of urban spaces are analysed in terms of both the comfort of public spaces and as a functional and social mix, in a way that obviates the phenomenon of social and economic segregation that is typical of metropolitan suburbs.

The code also appraises the appropriate and measured technological solutions to the types of buildings to be constructed in a way that doesn't differentiate them from the current approach of local promoters, though it does require a higher level of final technological performance for the environmental sustainability of the interventions. An analysis of the innovative technological solutions in the construction of residential buildings needs to be carried out, including the study of the construction materials used, in such a way as to direct intelligently the choice of the construction solutions and successive control in phases of building through management procedures. Using the same logic, the most appropriate system devices for efficiency in light of the indications of recent regulations regarding energy control management were analysed and evaluated. To support these indications, the code proposes an integrated model of analysis of the sites where interventions are being carried out that includes all of the environmental aspects and characteristics of the single sites, and to bring to the project and planning strategy the indications that derive from the natural and cultural characteristics of the sites in question.

2. Technical solutions to adopt in the planning of sustainable residential housing

2.1 The role of environmental analysis in the identification of the technical solutions to be adopted

The code of practice for the Zone Plans of the city of Rome foresees a reasoned appraisal, because good architecture depends on informed energy choices. The role of the architect, from this point of view, has to necessarily tend towards integrated planning, even if the specific object of the project is the planning of a city or on the scale of industrial design. Underlining the importance of logical planning throughout in terms of needs analysis, evaluation of requirements, and optimisation of performances, any architectonic element that doesn't look for a balance between the building system and the environment in which it is to be found and on which it will have an impact should be considered incoherent.

The experience of the code of practice for the Zone Plans of Rome explicitly inserts into this logic: an organised sequence of work phases in which every option, to do with timing or systems, is a consequence of the analysis of the environmental variables and their possible synergetic interaction in with planning. Environmental parameters, typological models, approved technical solutions, requirements, technical norms, synergy and compatibility matrices all assume great value within this research, in full coherence, therefore, with the objectives of the programme.

Specifically, with regard to methodology, as with environmental analysis, the use of Ecotect software (with particular attention on the Weather Tool module) is placed alongside traditional bibliographic research.

The idea on which the entire study of the code of practice is structured is as follows: to analyse the potential of a building-environment system, identify its eventual compatibility or incompatibility with the technical possibilities present on the market. A fundamental role, therefore, is assumed by the very concept of compatibility, intended in its widest sense, in terms of regulations, technology, economics and use. To delineate a process in this sense inevitably imposes a preliminary survey in merit of the characteristics of the urban environment, but this implicitly means looking at the technical performance of the functional models of the building envelope, successively defined as compatible.

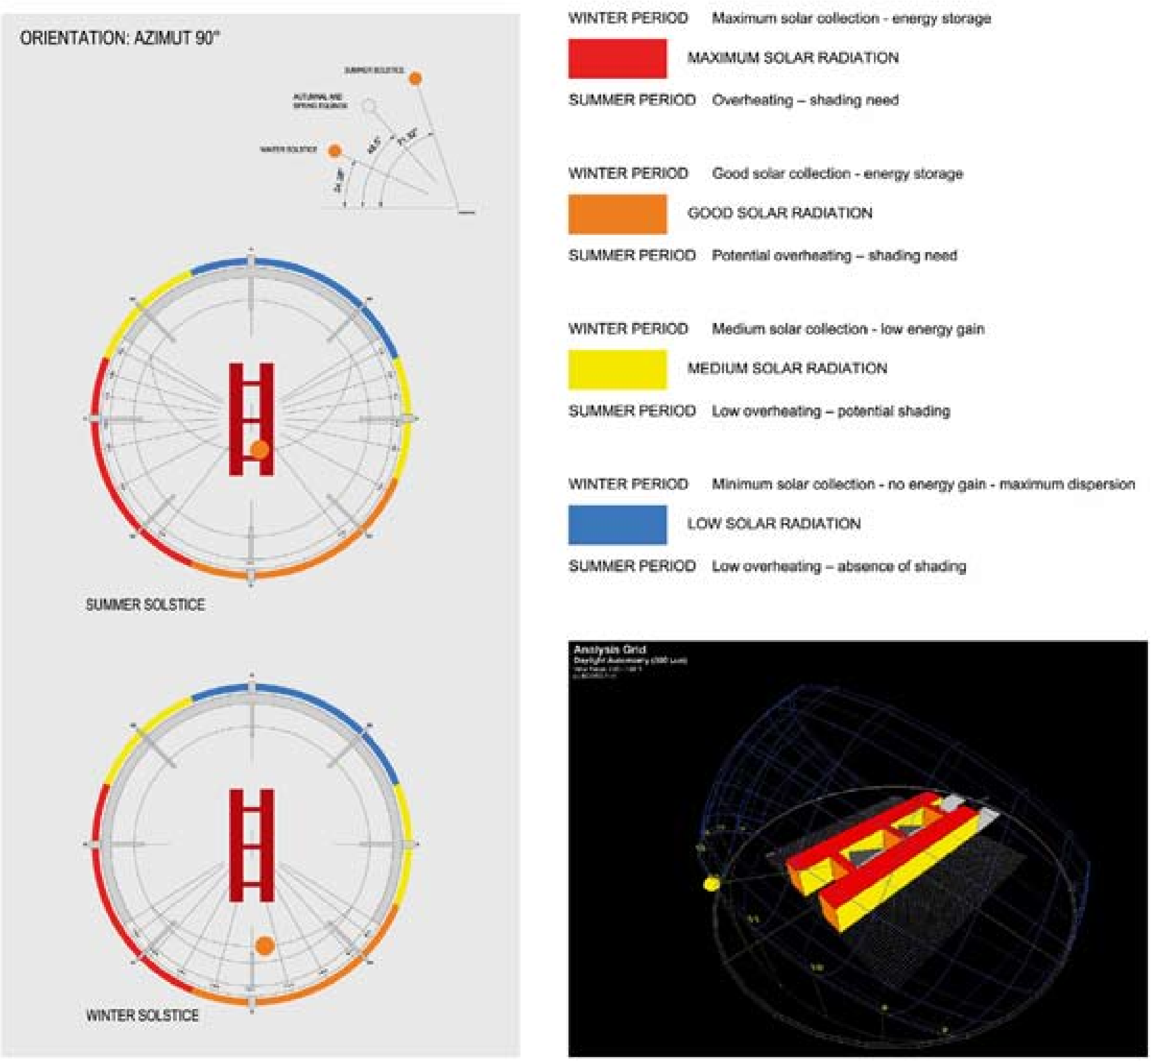

Figure 1 Building system solar analysis

The objective is to draw from the valid planning indications on both the scale of the neighbourhood and the scale of the single building: with this in mind, it should not be limited to a single vision of the phenomenon in a generalist and quality key, the imposition, rather than the option, of a specific deepening of knowledge where conditions are verified that require particular attention. These intentions are made concrete by means of a timely appraisal of the adoption of methods that verify and consolidate matters primarily concerned with solar radiation. It is a considered choice to deepen that environmental parameter over others: firstly, solar radiation is configured on the scale of the whole building, as having major significance in relation to the passive performance of closure packets and to their potential in terms of solar panel systems. In support of this position, it is necessary to underline the analysis of pre-existing urban environmental data: for example, the code has agreed from the outset to exclude an approach on the theme of energy optimisation in terms of the exploitation of wind systems; the reviewed data clearly show that wind phenomena are substantially negligible in terms of intensity and frequency in the City of Rome. The analysis of solar radiation at the level of the building gives quality indications for the exteriors of buildings, shared public spaces and the divisions of the project.

The promotion of an integrated approach to the sustainable planning is translated therefore into the suggesting of multi-level intervention strategies that take into consideration the planning and possible interactions between all the elements of the interaction between the urban and natural environment.

2.2 Integration of technical solutions in building design

The sustainability of a project and the quality of the construction from the energy point of view depend largely on, among various factors, how the building is built.

The reflections on the technological aspects of the building organism are reflected in the sometimes profound transformations that accompany it: new materials introduced on to the market are added to conventional technology, the new and elevated performance levels asked for are compared with the behaviour and functional schemes of contemporary living.

On the one hand, the need for greater operative clarity in the aiming of adoptable planning choices is gained, and, on the other, the importance of an explication of the criteria that subtend the choice of the technological solution, privileging one alternative over another.

In particular, it is necessary to pay particular attention to the definition of the superficial and border elements through the external and internal ambience of buildings (the envelope) that determine the requirements of the building and respond to the needs of the users who will live there.

On this theme, the most evident aspect is the emergence of environmental and economic advantages that have an impact not only on the external environment, but place first the user's quality of life. The adoption of new rules and new performance requirements will lead to a reduction in energy consumption for heating and air conditioning, therefore a notable reduction of electricity bills (installation of air conditioners, hot-water plant for cleaning, electrical plant) in the course of the useful life of the building.

On the other hand, the environmental advantages are a direct consequence of improving the efficiency of buildings and their plant systems: lower fuel consumption in fact means less emission of gas into the atmosphere and a lesser impact of materials used in the environment.

The theme of eco-efficiency should be attacked head on not just through the technological qualities that the technical solutions will be able to guarantee. The importance of building management - highlighted in the objectives of the European Council on spring (OR. EN 7224/07 of March 8th 2007), taken up then by national (Legislative Decree 311/2006) and local regulations (Del. 48/2006 City of Rome) - underline an ulterior element of reflection: the constantly growing role and importance of plant in the management of building stock. In this discussion we find the growing incidence of alternative plant needed to sustain buildings, as much from the point of view of initial costs as the dimensional impact of the same on an area under consideration.

The increase in requests to use renewable sources along with the demand to reduce energy consumption and CO2 emissions into the atmosphere, translates therefore into the need to think about the integration of plant both as a means to reduce the country's energy demands and as a source of co-generation able to guarantee positive economic returns in the conduction of the buildings.

In this context, the existing ties between plant systems and the building envelope assumes particular importance: every choice made in one of the systems weighs significantly on the planning and dimensions of the other.

The most evident aspect of the evolution of the legal framework for building activity is, therefore, the beginning of a demand for legal performance that can prime a "normal" practice of intelligent planning that is energetically and environmentally sustainable.

This leads to an evaluation not only of the immediate cost but also, and above all, for the projected future cost with regard to any of the fundamental components such as health, efficiency, life cycle and maintenance, that will continue to be evaluated case by case in single projects in relation to the urban context of the building.

The choice of the planner will undoubtedly be that of finding the most suitable solution within a combination of conditions, opportunities, and links that are reference points for the environmental characteristics of the site in the course of the seasons during the year, with a control of the external part of buildings in relation to their orientation and to the activities carried out internally, as well as - in virtue of the errors of the past – attributing to the morphological quality of buildings the specific character that distinguishes the history of each and every place.

The problem of sustainability encroaches on many distinct disciplines and demands their inter-relationships be taken into consideration.

In light of this last consideration, the control of environmental and technological requirements, as well as their satisfaction, are both essential objectives that should be reached in respect of architectural language proper to and expressed in each single culture.

Among the innumerable aspects contemplated in the concept of project sustainability, the aspects that relate to the different needs of individual countries should not be overlooked. This theme, which in the past was partly ignored, led to the problems that the current recovery of buildings tries in a diffused manner to overcome.

The monotony, the repetition and continued lack of aesthetic appeal of buildings in the recent past, in Italy as much as in other European countries, are the evident results of an approach to planning that is distant from the context into which it is to be inserted.

From the point of view of this “virtuous” planning in residential buildings, new building is assisted by research into envelopes that are characterised by innovative forms, technologically and formally, that encourage planners towards a careful analysis and conceptual experimental flexibility in both the search for new rules for the codified distribution of living spaces, as well as often importing construction techniques from other types of buildings.

The technological transfer of some solutions from analogous building sectors leads to an increase in its repertoire, performance and systems on offer, and, on the other, to the introduction of material that is more or less sophisticated and has the ability to satisfy the required performance levels with a minor impact on its environment but that is not always easy to control over time.

In this historic period, it is well known, in fact, that there is a construction industry with the ability to always offer new products that gives the planner many choices from a catalogue of more or less complex elements.

This last consideration points to the fact that, on the one hand, the more components become complex, the more they are composed of individual layers, or sub-elements; on the other, it is established that as much more of the element’s technical performance is the sum of its layers’ individual performances, it will be of great importance to control their final technological quality. It will also be necessary to verify analytically the performances that respond best to both the requirements and actions that define the needs picture of the residence, and the priorities that are used to define the objectives of the effective sustainable plan.

We can see, therefore, how the external envelope is one of principle areas called upon to satisfy a building project’s sustainability. At the same time, the elements that make it up are called on to provide, in a coherent manner, all those aspects of volumetric and spatial composition the building was not able to respond to.

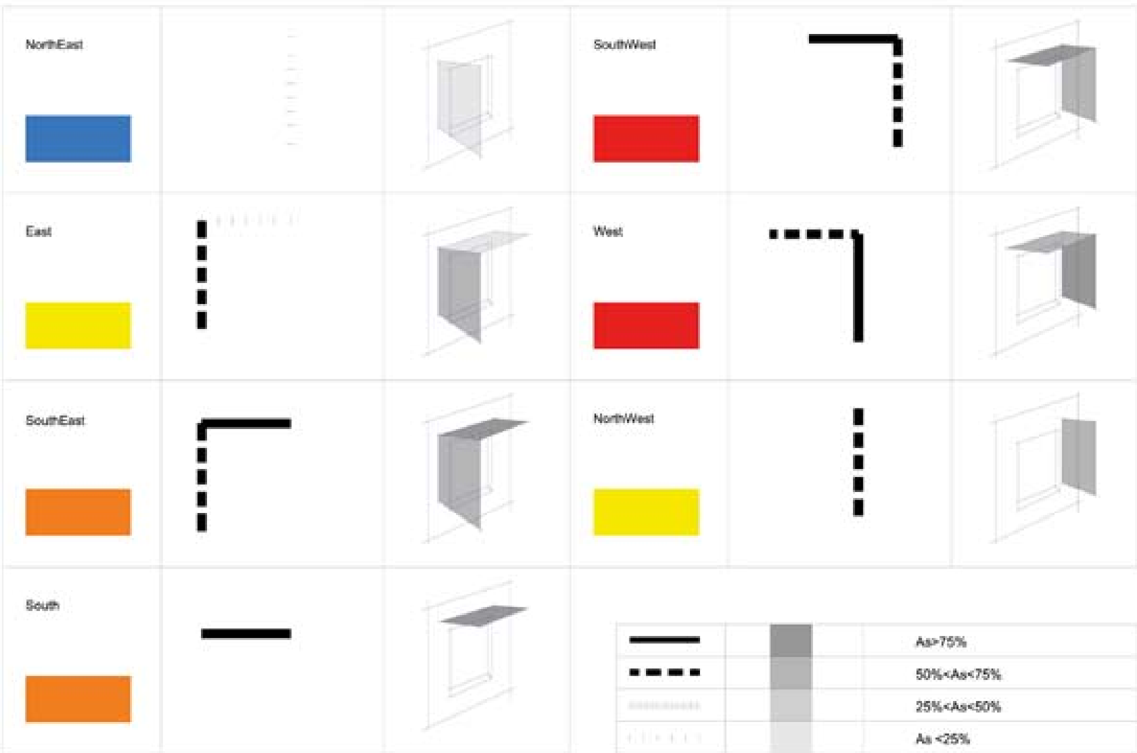

Figure 2 Design of solar shading in respect of façade orientation

Research into the envelope elements has therefore led to a moment of reflection and analysis about the morphological characteristics and specific performances of the solutions that may be considered meaningful and adoptable.

Given the great variety and complexity of systems and elements, it was felt necessary within the code of practice to include a methodological-operational indication guide and support for the choices to be made, through which to identify and choose the solution considered most suitable within currently available technology.

The new manner of thinking about technological sustainability is sought in the acknowledgement process of the values of architecture and in the adoption of a new planning method appropriate to the transformation of the natural environment into a man-made environment aimed at a new more knowledgeable community.

A similar approach modifies the planning of the technical elements, which must be thought of not only as a connection and/or separation from the other elements of the building system, but also as effectively "able to be integrated" thanks to an interdisciplinary meeting of the various specialists involved in the planning process.

2.3 Construction materials. Product and process innovation for residential buildings.

The code of practice for the Zone Plans of the city of Rome foresees a reasoned evaluation of construction materials to employ in projects; the identified evaluation criteria don't aim to construct an abacus of materials to use or not to use for these buildings, but intends to supply tools to the person who will plan and realise these buildings to choose materials and construction solutions in a way that will answer a system of technical requirements identified as determining for the efficiency and sustainability of the proposed solutions. The choice to use or not to use a certain product is reached through various selection criteria that are defined to satisfy the need to obtain good physical-technical performance but at the same time guarantee a low impact on the environment.

The evaluation parameters proposed are constituted in part by measurable elements, referring to the quantity level, and in part derive from numerical data and considerations referring to quality.

The evaluation takes place on materials that are able to guarantee performance of good thermal and acoustic isolation; these material are entrusted with creating comfortable environmental conditions in the internal habitation space at a perceptive and sensorial level. In particular, the choice proceeds through the following three levels.

The first level is through the reading of a numeric value of thermal conductivity choosing materials with a low value and technological solutions with greater insulator capacity.

The second level considers the volume of the material. In Rome's climatic conditions, a high amount of mass guarantees comfortable internal living conditions contributing to limited energy consumption, supporting and in some cases rendering superfluous air-cooling systems.

The thermal inertia or mass effect uses the physical property of the materials to increase the time (thermal lag) that the heat wave takes to cross the walls; this produces a stabilization of the temperature, guaranteeing a lower internal temperature during the day as well. Along with the good thermal qualities materials with large mass are associated with a better capacity for noise reduction. The attenuation of noise, measured in decibels, grows in relation to the mass interposed between the source of the noise and the environment to be protected. A decent quantity of acoustic isolation material leads to a greater level of internal comfort and quality of life of the space.

The data relating to volume mass is moreover connected with the regime of preferred use. This regards the difference of performance offered in case of either summer or winter. The code of practice has opted for the hot season as its preferential regimen. Buildings in the city of Rome, as in Italy and the centre-south of Europe, due to environmental conditions in the Mediterranean basin, which is characterized by mild winters and hot summers, present a greater need to defend themselves from low temperatures, the need to minimize the use of artificial air conditioners during the summer season and finally to limit energy consumption and create good internal conditions of comfort.

The third level of selection is based on LCA (Life Cycle Analysis) and the PEC value (Primary Energy Consumption). Through the LCA, the complete life cycle of the material is evaluated, from the sourcing of the first materials to the completion of the project; to evaluate the LCA of a material, multiple aspects are examined, some of which can't be directly measured and compared. In particular, the consumption of primary energy (PEI) offers a partial evaluation of the product's lifecycle. This constitutes an ulterior parameter of comparison; it is always preferable, wherever possible, to use an isolating material that uses low energy consumption in the production phase, because of the total minor impact on the surrounding environment. Some synthetic insulators, for example, even with a good level of performance of thermal isolation are characterized by a high consumption of primary energy: in their place, insulators of a mineral (fibreglass) or vegetable (wood fibres) nature should be preferred.

The three levels of evaluation contain elements relating to quantity and quality don't answer definitively the question of what would be the best solution; rather, they supply some indications which provide the possibility to make a choice with the aim of arriving at technological solutions for the Zone Plans that adhere to the principles of sustainability and biocompatible construction.

Table 1 Comparison between insulator materials parameters

Material	Use	Conductivity (W/mk)	Volume mass (kg/mc)	Potential environmental impact PEI (MJ/K)
Fibre glass	insulator	0.040	55	34.60
Expanded Polystyrene (XPS)	insulator	0.035		107.15
Wood fibres (cork)	insulator	0.040-0.046	100-300	7.05

3. Conclusion

The experience of the code of practice for the Zone Plans of the City of Rome proposes an integrated methodology of approach to planning, an organised sequence of phases of work, in which each option, temporal or systematic, is the fruit of the analysis of environmental variables and their possible synergetic interactions. Environmental parameters, typological models, legal and technical solutions, needs, technical legislation, compatibility matrices, all assume a great value within this research in full agreement with the programme's objectives.

The strategic relationship of the code of practice to the process of planning, designing, building and managing interventions is that of impacting on the definition of a complex quality profile that is expected or required from interventions on buildings, supporting the administration up to the phase of urban planning in the definition and detailing of the level of technological and environmental quality in building interventions.

The code of practice, therefore, functions as a preliminary technical briefing document or as a strategic planning document aimed at obtaining high levels of urban and environmental quality, influencing both the quality of the use of space in buildings, as well as the management of the resources used by the integrated system formed by the surrounding urban complex, of the building and of the plant system in the whole life cycle of the surrounding planned system.

The promotion of an integrated approach to sustainable planning translates therefore into suggesting multilevel intervention strategies that take into consideration the planning and possible interactions between all the elements of the manmade and natural urban environment.

Keywords: sustainable building, sustainable performance, assessment method, conceptual framework, obligatory practice, recommended practice, voluntary practice, flexibility to handle circumstantial changes

Summary

The aim of this study is to develop a sustainable building performance assessment method that is suitable for specific attributes of a developing country like South Korea. For a developing country in the stage of rapid economic growth, there is a need for appropriate intervention from outside the market to secure sustainable performance of buildings, as well as a need to develop an assessment method that can flexibly deal with fast changing conditions. Accordingly, we will suggest the assessment method of sustainable building with flexibility and with intent to improve sustainable performance of overall building. This study seeks to advance sustainable performance of buildings through conceptual framework of assessment method. The conceptual framework of assessment method refers to classifying assessment standards and adjusting category method for intervention in the market. Also it seeks to present an assessment method with flexibility to handle circumstantial changes through variable sub-goals. as well as through differentiation between constant and variable indicators. The variable sub-goals and indicators are proposed based on technical levels, market conditions, international pressure, and so on. Furthermore, by classifying the detailed standards as obligatory practice, recommended practice, and voluntary practice, and making them adjustable regular, we expect that the assessment method can provide flexible and effective measures.

1. Introduction

In conditions that the interest in environment and development issues increased and international efforts on related agenda were needed more and more during the past 10 years, many developed countries introduced various assessment methods, certification systems and policies for sustainable buildings. And then assessment methods have improved in consequence of analysis of successes and failures based on real examples. As a result, the assessment methods of sustainable building performance in developed countries appear to have reached a level of stability.

Contrastively, although diverse sustainable building performance assessment methods are being proposed in light of international requirements, energy cost increase and growing interest in environmental issues, the developing countries like South Korea are at a level of merely translating and applying the primary stage assessment methods of developed countries without modification to suit their own particular circumstances. Hence, there is a need to develop assessment methods that take into account each country's particular circumstances such as political situation, or technological level, market situation and so on.

In developing countries, due to their rapid economic growth compared to developed countries, energy and resources consumption and toxic material discharge will increase drastically. As well developing countries cannot be free from international agreements. Therefore, this is a very critical time for their sustainable building market. Proposing an appropriate assessment method for a developing country in such time of changes is urgent and useful.

As stated previously, developing countries have characteristic of rapid changes in external circumstances such as technological levels, market conditions, requirement degree of international agreements, and so on. Also, lower technological levels and weaker market conditions compared to developed countries make voluntary participation in the relevant market difficult. Therefore, it has a greater need to develop an assessment method of sustainable building performance that can flexibly deal with such circumstantial changes and give relevant market appropriate regulation or recommendation standards for advance in sustainable performance of building sector. If an assessment method can provide such function to be proposed by this study, it will contribute to the improvement of a developing country's sustainable building performance.

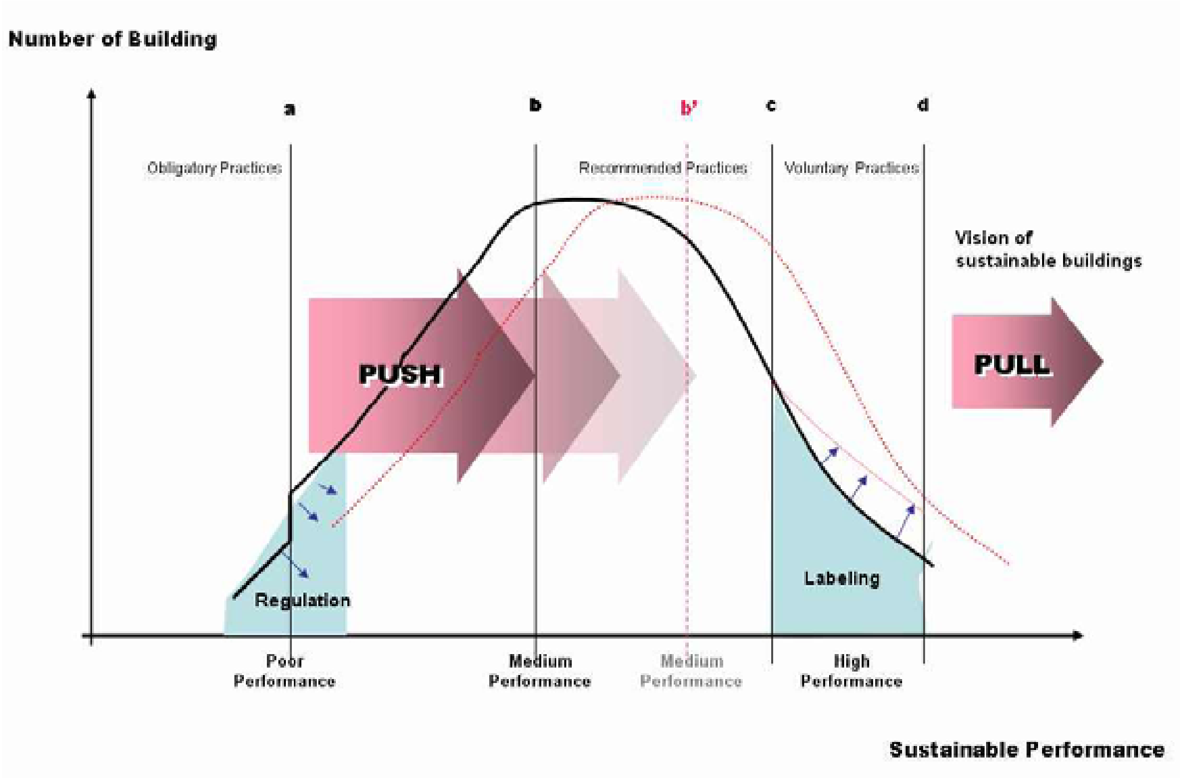
Accordingly, the assessment method to be proposed by this study comprises the following:

First, this study proposes a conceptual framework to evaluate sustainable performance of buildings. The conceptual framework refers to systematic classification method of assessment standards. It can help attain an assessment method's final objective more efficiently with integrative approach to improvement of environmental performance. Through this work, an assessment method will be able to appropriately intervene in the market and serve its role of regulating and providing recommendations.

Second, it proposes an assessment method with flexibility to deal with circumstantial changes. The assessment method can get flexibility by differentiation between constant and variable indicators. In this study, variable indicators refers to sub-goals that are, by periods, proposed based on circumstantial changes and classifying the detailed standards as obligatory practice, recommended practice, and voluntary practice, and making them adjustable regular.

2. What to Expect from an Assessment Method?

The fundamental goal of assessment method is to evaluate sustainable performance of buildings. And, it can provide information on the environmental impacts of detailed sustainable technology and related policy and help respond international agreements such as the United Nations Framework Convention on Climate Change, through objectively evaluating energy efficiency, greenhouse gas emissions and so on. Furthermore, if measures appropriately, an assessment method can be expected to serve a positive role as follows:



Figture 1. Roles of an assessment method proposed in this study

First, it can regulate and guaranteeing a minimum level of sustainable building performance. If the detailed indicators, classified as obligatory practice proposed in this study, are made to tie in with government regulations, the double burden of checking separately the government regulations and the detailed standards of assessment method can be eliminated. Moreover, because obligatory practices are adjustable to changing circumstances, this can prevent the unnecessary difficulty arising from continually having to amend the law or from failing to adapt by rapid changes. (See Fig. 1, line a).

Second, as seen from Fig. 1, line b and b', it can guide to improve sustainable performance of building sector by push and pull principles. Through the structuring of assessment standards category to be proposed by this study, an assessment method can be expected to serve the role of encouraging the advancement of the overall sustainable building performance for an entire country and not end at merely evaluating the performance of a product called building.

Third, it can encourage that more buildings attain high sustainable performance by providing consumers with information on and incentive to superior sustainable buildings through labeling systems, and so on. And, it will continuously provide models for future sustainable buildings and vision for the sustainable building sector. It can pull sustainable performance of building as intention of assessment method maker and policy maker

3. Proposals Based on Examination of Earlier Studies

3.1 Definitions of Sustainable Building Performance from Earlier Studies

As growing interest in environmental and developmental issues, the nature-centric architectural concept[1)] of ecological architecture, green architecture, and so on appears on the architecture area. Thereafter, the concept of sustainability emerged in relation to ecological development, and the sustainable development concept[2)], subsequently widely discussed in the international community. And then, the sustainable development concept became internationally accepted as the ESSD concept[3)] via the Rio Summit, and various related international agreements are being discussed with this concept as the foundation. Therefore, this study, also using the ESSD concept as a basis, wants to discuss sustainable building performance. In this study, the sustainable building performance means minimizing adverse impact on the ecosystem by construction- and habitation-related activities and managing an environmentally comfortable habitation within the human comfort zone.

3.2 Sustainable Building Performance Categories on Ken Yeang's Framework

Ken Yeang stipulated that organizing the consideration factors for the design of ecological architecture helps designers to select diverse guidelines for minimizing the adverse effect of construction on the ecosystem. This study believes that such structuring is useful not only from the perspective of determining the factors to be considered in the planning stage of building, but also from the perspective of evaluating the sustainable building performance, i.e., evaluating the adverse impact of construction on the natural environment. As such, the assessment categories of this study's assessment method will be classified based on the framework proposed by Ken Yeang.

As stated above in section 3-1, this study proposes the definition of sustainable building performance to be minimizing the adverse effect of construction- and habitation-related activities on the ecosystem and managing an environmentally comfortable habitation within the human comfort zone. If this concept of sustainable building performance is substituted into Ken Yeang's framework and examined, the results are as follows:

Table 1 Conceptual Framework for evaluating sustainable building performance

Interactions	Symbol	Description	Concepts of sustainable building performance
Its external relation	L22	This refers to the totality of the ecological processes of the surrounding ecosystems. It is these elements which are either altered, depleted, or added to by the built environment.	The preservation of eco-network
Iits internal relation	L11	This refers to the sum of the activities and actions that take place in or are related to and associated with the built environment.	The operation of environmentally comfortable habitation within the human comfort zone
Tthe system's inputs	L21	This refers to the total inputs into the built environment.	The minimization of natural resources consumption
The system's outputs	L12	This refers to the total outputs of energy and matter that are discharged from the built environment into the ecosystem.	Low environmental loadings.

1) Germany's Ecological Architecture (1978): Defined as architecture that makes healthy habitation and working possible from a nature-centric perspective by emphasizing harmony with the natural environment, as well as from an ecological perspective, by maximizing efficient use of resources and energy

2) The UN Bruntland Report's Sustainable Development (1987): From an anthropocentric perspective, defined as "sustainable development that meets the needs of the present without compromising the ability of future generations to meet their own needs" and has as its goal, the economical use of natural resources, participation and equal use by residents, and protection of the environment.

3) ESSD of United Nations Framework Convention on Climate Change (UNFCC) (1992) : To prevent environmental disaster from global warming, declared the principle of environmentally sound and sustainable development (ESSD) and required CO_2 discharge in developed countries to be reduced by 5% of the 1990 level.

L22: Minimizing the adverse effect of construction-related activities on the ecosystem. That is, using the land appropriately to cause minimum change and making sure the eco-flow is not blocked by a built-environment.

L11: Minimizing the artificial intervention needed to attain adequate comfort within the comfort zone for human habitation. That is, reducing environmental loadings and minimizing exposure of human habitation to environmentally toxic materials.

L21: Minimizing the consumption of energy (fossil fuels, non-recyclable energy), water, and materials due to construction-related activities.

L12: Reducing environmental loadings, especially, decreasing the discharge of HCFCs, HFCs, CO_2, Sox, NOx and others that destroy the ozone layer and cause global warming and soil acidification, reducing waste that are non-recyclable or take long time to decompose.

3.3 Proposed Concept of Structuring Assessment Method and other proposals

To effectively implement the role of assessment method proposed in chapter 2 above, the structuring of an assessment method is first needed. The assessment method structuring proposed in this study refers to classifying the assessment standards with particular intentions. The primary purposes sought with the assessment method are placed at the highest category level, and under them are placed specific content categories and sub-purposes. Under these, in turn, are placed more detailed goals, and at the lowest category level are criteria on detailed essential techniques. By doing so, the ultimate purposes of assessment method can be effectively accomplished, and detailed goals and criteria permit flexible measures to be taken depending on the circumstances of the specific time period. Furthermore, by classifying the detailed criteria as obligatory practices, recommended practices, and voluntary practices, and making them adjustable, the detailed criteria can provide flexible and effective measures.

Second, an assessment method must be linked to national policy. Especially in a developing country like South Korea, it is yet premature to expect voluntary participation, and there needs to be regulatory controls and incentives.

Last, continued publicity and education as well as evaluation results should be made available to consumers more user-friendly, and consumers' right to information should be satisfied. Through this, the vision of sustainable building should be persistently presented to consumers. Such efforts will improve the awareness level and change the life pattern of consumers, and will be effective in accomplishing the expected objective of a sustainable performance assessment method.

4. Structuring of Assessment Standards category

As stated previously, this study, by structuring the assessment standards category, aims to take on a leading role in improving the sustainable building performance for a whole nation through the assessment method. The assessment standards category method proposed in this study is as follows:

(1) Assessment Method's Purpose

This indicator placed as a topmost concept among assessment categories becomes an ultimate purposes. As proposed in section 3-2, the purpose of this assessment method shall be preserving eco-network, operating environmentally comfortable habitation within the human comfort zone, minimizing natural resources consumption, and maintaining low environmental loadings. This is topmost indicator in this assessment method.

(2) Assessment Method's Category

The second highest concept in this assessment method refers to the more detailed content within each purpose, or sub-purpose. For example, within a purpose, reduction of natural resources consumption, there may be categories of low energy, low water, low material and so on.

(3) Sustainable Performance's Goal

This refers to the concept of detailed goal required at a specific time point. This concept, as mentioned earlier, is proposed to enable more flexible response to changing circumstances. For example, the category of CO_2 reduction within the purpose of maintaining low environmental loadings is a indicator that rarely changes, but a goal of 5% CO_2 reduction for year 2000 can be changed, due to stronger international requirement, to a goal of 10% CO_2 reduction for year 2000.

(4) Sustainable Performance's Criteria

As the lowest level indicator, criteria comprise the detailed standards presented by experts from various fields to meet the detailed goals. These standards are classified and differentiated into obligatory practices, recommended practices, and voluntary practices. In addition, these criteria classification can be changed according to changes in circumstances. This is also one of the ways to provide flexibility in response to circumstantial changes. For example, if technological levels improve compared to existing standards, then some standards may be reclassified from voluntary practices to recommended practices. While other standards, although they may have been obligatory practices in the past, because the levels of technology and awareness have improved and other circumstances have also improved enough so that currently the majority of buildings satisfy given standards without regulatory control in a particular area, they may be reclassified to voluntary practices.

The outline of the assessment indicator category structuring proposed in this study is as follows.

Table 2 A Part of the Assessment Category System

PURPOSE	CATEGORY	GOAL
1.Eco-Network	1-1 ….	1-1-1. …
2. Environmentally Comfortable Habitation within the Human Comfort Zone	2-1. …	…
3. Low Natural Resources Consumption	3-1. Low Energy	3-1-1. ▪ 15% reduction of heating, cooling and lighting energy for year 1990 (2006. 01) ▪ 20% reduction of heating, cooling and lighting energy for year 1990 (2007. 01) ▪ 25% reduction of heating, cooling and lighting energy for year 1990 (2008. 07)
		3-1-2.
		3-1-3.
	3-2. Low Material	…
	3-3. Low Water	…
4. Low Environmental Loadings	4-1. …	…

Each indicator, such as Purpose, Category, Goal by proposed this study, is numbered as each positions. It represent by this numbering that each Goal serves what Purpose. As seen from Table 2. Goal 3-1-1., this Goal can be proposed newly and amended in changing conditions. So, we get several detail goals in Goal 3-1-1. Also, if the Goal 3-1-1 is needed no more, it can be deleted. If new Goal 3-1-4 is needed, it can be supplemented at that time. This point can help to get an assessment method with flexibility. In this assessment category system, the Purpose and the Category are constant indicators and the Goal and Criteria are variable indicators.

Table 3 The Example of Criteria List

Criteria	Goals to be contributed each criterion	Requirements Degree (2008.09)
…	3-1-1, 1-3-4, 2-5-1	Obligatory Practice
…	1-1-1	Recommended Practice
…	…	…

Because this list is presented that each criterion can help to achieve some Goals, evaluators can take cognizance how each criterion contributes for sustainable performance of buildings and consumers can be aware of the building's sustainable performance more clearly. One criterion may contribute to attain a Goal or other Criteria may contribute to attain several Goals. This point can exercise when we determine weighting of each criterion. As stated previously, requirement degree of each criterion can be altered as changing conditions. It is represented as 'Obligatory Practice ', 'Recommended Practice' and 'Voluntary Practice'. Criteria checked 'Obligatory Practice' is mandatory. They are linked national policy or local regulations. 'Voluntary Practice' is related to various financial or legal incentives. This exercise encourages stakeholder to get high performance of sustainable building. For fill out blank of Criteria, we want to use existing standards be proposed by experts in related area. It is useful that we skip similar studies over and over again.

Weightings of the assessment method proposed this study will complete through subsequent studies. But this study proposes basic concepts of weightings. Weighting of our assessment method will include priorities of each ultimate Purpose or second Goal, degree how much each criterion contributes to accomplish second Category or detailed Goal, how many times each criterion belongs to each Goal and so on.

5. Conclusion

This study aimed to develop a sustainable building performance assessment method suitable for South Korea, a developing country where there is still a need to promote improvement of sustainable building performance through strong intervention from outside the market, and where there is a need to be able to respond flexibly to changing circumstances. Accordingly, this study structured the assessment category system to help achieve intended goals effectively through the assessment method, and proposed a sustainable building performance assessment method that is flexible in responding to circumstantial changes by differentiating between constant and variable indicators.

However, because completing the intended assessment method is rather huge in scope, this study proposes the basic concepts of the assessment method and shall leave the completion of the assessment method for subsequent studies. Discussion will be needed on how to promote the completion of structuring the assessment method and to propose the detailed goals and indicators and the method of classifying them through subsequent studies. Discussion on how to link this with the national policy will also be needed. Study on how to properly place weighting and rating on the assessment results of each assessment guidelines needs to be done. There is also a need for continued discussion of how to provide consumer with information on final assessment results and to present a vision for the sustainable building market.

The Power of Symbiosis: Spiritual Life in the Symbiosphere

Dr. Chin Ken Pa
Chung Yuan Christian University
Email: chinkenpa@yahoo.com.tw

Abstract

This proposal presents a research on symbiosis, with the premise of "material reduction and mental explosion". This premise leads to a question: how can we successfully transform the world—before it reaches its critical point of materialistic economy—into a state of higher spiritual living? This proposal will attempt at a construction of "spiritual life" in accordance with the idea of symbiosis from three aspects: "memory of time," "coordinate of space," and "spiritual wellness". This kind of "spiritual life" will achieve symbiotic convergence through spiritual pursuit. It will be undertaken by investigating how we can establish a community of symbiotic living in the symbiosphere. This kind of life will supply the "spiritual power" to reach the goal.

Introduction

The most urgent issue that the human race is concerned with at present is how to cope with environmental deterioration: climate change and its severe threat to human life. To be prepared for the potential disasters of the future, a feasible solution has been formulated, that is, the philosophy of "symbiotic living". It is carried out by the Archilife Research Foundation in building the "Symbiosphere 1". In it, experiments were made and results were collected. Symbiotic living has become a reality in the material aspect, but we are still anticipating for the spiritual aspect. The latter is the goal that the research is aiming at, for which it proposes the theme of "spiritual life in the symbiosphere".

According to the report in a British periodical named *New Scientist*, published January 14, 2006, a "Doomsday vault" was being built in Norway in the Arctic mountain region. It has the capability to cope with global warming and withstand the impact of all external blasts. On February 10, 2007, Reuters reports that the construction has been completed at the cost of approximately five million dollars. This vault will keep the seeds of crops at maximum security; thus it is called a "seed bank". The construction is scheduled to be completed by the end of 2008. However, human sheltering is not included in the project. In other words, the designers have not considered how to keep human beings from the potential disasters. On the contrary, Symbiosphere 1 does put basic human needs into consideration, affirming that the ability of self-preservation during catastrophes is the key for "livelihood and life-prolongation". In other words, the Archilife Research Foundation pays attention to the strength needed in symbiotic living. This research is in view of constructing a kind of "spiritual life" in the symbiosphere in accordance to the idea of symbiosis.

Firstly, we need to clarify the relationship between the material and the spiritual.

> **A spiritual life is the first and foremost issue. The needs for the material are both limited and superficial. What man really wants is spirituality. Therefore, to pass through the trial of material shortage, one cannot simply decrease the dependence on material in a passive way. He should try to look at the material from a different angle, and try to transform the needs into spiritual power.**

The second is to have an understanding of the "twenty-four solar terms" in the agricultural society, and to elucidate how it responds to the time of material shortage.

> **The most dramatic and significant transformation of the society during the second half of the 20th century, a transformation that cuts us off from the past world, is the death of peasant life. The modern capitalist society has destroyed the enormous political structure of the agricultural civilization. It did not take long for the powerful agricultural empires to disappear. Therefore, we find that solar terms are not exactly helpful for us to improve the relationship between man and nature. The reason is not that the calendars are no longer in use, but that industry has replaced agriculture, and that the city has replaced the countryside. The primary issue is whether we can be brought back to countryside living and return to the life style of the agricultural era. The answer is negative.**

Thirdly, Symbiosphere 1 is set up as the empirical background and a component of the project of "symbiotic force". This project includes: clarification and construction of the special relationship between man and the environment, measures to avoid the weakening of the ability to adapt to the environment when the spiritualizing process is being internalized, as well as the structure and content of the new civilization.

This research believes that "symbiosis" is not inaction. On the contrary, it is a kind of "new involvement", different from that of the agricultural and the industrial society. According to our primary envisage, this kind of transformation of *Weltanschauung* is inevitably "religious" to a certain degree. Therefore, based on the related concepts mentioned above, we can imagine life in the symbiosphere that concerns nature, humanities and spirituality. We can also further arouse the "symbiotic force", which is firmer and stronger.

> **A symbiotic life is similar to a monastic life. A symbiosphere is like a monastery. The monks (symbiotics) are of one mind in the pursuit of elevation of the soul or the spirit (the internet replaces the Bible). The regular routine of life is based on the regulations of the program (getting up when the sun is out, resting when it's dark). Specified tasks are to be undertaken in specific time (mainly concerning manual labor). However, it is the idea of symbiosis that guides their minds, that is, a life-experience of symbiosis with the others, nature, and everything else in vicinity.**

Section One

Mankind, living with limited power and facing unpredictable natural disasters, has no right to be optimistic or pessimistic. Finding a way out is an instinctive reaction, and the philosophy life called "symbiotic living" is such a reaction. It shows an attempt to bear the burden. Though we cannot take hold of the future, at least all the efforts are worth trying.

The summarization of commune life in the symbiosphere these years is the philosophy of symbiotic life. The premise includes the following aspects:

1. Accepting Restrictions

Since the Enlightenment, freedom has become the highest value of the human race. It is commendable in the activities of humanities, but the interaction with nature is another matter. "Symbiosis" means to realize that the present world cannot be upheld anymore. Therefore, from the starting point of symbiosis of man and nature, we can understand the pertinent function of restrictions. Appropriate restrictions are necessary. It gives us space so that we can have time needed for adaptation and finding a more favorable way for mankind to survive. It is the very reason why we have to examine our understanding of democracy and the method of administration.

2. Full-scale Interactions

A pertinent mode of interaction, originated from the wisdom of construction and biology, is the one that determines our life style. Symbiosis is a mechanism of negotiation. Human involvement, with all its limitations, is the means to undertake a harmonious and benevolent interaction. As long as the human race is preserved, any mode of interaction can be put into consideration. However, though it is in the ultimate interest of mankind, "survival" can also cause problems. Symbiosis has to resolve the complications and dilemmas. Therefore, our interactions have to be in the prospect of a distant and shared future, instead of a short-sighted and partial "here and now". Thus, "full-scale interactions" refers to interactions in all aspects. It is more than an integration of intellectual disciplines, but also interpersonal interactions, as well as in-depth interactions with the natural and the spiritual.

3. Spirituality First

In history, mankind has made it safely through many an age of material deprivation. What they depended on is spirituality. However, we are living in an age of abundance, and are growing unaccustomed to relying on the spiritual power. Paradoxically, in the age of abundance, people are more inspired for the spiritual pursuit. This is evidence that, regardless of want or abundance, the spiritual alone can bring satisfaction. This is how we came to the conclusion of "material reduction and mental explosion".

The philosophical premise of the three afore mentioned aspects of symbiotic living is the basis, from which we start anew with the wisdom of traditional life. The "solar terms and festivals" demonstrate the symbiotic power of interactions with nature, and an awareness of the strength of traditional commune life. It also expresses *accepting restrictions, full-scale interaction, and spirituality first*. As for "coordinate of the soul", the gratitude for life, elevation of the spirit and full-scale interactions all receive the function of *accepting restrictions, full-scale interaction, and spirituality first*. In the view of "ease as happiness", this form of fellowship can be applied to promote each other's spirituality. Prayers, reflections, contemplations, and sit-in meditations can be the means for a returning to the inner self. When the self is cared for and reenters peace, then even the ease one feels at heart can be strength to ascertain the happiness and overcome difficulties.

Section Two

With no doubt, mankind's spiritual needs have never waned. A spiritual lifestyle answers to the needs of the soul, that is, psychological and spiritual needs, needs for security, leisure, friendship, care, joy, individuality, information, knowledge of one's limitations, and respect. All these are directed to the human conceptions, passions and customs, which are the major component of the human culture.

If the future is a time of "material reduction", then spirituality will be our only way out. If reducing dependence on the material is to turn for the spiritual, then, which kind of spiritual life is the one we should pursue? In a symbiosphere, the spiritual lifestyle appropriate with the idea of symbiosis is a further affirmation to "material reduction". In this way, spiritual life can become a force, strong enough to overcome the crisis caused by environmental deterioration and material want.

The spiritual life of Symbiosphere 1 should contain three aspects and their interactions with each other. These aspects are nature, humanities and spirituality.

First of all, the festivals and solar terms have been commercialized in the modern era. As a result, we have separated ourselves from a close relationship with nature. Besides, we are also cut off from the medium of the interactions between man and nature. What's more, mankind's spiritual life has been severely damaged. Therefore, we should restore the relationship between man and nature. The meaning of nature to man is reflected in the festivals and solar terms. Since the ancient times, the wisdom of human beings has been primarily revealed in the proper treatment of the delicate relationship between nature and themselves, especially in the rhythm and tempo of life, which is "in accordance with the solar terms and festivals based on the natural phenomena". On the one hand, the first chapter is devoted to finding the wisdom manifest in festivals and solar terms. This kind of wisdom can teach mankind to get closer to nature, and also embodies the value of symbiosis when mankind is living with the rhythm and tempo of nature. In other words, "festivals and solar terms" represent the fruit of the interactions of mankind and nature, which is mainly reflected in the advancement of human spiritual life.

"Festivals and solar terms" reflect the memories of the interactions between man and earth, the sea, and the stars. Their origins date back to a close tie with agricultural activities (such as the lunar new year, which symbolizes a resurrection of the plants), religious rituals (such as the Lantern Festival, when people pray for blessings in memory of their ancestors; Mid-Autumn Day, on which people pray to the moon; as well as the Double Seventh Festival or the Chinese Valentine's Day, on which girls pray to the Seventh-Star Princess and the Bed Protector for an adroit hand in knitting), ethics (such as the Pure Brightness Day or Tomb-Sweeping Day, on which people pay homage to the ancestors and mourn for the dead relatives), going after the auspicious and avoiding the inauspicious (such as the Dragon Boat Festival, when people hang up Asiatic Wormwood and drink realgar wine; and the Double Ninth Festival, when people attach Chrysanthemum branches to the windows and doors to "get rid of the evil and filthy" and to receive blessings).

"Festivals and solar terms" should be understood as a kind of "memory in time", which inspires awe in man, and help to form a symbiotic fellowship between man and nature, as well as between the individual and others. The purpose is to remind mankind of the close relationship between man and nature, of the respect for life, and of gratitude to the earth. We can see that only "memory in time" can help us to remember how our hearts have been touched with the nurturing of life. Similarly, we should treat nature with this kind of feelings.

Therefore, the interactions with nature in the symbiosphere are more than the personal ones recorded in www.archilife.org. Festivals are also to be celebrated to in the symbiosphere, and the preserved customs are to be heeded. Moreover, the transform “ill at ease” into a bearable feeling, and furthermore, into “comfort”. However, it should not be mistaken for a spiritual “dallying”. This is why we choose certain compositions to be played in the symbiosphere on a regular basis. Among them, the Western romantic works are the most suitable ones for the theme of “the natural transformed into the spiritual”. With its help, one can better adjust himself to the environmental hazards and other changes, with fortitude and enthusiasm.

Section Four

Unlike those afore mentioned sections, which deals with the relationship between nature and the humanities, the third chapter concerns spirituality. As a matter of fact, “spirituality” can be very personal. It is a returning to the secrecy of the soul, or, the spiritual realm. Contemplation and meditation are the means for one to attain introspection. The key is to have a strong will power and a sharp mind. Inner (or spiritual) strength and alertness are especially necessary when one faces the harsh and crude environment, which can help us to return to the inner self and find peace.

A spiritual life is consisted of reading and maintaining silence. The reading materials should be the classics, especially those on spiritual practice and the inspirational ones, from all great religious traditions. They are indispensable resources, serving as the model references and sources of strength. Silence is a regaining of peacefulness and a reentering of unity of person and “the spirit of the earth” via prayer, reflections, meditations, sit-in practices and contemplations.

Strict regulations are recommended for life in the symbiosphere. One should arrange for himself ten to fifteen minutes after he gets up in the morning and also before goes to sleep at night. This is a peaceful time for himself, spent in contemplation and prayers. The quiet time in the morning should be devoted to thoughts on the goals of the day. One can encourage himself to be strong and face all the challenges of life. The quiet time in the evening should be devoted to reflections and recollections of the day. On the one hand, one should be joyful and thankful. On the other hand, he should make self-examinations and corrections. Only by repeated thinking, praying and reflections can the strength to lead a symbiotic life be gathered, the idea of symbiosis be carried out methodically, and the interactions between man and nature as well as between individuals be undertaken.

Man does not only need to interact with nature and others. He also needs to have interactions with his own soul. But there must be a medium or material for the interactions to take place. The spiritual nurturing in symbiotic living is carried out by concrete practices according to the pre-designed schedules. The following schedule is drafted for all the residents of the symbiosphere to participate. The residents also have other interactions besides book clubs, ritual performances, and the weekly conference on the living condition. "Reports on the mood" and "sharings of the soul" are included as well. In the evening, there is "fellowship time" from half an hour to one hour for everyone to sing, play games, chat, and hold discussions. This is the reference of "spiritual parameter" in Symbiosphere 1.

The elevation of spirit emphasized here is not an isolated action. In other words, solitude is not self-enclosure, but strength to face others once again. Without this kind of experience, one cannot get to have a full grasp and knowledge of his inner self, nor can he reflect on the relationship between himself and others, between himself and nature, in an open and honest way. Therefore, solitude is a preparation to be ready to deal with others. Without this experience, all our actions and interactions would be blind and selfish.

One needs to face the challenges of life as well as his own self. In facing himself, he faces others as well as nature. Therefore, the symbiotic fellowship is a means for us to turn from the interactions with others in our daily labors to a kind of introspective and reflective interactions. "The renewing force would be missing in action, if there is no solitude for the soul." This is a link necessary in the commune life. It is lacked in today's life style, for people fail to realize the value and philosophy of the symbiotic life. To be symbiotic means to live together, which means to have a deeper understanding of oneself, which means to have a deeper understanding of the others. The symbiotic fellowship is an effort towards establishing a closer relationship. The opposite of "symbiotic" is "alienated", "indifferent" and "selfish". Symbiosis can help us to adopt an attitude of openness and enthusiasm. How can we face the harsh environment yet retain the hope and strength? How can we be prepared for action without enthusiasm?

A tentative brochure of "life plan" for fourteen days has been finished. It can be put into the "schedule for daily life" in the symbiosphere, so that the residents can make their response, meditations, and hold discussions.

Conclusion

From analysis of climate change and the existing fauna and flora, we can know much about the environment where the evolution of our ancestors took place. During the past several million years, the climate has been dominated by the instability of the Ice Age and unpredictable weather changes. These changes have given a new appearance to the living environment and the external environment of animals and plants. Thus the species can have more varieties that are highly adjustable and can fit into all biological niches. The adaptable and fast-growing ones can better adjust to the ecological disasters. The human beings are such species, who might have been the typical products of the Ice Age.

Climate change has transformed the general configuration of the earth's surface as well as the vegetation. Animals and plants have to learn to adapt, and the same goes for mankind. But they have different ways of adaptation; this is how the human society becomes more and more diverse. We have brought about environment transformations from the agricultural era to the industrial era: the agricultural revolution has changed the earth's surface, while the industrial revolution has changed the atmosphere. After all, any intervention means change, even symbiosis is no exception.

The emergence of agriculture has drastically changed the relationship between man and nature. Human behavior has affected other species as early as the Paleolithic Age. However, since the day when the human beings first engaged themselves in agriculture, they began to change the living environment—earth, rivers and the landscape—to create a new one to satisfy their needs. Agriculture means to change the natural courses to satisfy human needs. Therefore, it is an intervention into the biological cycles of nature. By eliminating the undesirable species (i.e. weeds), the farmers carefully create a man-made landscape. In this process, the natural replacement that could have restored the original state of the earth is prevented. The earth, without the removed species, is maintained below the natural level of productivity. On the other hand, the species favored by mankind are flourishing, for they have attained extra nutrition, water and sunshine. However, the decrease of vegetation has augmented the erosion of the earth, for the massiveness of the roots has been reduced. They could have kept the earth from being washed away by the rain.

As mankind has begun to rearrange their environment to live more comfortably, they have become more and more aware of the separation of man and nature. The idea of "man and the environment together as one community" is manifest in the modern food-collecting communities, but it may have disappeared in the agricultural communities.

The ecological crisis is very obvious to those who are executing power in the modern society. Thus, the people's attitude, especially in the developed countries, must see a change. Attitude is a decisive factor for everything. "It is good to keep the producing process going" is a widespread notion. But it is one of the hindrances to the change. As long as we are accustomed to pursue the so-called beautiful life via means of capitalist consumerism—that is, consume endless "better" products—then this notion will never cease. The change of the definition of "beautiful life" might be one important step towards maintaining a sustainable relationship between man and nature.

The industrial society has also come to a bottleneck. The ecological crisis and global warming are the result of the development. At the same time, we can still preserve the spiritual power in the traditions of all nationalities and make use of it, despite the fact that we cannot return to the agricultural society and adopt an agricultural lifestyle anymore.

Many ancient civilizations have vanished, yet some remains till this day. In all these cases we can find a massive "spiritual power". Their external environments can be harsh, they may be put at a disadvantage when facing other powerful nations; however, they still have considerable strength for survival. The destiny of the nation is supported by their old spiritual traditions. In other words, we have underestimated the power of spirituality. Of course, we should not overestimate it either. After all, many civilizations that are preoccupied with the spiritual rather than the material have done so at the price of extinction.

The relationship between man and the environment is by no means passive. Agriculture and industry are intervening into the environment, and so is symbiosis. Only by active intervention can this special relationship be maintained. Symbiosis is not passive. Through this means, the spiritual power is not overestimated, nor is the material over-relied on. There should be more and more balanced interactions of the environment and the mind, the body and the soul, the material and the spiritual. Only in this way can the deadlock—the spiritual is over-elevated to the effect that the people are passively restricted or even bound by the environment—be broken.

In conclusion, the structure of the future civilization should contain the element of "the spiritual transforming the material". The relationship between man and nature should be a separate-togetherness. We should not be over-dependent on the material, nor overlook the undertakings to transform the material. Frankly speaking, it is difficult to achieve the balance between the spiritual and the material. Nevertheless, it is the very aim that symbiosis endeavors to achieve.

TITLE: TO SET UP AN EFFICIENCY BIO-COMPOSTING SYSTEM FOR MATERIAL RECYCLING IN ARCHILIFE RESEARCH 1 CENTER

Keywords: resource use , material efficiency , recycling, microorganisms

Summary

In the past, people in the field of building a green house have put a lot of efforts on the research and development of the construction materials. Unfortunately, many people did not think if the green house is the real candidate for living in a long term. If treating a green house as if it is a big tree, this big tree can use its organs like leaves and roots to absorb nutrients from photosynthesis or water from the soil. Once the matters in the trees lose their internal functions, for example, falling of the leaves in the winter, these matters will fall on the soil and thus will form a recyc ling system that can be reused. In 2002, we started to imitate the behavior of Mother Nature, we used microorganisms to recycle those soil substances. B y treating the vertical planting system as if it is a leaf, it can undergo photosynthesis to produce con sumable vegetables; in addition, is it suitable to be used as a natural air conditioning system. However, how do we deal with feces and food residues produced from human? According to the past experiences, we came to two attempts: 1. using the traditional manure system, but this system is not stable nor time efficient; 2. using composting machine. However, it is not energy efficient and will decrease manure compositions. After 2006, we continuously reviewing the best solution and decided to use earthworms t o achieve the best material recycling efficiency in the biological manure system. Ultimately, we want to obtain one answer: in order to support the group of people living in a recycling system, yet, closed system, how many earthworms do we need to fit the environment?

1. Introduction

Manuring is an ancient technique, and this technique plays an important role inc ontrolling the utilization and reuse of solid substances from the natural resources. From the beginning of agricultural revolution, people started to explore a more advanced manure technique by the aid from the nature. After the industry's revolution, we can possibly control the air ratio, temperature changes and the bacteria abilities to enhance the development of manure industry. Until today, we are still in searching of how to efficiently and optimize the use of solid wastes like human feces, urea, and food residues, etc. Those organic matters are still the challenges for us to face. Only through the completion of composting, matter substances can eventually recycle in a closed space, and only this kind of space is suitable for human being thus becoming a long term living environment. This idea is exactly what we have been spreading upon: SB = GB + symbiosis, meaning what kind of biological ani mals are suitable to live with human symbiotically.

1.1 Origin of the experiment

In the past NASA had made a series of experiments. They wanted to build a completely closed system that human beings can support for themselves. This thinking is known as L ife-support system. I believe it is now the best green house so far. What so ever, NASA has encountered a crucial problem. The physicists are responsible for constructing a preferred physical living environment, the agricultural biologists are responsible to solve the food problems, and the biochemists attempt to find ways to effectively utilize and reuse matters. However, every delicate design or knowledge is difficult to put together as a whole.

1.2 Our goals

The meaning of symbiosis for many is simply the relationship between wild vegetables and us, which is the capability of vegetables providing nutrients for us in our diet. In the true meaning of symbiosis, eating vegetables are input, human produces output like feces, and urea. Those outputs have to become input for the plants in order to be considered as recycling. In other words, for these two to be interacted well, one has to be the input and the other has to be the output, and furthermore, the tighter the interaction, the tighter the ring. For humans the vegetables are just purely food, and for the vegetables, their leaves are their organs. Photosynthesis is their main food source, therefore, leaves are not for humans to eat, but humans eat them anyways. Through the concept of in and out, the relationship between human and wild vegetables is interconnected. The rest of problems are the human feces and urea. You might wonder if the wastes are the vegetables input? The answer is no. The vegetables are not necessary eating our feces as nutrients directly, so that is why we do not plant vegetables on top of the septic. There must be an essential process in the interaction between vegetables and our wastes, and this process is our main research topic.

2. Material and Method

2.1 Material

The experimental matters in this experiment do not influence the daily life routine of these inhabitants of the center in order to achieve many possibilities of this research. All the inhabitants live in the center were not less than one season. Experimental procedures are followed under the regulation of the PSA (Public Service Administration) committee.

2.2 Method

Culturing of the bacteria is done through the traditional method or through molecular biology. Add 10 grams of sample (wet weight) into 90 ml of sterilized distilled and de-ionized water to get suspension and continue diluting (10^{-2} 10^{-3} 10^{-4} – mould; 10^{-4} 10^{-5} 10^{-6} – actinobacteria ; 10^{-5} 10^{-6} 10^{-7} – bacteria), then inoculate to Rose Bengal Agar, to Actinomycete Isolation Agar, to Nutrient Agar (NA) for culturing mould, actiobacteria and bacteria, respectively.

3. Result

3.1 The quantity of solid wastes produced from each citizen per day

Table 1 The quantity of solid wastes produced from each citizen per day

Solid wastes	Mass（g）	participator
Human waste	220	3
Kitchen waste	80	6
Farming waste	30	4
Fallen leaves	100	10
Total	430	23

From 2002-2005, the wastes produced by the citizens per day are 220 g, and food residues are 80 g. Farming and natural falling leaves produced about 30 g and 100 g, respectively. In these 3 years, the centered formed four public committees who are responsible for taking care of the plants, food, clean environment and circulation of manure. All the numbers provided here are from the long-term experiment results and also provided by the participants. Finally, we accumulate the amount of reusable solid wastes from each person per day, and that is about 430 g.

3.2 The efficiency of different manure methods

Table 2 The efficiency of different manure methods

Products（Kg）	Traditional manure	Composting machine	Vermicomposting
Time（month）	6-9	1	2-3
Organic mass（Kg）	0.3	0.1	0.5
Microbial biomass	medium	low	high
Demanding energy	×	high	×
Stability	Low	high	high

According to time efficiency, the traditional manure method spends the longest time and the composting machine is the fastest to obtain manure products. However, the actual products from composting machine will fall short instead, which means many organic matters will become carbon dioxide and water. At the same time, composting machine is not energy friendly. Later, we spent time on breeding earthworms and were inspired by them. Earthworms can eat the digested organic matters of themselves body weight per day and have the ability to transform into half the weight of rich soil. In table 3, the results relieved us. In the past, we worried about using earthworms in the biological manure would not efficiently decrease the amount of harmful microorganisms, but the results tell us this is not the cas e of concern anymore.

Table 3 To analyze the microorganism of the casting of earthworms

Composition	Range
bacteria	1.1×10^{8}
Fungi	3.1×10^{8}
Actinomycetes	$10^{7}\times10$ c/g
Salmonella	none
E. coil	none

In the process during traditional manure method, the hig h temperatures could kill harmful microorganisms since they are mesophilic and leave out the thermophilic microorganisms. A mechanical composting machine uses heater plate can increase the temperature from 45 ℃ and above, and humidity of final products will keep at 30%. The earthworm method can substitute the beneficial bacteria for the original species due to substrates digested from intestine, and this method can be achieved under room temperature.

4. Conclusion and Disscussion

4.1 Conclusion

Figure 1 A prototype of symbiotic high efficient recycling system in ARF 1 center before 2002.

Figure 2 the comparison between the products produced from three different manure methods and the roots grow from carrots. (left: earthworm casting; middle: traditiona l manure: right: product from commercial composting machine

Figure 1 shows in the past when we were building the symbiotic high efficient recycling system, we hoped through the improved technology we could efficiently achieve a substance recycling system. However, during the first time of experiment between 2002-2005, we faced few challenges. For example, the cabbage and water spinach are easy to grow and produce in a large amount for us to eat, but before we harvest, the insects had eaten them all. In this way, we had to use wild vegetables as our main plants; in a ddition, in order to grow the vegetables in an adequate environment, the vegetables we obtained are within 5 km of the center. Secondly, manure is our matters, but according to the past agricultural manure experience, manuring is labor intensive and easily to produce smells. Finally, we chose to use commercial composting machine, but it wasted a lot of energies, plus the manure composition will decrease dramatically. Therefore, in 2006 we started to use earthworms as our final target.

Figure 2 is when we compared ability for growing carrots using different manure methods under the same condition. During the process of cultivating carrot seeds, the carrot is surprisingly grew the best in earthworm casting. This organism, known as "the stomach of earth" is efficiently aid in the recycling system.

4.2 Disscussion

Advantage of the earthworm composting system :

- Worm composting is an incredibly efficient way to convert kitchen scraps into nutrient -rich compost.
- Worm could digest the most recycle material ,even n ails and hairs.
- These elegantly efficient organisms have been on earth for hundreds of thousands of years longer than humankind, largely untouched by evolution due to their nearly perfect adaptation to their role in nature.
- Humankind has studied and learn ed to appreciate the talents of the earthworm, developing systems that capitalize on the natural role it plays in recycling organic matter back into humus.
- It's not easy to account for microorganisms by measuring the chemical factors.
- Earthworms are rich in protein contents. We can produce them in large amounts and use for food for the fish, or can be used for the citizens delicacies.
- In full operation, the Worm Tower houses 10,000 to 12,000 worms, consumes 5 to 8 pounds of food a day, allowing you to harvest a full tray of castings per month.

In the near future, we want to test if the earthworms can increase fertility of the soil and if they can survive in the dry stool? In addition, the pre-processed urea is fermentable and is efficient for organi c matter recycling? Maybe I will share with you all next time!

Keywords: double-skin facade, opening design, natural ventilation, high-rise residential building

Summary

Double-skin façade, as envelope system composed with 2 layer glasses while placing the Intermediate façade between both glasses, has the strong point that the Intermediate façade decreases wind pressure and it can positively respond to the external weather conditions and the internal ventilation requirements through the various openings, which is an alternative to resolve the problem of natural ventilation appeared in high-rise residential buildings.

Double-skin facade is planed according to each case. As the components of double-skin façade generally influence thermal, lighting, sound and air environment, although the study on the procedure of plan has been executed, the planned and applied buildings were mainly limited to office buildings and did not aim for the positive natural ventilation. Accordingly, to apply to residential buildings, the consideration on natural ventilation performance in planning also should be added.

In this study, to consider natural ventilation performance in planning double-skin façade for high-rise residential buildings, firstly, the characteristics and the status of the envelopes of existing high-rise residential buildings were grasped, secondly, the factors of double-skin façade plan influencing to natural ventilation performance were selected and then the evaluating model was determined. Finally, the distribution of Intermediate façade and internal air flow from the inducement of external windows for natural ventilation performance were evaluated and then the instructions for double-skin façade were derived.

1. Introduction

Whereas the residential sites in the downtown are recently decreased from the congestion of urban space, occupants' requirements on residence in the downtown for the convenience of life are increased and then the high-rise residential buildings are being accelerated. High-rise residential buildings restrict the openings of windows by the reasons such as wind pressure, stack effect and safety, etc and then the forms of envelopes were mainly changed. The envelope planned similarly with that of office building increased the value of house but could not consider the characteristic of residential building that natural ventilation was a main ventilation means, which was different from office building. Furthermore, from the legalization of balcony expansion, the balcony used as the thermal buffer space was modified as a residential space and the big differences not only in the form of envelope but also in performance were appeared. The problem of ventilation was largely appeared no less than the weakened insulation performance. As sliding window applied at balcony was changed into the shape of top-hinged out swing window of which opening area is small, the psychological feeling of opening of occupant was decreased and the occupants used to appeal the stuffiness because they cannot feel the feeling of air flow even in opening the widow. And the natural cooling inducing external air becomes difficult and then the problem like the increase of energy cost was increased also.

Another problem of high-rise residential buildings are that the households of which one side only faces the external air within unit household due to the core structure located at the central part of plane were frequently occurred. This made cross ventilation which efficiently utilized the natural ventilation impossible and then largely fell down the efficiency of ventilation.

To resolve these problems, the façade which can satisfy the requirements on the natural ventilation of residential building should be planned. However, at the present façade, because there is the limit of opening area and opening width from the safety reason, not only it is difficult to increase the opening area, but also it is difficult to decrease the wind pressure properly. As an alternative which can resolve the problem of wind pressure and safety at high-rise building of which opening area is restricted and simultaneously promote the natural ventilation, there is double-skin façade on which the active studies are being progressed recently. Double-skin façade, as the façade system composed with 2 layer glasses while Intermediate façade is being placed between them, has the strong point that Intermediate façade decreases wind pressure and it can

Figure 1 Non-expansion of balcony

Figure 2 Expansion of balcony

positively respond to external weather conditions and internal ventilation requirements through the various openings.

This study is to plan to consider the natural ventilation performance of double-skin façade to improve the natural ventilation performance as applying double-skin façade to high-rise residential building. In this study, firstly, the characteristics and the problems of the envelope of high-rise residential building were grasped. Next, the factors of double-skin façade plan influencing the natural ventilation performance were reviewed and evaluated.

Natural ventilation in this study means the ventilation which internal occupant can directly feel the effects of ventilation and what discharges the heats of Intermediate façade through air flow was not included. And rather than dealing with all planning factors influencing the natural ventilation performance, as increasing the evaluating factors based on the reviews on each factor, the evaluation was performed while focusing on the factors to be importantly considered for the plan considering the natural ventilation performance.

2. Field Survey

As double-skin facade should be planned according to the usage and the characteristic of building, this study wants to grasp the characteristic of high-rise residential buildings, the applied object of double-skin façade. For this purpose, the envelopes of high-rise residential buildings were investigated and the problems related to the natural ventilation through the questionnaire and the interview to the occupants and managers of existing high-rise residential buildings were investigated. Through the investigated matters and the standards and the laws related to natural ventilation, the required performance of natural ventilation of residential building was summarized to become the standards in evaluating natural ventilation performance after then.

2.1 Data Analysis

As planning the envelope as considering the natural ventilation performance is the purpose of this study, firstly, the investigation on the vent is surely necessary. The opening form of vent is an important factor determining ventilation rate along with the area of vent and determines the induction rate of external air. Accordingly, as the opening form of vent of the envelope of high-rise residential building, the present practice of the induction of external air was grasped. The investigation was executed to total 15 buildings at Yeouido, Yongsan-Gu, Gangnam-Gu and Yangjeon-Gu, Seoul where high-rise residential buildings were most distributed.

As the results of investigating on the form of envelope parts, most of investigated buildings applied curtain walls on the envelopes and divided a part of curtain wall area into the frame to use as the vent. As the kinds of vents, like Table 1, all cases except for the lower floor parts of T high-rise residential building at Yeouido were appeared to apply the method of top-hinged out swinging window and only at the lower floor parts of T high-rise residential building at Yeouido, the method of top-hinged out swinging window and of side-hinged out swinging window were combined. The case of ensuring the area of vent more widely as dividing the

Table 1 Opening window of the envelope of high-rise residential buildings

			
Top-hinged out swinging window		Top-hinged out swinging window + Side-hinged out swinging window	

districts widely despite of the same method of top-hinged out swinging window could be found.

To grasp the environmental performance related to the envelope which the occupants of high-rise residential buildings felt, the questionnaire and the interviews to mangers were executed. Through this, the problems on internal environment which the occupants of high-rise residential building felt at the real life were tried to be grasped. The questionnaire was executed at high-rise residential buildings, z and to improve the reliability of questionnaire, the objects of questionnaire were selected in order for the height and the direction of household in the building to be regularly distributed. And as the interviews to managers being executed together, the complaints come from occupants after the completion of construction were grasped.

As the result of questionnaire, the problems of envelope part which might influence to internal environment performance were pointed out. As the weak points of envelope part were raised by the expansion of balcony, heating and cooling load were increased and cold draft in the winter season was appeared to be induced. At the envelope, the water leakages and the infiltration were occurred, which means that the considerations on high external wind pressure at the higher floor parts were poor. And there was the opinion that, due to small opening area of vent ,the speed of air flow was decreased and then natural ventilation was poor, psychological feeling of opening was small and the stuffiness was felt.

2.2 Problem Analysis

The followings are the summary of the performances and the improving directions related to the ventilation among internal environment performances required by the occupants of high-rise residential building in planning double-skin façade to improve natural ventilation performance of high-rise residential building based on the problems appeared as the results of data analysis of envelopes and the analysis of those reasons .

1) The security of natural ventilation performance through the inducement of external air

As the buildings have the aspects of high-rise residential buildings, cooling load was increased and the increase of cooling load was deepened by the use of curtain wall envelope that the area rate of glass was high. On the contrary, the opening area of vent became small due to the problems of wind pressure and safety, which could not have the effects of free cooling and then make cooling period longer to have the negative effects on the energy use directly. Even at the same opening method of window, the security of opening area and opening angle making ventilating rate increased are necessary.

2) The security of the air flow speed

It was appeared that the occupants of high-rise residential building wanted to feel the feeling of air flow through the inducement of external air. The occupants who had experienced cross ventilation at existing plat type apartment before the residing at high-rise residential building appeared this tendency furthermore.

Accordingly, the opening method of window, the opening area and the opening angle, etc making air flow sufficiently induced into the inside should be considered.

3) The security of psychological feeling of opening

Table 2 Applying method of double-skin facade design through the analysis of problems of existing buildings

Characteristic of residential building	Requirement	Application to DSF
Floor height is lower than office building.	To maximize buoyancy force	Inlets and outlets are located in front of spandrel.
	To prevent short circuit	Inlets and outlets are located diagonally.
There is high demand of natural ventilation.	To increase ventilation rate	External openable windows can be added. (optional)
	To let occupants feel air flow	
Children should be considered.	To make occupants safe	The type of external openable windows cannot be sliding.
		The depth of external openable window is 15 ㎝.
The reduction of the living area is critical issue for occupants.	To maximize the living area	The depth of Intermediate façade is 30 ㎝.
Occupants maintain and clean DSF by themselves.	To give occupants convenience for maintenance and operation of DSF	The type of internal window is sliding.
Most occupants use curtain for interior decoration.		
-	To provide better view	The openable bays are placed at the edge of façade.
		The frame area is minimized.

Occupants wanted psychologically opened feeling regardless of actual ventilation rate. High-rise residential buildings questioned to occupants satisfied the required ventilation rate and was measured to have the good internal air quality. But, because the vents were not widely opened like sliding method used at the existing plate-type apartment and the opening areas were small, the occupants are judged to feel the psychological stuffiness. To resolve these, it is required to secure the effective opening area to the maximum as being away from the application of present top-hinged out swinging window.

And the matters to be considered in planning double-skin façade reflecting the requirements of occupants through the characteristics of high-rise residential building and the analysis of problems are as per the following Table 2.

3. The procedure of double skin façade plan considering natural ventilation performance

Double-skin façade largely consists of external façade, internal façade and Intermediate façade between both sides.The components influencing to natural ventilation performance are external opening, Intermediate façade space, Intermediate façade floor and internal opening and there is the necessity to review these planning factors to plan double-skin façade as considering the natural ventilation performance. In making decisions, the usage of applied building, high-rise residential building, was reflected. And because the natural ventilation performance should be considered together to make decisions, the procedure of double-skin façade plan was summarized.

3.1 Factors of double-skin façade plan

External façade is classified into the outlets and inlets and the external windows and the arrangement types of inlet are classified into diagonal, parallel, perpendicular and perpendicular type. Separately from the outlets and inlets, if external windows are placed at external façade, they can make external air positively enter into the inside during the intermediate period and make it possible to ventilate at the least to improve the quality of internal air during cooling and heating period and then double-skin façade can be variously

operated by the season.

The planning factors of Intermediate façade space are the height, the breath and the width of cavity. The height and the width of Intermediate façade are initially determined by the types of double-skin façade. The height of Intermediate façade is determined equally to the floor height at double-skin façade of singly story type. At the double-skin façade of hybrid type and multi story type, by the unit of how many floors the height of Intermediate façade will be planned should be determined.

Internal façade has been applied to the cases in the various forms like slit or window, etc but it is difficult to secure the sufficient ventilation rate in the form of slit in considering the required performances of natural ventilation of residential building. Internal window is at the most internal side and thus has the characteristic that it should be determined as laying stress on the conveniences of occupants (the use of internal space and the convenience of maintenance and repair and cleaning, etc) and the psychological feeling of opening. As the planning factors, there are the height, the width, the horizontal location, the perpendicular location and the opening method.

Table 3 is the summary of planning factors considered so far.

3.2. Procedure of double-skin façade plan considering natural ventilation performance

After considering the components of double-skin façade previously reviewed, the procedure of double-skin façade plan considering the natural ventilation performance of high-rise residential building was estimated.

3.2.1 The selection of double-skin façade type suitable to high-rise residential building

According to the study (Park et al, 2002) selecting double-skin façade type suitable to high-rise residential building according to the procedure, as a first step, it is suitable to apply single floor double-skin façade due that it is high-rise building. As the next step, due that the requirements of occupants are various and it is important to intercept the privacy among rooms and the expansion of pollutants, box type double-skin façade can be selected to be most advantageous. This study judges box type as the double-skin façade applicable to high-rise residential building after passing through the process of selecting the type of double-skin façade like the above and progresses the research on the components and the planning factors at box type.

3.2.2 The decision of arrangement type of outlet and inlet

Arrangement type of outlet and inlet decides the kinds of outlet and inlet planning factors and, in case of box-type double-skin façade, outlet and inlet is repeatedly installed every floor and largely influence the elevation. Among arrangement types of outlet and inlet previously reviewed, perpendicular is used only at shaft-box type and outlet and inlet can be arranged by parallel, diagonal and perpendicular type at box-type double-skin facade. This study applies parallel and diagonal type of double-skin façade which is applied to prevent air flow discharged from outlet from being flow again in the inlet of upper floor due that the gap of height between outlet and inlet of high-rise building.

3.2.3 Decision of façade module

As double-skin facade has the high cost of construction and requires the precision, planning as making into the unit is desirable. Accordingly, it is reasonable to applying to all rooms as fixing the external module.

As the basic dimension system of architecture, the basic module of ISO, 1M=100mm, was used and the multiple of 3M and 6M is commonly selected in the world. And considering that the house mainly uses 3M unit of horizontal plan module, 900mm is determined as the external module. But, as the view and the feeling of opening is regarded as the important at high-rise apartment, the fixed window which is not opened uses 1,800mm module to improved the psychological feeling of opening and the quality of view. Horizontally, 5,400mm was determined as the breath of studied space. To determine the layer heights of studied space, the layer height of domestic high-rise residential buildings were investigated and the layer heights were the range of 3,050~3,300mm. At this time, the size of studied space applied layer height of 3,250mm as the height of studied space. Of 3,250mm, layer height of studied building, ceiling height is 2,500mm and the height of spandrel part is 750mm.

3.2.4 Determination on the inducement of external window or not

External window, as an optional component, has not been applied at the cases of double-skin façade so far and most of cases installed only inlet and outlet. However, some cases like Devbis tower positively induced external air as opening the front side of external façade without outlet and inlet. In case that the opening area of external façade is big, not only many quantities of external air can be induced but also occupants can feel the psychological feeling of opening and the feeling of air flow and thus the natural ventilation performance of residential building is expected to be satisfied. According to the study (Kim et al, 2002) in the ventilation rate when the window was induced at the external side of double-skin façade was appeared 1.4times to 3times higher than the case without the window. Thus, this study induced PAF type window at the external side.

3.2.5 Decision of internal window

Internal window has the characteristic that it should be determined as laying stress on the conveniences of

Table 4 Diagram of double-skin façade

Continents		Characteristic	Diagram of double-skin façade
External Façade	Outlet and inlet	Diagonal type		External window	PAF type	
	External glass	Kind: Tempered glass Thickness: 6 ㎜	
Intermediate façade	Type	Box type	
	Blind	Kind: Venetian blind Location: 150 ㎜ from facade (Assuming the blinds are pull up in inducing the natural ventilation)	
Internal Façade	Internal window	Sliding	
	Internal glass	Kind: Low-E duplex glass Thickness: 6 ㎜ +12 ㎜(cavity) +6 ㎜	

occupants and the psychological feeling of opening as it is at the most internal side. Accordingly, sliding type which does not influence to the residing space even in opening and makes it easy to approach to the Intermediate façade due that the opening area is wide is most suitable. Internal glass was planned to have lower coefficient than 3.84W/㎡·K of coefficient transmission of the window facing external air stipulated at the laws as analyzing U-Value of general duplex glass and Low-e glass with WINDOW 5 program developed by Lawrence Berkeley National Laboratory(LBNL).

Diagram of double-skin façade planned by the procedure of double-skin façade considering natural ventilation performance is like Table 4.

4. Evaluation of Double Skin Façade Performance

To plan the façade to improve natural ventilation performance, the evaluation on the effects which each planned factor has on natural ventilation performance is necessary. For this purpose, among planning factors of several components influencing the natural ventilation performance of double-skin facade, the evaluating factors which is actually planned through the evaluation were selected and the model for evaluation was established.

To interpret the natural ventilation characteristic of double-skin façade for the evaluation, air flow was assumed as normal state 3 dimensional flow and 3-D steady state governing equation was used. As the model of turbulence, standard k-ε model of turbulence was selected and used. For the interpretation, STAR-CCM+ program coded to be suitable to the interpretation of air flow, heat transfer, pressure and pollutant movement among the general-purpose CFD interpreting model programs was used.

4.1 Evaluation Model

The installation of external window becomes the factor which can largely increase the ventilation rate. As evaluating factors, there are the opening method and the height of external window. Regarding to the opening method of external window, the evaluation on PAF type and top-hinged out swinging type used in the existing high-rise residential building were executed. At the diagonal type, the evaluation on each wind direction was performed. The basic mode of evaluating factors is like Table 5.

Table 5 Basic model of evaluating factors

Component	Explanation
Outlet and inlet (Diagonal type)	Height of outlet and inlet: 600mm Ratio of the breath of inlet and outlet: 1:1
Width of cavity	300mm
External window	Opening method: PAF, Height: 1300mm

At the high-rise apartment and stores building, the rooms are not oriented to the specific direction. Says, there is the possibility of facing all directions. Accordingly, assuming the plane of building as the plane of square which is most common and basic at tower type buildings, the incident angle of wind, ϴ, at each household, ϴ, has the value of 0~90°(absolute value). Thus, the evaluation on the speed of wind and the incident angle, 0°, 30°and 90° according to wind scale table by Beaufort is performed, provided that the value of the direction of wind required according to natural ventilation performance is analyzed.

4.2 Simulation result

The results of evaluation are as per Figure 3 and, as compared with the basic model without external window, in case that the incident angle is 30°, the ventilation rate is increased more than 1.5times and, in case that the incident angle is increased more than 8 times. Figure 4, even though the superiority and inferiority of ventilation ratio becomes different by the opening method according to the direction of wind, considering that 90° direction of wind is frequent, it seems that PAF method which has much higher

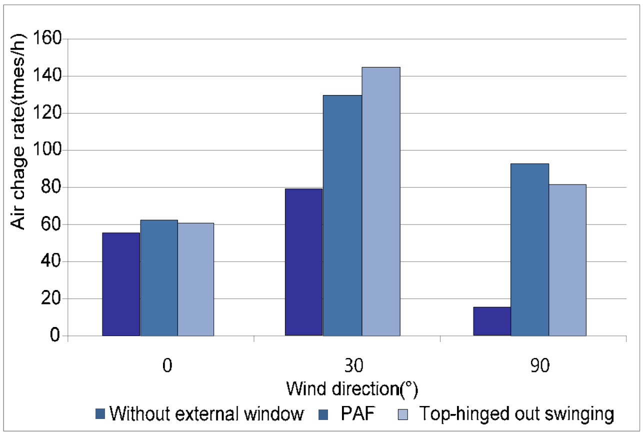

Figure 3 Ventilation rate according to the opening method of external window

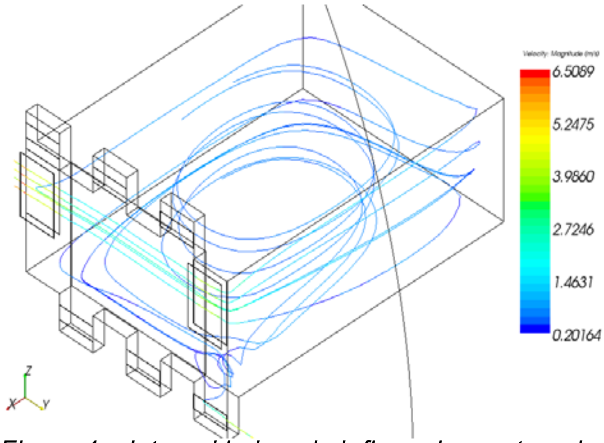

Figure 4 Internal induced air flow when external window was installed

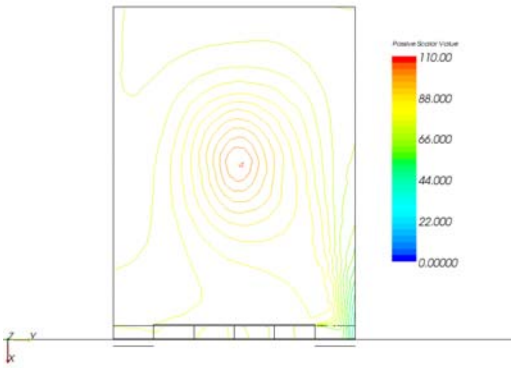

Figure 5 Average air age when PAF window was installed

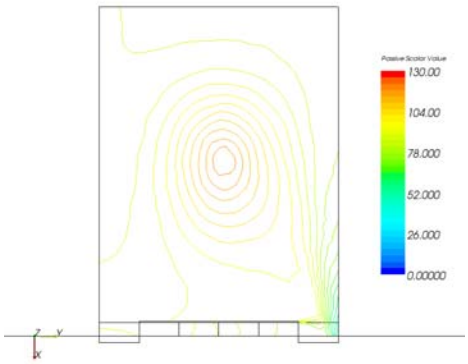

Figure 6 Average air age when 5Top-hinged out swinging window was installed

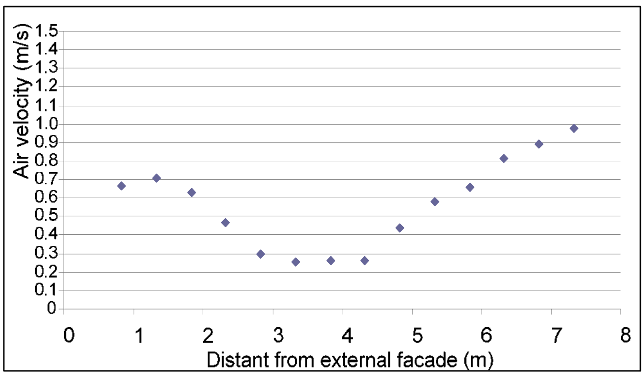

Figure 7 The speed of internal air flow when PAF window was installed

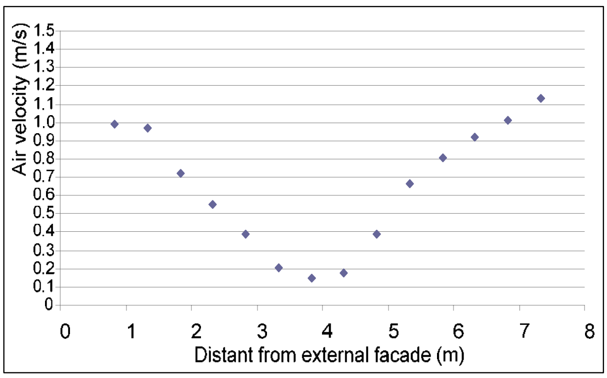

Figure 8 The speed of internal air flow when Top-hinged out swinging window was installed

ventilation ratio at the incident angle of 90° is advantageous. And, the case that the incident angle is 90° was decreased to less than 1/7 as compared with the maximal value in the basic model without external window and the efficiency of ventilation was improved and it was confirmed that the air circulated the whole room.
The case that external window was PAF type, due that the maximal value of air age was small, was appeared to make it possible to ventilate more efficiently.
As the ventilation rate was increased, many quantities of external airs were induced and thus the speed of air flow was also increased together. However, it did not exceed 1.5m/s and then the unpleasant was not occurred. On the contrary, the speed of air flow between 0.25~1.50m/s was generally occurred in the room and then there was the pleasant feeling because the occupant could feel the feeling of air flow.
As the result, when the height of external window was decreased from 1,300mm to 1,100, the number of ventilations was decreased by 14%, when decreased to 900mm, 8% of that of 1,100mm was appeared to be decreased again. However, even in case of 900mm, the ventilation of more than 70 times per hour was possible and then if external window is induced, ventilation rate is sufficient even though the size is planned small. As the result of reviewing the opening method which can secure the ventilation rate while keeping the stability as the external window, PAF type and top-hinged out swinging are judged to be suitable and PAF type was appeared to be more advantageous at the aspect of ventilation rate and ventilation efficiency under the condition that the incident angle was 90°. And the speed of internal air flow did not exceed 1.5m/s. And the speed of air flow of 0.25~1.50m/s was appeared at the room generally and the occupants could feel the feeling of air flow, which is expected to have high satisfaction.

5. Conclusions

This study, as establishing the evaluating model after selecting the planned factors of double-skin façade influencing the natural ventilation performance to consider the natural ventilation performance in planning double-skin façade for high-rise residential building and evaluating the distribution of air flow of the cavity and the inside, tried to verify the performance of double-skin façade system considering the natural ventilation.

1) It was appeared as the result of investigation that the occupants of high-rise residential building want the security of natural ventilation performance, of the speed of air flow and of the psychological opening feeling through the inducement of external air.

2) Among the components of double-skin façade, the components mainly influencing the natural ventilation were external openings, inlet and outlet, external window, cavity space, opening ratio of cavity floor and internal openings and the evaluating factors were derived from these planning factors. The parts where decision-making was necessary as the aspect of architectural plan had priority were the arranging type of outlet and inlet, the module of façade, the inducement of external window or not, internal window and opening ratio of cavity floor and, according the decision of these items, the evaluating factors are derived.

3) Among the opening methods of external window, PAF type can furthermore increase ventilation rate at the direction of wind of 90° and has low average air age as compared with top-hinged out swinging window which is presently used at most of high-rise residential buildings, which was appeared to have high applicability.

The guides of plan presented in this study were determined through the simulation based on the conditions of the direction of wind and the speed of wind at high-rise residential building. Even though this was to plan the façade with which natural ventilation performance was improved through the relative comparison among the cases, it should be additionally verified through the experiments in future to design the concrete values. As to the planning factors influencing both the ventilation by the buoyancy and the ventilation by wind pressure, the interpretation which is closer to the actual practice at the state that all of the temperature, sun rate, wind speed and the direction of wind are inputted should be additionally executed.

Keywords: Ryodoraku, sympathetic nervous system, physiological responses

Summary

Due to the overdevelopment of industry that contributes to the disassimilation of the earth's environment, in order to engage the limited resources in terms of energy saving and good use, this research proposes a regulation of daily sunlight strategy, simultaneously giving dual attention to the human physical labor productivity aspect and the development of spiritual thought productivity aspect, and analyze the influence of the factor of intensity of illumination, includes 50Lux, 500Lux and 2000Lux. The study evaluates human physiological responses by means of analysis of the Ryodoraku values, which could reflect the condition of sympathetic nervous system entirely, and the result was further analyzed statistically.

The experimental result shows that the higher intensity of illumination is, the greater influence of Ryodoraku is more obviously. It reflects that the lighting environment of high intensity of illumination contains the influence that the neural excitement degree change can't be ignored.

1. Introduction

Due to the overdevelopment of civilization and industry that contributes to the disassimilation of the earth's environment- the speed of which is increasing possibly towards a violent event, or even human extinction. To avoid such possibilities and for the survival of humans and their cultural extensions when the environment changes is the background for a realization of a specific research incorporating paragenesis, demarcating a new civilization and its use limited resources.

1.1 Schemes for Daily Sunlight Succession Regulation Pattern.

In order to engage the limited resources in terms of energy saving and good use limits the human material demand aspect and the inflation of the spirit of civilization aspect. This research proposed is an appropriately feasible sunlight daily succession strategy, a constructed mutual correspondence daily life type, time interval and the space, simultaneously giving dual attention to the human physical labor productivity aspect and the development of spiritual thought productivity aspect, as basis of and criterion for the future life style.

According to the investigation result and in view of ‘To strive for the survival, to seek the livelihood, to extend the life’ different faces, the immigrant in daily activity may differentiate in two types, and aims at its daily activity characters.

(1) Physical labor productivity aspect

Because of the payout of physical labor, to gain the concrete achievement, including: immigrant in literary arts, technology, daily necessities and craft correlation creation and so on is engaged in each kind of public service and is engaged in ...... and so on.

(2) Spiritual ponder productivity aspect

By participation, the observation, reading and the ponder, the discussion to enriches and promotes the knowledge and the energetic stratification aspect, including: engaged in each learning activity, individual ponder, the associates discusses ...... and so on.

But to meet with it's the spatial illumination environment characteristic needs, including low intensity of illumination (50Lux), ordinary intensity of illumination (500Lux) and high intensity of illumination (2000Lux).

1.2 The Human Physiological Reaction Evaluation Method

In the previous studies, the relationship between the changes of intensity of illumination and the corresponding human physiological responses was usually surveyed by using single physiological measurement such as electrocardiogram, brain waves, etc. The whole body responses were seldom evaluated. In this study, the ' systematic measurements of Ryodoraku ', which is currently widely used in the area of Chinese medicine to assess the benefits of acupuncture treatments, was used to study the effects of the ' non-contact environmental stimulation ', such as illumination changes on human physiological responses. The study evaluates human physiological responses by means of analysis of the Ryodoraku values (Nakatani Y, 1956), which could reflect the condition of sympathetic nervous system entirely and was based on Chinese medicine. Systematic measurements of Ryodoraku are to measure the change of electric conduction amount of. By measuring the change of electric conduction amount of 12 collateral channels present points with quantity in order to understand that the quantity examines the physiological state of the corresponding viscera organ of position. (Table 1 and Table 2)

Table 1 The meanings of Ryodoraku measurement value

The change of Ryodoraku measurement value	Meanings
Measurement value rises	Feel excitedly and nervous, high awaken degree
Measurement value reducing	Mood is steady, feel tired or relaxed

Table 2 12 channels and collaterals of spot and corresponding internal organs

12 collateral channels present points	Corresponding human organs
Lung Meridian	Lung , Nose , Skin
Pericardium Meridian	Pericardium, Blood vessel
Heart Meridian	Heart , Tongue , Eyes
Small Intestines Meridian	Small intestine , Eyes , Tongue
Triple Heart Meridian	Lymphatic vessel , Ear , Eyes
Large Intestines Meridian	Large intestine , Mouth , Tooth , Nose , Tongue , Skin
Spleen Meridian	Spleen , Pancreas , Stomach , Brain
Liver Meridian	Liver , Eyes , Genitals , Muscle
Kidney Meridian	Kidney , Brain , Eyes , Bone , Nasal cavity
Bladder Meridian	Bladder , Ear , Nose , Eyes , Brain
Gallbladder Meridian	Gallbladder , Head , Eyes , Muscle
Stomach Meridian	Stomach , Mouth , Tooth , Nose

The main focus of this research is to discuss the influence of different lighting environments on human bodies based on local weather conditions, including temperatures and humidity. In addition, the research will propose a more suitable model with choices of degreed Illumination of lighting environment from the result analysis.

2. Experiment Design

2.1 Experiment interpretation

In this study, we stimulated 22 participants with 3 different lighting environments with an intensity of 50Lux, 500lux and 2000lux respectively under precise controlled indoor environment qualities, such as thermal comfort, sound noise level.

Experiment time is all 60 minutes and under the different lighting environments of experiment, determine the change of physiological reactions of participants with human physically responses system- ' systematic measurements of Ryodoraku ', and carry on statistical analysis of the experimental result. Via than to the change that the human body reacts before and after the experiment, we can find out about the human influence received of physiology of different moments under each lighting environment experiment. Experimental result via all group meanwhile one to right to analysis, can differentiate the difference that different lighting environmental impact on human physiological reaction in order to be clear.

2.2 Subjects and Workplace Conditions

In this study, 22 healthy participants were selected (12 females, 10 males; age 22–30 years), all subjects were clothed in shirts and slacks, total thermal resistance from the skin to the outer surface of clothing was 0.7 clo. The experiment utilizes a full-scale laboratory as the target and evaluates the effects of different lighting environments on human bodies under long- term exposures. Measurements were performed under steady conditions: room temperature 28.5±0.5• ; humidity 70±0.5, wind velocity under 0.09m/s, background noise level between 48dB(A).

3. Results and Discussion

3.1 Influence on the Psychology of the Lighting Environment

In this experiment, the factors of the questionnaire of psychology experience include ' sense of comfort ', ' sense of stable ' and ' awaken degree ' to analyze with Microsoft Excel to assess the experienced changing and influence by the persons who examine psychology under different lighting environments for 60 minutes.

3.1.1 The lasting of sense of comfort changes

Under the 50Lux lighting environment make the person not comfortable after turning on the light and lasting 30 minutes, but under the general lighting environment of intensity of illumination (500Lux),this kind of lighting environment makes people feel more comfortable after turning on the light and lasting 60 minutes.(Fig. 1)

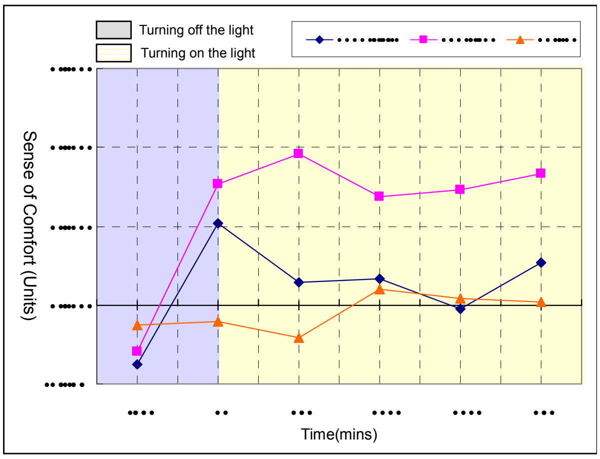

Figure 1 The lasting of sense of comfort changes under 3 kinds of lighting environment for 60 mins.

3.1.2 The lasting of sense of stable changes

As fig. 2 shows that under the high lighting environment of intensity of illumination (2000Lux), make participations begin to feel unstable after turning on the light between 15 minutes and 60 minutes. To compare the psychology experience under 3 kinds of different lighting environment, we can know that the low intensity of illumination (50Lux) give participants more stable sense.

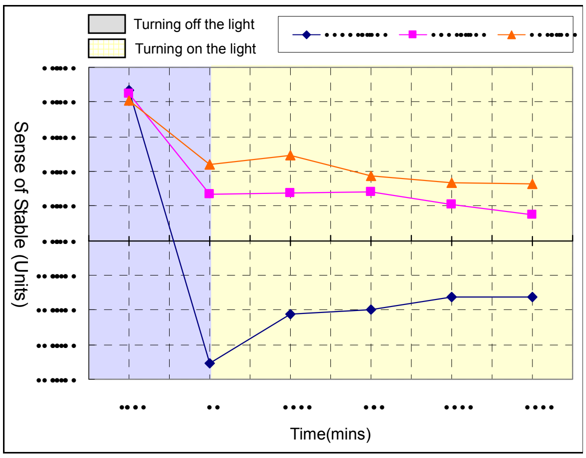

Figure 2 The lasting of sense of stable changes under 3 kinds of lighting environment for 60 mins.

3.1.3 The lasting of awaken degree changes

Under the entire lighting of the high intensity of illumination(2000Lux) could improve the participations' awaken degree after turning on the light between 15 minutes and 60 minutes, but under the low intensity of illumination(50Lux) lighting environment make the person feel low-spirited after turning on the light and lasting 60 minutes.(Fig. 3)

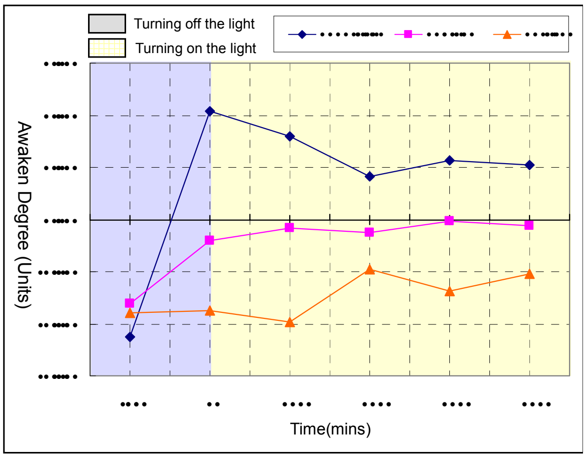

Figure 3 The lasting of awaken degree changes under 3 kinds of lighting environment for 60 mins.

3.2 The Result of Physiological Response

3.2.1 The whole reaction of Ryodoraku at different examine period

Under the entirely lighting environment of color temperature 2700 K of light source, in 3 kinds of lighting environment change, 50Lux, 500Lux and 2000Lux, the result of reaction of Ryodoraku as figure 4 shows. The experimental result show that under the environment of 3 kinds of lighting, the average of participations' Ryodoraku improving after turning on the light, but there are different variation tendencies during 60 minutes.

Under the high lighting environment of 2000Lux, the average of participations' Ryodoraku improving with time, while lasting 60 minutes after turning on the light, the average of participations' Ryodoraku increase 14.8μA than basic value. Under the lighting environment of 500Lux, the average of participations' Ryodoraku improving 4.6 μA lasting in 15 minutes after turning on the light, but while lasting 45 minutes after turning on the light , the average of Ryodoraku has no obviously difference.

To compare the physiological experience under 3 kinds of different lighting environment, under the high lighting environment of intensity of illumination (2000Lux), Ryodorku leads and holds the trend appearing and rising well gradually in increase that reacts and perceives time lasting in 60 minutes after turning on the light, but after lasting 30 minutes, the influence power of general and low lighting environments of intensity of illumination (500Lux and 50Lux) to human physiological reaction is reduced gradually. So we have to pay more attention to the sustained influence to human sympathetic nervous system responses, when under the high intensity of illumination for a long time.

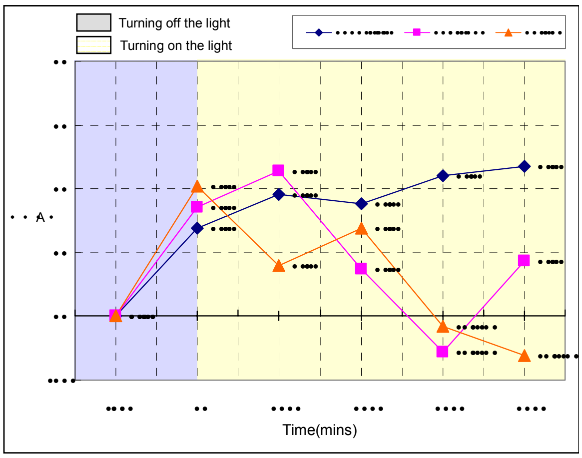

Figure 4 It shows the different changes of human body 12 Ryodorru average value under the environment of 3 kinds of different lighting for 60 mins.

In order to realize the changes of whole reaction of Ryodoraku under different lighting environments at different percipience period, this study carry on statistical analysis of the experimental result. Via than to the change that the human body reacts before and after the experiment.

As table 3 showed that under the lighting environment of 2000Lux, the participations' Ryodoraku value has difference (P< 0.05) counted after turning on the light in lasted 45 minutes. Under the lighting environment of 500Lux, the participations' Ryodoraku value have difference• P• 0.05• counted in the twinkling of an eye turning on the light and in lasted 15 minutes, but while lasting 30 minutes after turning on the light, the

Ryodorku value has no obviously difference• P• 0.05• counted. Under the lighting environment of 50Lux, the participations' Ryodoraku value have difference (P<0.05) counted in the twinkling of an eye turning on the light. But the change of the Ryodorku value has no obviously difference• P• 0.05• counted, while lasting 15 to 60 minutes after turning on the light.

From Fig. 4 analysis and Table 3 statistics show that within lasting 60 minutes after turning on the light, the higher the intensity of illumination is, the more obvious the influence to human physiological reaction is.

Table 3 It shows the comparative result of the participations' Ryodorku value average value before and after turning on the light.

3.2.1 Analyze the collateral channels position which be influenced

Because 12 collateral channels correspond to human body's change of different viscera and relevant organ separately, therefore, different white light source impacts on human body can be found out by the change of 12 collateral channels Ryodorku value under 3 levels of lighting environment. So all that this research examines in every period amount the experiment lighting environment of every group is led the statistical analysis of all the participations' 12 collateral channels Ryodorku value. To exanimate 12 collateral channels Ryodorku value having a dominance difference (P<0.05) counted before and after lighting.

The analysis result shows that under the high intensity of illumination (2000Lux-2700K), the Pericardium Meridian and Large Intestines Meridian are obviously influenced by the stimulation of lighting. Under the general intensity of illumination of lighting environment (500Lux), left side Pericardium Meridian, Heart Meridian, Gallbladder Meridian and Both sides of Large Intestines Meridian are also beginning to be influenced , but the change of 12 collateral channels Ryodorku value has no obviously difference• P• • 0.05• •under the low intensity of illumination (50Lux).

Table 4 It shows the comparative result of the Ryodorku value which 24 present points average value before and after turning on the light under the high lighting environment of intensity of illumination (2000Lux).

4. Conclousion

In order to engage the limited resources in terms of energy saving and good use limits the human material demand aspect and the inflation of the spirit of civilization aspect, this research proposed is an regular work and rest pattern, simultaneously giving dual attention to the human physical labor productivity aspect and the development of spiritual thought productivity aspect, and carry on the discussion to human body reactions to the 3 kinds of corresponding lighting environment.

To compare the physiological experience under 3 kinds of different lighting environment, the analysis result shows the higher the intensity of illumination is, the more obvious the influence to human physiological reaction is, and under 2000Lux lighting environment, human Ryodorku value rise continuously, it shows this kind of lighting environment has constant influence on human sympathetic nervous system, especially to such organs as the pericardium, circulatory system and large intestine, etc.

Keywords: indoor thermal environment, computation fluid dynamics（cfd）, underground air channel system.

Summary

While Taiwan spares no effort in fully developing a livable and sustainable environment, various regions are facing and aggressively considering the topic of how to make the architecture design of existing and newly constructed buildings to be sustainable, forward-looking and environmentally sound. This study is mainly to ensure the performance of underground air channel system that draws the ambient air into a building. It focuses on the specially designed underground air channel system for this case to overall evaluate the performance of the system. The results of the actual tests suggested that under the normal usage mode air-conditioning and underground air channel systems were used simultaneously,, the overall PMV value of the indoor tepid environment was -1.1, a low value that indicated an environment leaning toward the cool side. Under the mode of turning on the air-conditioning and shutting down the underground air channel systems, the PMV value was -1.07, an environment leaning toward the cool side as well. Under the mode of shutting down the air-conditioning and turning on the underground air channel systems, the PMV value was 0.51, an environment leaning toward the comfortable side. A Computation Fluid Dynamics was developed in this study to analyze the structure of space airflow field through the simulation and analysis of different scenarios and conditions, in order to find the best effect of the underground air channel system and to derive the related performance and recommendations.

1. Introduction

At the same time Taiwan's going ahead with developing sustainable environment, how to design the existing and new-constructed buildings for being sustainable, environmental and visionary, is a challenge that different areas must to be deal with. Therefore, this research is based on the foundation of underground ventilation per-cooling technology analysis, then to take feasibility study on the technology for underground ventilation per-cooling in subtropical areas like Taiwan. Further more, the research assay the construction of airflow space through the simulation of different surrounding conditions to find the most appropriate tunnel wind system.

According to the evaluation in ecological housing of World Health Organization (WHO), we find out that buildings are that only protecting people from invasions, but also effecting users' lifestyles and indoor environment quality (IEQ).in our daily life.

2. Analysis of the research subject

2.1 Analysis of environment climate

This area's average temperature is about 25℃ because located on the south of the Tropic of Cancer. With the variation of average temperature, the coldest month average temperature is about 19.4 ℃ and occurred in January. Summer is obviously felt. The time of temperature witch exceeded 24℃ lasted more than 8 months long. And August is the hottest, the highest temperature is about 32℃.

2.2 Building and the underground ventilation system

There are about 60 occupants in the office-type building. To afford the occupants a comfortable working environment, even being more efficient and easily management, we separate the office and public service functions, avoiding the interference between them. Nearly existing landscape park can supply fresh air as figure 1.

Underground ventilation system with fresh air importing device is a method that burying the wind pipe into ground and let it been naturally cooling, as follows figure 2.

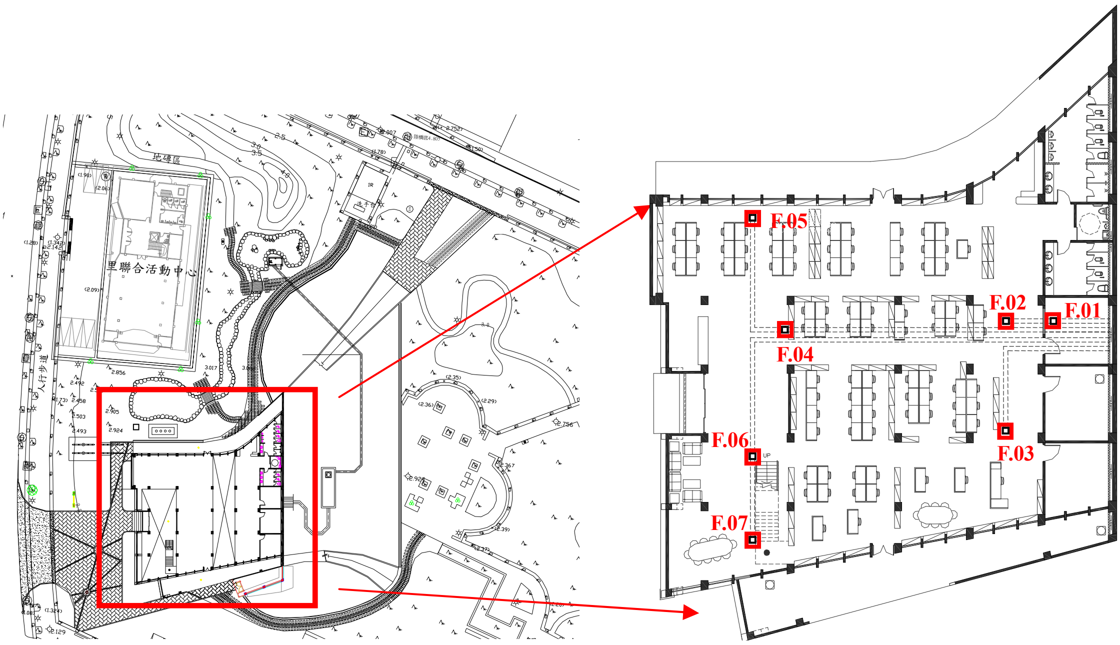

Figure 1   actual testing building and the outlet positions of underground ventilation system

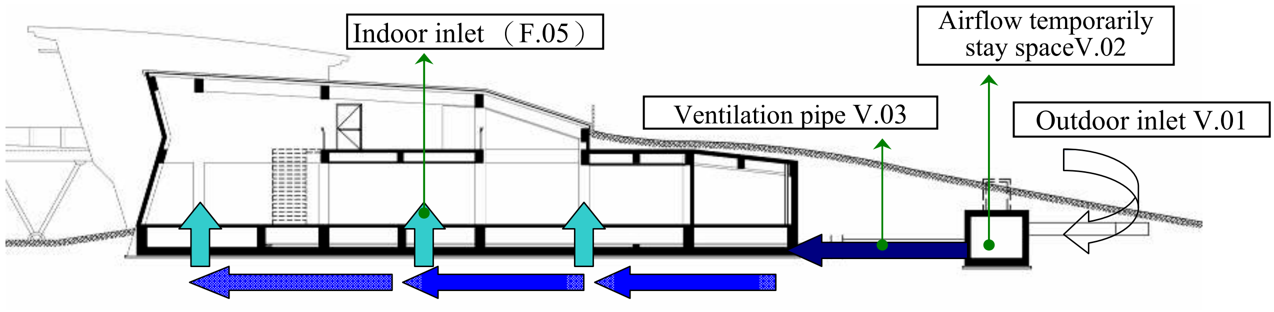

Figure 2   section of underground ventilation system

3. Research Content

3.1 About indoor thermal comfort:

Standing on the building occupants' point of view, we can decrease the air condition cost by raising the air condition setting temperature in summer time using; in winter time, we can turn off all the air condition system and completely using underground ventilation system to achieve indoor thermal comfort.

The results of the actual tests suggested that under the normal usage mode (air-conditioning and underground air channel systems were used simultaneously), the overall PMV value of the indoor tepid environment was -1.1, a low value that indicated an environment leaning toward the cool side. Under the mode of turning on the air-conditioning and shutting down the underground air channel systems, the PMV value was -1.07, an environment leaning toward the cool side as well. Under the mode of shutting down the air-conditioning and turning on the underground air channel systems, the PMV value was -0.51, an environment leaning toward the comfortable side. other relative thermal factors as table1.

Table1 numeric of different type to thermal environment factors

Indoor ventilation type			temperature	humidity	velocity	PMV	PPD
Air condition	On	indoor	24.36	68.63	0.36	-1.10	30.84
Underground system	On	outdoor	29.05	52.25	0.51	9.82	100
Air condition	On	indoor	24.49	68.44	0.34	-1.07	29.76
Underground system	Off	outdoor	28.55	52.9	0.22	9.77	100
Air condition	Off	indoor	27.74	60.42	0.01	-0.51	10.91
Underground system	On	outdoor	29.30	45.08	0.49	9.9	100

3.2 About underground ventilation per-cooling:

According to the test data, per-cooling system of underground ventilation does really have its effect. While the testing day, the average outdoor temperature was 29.1℃,but the at outdoor inlet and in the pipe of per-cooling system of underground ventilation are 27.8℃ and 26.1℃. Even the average temperature at indoor inlet had dropped to 24.9℃, as follows table2:

Table2 Temperature measurements at different position

No.	Position	Numerical	No.	Position	Numerical
1.	Outdoor	27.8℃	7.	F.01	25.8℃
2.		29.7℃	8.	F.02	25.5℃
3.		29.8℃	9.	F.03	24.9℃
4.	V.01	27.8℃	10.	F.04	24.8℃
5.	V.02	26.6℃	11.	F.05	24.5℃
6.	V.03	26.1℃	12.	F.06	24.1℃

3.3 Computational Fluid Dynamics

Before running the whole numeric simulation, we should proceed the relativity contrast between the simulation and actual examination. The relativity between the numeric simulation and actual testing value had achieve to R^2=0.94. We can use CFD simulation for follow-up research on different variation factors.

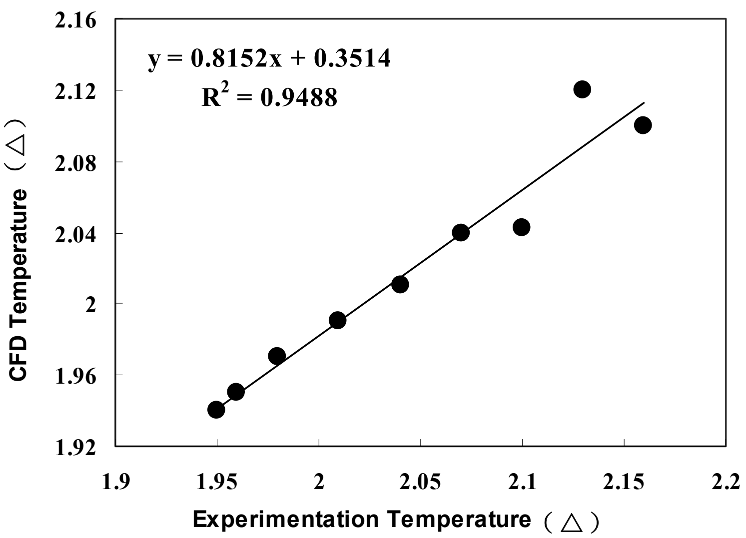

Figure3 Contrast of the relevance between CFD and actual test data

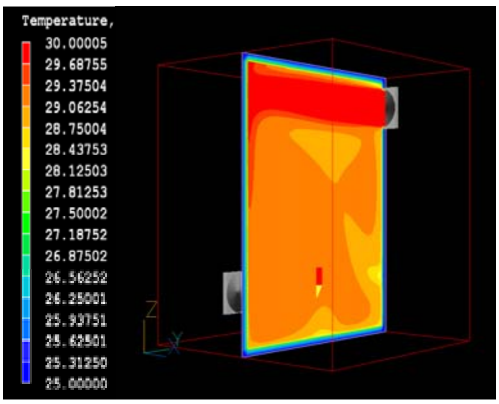
This research proceeded computer numeric simulation (As figure 4) to find the possibility of appropriate extension for the place in the future. And the result is showed as table2. Through the efficiency of different cross-section size of underground ventilation pipes' cooling performance, we can conclude that the more suitable length for space is 6m, 8m 10m.



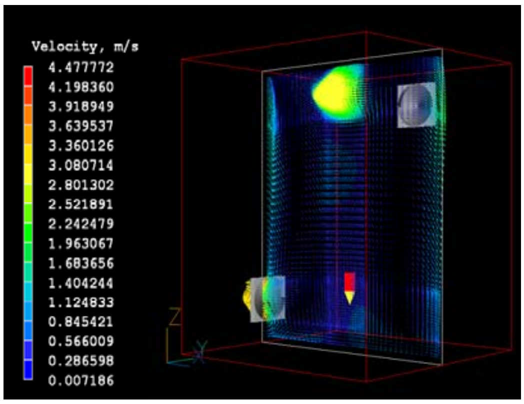


Figure 4 computation fluid dynamics（cfd）model.

By calculating the result of Computational Fluid Dynamics（CFD），we could discover the difference of temperature dropped tendencies. And according to results of different cross-section size, we know that range of 0-10m is a rapidly cooling distance. The temperature lower slowly when the distance is longer than 10m. So 10m is a critical point for distance.

Table 3 CFD simulation data of different cross-section size

No.	Length of space	Cooling performance（△T）		notation
		200cm∗250cm	400cm∗340cm	Boundary condition: inlet temperature is 30℃
1.	2 m	1.4℃	—	2.	4 m	1.8℃	—	
3.	6 m	2.3℃	2.6℃	
4.	8 m	2.7℃	2.9℃	
5.	10 m	3.2℃	3.4℃	
6.	20 m	3.8℃	—	

4. Conclusion

Underground ventilation system can lower the load of fresh air and the air temperature could decrease through the distance of ventilation pipe. We can achieve energy saving by underground ventilation system. And by increasing the length of ventilation pipe, we can lower fresh air load. Indoor thermal environment in normal condition (air condition and fresh air input are both working) will cause lower PMV value. The whole prediction value is slanted towards cool. The whole prediction average value can be controlled in comfortable range if air condition setting is about 23-28℃ and being used with the underground ventilation system at the same time. In the condition that underground ventilation system is on but central air condition system is off, the velocity would be lower. But the velocity could be controlled in the comfort range in both of the condition above.

Having a wish to complete the indoor environment health quality and increase people's living value through establishing "UNDERGROUND VENTILATION SYSTEM". And using strategies like "preventive design", "diagnosing to improvement" and methods to integrate other fields as a specific way to promoting indoor environment health quality in Taiwan.

Keywords: regeneration, industrial areas, building, heating, energy consumption

Summary

This paper deals with buildings located in industrial areas in the Ostrava region, Czech Republic. Poor maintenance in past as well as considerable impacts of industrial plants located in the region is rather typical for the buildings. Some buildings are located in the centre of Ostrava, on undermined territories (escape of explosive methane, land subsidence, higher level of ground water, air pollution, industrial seismicity, noise, land contamination caused by industrial plants...). In the second half of the 20th century, many apartment blocks from panels were built there. Living conditions lack comfort there and general reconstruction is needed in order to improve building parameters and to decrease energy performance. 5 buildings where the reconstruction is essential have been chosen. Studies have been prepared in order to find out future applications for the buildings, to regenerate them in line with state-of-the-art building requirements and to decrease the energy performance, using as much renewable sources of energy as possible. Best alternatives are being looked for so that the optimum combination of finances and technologies can be used for future regenerations of various types of buildings.

1. Czech Republic, Ostrava region and industry

The Czech Republic is located in the centre of Europe. For more than 100 years, some parts of the country have been heavily loaded with industrial activities. This results in problems that affect both the people living there and the environment that suffers considerably. After the Second World War, the industry became more intensive in those regions and the situation continued deteriorating. This is in particular the case of the North-West (near Most) and North-East (near Ostrava). Before 1989 the priority of the communist regime was, in particular, heavy industry. After the communist regime had been thrown off, the oppressive situation started improving. Other big cities in the Czech Republic were influenced by that situation too. But the region of Ostrava is rather specific because the heaviest industry was concentrated there: mining, metallurgy, engineering and chemical industry. The city and wide surroundings have been affected by those industries up until now. At the beginning of the 20th century, the mining activities in the city of Ostrava were totally closed. Now, black coal is mined in neighbouring land only. Many heavy industry plants have been closed down and measures have been taken to decrease air pollution. The Czech Republic, being a EU member state, has undertaken to decrease emissions in the Kyoto Protocol. It accessed the Kyoto Protocol in 2001. With the production of almost 12 tons of emissions per head, it ranked among worst contaminators in Europe and all over the world. In the Czech Republic, the power generation produced 42 % of CO_2 emissions (source: UNO, 1996). The state has been trying so far to fulfil the obligation. The Kyoto Protocol is closely connected with the EU Directive No. 2002/91/EU on the Energy Performance of Buildings.

The Ostrava region suffers most, because of the heavy industry, from increased CO_2 in the air, noise, dust, seismicity (both transport and industrial seismicity), escape of methane from abandoned mines, soil contamination and disappearing influences after underground mining.

All this influences people living in Ostrava, being the third biggest town in the Czech Republic, but also those who live in conurbation near Ostrava (cca. 780.000 people). During the communist regime (1947-1989), construction of prefabricated elements (frequently from panels) and mass housing construction was preferred – about 45 % of housing stock and many industrial plants were built in that way.

2. Research

In 2005, three biggest universities in the Czech Republic and three construction companies established, under auspices of the Ministry of Education and Sport, CIDEAS (Centre for Integrated DEsign of Advanced Structures). CIDEAS focuses on advanced materials, constructions and technologies in terms of service life and reliability throughout the living cycle. General aspects of interactions between the building structures and environment are taken into consideration from a long-termed perspective of sustainable development. One department deals with management and maintenance of buildings in industrial areas. In Ostrava, where many buildings were built from panels, it is necessary to address various issues because the panel buildings are affected by the aforementioned influences (such as seismicity, air pollution, noise, escape of methane, disappearing mining effects) and also by bad conditions caused by lack of maintenance or poor production. And people living there have been more and more demanding, requiring more comfort. Consumption of energy has gone up, and prices for energy have increased too in past years. Therefore, it is necessary to renovate and maintain the buildings, because their service life is far from being exhausted.

Since 2006 when CIDEAS has started working, five buildings have been chosen and analysed in detail. The buildings are located in Ostrava and are typical samples of buildings (except for industrial buildings) located in the industrial region. Studies have been prepared, the objective being to identify steps to be taken, most efficient repair methods and the lower energy performance in the future.

3. Evalution in therms of energy demands

The key weakness of the buildings and not only those on the industrial sites is that the heat-insulation parameters are not sized enough. Originally, the standards for the heat insulation of cladding were derived from masonry walls lined with kiln bricks with the thickness of 450 mm. Those standards have become more restrictive in the course of time. Figure 1 shows the development of the required heat insulation since 1954. Therefore, it is clear that the buildings that have been constructed in past do not meet often the present-day stringent requirements. The reason for the severe requirement has been the growth of energy prices and pressure of the company to decrease the energy demand and, in turn, to improve the quality of the environment, namely reduce undesirable emissions of carbon dioxide CO_2 that gives rise to green house effects.

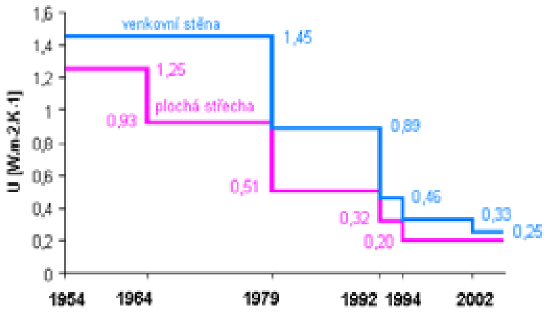

Figure 1. Development of coefficient of thermal transmission U [W.m^{-2}.K^{-1}]. U is calculated from the heat transmission resistence (R) that was stipulated in Czech standards in past, (venkovní stěna = outdoor wall, plochá střecha = flat roof).

A suitable solution within the general reconstruction of the building would be to improve the heat insulation parameters by over-cladding all structures where heat loss and thermal break occurs. At the same time, it is advisable to take other measures, for instance to reduce the loss of heat through windows, doors, gates, and passages. Another solution is to optimise the heating system. The thermal insulation not only improves the heat protection of the buildings but also reduces the energy needed for the heating, minimises mould fungus on inside surfaces of enclosing walls, decreases temperature dilations of building structures, improves appearance of the building if the over-cladding is carried out, and enables cost-saving heat systems and alternative sources of energy (such as solar, water, or wind energy) to be used. The purpose of the energy measure is, as mentioned above, to reduce the energy demands of the building. This means the total quantity of energy to be consumed for the adjustment of the environment inside the building should go down. This energy is needed for: heating, heating of water, cooling (A/C), ventilation, and lighting.

When rehabilitating a building, particular attention is paid to those components that are most important for the energy demand of the building. Following buildings have been investigated: a four-floor living building from T06B panels in Ostrava-Poruba, a school facility with a MS-0B skeleton system in Ostrava-Poruba, an office building made from MS-KO systems in Ostrava-Přívoz, a brick building in Ostrava-Přívoz that was used as a health facility for a mining company, and a brick building from the 1930s that ranks among national protected buildings.

4. Panel building (T06B system) and school facility (MS-OB system) in Ostrava-Poruba

The thermal assessment has been carried out for two buildings: for the living building made from T06B-BTS panels with minimum building adaptations throughout the service life of the building, and for the civic amenities building made from typified MS-OB units used by the school where actions have been performed that were proposed within an energy performance audit.

For the living panel building, following values have been calculated: heat transmission coefficients, inside surface temperatures and total quantities of evaporated and condensed water vapours for the year balance inside the cladding for the current situation as well as for two alternatives of building modifications the objective of which is to reduce the energy performance/heating costs for the building. In case studies, the assessment has been made of total heat losses of the buildings (where such heat losses comprise heat losses caused by heat transmission through structures as well as ventilation heat losses) and a heat demand level resulting from U_{em}, an average heat transmission coefficient.

Figure 2. Panel building (T06B system) and school facility (MS-OB system) in Ostrava-Poruba

U_{em} being the average heat transmission coefficient is determined for the building and areas heated there as a H_T [$W.K^{-1}$]/total area ratio where H_T [$W.K^{-1}$] is the specific heat transmission loss and the total area represents all cooled structures that define the volume of the building, the zone to be heated.

$$U_{em} = \frac{H_T}{A} \left[W.m^{-2}.K^{-1} \right] \quad (1)$$

The requirements of the standard have been fulfilled for the skeleton MS-OB structure used by the school. The studies focused in particular on evaluation of the current situation as well as on modification of building services and facilities, in particular of the heating system. Within the study, new efficient uses of the heating system as well as heating management have been proposed. Attention has been also paid to a training programme and a regular maintenance of the system.

One of most important and main changes in the heating system is the installation of an interactive system of management and control. The interactive system controls the heating in real time, using optimally the supplied heat. Almost in each room, there are sensors that are connected with the central PC controlling the whole system. In main branches, the difference pressure needs to be modified. Because of the over-cladding, a temperature gradient of the heating medium must go down. Te balance between the heat supply and heat demand will be maintained. Other partial modifications and recommendations are listed in case studies (see the Literature).

All this has finally resulted in improved thermal comfort inside the building and, in particular, in a lower energy performance of the building. This is proved by the chart drafted for one of the buildings under study. It is evident that the heat consumption has gone down by 39 per cent. Energy costs have decreased by cca. 35 % (including a lump sum fee).

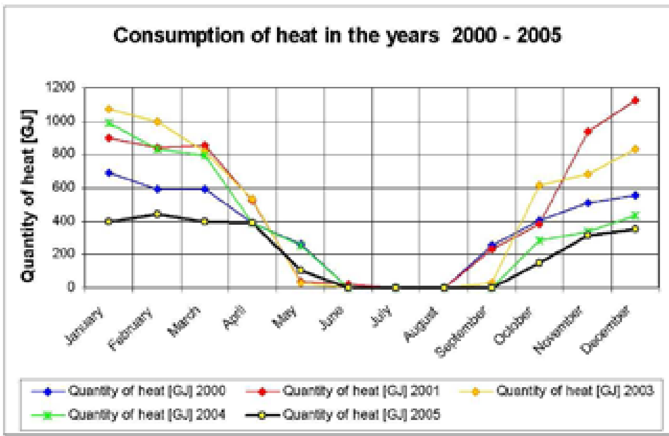

Figure 3. Development of heat consumption from 2000-2005 (excl. 2002) Note: source data from 2002 were not available

5. Administrative building (MS-KO system)

From the point of view of heat performance, the current conditions of the headquarters have been assessed. As expected, the building has not met requirements set forth in the heat performance standard ČSN 730540.

Two alternatives have been proposed for the external cladding in order to improve the energy performance and heat properties. In the first alternative, the existing external cladding will be removed, the skeleton will be covered with accurate porous concrete formed bricks (Ytong). Additional insulation will be created by the thermal system Stomix and polystyrene foam insulation. The result will be that the requested (or recommended) values of the heat transmission coefficient pursuant to ČSN 730540 will be met.

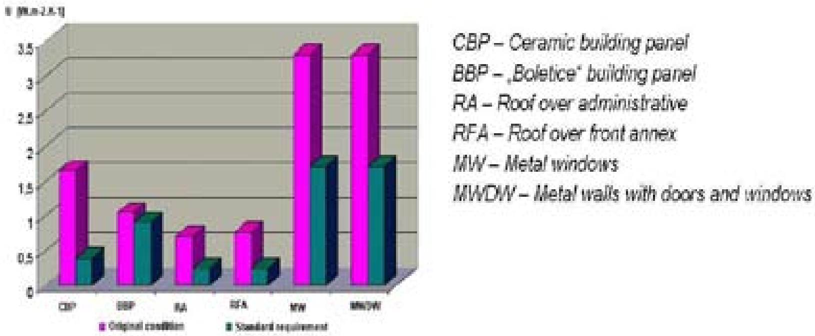

Figure 4. Administrative building with system MS-KO v Ostrava-Přívoz

Figure 5. Heat transmission coefficient of the constructions for original conditions and standards requirements

5.1 The first alternative

The first alternative is preferred if the function of the building changes and some floors will be used for apartments. Plastic windows with thermal double-glazing will be installed. (Note: It is necessary to check whether the Ytong bricks and additional insulation of the external cladding is feasible in terms of the mechanical resistance and stability).

5.2 The second alternative

The second alternative also reduces the energy demands: the existing cladding will be partly removed (glass, aluminium rail, supports, and windows will be removed). The bearing construction of the cladding (the steel frame of each panel) will be kept and used for a new lightweight steel cladding made from Kingspan thermo-insulation panel. Special plastic windows with insulating double-glazing will be installed in the external cladding. In the second alternative, the load of the bearing structure will not be so high. The main advantage of that method is the speed of building works.

Table 2. Values of heat transmission coefficient for a part of the external cladding of the headquarters building

	Original condition	Alternative 1	Alternative 2
U - real	1.03	0.3	0.29
Un - requested	0.89	0.89	0.38
Un - recommended	0.62	0.62	0.3

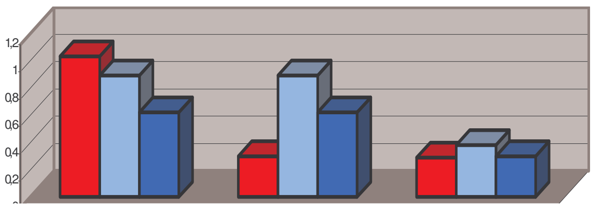

Figure 6. Heat transmission coefficient for a part of the external cladding (original condition) and two alternatives in comparison with standard requirements

In both alternatives, the flat single-cladding roof will be additionally insulated with mineral fibre insulation, simple metal covers will be replaced (in order not to interrupt the heat bridges), and single-glass windows, doors, and glass walls will be replaced with insulating double glazing in plastic frames. Next year, the team will deal with other alternatives for the external cladding. The heat transmission conditions for particular parts are stated in the figure 5. (Different between original conditions and standard requirements, nowadays, is approximately 33 years).

5.3 Building services

From the point of view of building services and facilities, the building is absolutely non-compliant. Originally, the building was heated with hot water with the gradient 90/70 °C from the near-by Svoboda coke plant. The heating system is out of order now. Sewers in top floors might be used, while those in the basement are heavily corroded. Water pipelines in top floors are not damaged, while those in the basement are also heavily corroded. In some places, discharge valves are missing. Wiring is also heavily damaged. Lighting switches and junction boxes have been removed in some places, and wiring is exposed now. HVAC has been removed and is missing now. Two solar energy systems have been proposed for use of renewable sources of energy:

In the first case, solar collectors will be installed on the roof. In summer, they will heat up the hot water, in transitional periods (winter-spring and autumn-winter) the solar collector will maintain the temperature. Bivalent reservoirs will be used there.

In the second case, the solar energy will be used in a photovoltaic system that will supply the alarm system, circulation pumps, or lighting in some areas (where intensive lighting is not necessary – such as staircases or corridors).

5.4 Solution results

The proposed revitalisation of the building will reduce the energy demands of the building. If the proposed actions are taken, the heat demands will decrease from 290% to 100% the solar heating of water will cover demands of people living/working in the house. The photovoltaic system will save 17 kW/d only but will be able fully to supply the power to dedicated consumers. The comfort of use of the building will increase, and impacts on the environment will be more positive. In this time is building in the reconstruction phase, and owner want use about 70% suggested solving witch were mentioned in the case studies.

6. Brick building and traditional historical protected brick building

6.1 Heating and energy performance of the buildings

The energy performance of the both buildings was analysed in terms of consumption of heat needed to heat up the buildings. The energy performance is given by an average heat transmission coefficient, U_{em}, and is based on individual heat and technical characteristics of the structures. The existing condition of the buildings does not meet thermal and technical requirements set forth in standards. Two alternative solutions were proposed for the administrative building in Ostrava–Přívoz, the aim being to reduce the energy demands. Over-cladding and replacement of windows/opening panels as well as changes in a layout of the building have been proposed. The proposed alternatives meet the required and recommended values of the heat transmission coefficient. The total energy performance resulting from the energy label of the building envelope has been determined based on those alternatives.

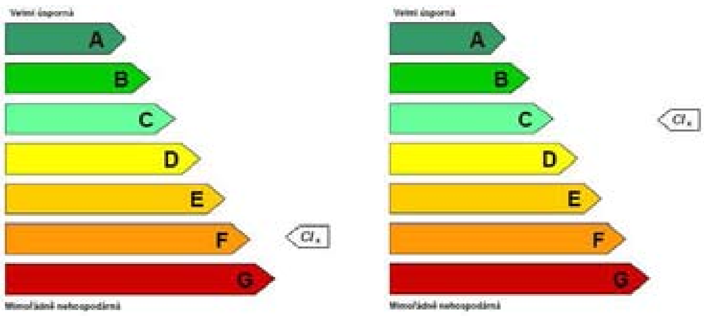

Figure 7. Chart of the energy performance for the original building and overcladded building

In order to evaluate the energy and thermal characteristics, thermo vision snapshots were recorded of the multiple dwelling houses that is protected as an national registered building.

6.2 Building services

A recommended solution resulting in a lower energy performance total is heating of hot water by means of solar collector panels. This solution is rather easy to be applied in the Czech climate and consumption of hot water and energy is more or less constant during the year, this not being the case of solar energy used to heat up the building. In summer when the incident solar energy is maximal, the consumption of heat for heating is zero.

Other renewable sources of energy cannot be used. A *heat pump* cannot be installed because the territory is exposed to disappearing mining effects. *Photo voltaic cells* do not repay for generation of electricity in the current price situation as this would need an island connection system and the photo voltaic cell area should be rather extensive. Since the housing development is rather dense there and one building is listed among national registered buildings this solution is difficult to implement.

Figure 8. Brick building and multi-flat historical protected brick building

When designing the method and type of over-cladding and replacement of windows in the existing administrative building in Ostrava-Přívoz, the aim was to meet recommended and required heat transmission coefficient of steel structures. For both alternatives, the resulting total energy perforce was “C”, this means the building was compliant. Thanks to the over-cladding, the original building with the “F” energy rating (very uneconomical) becomes a building with a considerably better energy performance. It is however essential to point out that even for the alternative 2 applied in order to meet the recommended heat transmission coefficient, it was impossible to reach a better power performance rating than “C”.

The proposed changes in the building services and facilities resulted in a lower energy performance of the both buildings. Installation of a gas boiler and solar collectors ranks among best solutions (this solution is better that “central heating delivery” in Jubilejní street no. 51) because the existing facilities are used and operated all the time during the year. The equipment is used and does not lose its value. The solar energy is among most environment-friendly methods where harmful substances are not discharged into the air.

7. Conclusion

Utility properties of all buildings have improved in general. The living comfort has increased too. Some buildings have been regenerated using same or similar procedures that are mentioned in studies prepared for individual buildings. The volatility on the outside sources and the total energy consumption for building operation decreased. The buildings have become more ecological. After these reconstructions were insert in the classes “C” of the energy performance, MS-OB and MS-KO to the class “B”, from the classes “E” and “F”. The energy consumption decreased over 30%! (see the Figure 3., MS-OB). Buildings‘ owners save. The buildings will take less energy. For the production of the electric energy is needed atomic fissure or coal’s burning (volume of CO_2 emitted to the air by power-station decrease). There is 60% of the electric energy made in coal power stations in the Czech Republic! It is too high number. Atomic energy is about on 30%, and other sources on 10% in the Czech Republic. And the consumption of the whole world still grows up! Now, steps are taken to create an optimum single approach that should be taken as a guide when dealing with regenerations of different buildings in the future. Whole project will we finished in December 2009. The state direction will be produced - recommending to owners how to proceed by the reconstructions. The economic, energy reduction, service life, investment return and spending on operating viewpoints will be accented.

This outcome has been achieved with the financial support of the Ministry of Education, Youth and Sports of the Czech Republic, project No. 1M0579, within activities of the CIDEAS research centre.

EXPERIENCE FROM MEASURING ACOUSTIC PARAMETERS IN BUILDINGS

Pavel ORAVEC Ing.[1]

[1] VŠB-TUO, Faculty of Civil Engineering, Ostrava, Czech Republic, pavel.oravec@vsb.cz, http://www.atop.xf.cz

Keywords: Reduction of noise, sound reduction index, impact sound transmission loss.

Summary

This paper shows an issue of measuring and assessment of acoustic parameters in building constructions.Examples, which demonstrate the building acoustics problems – air and sound transmission loss, have been chosen and described here. It summarises information and experience which the team deals with the most often. It also focuses on the possibilities of solving the particular acoustic problems regularly occurred in practice which are caused by underestimating or disrespecting the principals of noise-proof protection. The author's experience shows the evidence of underestimating the acoustic problems in buidings. Building constructions do not have reasonable sound reduction parameters and that is the reason why they are not able to reduce undesirable surrounding sounds. Supplemental adjustments in buildings leading to rectification of failures are complicated from technical, social and financial point of view.

1. Introduction

Buildings, as a product of human activities, have accompanied us from everlasting. The objective has been always to create an insulated (perfect, controllable and controlled by people) area that would not depend on climate so much. The inside environment of the structures plays an important role. A number of requirements have been set for that. An attention is paid, among others, to architecture, ergonomy, functionality, optimum microclimate, optimum light and thermal comfort. It is also necessary to consider acoustics because quiet environment is regarded as a pre-requisite for comfortable living. For a human body, it is not possible to prevent reception of sound stimuli. We are exposed to noise all the time, even when sleeping. An increased level of noise results in stress and dysfunctions of internal organs.

Noise parameters of surrounding structures, such as walls, ceilings, windows and roofs, must be such so that the users would not be disturbed with outdoor noise that is generally out of their control.

While measuring, non-compliant structures in terms of acoustics are often found. In particular, in apartment blocks this can be a matter of dispute.

2. Sound reduction index

The sound reduction index R_w represents a loss of acoustic power of sound transferred through the air in a structure. The higher the sound reduction index of the structure is, the better the sound insulation is. The sound reduction index is influenced by surface density and bending rigidity of used materials. Requirements relating to the sound reduction index for structures are defined in [1].

Sources of sound inside the buildings are typically music and loud conversation. Most often, separating walls between apartments are measured. This situation is shown in Example 2.1.

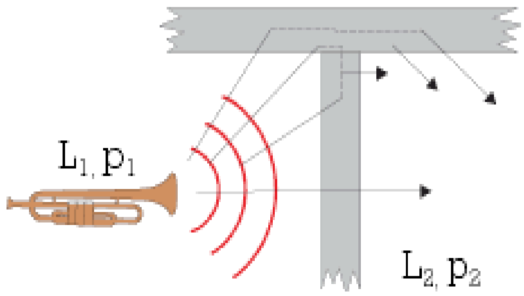

Fig. 1 Sound reduction index (source: www.rockwool.cz)

Sound reduction measuring is followed by the ČSN EN ISO 140-4 standard. Evaluation of measured processes and indication of one-figure number data is done according to the ČSN 717-1 standard. Evaluation of building constructions according to the set requirements are based on the ČSN EN ISO 140-4 standard.

2.1 Example from practice – a block of apartments in Frýdlant nad Ostravicí

Characteristics:

This house was built in 2004 from hollow moulded bricks (Porotherm).

Reason for measurements:

To verify real properties of the structures. People living there have complained often about noise from neighbouring apartments.

Measured construction:

Wall between two apartments made from Porotherm 24 P+D (240 mm), plastering on both sides, thickness 15 mm. Total wall thickness: 270 mm.

Fig. 2 Apartment block in Frýdlant nad Ostravicí

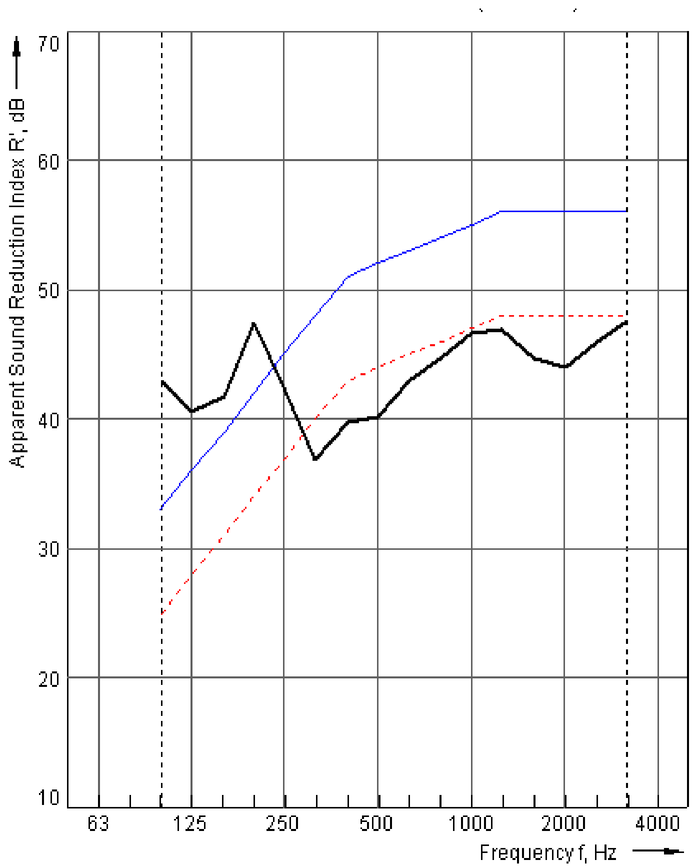

Fig. 4 Course of R'_w - Porotherm 24 P+D.

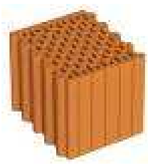

Fig. 3 Moulded bricks, Porotherm 24 P+D

Fig. 5 Measured wall in the apartment

Comments to the measurement:

In terms of acoustics, the construction was deteriorated by wiring/pipes. This is absolutely unacceptable from the acoustic point of view. The measured value was $R'_w = 44$ dB. In order to make the construction compliant with requirements set forth in [1], the minimum value should be $R'_w = 52$ dB.

This means that incorrect actions have been taken when preparing a project for the construction. A material has been proposed the sound insulation properties of which ((R_w - communicated by the manufacturer) decreased by correction routes for sound propagation (k) make it impossible to use it for that wall between the apartments and to fulfill requirements of [1]. $R'_w = R_w - 2 = 52 - 2 = 50$ dB(!)

Tab. 1 Parameters of walls between the apartments

construction	thickness (mm)	type of room	note	R´w (dB) required value [1]	R´w (dB) measured value	Rw (dB) as given by the manufacturer
Porotherm 240	270	living room/bathroom	wiring/pipes	52	44	52

Improvement proposals:

It is impossible because of building and technology aspects to demolish the wall and replace it with another one with better sound parameters. A solution might be to install an offset wall with sound absorbing materials. The offset wall should be flexibly separated from other structures.

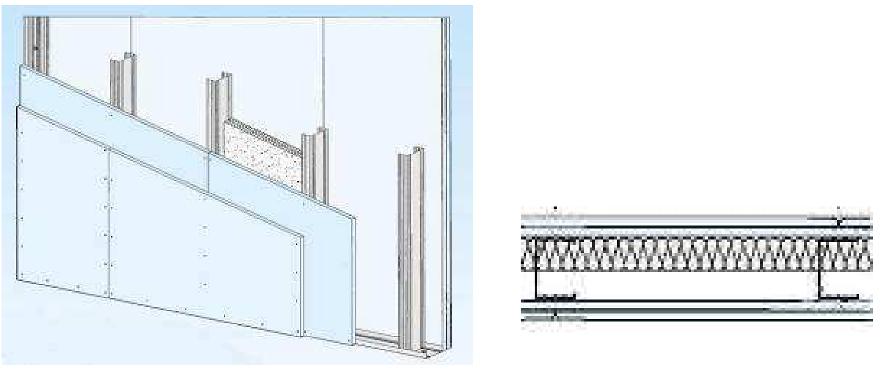

Fig. 6 Offset wall from gypsum board

2.2 Example – Building of Ostrava University

Characteristics:

Reconstruction of a building located in a historic centre of a city.

Reason for measurements:

To verify real parameters of the structure before the structure is handed over for use.

Fig. 7 Building of Ostrava University

Fig. 8 Location of devices

Measured construction:

Walls separating classrooms - the walls are made from moulded bricks Porotherm 30 AKU (145 mm), plastering on both sides, thickness 15 mm. Total wall thickness: 175 mm.

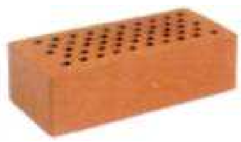

Fig. 9 Moulded bricks, Porotherm 30 AKU

Comments to the measurement:

The designer used the material with $R_w = 48$ dB (this value is given by the manufacturer). After correction routes (2 až 3 dB) for sound propagation are deducted, the material does not meet requirements in [1].

The acoustic performance of the construction is also reduced by A/C pipes and water pipes. The measured value $R'_w = 35$ (36) dB is well below the required value $R'_w = 47$ dB.

When both classrooms are used at the same time, it is highly likely that people in both classrooms will be disturbed with noise that passes through the wall.

Fig. 10 *Measured wall between the classrooms*

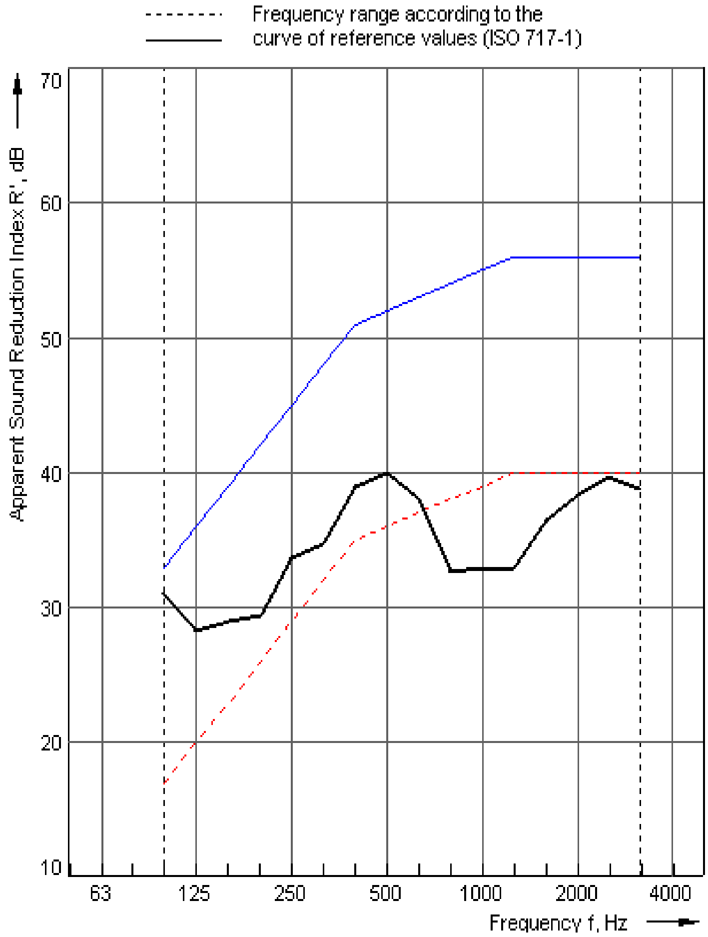

Fig. 11 Course of R'_w - Porotherm 30 AKU.

Tab. 2 Parameters of walls between the classrooms

					Rw´ (dB)		Rw (dB)
room #	construction	thickness (mm)	type of room	note	required value [1]	measured value	as given by the manufacturer
401-402	Porotherm AKU 30	175	classroom/classroom	deteriorated by pipes	47	36	48
201-202	Porotherm AKU 30	175	classroom/classroom	deteriorated by pipes	47	35	48

Improvement proposals:

Alternative 1: This is not a bearing wall. Theoretically, the wall can be demolished and completely replaced with another one. For instance, Porotherm 24 AKU (produced by the same manufacturer) can be walled up to the thickness 240 mm $R_w = 48$ dB. In practice, demolition is possible only within a claim procedure. More frequently, Alternative 2 is preferred.

Alternative 2 – a pre-wall will be built in front of the existing wall. The pre-wall will be made from sound absorbing materials (similarly as in Case 2.1). Reasons are both technical and economic.

3. Impact sound transmission loss

This represents construction's ability to attenuate noise caused by a direct contact of a source of sound with structure. A typical pattern inside the buildings is the walking on walls, moving furniture, or elevator equipment.
Basic rule: The lower the impact sound transmission loss (L'_{nw}) is, the better.

Impact sound transmission loss measuring is followed by the ČSN EN ISO 140-7 standard. Evaluation of measured processes and indication of one-figure number data is done according to the ČSN 717-2 standard. Evaluation of building constructions according to the set requirements are based on the ČSN EN ISO 140-7 standard.

3.1 Example – Apartment Block in Ostrava

Characteristics:

Panel building built in 1971. Building system: T 06B.

Fig. 12 Panel building in Ostrava

Fig. 13 Tapping-machine.

Reason for measurements:

An owner of the apartment complained of excessive noise from the apartment above him. Verification of properties of the ceiling structure.

Measured ceiling structure:

Because people live in the apartments, it was not possible to install a probe to find out construction layers. During the inspection it has been found out that ceramic tiles were laid in the upper apartment. This damaged the floor finish.

For the original composition see Table 3.

Tab. 3 Original composition of the ceiling in T 06B

structure of ceiling with floor	thickness [m]
flooring - PVC	0.003
varnished particleboards	2x0.010
alveolate board plate - IZOPLAT	0.012
polyethylene plastic	0.001
dross sand	0.015
ceiling reinforced concrete panel	0.150
plaster	0.015
Total thickness	0.216

Fig. 14 Composition of the original floor

Comments to the measurement (Fig. 15)

The weighed normalised impact sound transmission loss of the ceiling with the original floor structure is L'_{nw} = 55 dB. After unprofessional change, the weighed normalised impact sound transmission loss of the modified ceiling (with tiles on the floor) is L'_{nw} = 70 dB ⇒ this means, requirements set forth in the standard [1] are not met. The reconstruction decrease the sound loss of the ceiling structure by 15 dB!

A reason for the worse impact sound loss of the structure is probably that an incorrect technology was chosen for the new floor. Some layers of the original floor were removed (for instance, shredded wood boards) and new sound insulation was not placed under the tiles. Dilation along the floor is also missing there.

People living in apartments make such undesirable changes rather often.

Tab. 4 Parameters of the ceiling between the apartments

construction	thickness (mm)	type of room	L´nw (dB) required value [1]	L´nw (dB) measured value
modified ceiling	220	room/room	58	70(-9)
original ceiling	220	room/room	58	55(1)

Improvement proposals:

To remove the files and lay a new floating floor with a dampening insert (for instance, Rockwool Steprock).

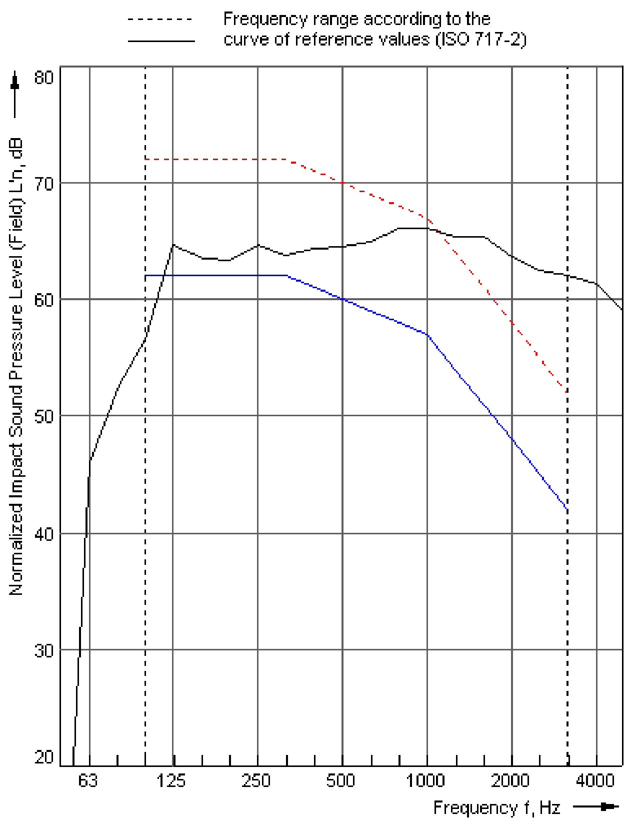

Fig. 15 Course of L'_{nw} – tiled ceiling

Fig. 16 Measuring devices

4. Apparatus equipment

The Building Faculty disposes of the top measuring apparatus from a Dane company Brüel & Kjær. System consists of:

1) Investigator 2260 D – programmable sound analyser.
2) Programme for sound analysis BZ 7204.
3) Sound source OmniPower type 4296.
4) Normalized source of impact sound transmission loss – Tapping machine 3207.
5) Amplifier - Power Amplifier type 2716.
6) Calibrator.
7) Microphones, cabels and attachements.

Fig. 17 Apparatus equipment.

5. Conclusion

Because of differences that occur as a result of installed structures, it is rather complicated to describe the sound propagation inside buildings, if currently used methods are applied for the calculation of sound transmission loss (graphic or course methods). Laboratory parameters of elements found out in a sterile environment of acoustic chambers can also hardly consider the situation on the site. The situation of designers is rather difficult: they can rely neither on calculations nor on laboratory values (after deduction of necessary corrections in order to acquire construction values). It is necessary to avoid situations where pipes and wiring are laid in a separating wall! The measurements have proved that the deteriorated structure has considerably impaired sound parameters. Though this unacceptable solution is not visible, it can make people living there "hear" too much.

[1] ČSN 73 0532/2000, amendment Z1/2005 Acoustics – Protection against noise in buildings and related acoustic properties of building elements – Requirements.

This issue is solved with financial assistance of the Ministry of Education, Yourth and Sports of the Czech Republic, the project no. 1M0571, within activities of the CIDEAS research centre.

SBTOOL CZ – CZECH ASSESSMENT METHODHOLOGY FOR SUSTAINABILITY

Vladimír ZDARA Dr.[1,2]
Martin VONKA Ph.D[2]
Antonin LUPISEK MSc[1,2]
Petr HAJEK Prof. [1,2]

Keywords: SBTool, assessment method, sustainable development, sustainable construction, weighting

Summary

The SBToolCZ is a building performance assessment tool designed for assessment of buildings in various phases of their life cycles. For a new tool (called SBToolCZ) has been developed adapted structure of indicators, benchmarks and weights based on the original SBTool structure and using some experiences from development of LEnSE methodology (Methodology Development towards a Label for Environmental, Social and Economic Buildings – EU FP6 research program). The parameters included in the system cover sustainable building issues within the three major areas: environment, social and economic issues. The system is designed on three levels including the core of the application, an expert level and the user's boundary-line. The core of the application is accessible only on the level of the program language. The expert level enables the forming and modification of evaluation methods. The middle level enables the description of methods and evaluations algorithms, by the user's way. The user's level serves the evaluation of specific building.

1. Background

1.1 Situation in the Czech Republic

The Czech Republic followed the international process Green Building Challenge and iiSBE organization in 2005 and established Czech Sustainable Building Society (CSBS) iiSBE Czech. The CSBS is an official representative of iiSBE in the Czech Republic and keep the key role in promotion of SBC principles into the Czech construction sector. CSBS iiSBE Czech together with the research centre CIDEAS (at the Czech Technical University in Prague) started the process of adaptation of GBTool/SBTool for specific Czech conditions. For a new tool (with the working name SBToolCZ) has been developed adapted structure of indicators, benchmarks and weights based on the original SBTool structure and using some experiences from development of LEnSE methodology (Methodology Development towards a Label for Environmental, Social and Economic Buildings – EU research programme).

The SBToolCZ is a building performance assessment tool designed for assessment of buildings in various phases of their life cycles. The parameters included in the system cover sustainable building issues within the three major areas: environment, social and economic issues.

The system is designed on three levels including the core of the application, an expert level and the user's boundary-line. The description of the evaluated building and the form of the output are oriented towards practical use.

1.2 SBToolCZ – principles and localization of the tool

The SBTool (formerly GBTool), has been chosen as a basis for development of the Czech buildings assessment methodology because it offers a complex approach in association with a wide scale of reasonable detailed criterions.

SBTool is represented by a set of assessment criteria organized in a tree structure. The particular criterions are first converted to relative value in compliance with achieved performance level, second count up according to the preset weights.

When the works on localization had started, some problems occurred. The original SBTool software was developed in MS Excel which is a powerful solution for a rigid assessment tool. However it is not suitable for adaptation to different languages and specific local conditions and keeps everything up to date at the same moment.

Therefore a new structure of the assessment tool based on database architecture and new methods for distribution of information has been developed. The effort resulted into a new universal assessment tool named SBToolCore.

2. SBToolCore

2.1 General structure of the system

SBToolCore is a universal methodology and tool for complex assessment of buildings. It enables maintenance of origin and derived assessment methodologies and their national or regional localizations (see Figure 1).

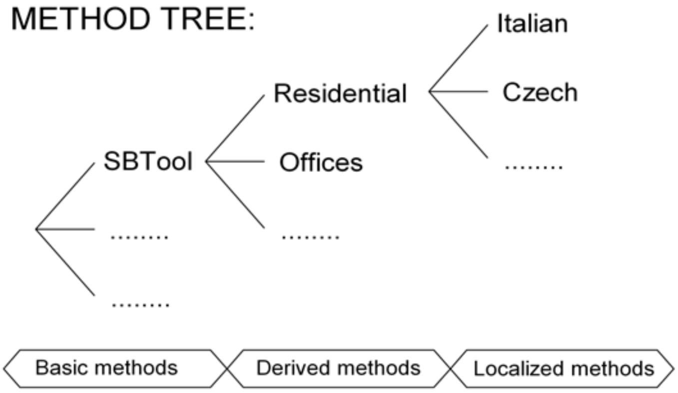

Figure 1 Method tree

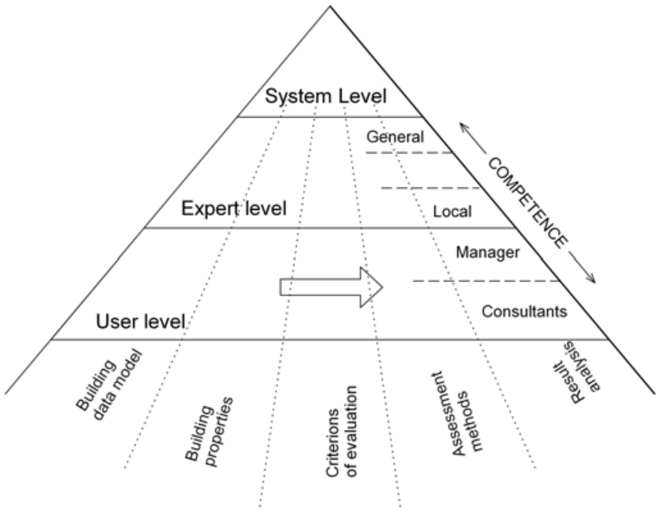
The tool is suitable for development, testing and comparison of different assessment methods as well as for their practical applications. SBToolCore has three strictly separated functional levels (Figure 2):

- system level (tool setting and maintenance);
- expert level (definition of assessment methods);
- user level (assessments of buildings).

Assessment methods are described in a database form and presented in a simple and user friendly form.



•

Figure 2 System levels and competitions.

2.2 Database of building properties, boundary conditions and criterions

Building properties, assessment boundary conditions and criteria are described in a database form. Ease of description and transparence of the system is improved by organization all categories into tree structures.

Building properties can be described by verbal indicators, by exact values or even by fuzzy values. Two value types of properties and boundary conditions are set – basic and localized.

Data for criterions are dynamically obtained from building properties and boundary conditions. Benchmarking operations can be user defined using symbolic script formulas.

2.3 Multicriterion analysis

Assessment method is in the SBToolCore system defined by criterions selection, their mutual organization and weights.

For simpler weightings are criterions first relativised (meaning transformation from measurement units to relative scale from -1 to 5) and then summed up according to weights.

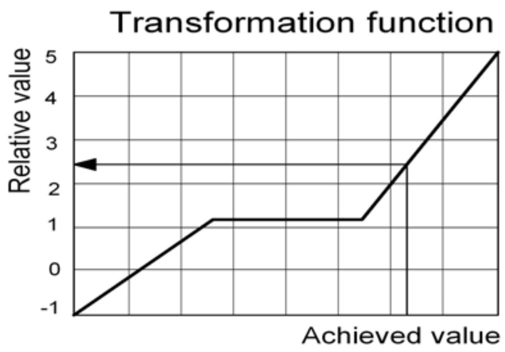


Figure 3 Transformation function

Criterions are placed in the method tree and impact tree.

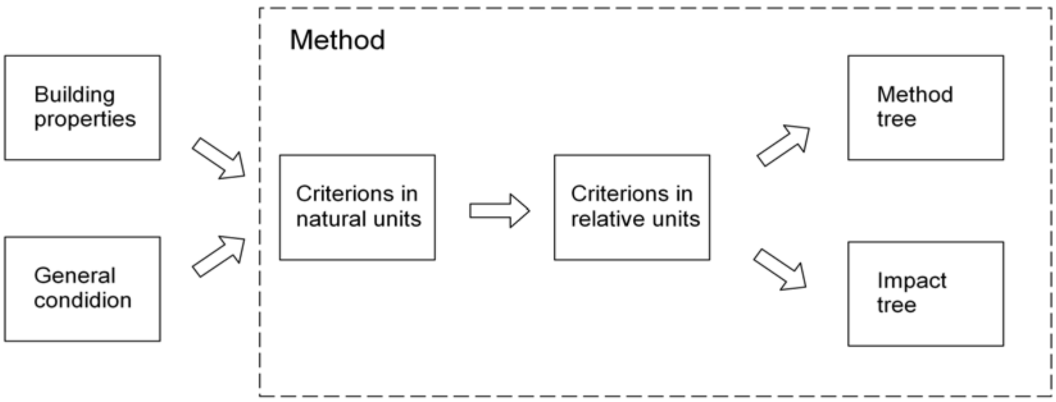

Figure 4 Assessment scheme

The position of the criterion in the method tree expresses its belongings to a particular subsystem of assessed building. Positioning the criterion into the impact tree represents belonging to the selected impact category.

Both method tree and method tree together make a multilayer criterion tree that enables not only complex quality of proposed building project but also the quality of its particular subsystems. The latter dimension enables to connect the assessed quality of the particular subsystem with the specialists' responsibilities in the project team (see Figure 5).

Criteria organization in the multilayer SBToolCore tree enables:

- independent weights settings;
- detailed complex analysis of proposed project;
- splitting expert and political weights;
- easy modification of the methodology for several purposes.

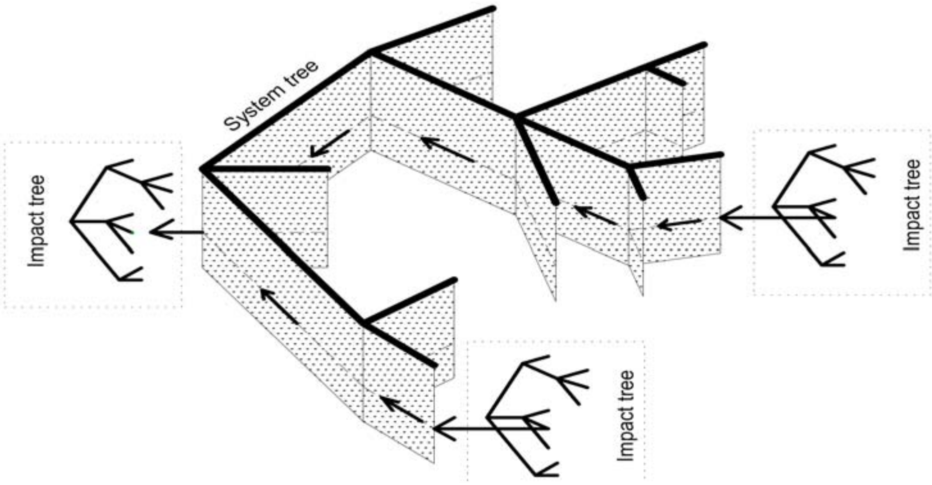

Figure 5 Multilayer tree structure

2.4 User level and assessments outputs

Assessment algorithms are in SBToolCore system extracted straight from the methodology definition on the expert level. The tool supports building assessments using more methods at one moment. It also handles more variants of one project and their comparison. The user can choose what data sets are for the derived variant inherited (when a change is made in original basic variant, it automatically changes values that has enabled inheritance) and what are settled rigid.

The outputs are very illustrative and enable to perform a complex assessment of any part at different detail levels (Figure 6).

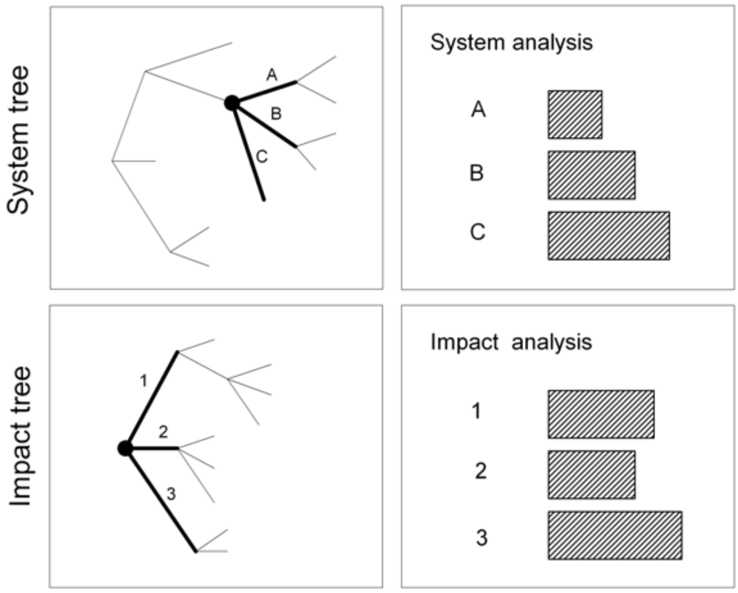

Figure 6 Analysis levels

The final result consists of total score of environmental, social and economic issues and can be represented for example by a TRICRI graph on Figure 7.

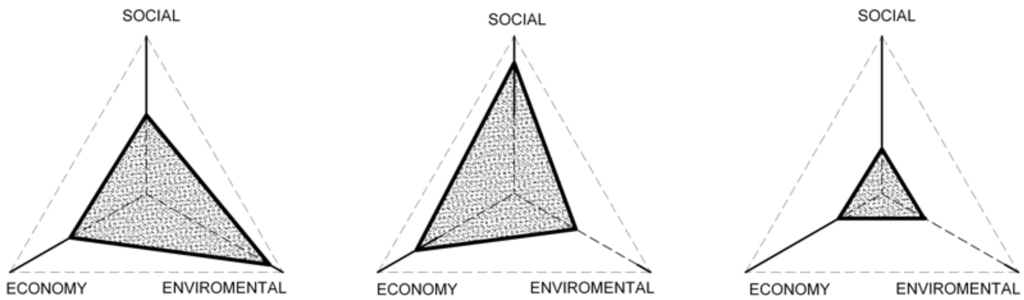

Figure 7 Example of possible results: a) building having very high environmental performance; b) economical building having high social performance; c) low-quality building.

2.4 SBToolCore implementation

SBToolCore implementation employs the latest IT technologies (MS SQL Server, NET Frameworks 3.5). The tool is designed to manage international cooperation on development and localization of complex assessment methods. System supports multilingual user interface as well as multilingual methodologies definitions. System implements multi-user management on both expert and user level and enables efficient control of projects preventing information duplications. Access rights management handles different roles (international expert, national expert, project manager, specialists). Principle of information inheritance enables easy creation and modification of building properties and criterions according to the national specifics. SBToolCore is open data system ready for interconnection with IFC data model (Industry Foundation Classes).

3. SBTool CZ

The structure of criterion used in SBToolCZ is presented in the next tables (Tab. 1, Tab. 2, Tab. 3).

Table 1 Environmental assessment issues

Main category	Assessment issue
Climate Change	Greenhouse Gas - CO_2 emissions – operation of buildings & transport Embodied emissions CO_2 Destruction of the stratospheric ozone layer
Air Quality	NOx emissions - buildings & transport Operation SO_2 emissions
Biodiversity	Ecological value of land NFA compared with green area Ecological value impact of land
Resource use and waste	Nonrenewable primary energy consumption Renewable primary energy consumption Embodied energy Use of freshwater resources Use of rainwater Use of renewable construction material Use of recycyled construction material Use of toxic construction material Construction waste Waste in operation of building
Environmental Risk	Floods Outcome of rainwater
Management	ISO 140001 ISO 9000

Table 2 Social assessment issues

Main category	Assessment issue
Occupant wellbeing	Lighting comfort Acoustic comfort Thermal comfort Indoor air quality
Accessibility	Provision of place for free time Public transport accessibility Provision of safe and adequate cycle lanes and cyclist facilities Key amenities - provision and proximity
Security	Site security Building security
Social and cultural value	Community impact consultation Aesthetic quality External neighbourhood impacts
Functionality	Critical management Adaptability Spatial efficiency Availability of as-built drawings and documentation

Table 3 Economy assessment issues

Main category	Assessment issue

	Innovation

Each issue has it own assessment list, which contains the name of assessment issue, for which stages it is set, for which type of building it is set, intent of assessment, indicator, benchmarks for relevant type of building and relevant stage, information source, methodology of assessment and responsible administrator. The most of benchmarks is set for the level -1 (negativ), 0 (acceptable practice), +3 (good practice) and +5 (BAT – best practice). It is possible to interpolate intermediates values.

The structure of indicators is in progress. Comparison between issues included in SBToolCZ and LEnSE gives not only experiences in European trends, but ensure the compatibility of SBToolCZ with other European tools as the BREEAM for example.

There will be stated the final benchmarks of criterion and weights among criterion in the next steps of research. These weights will be set according to the questionnaire of researcher.

The main objective of the LEnSE project in the nearest future is to form an international framework for the development of a common building labelling methodology with creating a set of the main assessment criteria. On the basis of the main criteria there will be designed a prototype assessment tool that facilitates testing of the methodology on a specific building types (new residential and commercial buildings). After analysing the results the methodology will be expanded for the other types of buildings.

4. Conclusions

The evaluation and optimization of buildings have a practical meaning only when they can influence the final design of the building. Design is a process of gradual decision making, where conceptual decisions done at the beginning have the biggest effect. For the evaluation to have an effect on the project solution, it has to be done simultaneously with the decision process.

The project work in buildings at present comes from evolution algorithms. This work well in the environment with long term stability and feed-back and then offer suitable solutions relevant to actual needs and possibilities.

Current development is typical of it's intense demands on energy savings, use of renewable materials and satisfaction of new needs, while exploring the use of new materials and technologies. That is why the traditional way of designing, based on the use of empirical experience, does not have good results.

This problem can be solved by computer simulated variation of designs, with following complex evaluations. A starting-point is the development of methods for integrated designing and complex evaluation of buildings.

This paper has been achieved with the financial support of the Ministry of Education, Youth and Sports of the Czech Republic, project No. 1M0579.

Keywords: Sustainability, ISO Series, DEA, Existing Building Performance, Efficiency, Life Cycle Cost (LCC)

Summary

"Sustainability" is meant to be the desirable concept of human development that meets the present demands without compromising the future supply of next generations for their own liveability. This concept needs to be adapted relevant object of assessment to fulfil the term, sustainability, with regard to environmental, economic and social conditions. Based on the "Sustainability in Building Construction-Framework for methods of Assessment for Environment Performance of Construction Works-part.1: Building" covered in ISO 21931-1 and the evaluation method of building Life Cycle Cost in ISO 15686 and ISO14040, this study will aim at 97% of the buildings ratio occupied by the existing buildings in Taiwan to preliminarily structure a new model to assess the Existing Building Performance in the life cycle of a building. The assessment adapted the methodology of Data Envelopment Analysis (DEA) is discussed using a case study to offer the "decision-making references" to management personnel, users and designers for "upgrading the building performance" approaching the perspective of Sustainable Building Environment.

1. Introduction

In the 21st century, an age of sustainability, in response to the concept of sustainable environment, building construction industry must develop "a method of assessment to building performance" in order to meet different phases of the building life cycle assisting to effectively cope with the issues of global warming and harmfulness to environment and health. International organization OECD (Organization for Economic Co-operation and Development) investigated the current situations of the buildings in member countries. The statistical data indicated that the ratios of new buildings in many advanced countries were almost below 2% (shown in Table 1). The ratio of new building license from 1990 to 2006 in Taiwan has reduced by 3% and ratio of the existing buildings was up to 97% (shown in Figure 1). With the increase of building duration, there will be many problems generated. The metropolis is the population and economy centre in the world and with the major pollutants of energy consumption and Greenhouse air emission. Therefore, the functions and environmental quality of existing buildings were deteriorating and these buildings also caused environmental pollution and landscape damage. If we can propose correctly sustainable improvement strategies and accelerate reactive usage of the buildings, human environment will also be improved.

Table 1 Rate of new except exist of OECD country

OECD Country	Housing starts/stock

■ Performance degrees (PD) are defined in 5.4.3.2.2.

Figure 2 Life Cycle Performance of Construction this study will aim at 97% of the buildings ratio occupied by the existing buildings in Taiwan to preliminarily structure a new model to assess the Existing Building Performance in the life cycle of a building. In addition, a sustainable building is meant to be a building that contributes through its characteristics and attributes to sustainable development. By safeguarding and maximizing functionality and serviceability as well as aesthetic quality a sustainable building should contribute to the minimization of life cycle costs (Thomas and David 2007). However, the built environment of today uses large amounts of energy and materials affecting the health of humans and natural environment in negative effects. Obviously, rising interest in developing environmental assessments of the built environment generates a large number of tools for the assessment of built environment focusing on energy use in buildings, the sick building syndrome, indoor climate, building materials containing hazardous substances and many other aspects in fragmented or integrated manners (Anna and Fredrik 2004). In association with these divergent tools of environmental assessment, the concept of Integrated Building Performance approach (IBP) was proposed and led to a wide range of discussion for assessing a building's contribution to sustainability including the spectrum of functionality and serviceability as well as the quality of planning, construction and management process (Thomas and David 2006) (Shown in Figure 3).

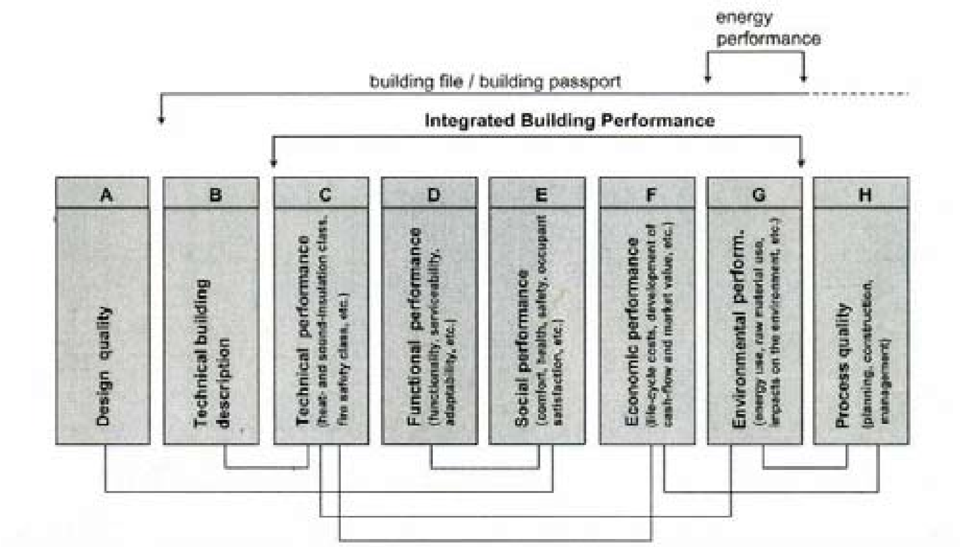

Figure 3 Integrating sustainability aspects into an overall framework

To extend, the purposes for the assessment of sustainable buildings are to satisfy the needs of the building users in aspects of environmental performance, social performance, economic performance and technical performance; this statement has also revealed a new vision as a supplement to current assessments of LCA-based tools. As a result of the above mentions, the series of ISO standards and IBP approach attempt to clarity the cross effects of Cost or Loading and Quality on its individual role as indicators for robustly assessing the performance of existing buildings.

2. Life Cycle and Building Life Cycle Costs

ISO-EN-UNE-14040 regulation, defines life cycle as the consecutive and interrelated stages of a product system, from the acquisition of raw materials or the generation of natural resources until its final elimination. Life cycle is closely related to cost-accounting system as conducting the life cycle assessment (LCA) that has been applied for some time to assess the environmental impact of industrial products (ISO14040), also makes senses in construction and may be equally applied to civil works and architecture (Yokohama, Oka and Kibert etc. 2000). Nevertheless, many traditional cost-accounting systems lead to incorrect investment decisions concerning environmental costs. One problem is for example that demolition and recycling costs appear outside the boundary of the traditional accounting system. A popular way of solving this problem has been to suggest the use of life cycle costing (LCC) which includes such costs. The main difference between traditional investment calculus and LCC is that the LCC approach has an expanded life cycle perspective, and thus considers not only investment costs, but also operating costs during the product's estimated lifetime (Pernilla and Henrikke 2004). As well known, in the life cycle of a building, the major activities can be defined where environmental performance can be assessed: construction of a new building, rebuilding, extension, operation, maintenance and demolition. By the research from Martin and Per 2005 conclude that rebuilding is an environmentally better choice than building a new building, if the essential functional performance is the same. This conclusion indicates the cost of a building over its lifetime is no longer the general feeling that the lowest capital cost option will also be the lowest total cost option because of operation and maintenance costs incurred either annually or at periodic intervals over the life cycle of a building.

According to the aforementioned the percentage of new and existing buildings (3%: 97%) in Taiwan, it is important to orient building life cycle costing tools adapting the evaluations for operational and maintenance efficiency.

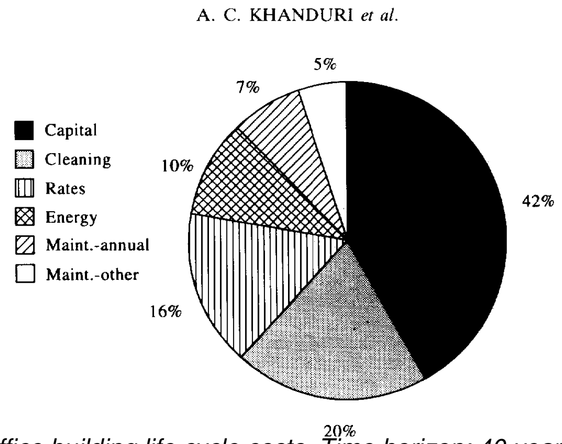

Figure 4 Office building life cycle costs. Time horizon: 40 years, discount: 2%.

The figure 4 illustrates the life cycle cost commitment for a typical office facility.' In this figure, operation and maintenance costs, which are incurred either annually or at periodic intervals over the life of the facility, account for 58% of the total life cycle costs, are thus greater than the capital costs which are incurred at the initial construction stage. It can be seen that the long-term costs can far outweigh initial capital costs (A.C. Khanduri 1996). LCA methodology should take into account preventive maintenance programmes which will require an effort and commitment by future generations (Eduardo Peris Mora 2007). Neely and Neathammer have presented several different maintenance life cycle data bases developed by the U.S. Army Construction Engineering Research Laboratory to assist in life cycle cost analysis. Computer-aided procedures to evaluate the financial feasibility of construction projects have existed for some time, but their use has frequently been cumbersome, requiring too much data. The methodology of Data Envelopment Analysis (DEA) developed by Farrell et al. (1989) that proposed a nonparametric mathematical programming technique is software for calculating the efficiency both technically and environmentally.

3. Evaluation Methods Adapted Data Envelopment Analysis (DEA)

Data Envelopment Analysis (DEA) is a methodology based upon an interesting application of linear programming. It was originally developed for performance measurement. It has been successfully employed for assessing the relative performance of a set of firms that use a variety of identical inputs t was originally developed for performance measurement. It has been successfully employed for to produce a variety of identical inputs to produce a variety of identical outputs (R. Ramanathan 2003).

3.1 Decision-making Units

Data Envelopment Analysis is a linear programming-based technique for measuring the performance efficiency of organizational units which are termed Decision-Making Units (DMUs). This technique aims to measure how efficiently a DMU uses the resources available to generate a set of outputs (Charnes et al. 1978). Decision-making units can include manufacturing units, departments of big organizations such as universities, schools, bank branches, hospitals, power plants, police stations, tax offices, and defence bases, a set of firms or even practising individuals such as medical practitioners. The performance of DMUs is assessed in DEA using the concept of efficiency or productivity, which is the ratio of total outputs to total inputs that can be formulated as the following:

$$\text{Efficiency} = \frac{\text{Output}}{\text{Input}} \tag{1}$$

Efficiencies estimated using DEA are relative, that is, relative to the best performing DMU (or DMUs if there is more than one best-performing DMUs). The best-performing DMU is assigned an efficiency score of unity or 100 per cent, and the performance of other DMUs vary, between 0 and 100 per cent relative to this best performance (R. Ramanathan 2003).

3.2 Frontier Analysis in DEA

The economic treatment of Frontier Analysis is normally explained using the concept of production possibility frontier (Samuelson and Nordhaus 1989; Thanassoulis 1999). A production possibility set for the example in this section can be constructed by considering all possible combinations of the two inputs (capital employed and employees) that will result in the same, given level of output (value added), and the production possibility frontier is the frontier enveloping the production possibility set. The efficiency frontier is indicated in Figure 5. It represents a standard of performance that the firms not on the frontier should try to achieve. Firms on the frontier (Firms A and C here) are considered 100 per cent efficient.

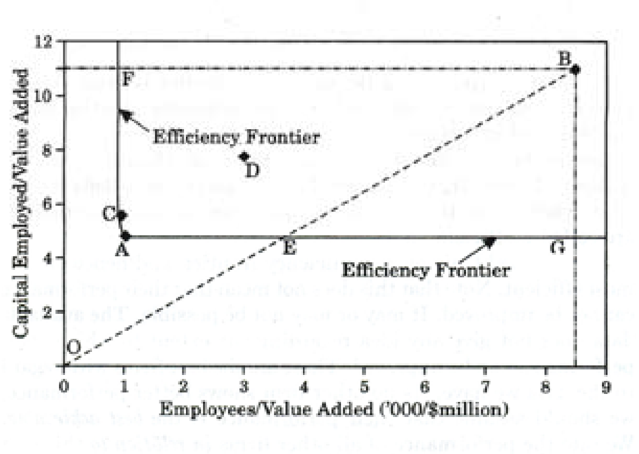

Figure 5 Frontier Analysis in DEA

Such an analysis using the efficiency frontier is often termed Frontier Analysis (Farrel 1957). This efficiency frontier forms the basis of efficiency measurement. The efficiency frontier envelops the available data. Hence, the term Data Envelopment Analysis. In the DEA literature, Firms A and C are called efficient firms while Firms B and D that do not lie on the efficiency frontier are called inefficient firms (R. Ramanathan 2003).

The purpose of DEA is to offer a method for the evaluation of efficiency that have been broadly used by Non-Profit Organization (NPO). This is because the value of the products and services from NPOs are very difficult to be appeared by quantitative figures as same as their prices in a free market. Nevertheless, the DEA method can be a useful tool for the evaluation of productivity by the scores of relative efficiency between departments in a firm, firms and regions.

In the field of building industry, evaluations of a building performance involve a wide range of factors, including initial cost, construction cost and maintenances etc.. These factors are so complicated that quantitative analyses for a building performance and efficiency are not easy to be conducted. Generally, evaluator will set up some indexes and weightings that normally based on surveys or questionnaires to compute the building efficiency that become subjective results by the valuator due to the lack of reliability and validity. Consequently, this paper attempt to apply DEA, which takes different spaces in a building as DMU, for assessing building efficiency and performance. By the comparisons of relative efficiency to find out the most efficiency DMU is to provide references for the future improvement and to help the decision making for the building owner (refer to Figure 6).

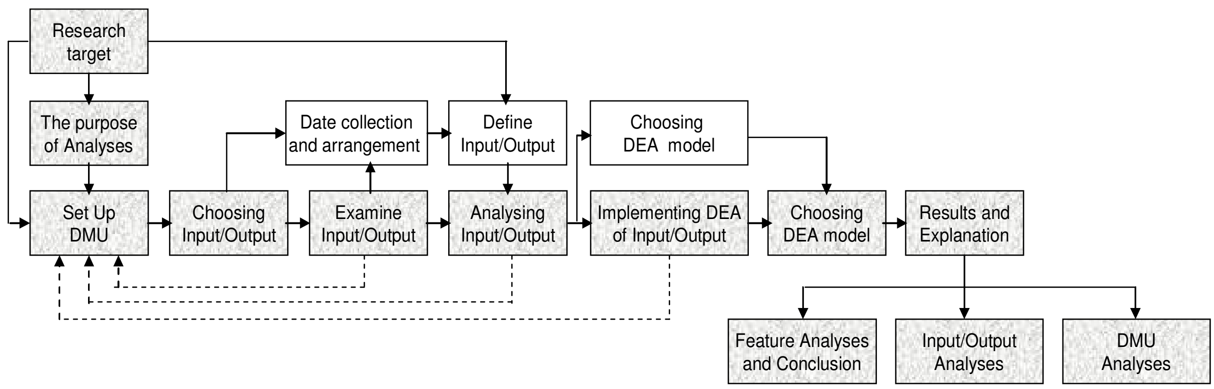

Figure 6 DEA Procedure

4. Case Study- Proposed Evaluation Model of Existing Buildings Performance

A well operated building should meet the status of High-Performance and Low-Energy consumption with Healthy-Quality of users to illustrate the efficiencies of use and economy in a building lifecycle.

Therefore, this study takes a research building of Academia Sinica as a case study to adapt the methodology of Data Envelopment Analysis (DEA) for the evaluation of indoor environment quality monitored the correlations between factors of indoor environment quality (IEQ) and the building performance. It also provides the quantitative data as the references for Life Cycle Costs analysis (LCCA) to enhance the technical and environmental efficiency. This case chooses 14 research units with the same floor area as DMUs to set up the employees and the indoor decoration costs as INPUTS and the factors of indoor air quality (IAQ) as OUTPUTS (ie: TVOC and CO2) to explore feasible approaches for the evaluation of building costs toward overall efficiency in a building lifecycle. This research target is chosen 「Genomics Research Center」 as a case study, selecting 14 spaces become research DMU that listed as Figure 7-Standard Plan and Table 2-DMU Layout.

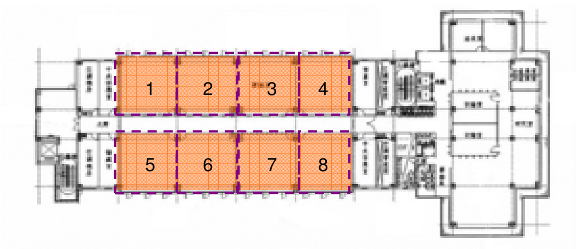

Figure 7 standard plan

Table 2 DMU Layout*

DMUs	Floor	Location
A	2	1
B	2	7
C	3	3
D	3	8
E	4	1
F	4	3
G	4	2
H	5	5
I	5	1
J	5	4
K	6	3
L	6	4
M	7	6
N	7	8

* DMU A, E, I marked as 1 because these DMUs have the same spatial type as same as the reason for DMU C, F, K, D and N.

4.1 The Factors of Indoor Air Quality (IAQ) and Scoring Method

4.1.1 Converting the questionnaires results of on-site survey and Analytic Hierarchy Process (AHP)

This study converts the questionnaires evaluation of interviewed users in 14 types of research units into scoring for comparisons. Simultaneously, AHP method was conducted to further verify the factors of IAQ need to be prior improved. To help compare physical and mental scorings of various spaces, X-axis in Table 3. is converted into mental scoring as 20, 40, 60, 80, and 100. Y-axis represents the scoring of physical evaluation from the measurement results.

Table 3 Scoring of the IAQ Factors in physical aspect

Indoor Air Environment	Score / Factors	20	40	60	80	100
Indoor Air Quality	CO_2 (ppm)	>1200≥	>1000≥	>800≥	>600≥	
	TVOC (ppm)	>4≥	>3≥	>2≥	>1≥	

4.1.2 Proposed Evaluation Model Adapted DEA Methodology

To adapt DEA methodology for the evaluation model of the building performance is prior to identify INPUTS and OUTPUTS. In this case as aforementioned, INPUTS are the employees and the indoor decoration costs, while OUTPUTS are the factors of IAQ (TVOC and CO2) listed as below Table 4. the list of Inputs and Outputs for DEA.

Table 4 The list of Inputs and Outputs for DEA

INPUTS	EXPLANATION
Number of Employees	The Employees of Each research units
The Decoration Costs	The Decoration Costs of Each research units
OUTPUTS	
The Factors of IAQ	CO_2 and TVOC as the factors。

4.2 Results and Discussion

4.2.1 Variables of DEA

The calculable variables between INPUTS and OUTPUTS for 14 are listed below:

Table 5 The list of calculable variables in 14 DMUs

DMUs	Number of Employees	The values of Decoration Costs	IAQ
A	12	527988	**20**
B	12	523345	**40**
C	16	509839	**20**
D	12	527988	**60**
E	15	527988	**40**
F	25	543489	**20**
G	16	563301	**20**
H	24	527988	**20**
I	13	498831	**80**
J	10	498831	**100**
K	15	527988	**60**
L	12	529842	**80**
M	11	493468	**100**
N	26	597331	**20**

4.2.2 Analysis of DEA results

There are three aspect analyses included Efficiency analysis, Benchmark analysis and Slack analysis.

Efficiency analysis:

From the comparison of 14 DMUs (Table 6. and Fig.7), J and M are the DMUs with better efficiency and performance scored as 100%. The others are K, D, B, E, C, H, A, F, G and N scored under 60%, and DMUs with inefficiency are C, H, A, F, G, and N.

Table 6 The comparisons of 14 DMUs

No.	DMU	Score	Rank
1	A	0.2	9
2	B	0.4	7
3	C	0.2	9
4	D	0.6	5
5	E	0.4	7
6	F	0.2	9
7	G	0.2	9
8	H	0.2	9

9	I	0.8	3
10	J	1	1
11	K	0.6	5
12	L	0.8	3
13	M	1	1
14	N	0.2	9
No.	DMU	Score	Rank

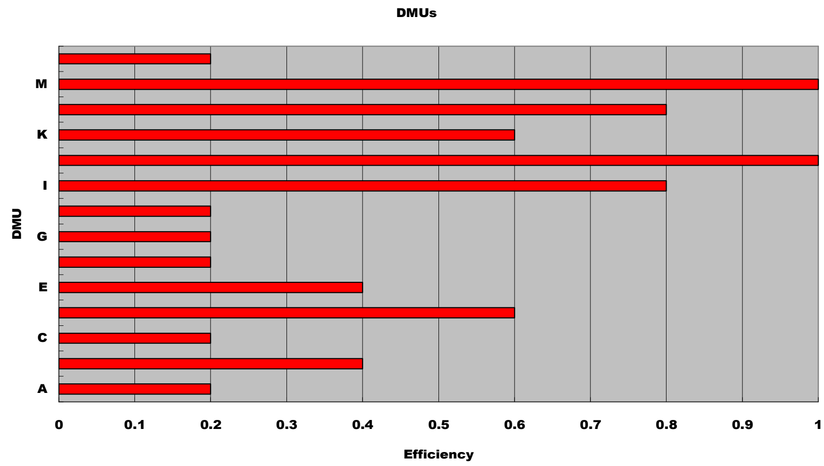

Figure 8 The comparisons of 14 DMUs

Benchmark analysis:

The purpose of Benchmark analysis is to examine DMUs with relative efficiencies that had been referred by the numbers of comparisons among other DMUs with inefficiencies. It is to be a foundation for inefficiencies DMUs to be improved in the future. Table.5 represents M and J is efficient DMUs, M however, had been referred 13 times of comparison by the others. Therefore, M is the Benchmark unit contributing the better value for the references of future improvement than unit J.

Table 7 The numbers of comparison between unit M and J

Unit name	Comparison 1	Other spaces referred
M	13	A, B, C, D, E, F, G, H, I, K, L, M, and N
J	1	J

Slack analysis:

Slack analysis is to provide the solutions and recommendations of improving DMUs with inefficiencies by understanding the differences between Inputs and Outputs variables. Unfortunately, this case study is limited by the data collections at the period of choosing Inputs and Outputs that can be firmly conducted in the future researches to complete the contributions of DEA applications for evaluating existing building performance in Taiwan.

Table 8 Slack analysis

No.	DMU	Score	Excess Cost S-(1)	Excess Employs S-(2)	Shortage IAQ S+(1)
1	A	0.2	29157	2	0
2	B	0.4	24514	2	0
3	C	0.2	11008	6	0
4	D	0.6	29157	2	0
5	E	0.4	29157	5	0

6	F	0.2	44658	15	0
7	G	0.2	64470	6	0
8	H	0.2	29157	14	0
9	I	0.8	0	3	0
10	J	1	0	0	0
11	K	0.6	29157	5	0
12	L	0.8	31011	2	0
13	M	1	0	0	0
14	N	0.2	98500	16	0
No.	DMU	Score	Excess Cost S-(1)	Excess Employes S-(2)	Shortage IAQ S+(1)

By DEA analyze, the DMUs with better efficiency are J and M, DMU A, C, F, G, H and N are relatively inefficiency. Therefore, DMU A can consider to dismiss two employees and to reduce 29,157 NT dollars of decorating cost for the improvement of the building efficiency.

5. Conclusion and Recommendations

The results of this study have paved an alternative for the evaluation model of "Life Cycle Cost" in building lifecycle for existing buildings in Taiwan to apply for the methodology of DEA as a new assessment tool. In the future, conducting the further researches on the diagnosis of existing buildings is needed to find (1) the impact factors for the quantitative evaluations of the Environmental Load as well as the analysis of building duration, (2) the Life Cycle Costing with DEA model for the evaluations of the existing building improvement in different phases, (3) that can be converted other factors of Indoor Environmental Quality into the phases of "Design", "Construction", "Use" and "Renovation" demonstrated a variety of building Performances, in order to effectively complete the cost evaluation of building overall features.

[2] Department of Architecture, National Cheng-Kung University, 704, Tainan City, Taiwan, ROC, cmchiang@mail.ncku.edu.tw

Keywords: multi-layer porous screen, ventilation, openings of dwelling, wind drop effect

Summary

It shows strongly relationship for living comfort among the surrounding topography, location patterns and the interface of the building when thinking about the natural ventilation of buildings. Taiwan, as Formosa, located on tropical of cancer with high temperature and humidity situation, and also caused mosquito disasters all over the year. Porous screen is one of the most effective applications for building openings to prevent the insects into the house. However, the ventilation efficiency will be cutting down for installing with these screens. (B.J. Taylor, 1999) This study focuses on the wind control strategy utilizing multi-layer porous screens in concerning of natural ventilation effects and to figure out the better strategy of porous screens. Both small scaled wind-tunnel experiments and computational fluid dynamics (CFD) method were taken to verify the characteristics of multi-layer porous screens. The layer was selected as popular used PVC screen with alumina frame and its opening ratio is 64.0% with 256 nets per square inches. The inlet velocities were set on 0.13m/s, 0.27m/.s, 0.57m/s, 1.0m/s, 1.36m/s, 2.0m/s, 3.0m/s and 10.0m/s types, and the layers were from one to nine. The results show that decline ratio with different layers gets a flat curve when installing with one to three layers, and more than 4 layers will have rapid down effects. More than 8 layers, the effect will be almost the same with 9 layers. Moreover, interlace of screens and wind inlet angle will be the most important control strategies when building ventilation design. The results can be effective reference to natural ventilation building with wide-open-openings installed with porous screens.

1. Introduction

Most buildings in Taiwan utilized porous screens on openings between indoor and outdoor environment to prevent harmful factors getting into rooms, such as insects and particles. There are also benefits in controlling the physical factors in subtropical region, which can reduce the inlet wind velocity, maintain thermal environment, cut down sunshine exposure, among other functions. However, it appears that the porous screen also worsen the indoor environment in most structures located in urban area operating natural ventilation. The characteristics of the porous material with the wind through were seen as some researches, (Hagen and Skidmore, 1971), (Perea,.1981), (P.J.Richards,1999) (Antonio, 2000) The results and conclusions show the wind flow through one-layer porous screen has the effect to cut down the wind velocity and it depends on the ratio of the net. The situation can be concluded as *Bernoulli's Equation*, and the following research made by Antonio show the Reynold Number will take the important role in viscosity effect.

However, the green building issues has rised to let the building research institute in Taiwan to review the construction and the envelop of the building to see the proper way for the region as Taiwan, with the typical climate. Thus, considering the building typology in south-east region or the traditional house located near the equator, such as the Indonesia or Malaysia, alomost all faces will be the ventilation inlet or outlet, and it really shows good thermal condition in hot and humid weather. At the same time, the building envelop in cold and temperate zone shows highly thermal capacity or the isolation to keep the heat in house, and the ventilation system will be installed to maintain the air-exchange. Taiwan, located in-between these two typical zone as hot-humid in summer and cold-humid in winter. Is there any suitable and effective solutions to face this kind of climate and create a better thermal condition for living? Therefore, the multi-layer porous screen concept will be proposed to verify the capability and performance when installed in typical dwelling.

This study therefore aimed to identify the effects of the multi-layer porous screen interfaces when the wind get in and how 's the characteristics for different number of the screens. The wind inlet volume can be the data to calculate the volume of the fresh air and estimate the indoor air and thermal conditions. I was hoped that such an conclusion could be applied to establish a new thoughts of building envelop.

2. Materials and methods

2.1 Selection of the porous screens

The climate in Taiwan usually is hot and humid, and the average relative humidity level is always more than 80% outside. Thus the selection of the porous screen used in Taiwan is the PVC net. This material has the advantages of flexible, cheap, easily to change and keep good looking. Therefore, this study tries to focus on the PVC material with multi-layer screens to test the characteristics of the wind cut-sown influence. The variables control as same material with same porous ratio in the same opening size, and each of the net has the same 2cm distance to combine together for testing. The characteristics of the screen are listed as follows:

Table1. The characteristics of the selected PVC porous screen

Selection of the PVC porous screen	The detail of the PVC porous screen	Definition of the characteristic	The detail specifications of the selected screen
		$\varepsilon = \frac{Ah}{At} = \left(1 - \frac{Tn}{Dn}\right)^2 = \left(1 - \frac{0.32}{1.6}\right)^2 = 0.64$	Porous ratio: 64.00% Width of the mesh: 1.6mm Height of the mesh: 1.6mm Width of the wire: 0.32mm Thickness of the wire: 0.32mm Per mesh area: 1.6384 mm^2 Numbers of the mesh per square inch: 16*16 = 256
The PVC wire is produced as round section and same diameter as	t=width of the mesh d=thickness of the PVC net	ε : porous ratio Ah : area per mesh At : area of the wires Dn : height of the wire Tn : diameter of the wire	

2.2 Small-wind-tunnel chamber experiment with full-scaled porous screen

In order to verify the wind effect of the multi-layer porous screens, and to measure the quantity data in a stable situation, small wind-tunnel chamber was taken with the full-scaled screens for several numbers of layers to measure the differences of the velocity in several before and after positions. The chamber was constructed by acrylic plates with 7 sampling points. The distance for each was set as 10 cm. In order to realize the velocity difference and profile, seven vertical sampling points in center of the width were measured. The steady tests were conducted to check for the stability of the system. After the validation of the system, five inlet velocities, 1.36m/s, 1.00m/s, 0.57m/s, 0.27m/s and 0.13m/s, were set for experiments. The layers of the porous screens were set from 1 to 9 layers, and there was 1 cm distance for each of the layer. The wind velocity was measured by TSI model 8346 hot-wire air-velocity meter. Figure 1 shows the structure of the chamber, and figure 2 shows the variables of the experiments.

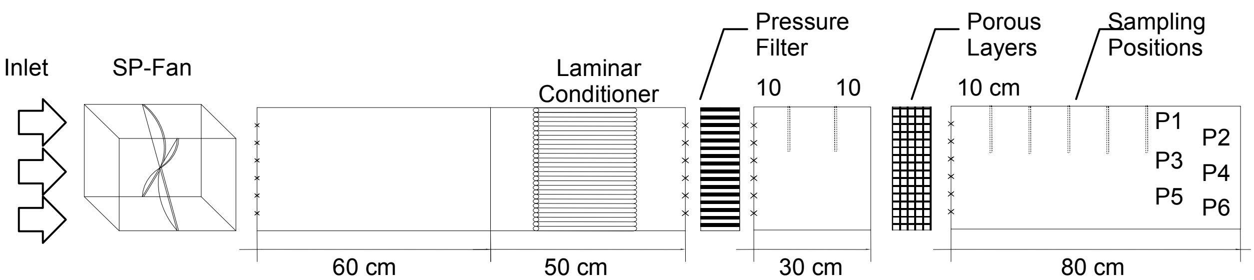

Figure 1 the small-wind tunnel chamber experiment with full-scaled porous screen

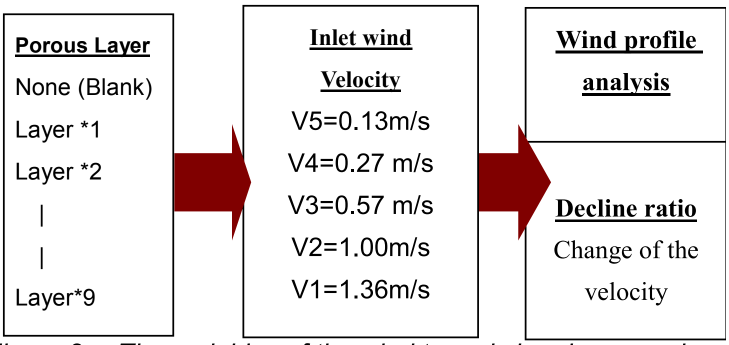

Figure 2 The variables of the wind tunnel chamber experiment

2.3 Computational Fluid Dynamics Simulation (CFD)

The numerical simulations of the current physical problem were performed using a finite volume method to solve the governing equations associated with the boundary conditions. Specifically, this study applied the SIMPLEST (semi-implicit method for pressure linked equations) algorithm to solve the pressure-linked equations using a hybrid scheme in order to calculate the convection and diffusion terms. The turbulence of the airflow was described by a standard k-ε model, in which k denotes the turbulent kinetic energy and ε the dissipation rate. Furthermore, the inlet airflow velocity was assumed to be normal and uniform across the section, no-slip boundary conditions were applied on the walls, and Neumann boundary conditions were applied for the velocity boundary conditions on the inlet side. No energy equation was applied. Iterative calculations were performed until residual values of 10^{-3} were obtained for all of the field variables. The calculating grids were set through optimized process with NX * NY * NZ ＝151 *138 *151. The inlet velocities were set as the experiment as 1.36m/s, 1.00m/s, 0.57m/s, 0.27m/s and 0.13m/s. The porosity of the porous screen was set for 0.64 and the boundary condition of the wire is set as no-slip on the surface. Figure 3 shows the CFD model of different layers.

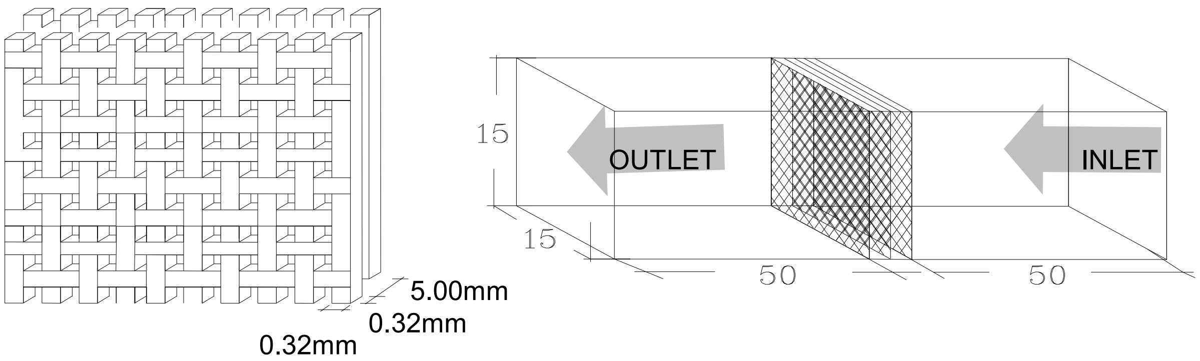

Figure 3 The CFD model for multi-layer porous screens

3. Results

3.1 Chamber test results

The experiment results are shown as figure 4 to figure 9. The characteristics of the wind effect through porous screen can be conducted as following results:

1. When the velocity is large than 0.8m/s, the more number of the layer used, the higher ratio of the wind declined effect, especially when the number of layers are large than three.
2. The wind velocity showed the semi-jet effect happened after the wind going through the porous screen. Especially just right the hole of the wires. However, the energy soon transferred and let the velocity became average.
3. When the velocity is less than 0.2m/s, and the difference of effects which caused by the layers are all weak.

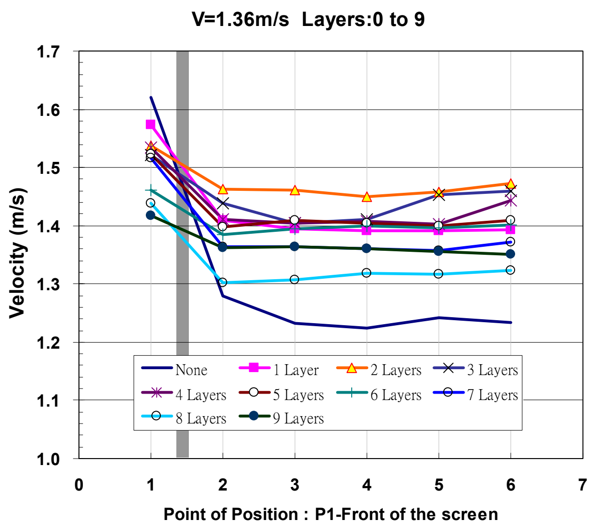

Figure 4 V=1.36m/s experiment results

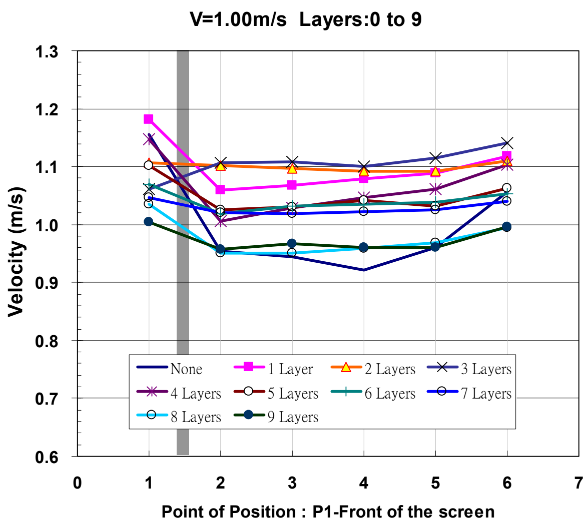

Figure 5 V=1.00m/s experiment results

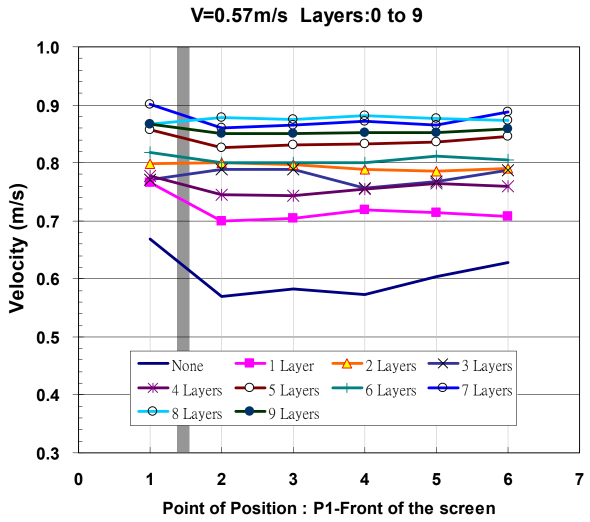

Figure 6 V=0.57m/s experiment results

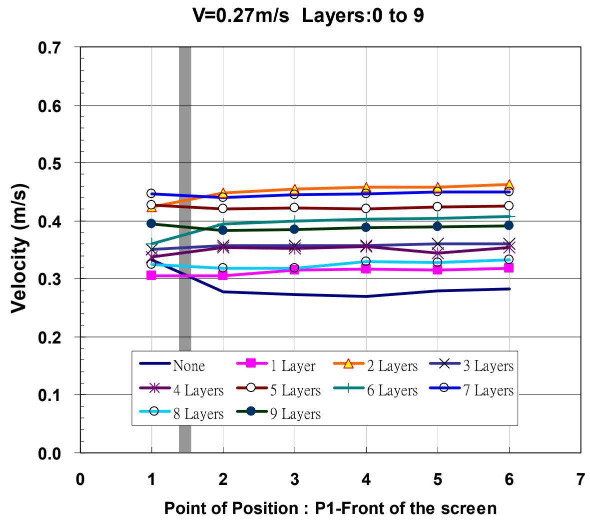

Figure 7 V=0.27m/s experiment results

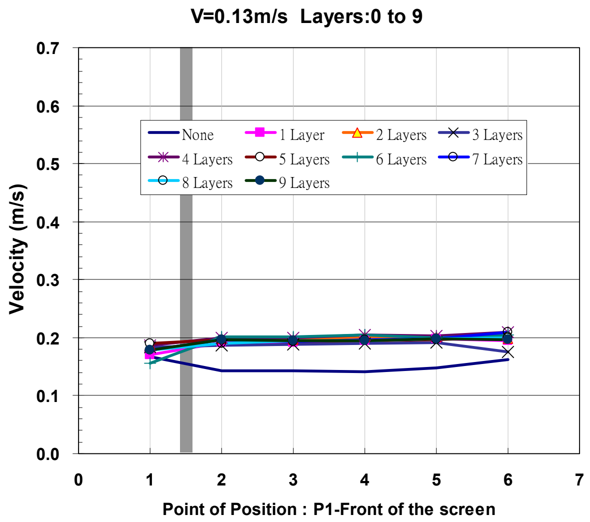

Figure 8 V=0.13m/s experiment results

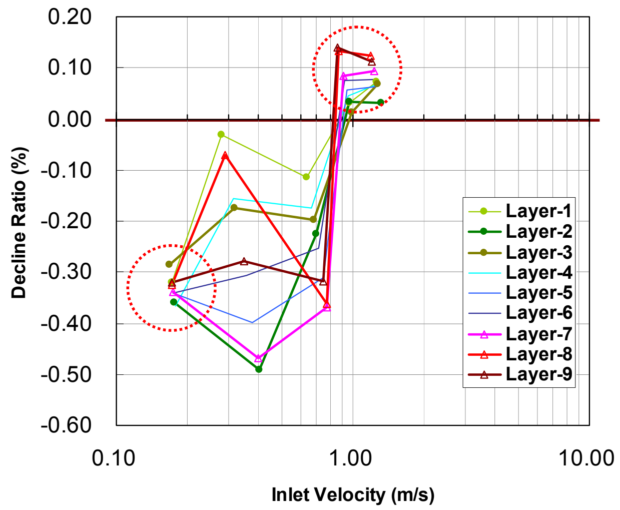

Figure 9 experiment results analysis

Figure 9 shows the relationship between decline ratio and inlet velocity. According to the results, the characteristics shows the decline effect happened, and the screens let the wind go through when the velocity is less than 0.8m/s. Furthermore, when the inlet velocity is higher than 1.0m/s, it shows the increasing velocity just after the porous screen. The chamber design for forced the same volume of the wind went through the chamber could be the reason to explain. The transformation of the energy and pressure could cause the effect.

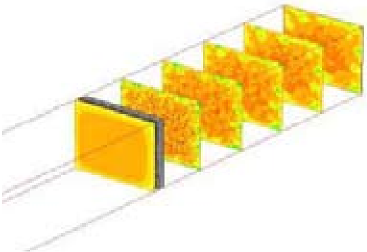
3.2 CFD solutions

In order to realize more about the wind situation, the CFD method was taken to check and visualize the possible situation. The results show that the wind distribution pattern in front of the screen has higher resistance effect in 8 to 9 layers than 1 to 2 layers. Moreover, the wind distribution after the screen shows the spotted focus area of the enforced wind acceleration, and the wind velocity mixed more and more well by the distance away from the screen. There are three results were conducted to explain the situation.

1. When the inlet wind velocity is lower than 0.5m/s, the decline ratio is getting almost the same with the lower velocity.
2. When the inlet wind velocity is larger than 2.0m/s, the decline effect is getting larger as the growth of both the velocity and the layers. Moreover, it shows a critical change at the screens with 4 layers.

Table2. the Y-section CFD results in one of the inlet velocity group V=1.36m/s

Cases	Front of screen	10 cm away after screen	20 cm away after screen	30 cm away after screen
Layer-01 V=1.36m/s				
Layer-02 V=1.36m/s				
Layer-03 V=1.36m/s				
Layer-04 V=1.36m/s				
Layer-05 V=1.36m/s				
Layer-06 V=1.36m/s				
Layer-07 V=1.36m/s				
Layer-08 V=1.36m/s				
Layer-09 V=1.36m/s				



Part of the model and Y-section

4. Discussions and Conclusions

The results show that decline ratio with different layers gets a flat curve when installing with one to three layers, and more than 4 layers will have rapid down effects. More than 8 layers, the effect will be almost the same with 9 layers. Through the CFD simulation, the characteristics of the wind through the porous screens may be conducted as the following figure 10. There apparently is the critical change of the flow pattern for low wind speed and high wind speed. The energy transfer and consuming caused by the wire friction can be the answer. Therefore, the slight wind can let the wind passed with full development of the wind profile, and the strong wind could be developed as a mountain shape. However, if the multi-layer porous screen interface has been adopted with interlace setting, the strong wind could be interrupted for the development of the wind profile, and it caused more energy consumption. It can be conducted with utilizing the PVC screens with regular 66% porosity as multi-layer interface, and the distance for each screen is set as 5mm, there will be the three flow types: 1. Friction effect: the wind velocity less than 0.5m/s. 2. Pressure resistance effect: the wind velocity is higher than 1.00m/s. and the 3.Mixed situation: the friction resistance almost equals to pressure resistance effect at the range of 0.57m/s to 1.00 m/s.

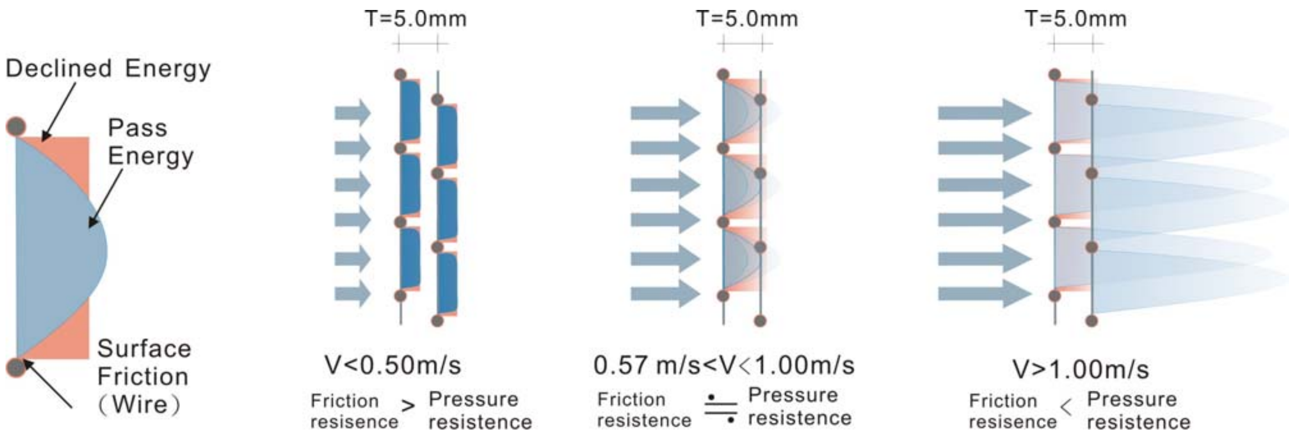


Figure 10 experiment results analysis

Moreover, interlace of screens and wind inlet angle will be the most important control strategies when building ventilation design. The results can be effective reference to natural ventilation building with wide-open-openings installed with porous screens. The conclusions can be a good impact to rethink the interface of the outdoor wall with the necessity of screen using in Taiwan. The “slight wind come and strong wind cut” with large and effective openings will be the best usage for the housing design in sub-tropical region.

Keywords: Residential energy consumption, Household type distribution, Energy-saving measures

Summary

Energy consumption in the residential sector of Japan was modeled on a nation-wide scale. In this study, we estimated the energy consumption and CO_2 emissions from 2005 to 2025, considering the change in various parameters with time. In addition, we evaluated the effect of implementing energy conservation measures in this period, such as improving the thermal insulation in buildings, introducing high-efficiency water heaters and distributed generation systems, and changing the preset temperature. If all the energy-saving measures are implemented by 2025, the energy consumption and CO_2 emissions will be reduced by 41.1% and 50.5%, respectively, as compared to the 2005 levels. Consequently, it was proved that only a combination of measures that are already feasible will have a drastic effect in 2025.

1. Introduction

In Japan, the energy consumption in the residential sector has increased steadily in response to the increase in the standard of living, which has resulted in larger houses, widespread use of various types of appliances, and increase in the number of small families. In the last 25 years, energy consumption in this sector has doubled, while the population has increased by only 10% (The Energy Conservation Center, 2002).

Consequently, the “Guideline for Measures to Prevent Global Warming,” adopted by the Japanese government in March 2002, aims to maintain CO_2 emissions related to energy usage at the 1990 levels. In April 2005, the “Kyoto Protocol Target Achievement Plan” was also adopted. By improving the energy efficiency of household appliances and improving buildings’ thermal insulation, the objective of the plan was to reduce CO_2 emissions from the residential sector to a level that is only 6% higher than that in 1990. A revision of the “Law Concerning Rational Use of Energy” established one of the highest energy efficiency standards in the world for appliances. The standard, commonly referred to as the “top runner standard,” required that the average energy efficiency of an appliance manufactured in 2004 had to be higher than that of the most efficient model manufactured in 1999. This standard was revised in 2005 to extend its application to a greater variety of appliances. In addition to the top runner standard, the Guideline for Measures to Prevent Global Warming prescribed a variety of energy conservation measures, including increasing energy efficiency of residential buildings, reducing standby power consumption, and promoting the use of high-efficiency water heaters. The program also encouraged changing the consumer behavior, such as changing the preset temperature, encouraging family members to spend more time together in the living room, and reducing the time watching TV (Global Warming Prevention Headquarters, 2002).

Thus far, we have evaluated the potential of various energy-saving measures. However, these evaluations are not realistic because all the measures have been implemented at once. We have to consider the update rate of houses or home appliances stock to evaluate the measures practically.

In this study, we evaluate the effect of introducing 7 energy-saving measures—improving energy efficiency of household appliances, improving thermal insulation in buildings, introducing high-efficiency water heaters and distributed generation systems, changing preset temperature, and all family members watching TV together—for a long period from 2005 to 2025, considering the rate at which each measure is implemented.

2. Simulation Model

2.1 Structure of End-use Simulation Model

The authors developed an original bottom-up model to simulate the city-scale energy consumption in the residential sector considering various types of households and buildings. In the simulation, the annual energy consumption of one household is calculated iteratively for 19 household categories and 12 building categories, six of which were classified as detached houses and the other six as apartments depending on the floor area. In addition, four different thermal insulation levels in buildings were considered. In the model for appliance energy consumption, the energy consumption of each appliance was simulated separately, which depended on the consumer behavior. For heating and cooling of rooms, dynamic heat load simulations were carried out using both building data and weather data. The ventilation and heat conduction between rooms were determined using a thermal circuit network. Heat loads were simulated relative to the internal heat gain, which was calculated using the appliance energy consumption model and the behavior of the family members. The time step of the heat load and energy consumption simulations was 5 min.

The total residential energy consumption in the target region was estimated by multiplying the simulated energy consumption by the number of households in each category and summing up the results. Further, it was confirmed that the results of our model was in a good agreement with actual data (Shimoda Y, 2007).

2.2 Structure of Stock Simulation Model

The authors have previously developed a "stock model" (Shimoda Y, 2007), which has been used in this study to estimate the average energy efficiency of appliances and the distribution of buildings' thermal insulation levels in the target region. This model enables us to generate input data, e.g., the average energy efficiency of appliances, for the target year. Figure 1 shows the change in the efficiency of appliances estimated by the stock model.

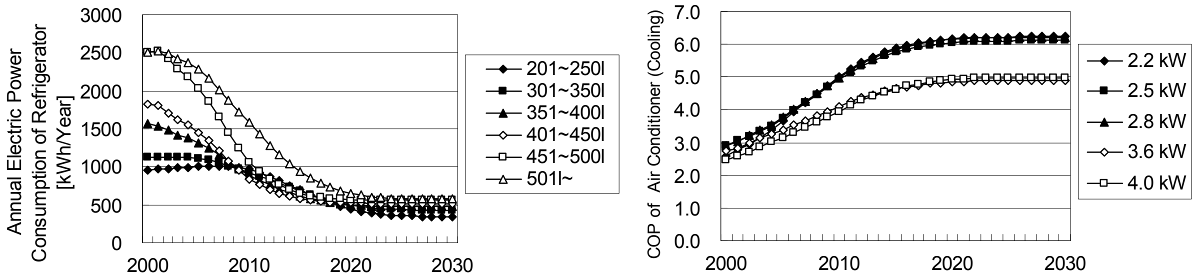

Figure 1 Change in efficiency of appliances (left: refrigerator, right: room air conditioner)

3. Simulation Results for 2005

3.1 Region-wise Classification and Major Cities

The climate of Japan varies significantly from north to south. In addition, the standards set by the Law Concerning Rational Use of Energy with regard to households vary for different regions. Therefore, when we calculated the energy consumption in the Japanese residential sector, we divided the entire country into small regions, calculated the energy consumption in each region and then summed up the results.

Table 1 lists the region-wise classification based on the Law Concerning Rational Use of Energy and the major cities, which are the most populous cities in the region. We used the weather data from the major cities and the others from the prefectures included in the regions.

Table 1 Region-wise classification and major cities

	Prefectures in the Region	Major Cities
I - 1	Eastern Hokkaido	Asahikawa
I - 2	Western Hokkaido	Sapporo
II	Iwate, Aomori, Akita	Morioka
III - 1	Miyagi, Fukusima, Yamagata	Sendai
III - 2	Ibaragi, Tochigi, Gunma, Yamanashi	Utsunomiya
III - 3	Niigata	Niigata
III - 4	Toyama, Isikawa, Fukui, Shiga	Otsu
III - 5	Nagano	Nagano
IV - 1	Saitama	Urawa
IV - 2	Chiba, Tokyo, Kanagawa, Shizuoka	Tokyo
IV - 3	Gifu, Aichi, Mie	Nagoya
IV - 4	Kyoto, Nara	Kyoto
IV - 5	Osaka, Hyogo, Wakayama	Osaka
IV - 6	Tottori, Shimane, Okayama, Hiroshima, Kagawa, Ehime, Tokushima, Kochi	Hiroshima
IV - 7	Yamaguchi, Fukuoka, Saga, Nagasaki, Kumamoto, Oita	Fukuoka
V	Miyazaki, Kagoshima	Kagoshima
VI	Okinawa	Naha

3.2 Parameters Examined for Each Region

The parameters that have been examined for each region are as follows:

- Thermal resistance of insulation
- Duration of heating and cooling
- Proportion of different energy sources used for heating rooms and water
- Heating schedule at nigh in Hokkaido
- Number of households in each category
- Weather data
- Relative proportion of room air conditioners and electric heaters
- Frequency of bathing
- Equation for estimating city water temperature

From the Proceedings of the World Conference SB08 - ISBN 978-0-646-50372-1 www.sb08.org

- Number of appliances

3.2.1Thermal Resistance of Insulation

Heating and cooling loads were simulated for four levels of thermal insulation: no insulation, insulation up to the 1980 standard, insulation up to the 1992 standard, and insulation up to the 1999 standard. The values of thermal resistance of insulation for the exterior walls of the buildings in each region are listed in Table 2. We assumed that there were no houses with no insulation in Hokkaido and made original standard; below 1980.

Table 2 Thermal resistance of exterior wall insulation

	Thermal Resistance [$m^2 \cdot K/W$] (Apartment)						Thermal Resistance [$m^2 \cdot K/W$] (Detached House)					
	Region I	Region II	Region III	Region IV	Region V	RegionVI	Region I	Region II	Region III	Region IV	Region V	RegionVI
Below 1980	0.56	-	-	-	-	-	1.10	-	-	-	-	-
1980 Standard	1.13	0.75	0.75	0.50	0.00	-	2.20	0.90	0.90	0.60	0.00	-
1992 Standard	1.72	0.95	0.95	0.77	0.52	0.00	2.49	0.95	0.95	0.86	0.52	0.00
1999 Standard	2.30	1.80	1.10	1.10	1.10	0.30	3.30	2.20	2.20	2.20	2.20	2.20

The energy consumption in heating and cooling for each category of household and buildings was obtained from the weighted average of the simulation results for each thermal insulation level relative to the proportion of each thermal insulation level estimated using our stock model (Figure 2). Since there was no regulation regarding buildings' thermal insulation in Japan, the proportion of houses that conformed to the 1992 and 1999 standards was very less.

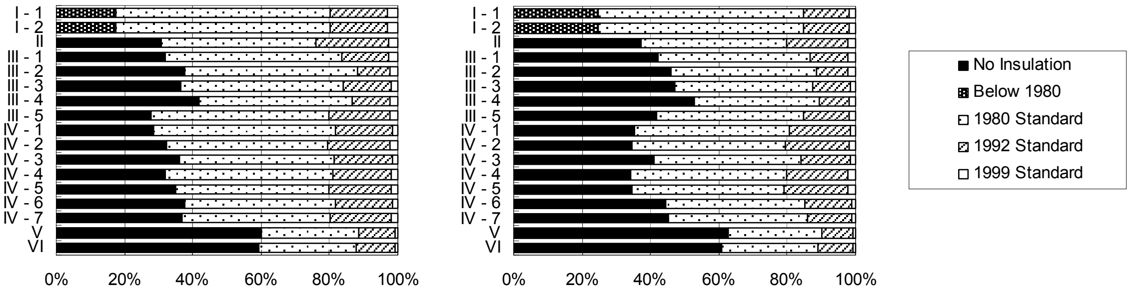

Figure 2 Proportion of different thermal insulation levels (left: apartments, right: detached houses)

3.2.2 Duration of Heating and Cooling

The duration of heating and cooling was defined as for SMASH; the Japanese residential thermal load calculation model.

3.2.3 Proportion of Energy Sources Used for Heating and Hot Water

The proportion of energy sources used for heating and hot water (electricity, city gas, and kerosene) was obtained from the Annual Report on Residential Energy (Tables 3 and 4).

Table 3 Energy sources used for heating

	Electricity	City Gas	Kerosene
Hokkaido	6.3%	33.6%	60.1%
Tohoku	8.2%	47.0%	44.9%
Kanto	4.4%	83.0%	12.6%
Hokuriku	15.8%	60.7%	23.5%
Tokai	12.7%	72.8%	14.5%
Kinki	7.8%	81.6%	10.5%
Chugoku	18.8%	54.2%	27.0%
Shikoku	19.9%	53.3%	26.8%
Kyusyu	14.4%	61.2%	24.4%

Table 4 Energy source used for heating water

	Apartment			Detached House		
	Electricity	City Gas	Kerosene	Electricity	City Gas	Kerosene
Hokkaido	4.6%	1.6%	93.8%	4.0%	1.6%	94.4%
Tohoku	9.7%	3.6%	86.7%	8.6%	3.6%	87.8%
Kanto	36.4%	23.7%	39.9%	37.2%	23.4%	39.4%
Hokuriku	30.9%	18.7%	50.5%	35.7%	17.4%	46.9%
Tokai	18.6%	20.0%	61.4%	13.6%	21.2%	65.2%
Kinki	47.7%	18.8%	33.5%	49.5%	18.1%	32.4%
Chugoku	36.3%	10.6%	53.2%	38.0%	10.3%	51.7%
Shikoku	38.1%	8.8%	53.1%	39.8%	8.6%	51.6%
Kyusyu	32.8%	10.1%	57.1%	33.2%	10.0%	56.7%

3.2.4 Heating Schedule at Night in Hokkaido

In this model, heating/cooling at night was estimated using a timer-controlled operation. In Hokkaido, it was assumed that heating continued throughout the night.

3.3 Annual Energy Consumption in Residential Sector

Figure 3 shows the simulation results for energy consumption per household and per person. Interestingly, the energy consumption per household for heating and cooling vary significantly for different regions, while the energy consumption for other purposes was considerably low. Further, the energy consumption for heating was high in I-1, II, III-3, III-4, and III-5, while the energy consumption was considerably low in I-2 and III-2, despite the regions being located in a cold area. The reason for this apparent anomaly is I-2 and III-2 have a high proportion of apartments.

The difference in energy consumption per household has been found to be higher than that per person. This is because it is the average number of people per household that affects the energy consumption.

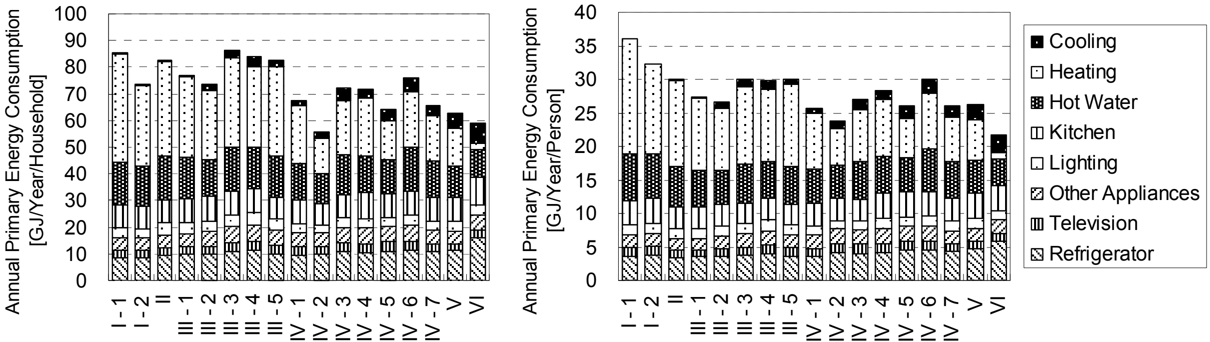

Figure 3 Simulated annual primary energy consumption (left: per household, right: per person)

4. Simulation Results for the Period 2005-2025

4.1 Parameters Examined for Each Year

The parameters that have been examined for each year are as follows:

- Number of households in each category
- Proportion of different thermal insulation levels of house stock
- Number of appliances
- Efficiency of appliances
- Proportion of energy sources used for heating rooms
- Electric power generation efficiency and CO_2 emission rate during electricity generation

4.1.1 Number of Households in Each Category

The numbers of households in each category for the period 2005–2025 were estimated on the basis of the estimation results obtained from the "National Institute of Population and Social Security Research." Initially, we estimated the number of households in each category in a prefecture and summed up the results to obtain the number of households in each category for the 17 regions. Figure 4 shows the change in the number of households in each category in Japan.

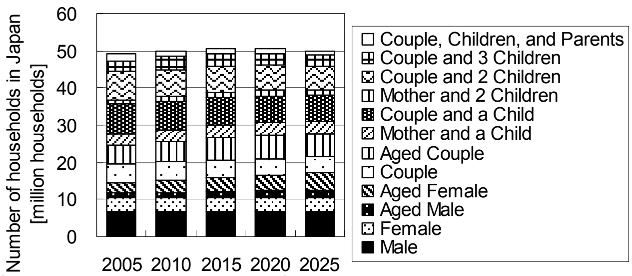

Figure 4 Change in the number of households in each category in Japan

4.1.2 Proportion of Different Thermal Insulation Levels of House Stock

The proportion of different thermal insulation levels of house stock for the period 2005–2025 was estimated by accumulating data of new houses considering house type, thermal insulation level, lifetime function, and the year in which they were built. Figure 5 shows the proportion of different thermal insulation levels, for example, in Tokyo.

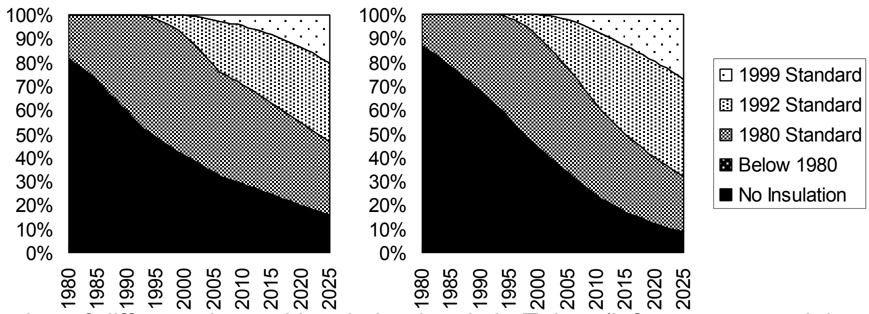

Figure 5 Proportion of different thermal insulation levels in Tokyo (left: apartment, right: detached house)

4.1.3 Number of Appliances

Figure 6 shows the change in the numbers of some appliances for the period 2005–2025, which were estimated by classifying the appliances into 3 groups: (1) Constant appliances which spread enough, (2) gently increasing appliances which spread in part, and (3) increasing appliances which not spread.

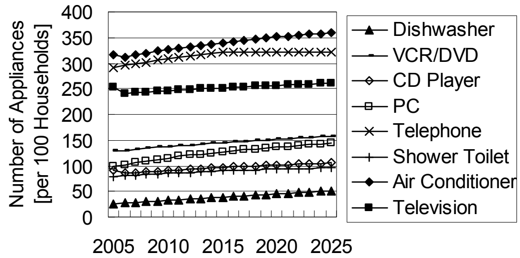

Figure 6 Change in the number of appliances for the period 2005–2025

4.1.4 Efficiency of Appliances

The efficiency of TVs, PCs, refrigerators, VCR/DVDs, and air conditioners for the years 2005 and 2025 was estimated. The efficiency of other appliances did not change. The efficiency was estimated by accumulating data of new appliances considering type, efficiency, lifetime function, and the year of manufacturing (Table 5).

Table 5 Efficiency of appliances

	Power Consumption [W]					
	TV		VCR/DVD		PC	
	Operating	Standby	Operating	Standby	Operating	Standby
2005	114	1.6	23	3.7	58	2.0
2025	198	0.5	26	4.2	52	1.2

	Annual Electric Power Consumption of Refrigerator [kWh/Year]					
	201~250l	301~350l	351~400l	401~450l	451~500l	501l~
2005	1002	1116	1320	1446	2031	2291
2025	356	437	475	515	556	582

	COP of Air Conditioner									
	Cooling					Heating				
	2.2 KW	2.5 KW	2.8 KW	3.6 KW	4.0 KW	2.2 KW	2.5 KW	2.8 KW	3.6 KW	4.0 KW
2005	3.65	3.73	3.78	3.40	3.16	3.96	4.10	4.08	3.93	3.47
2025	6.22	6.10	6.21	4.89	4.99	6.71	6.53	6.52	5.70	5.58

4.1.5 Proportion of Energy Sources Used for Heating

We converted the energy consumption of each source in statistics into demand, and the proportion of demand was set as the proportion of energy source for heating. The proportion of energy sources for the future was estimated from the past trend. Figure 7 shows the change in the proportion of energy sources in Hokkaido and Tokyo.

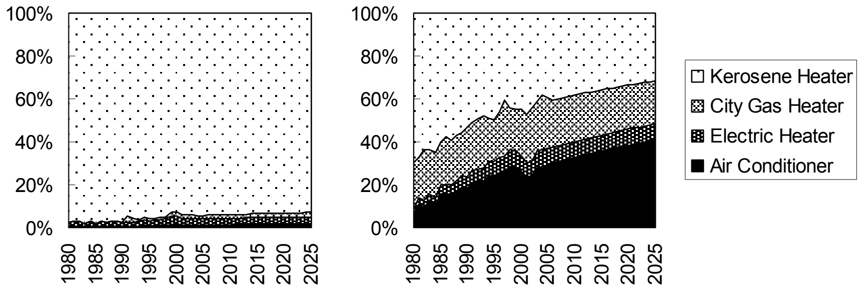

Figure 7 Change in the proportion of energy sources used for heating (left side: Hokkaido, right side: Tokyo)

4.1.6 Electric Power Generation Efficiency and CO_2 Emission Rate during Electricity Generation

We set the electric power generation efficiency and CO_2 emission rate for the future on basis of the target values for 2015 by different electric power generation companies (Figure 8).

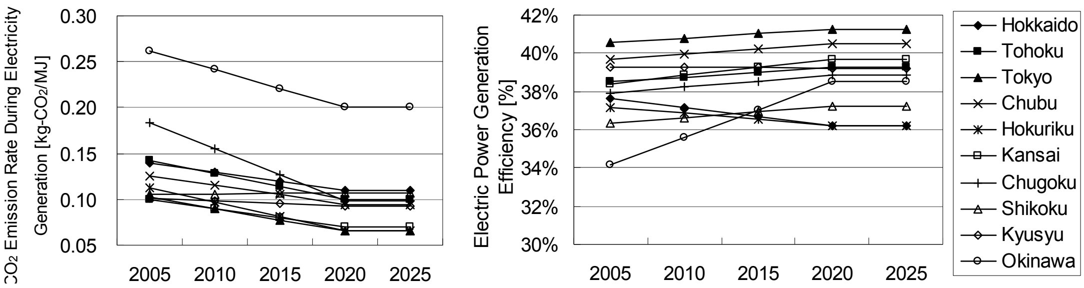

Figure 8 Electric power generation efficiency and CO_2 emission rate during electricity generation

4.2 Annual Energy Consumption in Japanese Residential Sector

Figure 9 shows the simulation results for the energy consumption in Japan. In Japan, the energy consumption in the residential sector changed from 3311 to 2649 [PJ/Year], and the proportion of change was –20.0%. This change was influenced by the population, number of households in each category, efficiency of electric power generation, etc. Figure 10 shows the various factors influencing the change in energy consumption from 2005 to 2025.

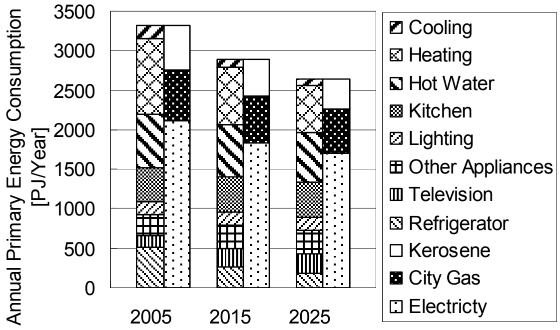

Figure 9 Annual primary energy consumption

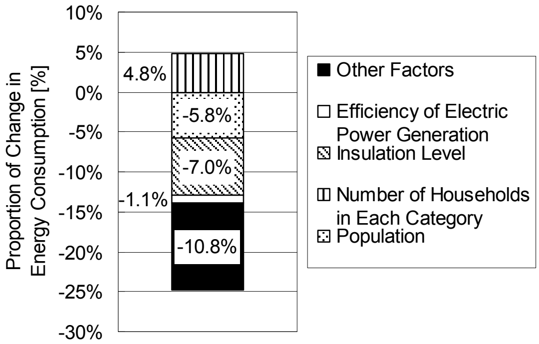

Figure 10 Proportion of change in energy consumption

5. Evaluation of Long-term Effects of Energy-saving Measures

The effects of the energy-saving measures have been evaluated for the period from 2005 to 2025, considering the update rate of houses or household appliances stock. The measures are as follows:

- Step 1: Setting an energy efficiency standard for household appliances
- Step 2: Improvement in buildings' thermal insulation
- Step 3: Introduction of high-efficiency water heaters and distributed generation systems
- Step 4: Introduction of HEMS (Home Energy Management System)
- Step 5: Change in the type of house—from a detached house to an apartment
- Step 6: Change in preset temperature
- Step 7: All family members watching TV together

These measures are implemented in the order mentioned above. From steps 1 to 5, the measures can be implemented without affecting the quality of life, but the measures in steps 6 and 7 affect the quality of life.

5.1 Step 1: Setting an Energy Efficiency Standard for Household Appliances

In this step, we set an additional top runner standard and evaluated the effects. Table 6 shows the efficiency and power consumption of various appliances.

Table 6 Efficiency of appliances (step1)

Annual Electric Power Consumption of Refrigerator [kWh/Year]					
201~250l	301~350l	351~400l	401~450l	451~500l	501l~
320	370	394	422	432	462

Power Consumption [W]						COP of Air Conditioner									
TV		VCT/DVD		PC		Cooling					Heating				
Operating	Standby	Operating	Standby	Operating	Standby	2.2 KW	2.5 KW	2.8 KW	3.6 KW	4.0 KW	2.2 KW	2.5 KW	2.8 KW	3.6 KW	4.0 KW
145.5	0.10	32	2.0	51	1.2	6.47	6.25	6.36	5.26	5.19	6.76	6.51	6.60	5.68	5.65

5.2 Step 2: Improvement in Buildings' Thermal Insulation

In this step, all new houses built after 1999 conform to the 1999 standard. Figure 11 shows the proportion of different thermal insulation levels in Tokyo calculated by our stock model for this step.

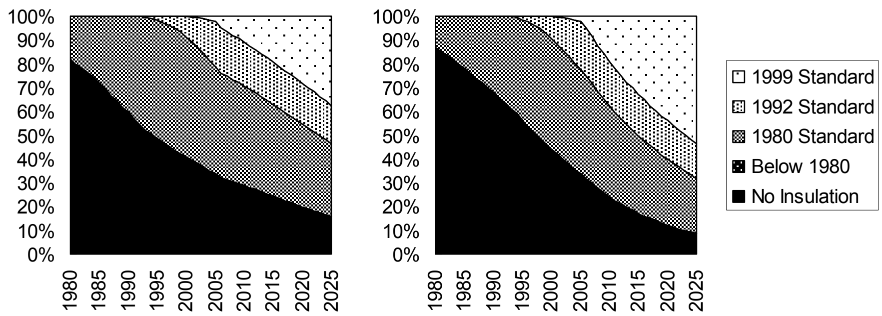

Figure 11 Proportion of different thermal insulation levels in Tokyo (left: apartment, right: detached house)

5.3 Step 3: Introduction of High-efficiency Water Heaters and Distributed Generation Systems

In this step, we evaluated the effect of the introduction of high-efficiency water heaters and distributed generation systems, such as a high-efficiency gas water heater (HEGWH) that can recover the latent waste heat, solar thermal water heater (STWH), heat pump water heater (HPWH), and micro gas engine cogeneration system (MGECGS). Initially, we calculated the energy consumption for each household when a system was introduced and determined suitable systems for each household for reducing CO_2 emissions. Then, assuming that the lifespan of water heaters were around 10 years and all water heaters have to be replaced in 2025, we calculated the energy consumption in the Japanese residential sector and evaluated the effect when the suitable systems were introduced in all households. Figure 12 shows the proportion of suitable systems in each region for the reduction in CO_2 emissions.

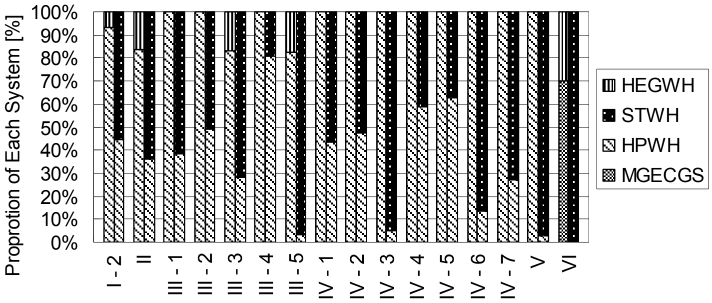

Figure 12 Proportion of systems in different regions (left bar: apartment, right bar: detached house)

5.4 Step 4: Introduction of HEMS

In this step, we evaluated the effect of the introduction of HEMS. By the introduction of HEMS, the standby energy consumption of some appliances was reduced, and thermal insulation mode of electric pots and rice cookers was set off as it was not required.

5.5 Step 5: Change in House Type—from Detached House to Apartment

In this step, we increased the proportion of apartments by using an estimation method (Figure 13).

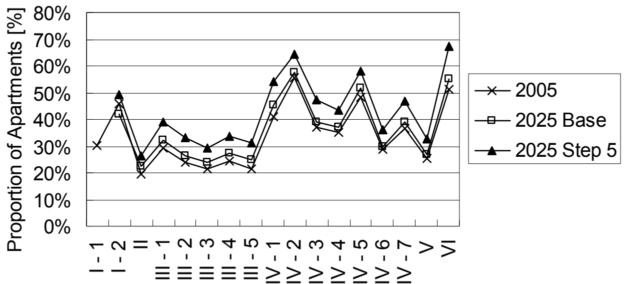

Figure 13 Proportion of apartments

5.6 Step 6: Change in Preset Temperature

The implementation of this measure affects the quality of life. In this step, the heating and cooling preset temperatures were changed as listed in Table 7.

Table 7 Preset temperature

	Heating [°C]		Cooling [°C]	
	Base Case	Step 6	Base Case	Step 6
No Insulation	18	18		
Below 1980	20	19		
1980 Standard	21	20	27	28
1992 Standard 1999 Standard	22	21		

5.7 Step 7: All Family Members Watching TV Together

In this step, the family members watch TV and relax together in the living room in order to reduce the energy consumption of TVs, lighting, and heating or cooling.

5.8 Results of Each Step

Figure 14 shows the results of each step. It reveals that we could bring out a gradual reduction in the energy consumption and CO_2 emissions. In the business as usual case (BAU), CO_2 emissions reduced by 27.2% as compared to the 2005 level because of the change in various parameters such as efficiency or diffusion of household appliance, thermal insulation levels in buildings, and population. In step 1, CO_2 emissions reduced by 29.4% as compared to the 2005 level because of the enhancement of the efficiency of appliances. In step 2, by improving buildings' thermal insulation, CO_2 emissions reduced by 30.4% as compared to the 2005 level. In step 3, CO_2 emissions reduced drastically by 43.0%; hence, the introduction of high-efficiency water heaters and distributed generation systems were highly effective in saving energy. In step 4, since the standby energy consumption of some appliances has reduced by the introduction of HEMS, CO_2 emissions reduced by 45.3% as compared to the 2005 level. In step 5, by increasing the proportion of apartments, CO_2 emissions reduced by 47.5% as compared to the 2005 level. In step 6, by changing the preset temperature of heating and cooling, the energy consumption due to air conditioning reduced and CO_2 emissions also reduced by 48.6% as compared to the 2005 level. In step 7, because the energy consumption of TVs, lighting, heating, and cooling reduced due to the family members spending more time in the same room, CO_2 emissions reduced by 50.5% as compared to the 2005 level.

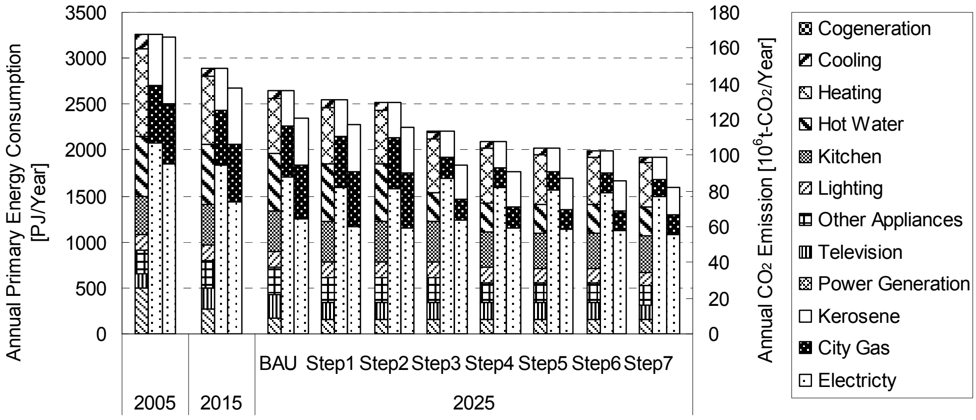

Figure 14 Annual primary energy consumption and CO_2 emissions in each step (left bar: energy consumption based on use, middle bar: energy consumption based on sources, right bar: CO_2 emissions)

6. Conclusion

In this study, the implementation of energy conservation measures in the Japanese residential sector was evaluated for a long period using a residential energy end-use model developed by us. We estimated the practical reduction in energy consumption associated with the implementation of 7 energy-saving measures—setting an energy efficiency standard for household appliances, improvement of thermal insulation in buildings, introduction of high-efficiency water heaters and distributed generation systems, introduction of HEMS, changing house type from a detached house to an apartment, changing preset temperature, all family members watching TV together—which were implemented in succession.

As a result, the annual primary energy consumption and CO_2 emissions reduced by 37.8% and 47.5%, respectively, as compared to the 2005 levels in step 5, in which all energy-saving measures were implemented without affecting the quality of life. Then, in step 7, in which all measures were implemented, the annual energy consumption and CO_2 emissions reduced by 41.1% and 50.5%, respectively, as compared to the 2005 levels.

Summary

Since 2003, a national research program has been launched to renovate the HVAC systems of governmental buildings. Up to the year of 2007, 97 projects have been completed, with Chiller plant over-design capacity reduced in 3,000 RT, and overall energy savings of 24%. The budget spent on actual engineering cost was around 20 million US Dollars, with an average payback of 5 years.

This paper highlights the essence and most important points during the retrofitting process, and is discussed in detail with demonstrative examples.

1. INTRODUCTION

Being located in subtropical area, the weather in Taiwan is constantly hot and humid, with ambient temperature around 35℃ and relative humidity of 85%, which imposes heavy cooling load on commercial buildings. In 2003, the Ministry of the Interior (MOI), Taiwan decided to conduct an HVAC renovation program for the existing HVAC systems of governmental buildings. This program not only constructs an important step in responding to the national movement toward the Green Building concept, but to the quest of Kyoto protocol on energy savings and CO2 emission reductions.

It is a common problem in Taiwan that HVAC systems were designed with rough hand calculation methods, instead of using detailed computer simulation process, so that chiller plants were very often, over-sized. An over-sized chiller, which runs under a very low partial load factor, will suffer from poor energy efficiency, and results in higher operation cost in addition to the excessive investment in installation. This kind of chiller plant not only needs to be downsized, but should also adapt a better-fitted chiller size combinations so that optimal operational strategies can be applied during various load conditions.

In addition, chilled water distribution system was normally designed with constant speed pumps, which runs on their maximum capacities all the time, no matter how cooling load was fluctuating. A Variable Water Volume, or VWV system, which can change the pumping speed by inverters should be adapted, so that pumping power can be saved during low load conditions.

Furthermore, some ice storage air-conditioning systems, which can shift the on-peak power demand to off-peak hours and thus saves tremendous amount of operating cost, had been removed from commercial operation due to lack of proper maintenances, presenting a huge loss of the investment. To restore these systems, it takes a lot of technical challenge and innovation, but the result could be very fruitful. In this paper, the restoration and revival of such an Ice storage system in the NMMR Aquarium has been selected as a demonstrative example to explain the whole procedure.

2. RENOVATION PROCEDURE

After this program was officially launched, applicants all around the country sent in their basic data of HVAC systems for evaluation. Following the selection criteria, in considering the chiller plant capacity and number of years of operation, significance of operation cost, a handful of candidates were selected for the first run of field survey. The chiller plant energy auditing would then be performed to construct the baseline data, in recording the cooling capacity provided using temperature sensors and ultra-sonic flow meters . The accumulated cooling capacity provided was then compared with the power consumption to yield the COP (Coefficient of Performance) of each chiller. The measured COP value creates a solid figure where it can be compared with the COP threshold value issued by the Bureau of Energy. Later on, a comparison between the COPs before and after renovation, energy savings effect can be realized quantitatively and accurately .

This selection process to estimate the energy savings potential, and thus priorities for renovation, is a typical bottom-up procedure. As the old Chinese saying depicts: "To catch the thieves, catch the Chief first."

Furthermore, the scope of the renovation work would then be determined by the research team, such as to replace the chiller , to convert it into an VWV or VAV system , or to renovate the cooling towers, etc, with engineering budget allocated accordingly. The total budget was finally allocated and fine-tuned in considering the balance among the northern, central, and southern parts of the country and then offered for open bids. This Green HVAC Drive also provided a lot of good business opportunities for the local HVAC industry and was highly welcome.

3. RESULTS AND OUTCOME OF THE PROGRAM

3.1 Chiller Plant Oversize Reduction

The chiller plant of each renovation project has been carefully simulated and re-calculated, using DOE 2.1, a computer program developed by the Department of Energy in the U.S., as a tool, to achieve a new chiller combination, so that each seasonal cooling demand can be met with energy-efficient operation modes.

For example, in the NPNU project, the administration center is a 10-story building. The chiller plant, originally equipped with 2 sets of 15-years-old 500 RT centrifugal chillers, was replaced with 3 chiller sets, including a 180 RT, 300RT, and 400RT capacity each. The new chiller plant total capacity is thus reduced by 12% accordingly. And the new chillers, with higher energy efficiency in complying with the COP criteria, saves tremendous energy and operation cost as shown in figure 1. In addition, the new chiller plant has a better combination in operating its multiple chillers as shown in figure 2. For example, in the winter, the 180 RT chiller alone, will operate, which accounts for 32% time of the year. Originally, this would have to be done by operating the 500 RT chiller, but in an exceedingly low load factor of 40%, resulting in low energy efficiency and mechanical problems. In intermediate seasons, such as in spring and fall, the 300 RT or the 400 RT chiller should be able to take care of the cooling load, accounts for 49% time of the year. While in hot summer, based on the historical operation data, the 480 RT chiller combination should be able to meet the peak cooling demand, counting for 19% of the total operating hours. Even in rare cases, in an extra-ordinary hot summer due to the global warming effect, the 180 + 400 , or 580 RT chiller combination will be able to meet the exceedingly hot summer demand, representing a safety factor of around 20%, unlike the original design, claiming for 100% redundancy all the time. In addition, the actual cooling capacity under operation modes now, is 580 RT vs. the original 1000 RT, or a 42% reduction! The chiller plant is now operating under its optimal conditions all year round ---thanks to the computer simulation in predicting the seasonal cooling load conditions beforehand, and the timely renovation process to cut down the chiller sizes and to reach a smarter combination.

The whole renovation program within 4 years results in an overall chiller oversize reduction of 3000 RT, or accounts for 21% of the total cooling plant capacity, with 24% energy efficiency improvement.

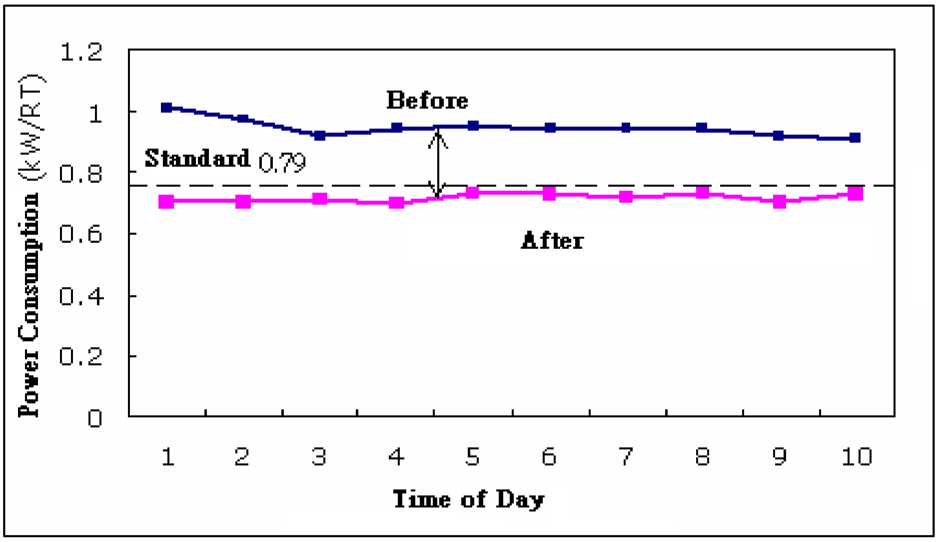

Figure 1 The Comparison of Chiller performances before and after renovation indicating an 23% energy savings effect

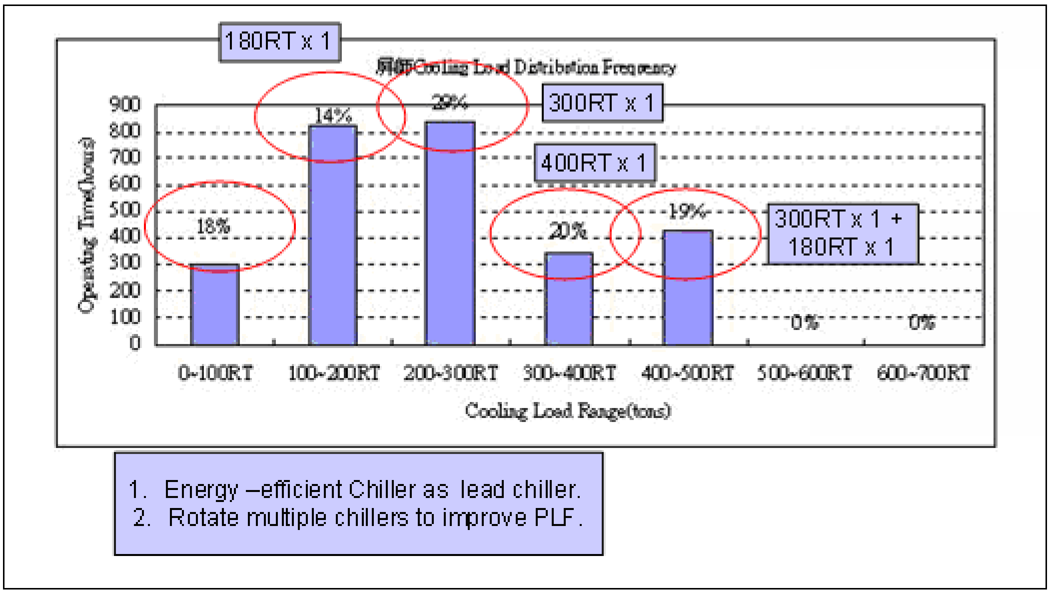

Figure 2 In NPNU Project, Intelligent Operational Modes of the renovated, smaller, Chiller Plant Enables an Optimal Combination in Operating Chillers and with Higher Energy Efficiency as Predicted by Computer Simulation

3.2 PARASITE POWER SAVINGS

Among the 97 projects, totaled 228 KW power demand was reduced by adapting the VWV system, while the VAV systems also reduced 19.7 KW power demand.

In most cases, the chilled water distribution system were designed with constant speed pumps. When cooling load is reducing, lower amount of chilled water is needed but the system is still pumping the same volume flow rate, and depending on closing valves to introduce the additional system resistances. This is similar to an automobile, always on full pedal, but hitting the brake at the same time to slow down. The inverter-driven pumps, on the other hand, runs in a lower frequency and speed in a lower load condition, thus saves significant pumping energy.

In addition to this obvious merit, the VWV system, by pumping the exact volume flow rate needed, enabled a better system hydronic balance. This is crucial in some projects where primary-secondary pumping system had been designed. For example, it is common practice for these systems to design a “common piping” to alleviate the overflow chilled water flow when cooling demand is reducing.Yet, this will create an undesirable mixing problem between the supply (7 ˚C) and returned (12 ˚C) chilled water . The “mixed” chilled water, with a relatively higher temperature such as 9 C, cannot meet the cooling load, and thus demanding even higher chilled water flow rate, creating a cyclic defect. The system then goes on hunting until a biased equilibrium situation is achieved, which is highly energy consuming.

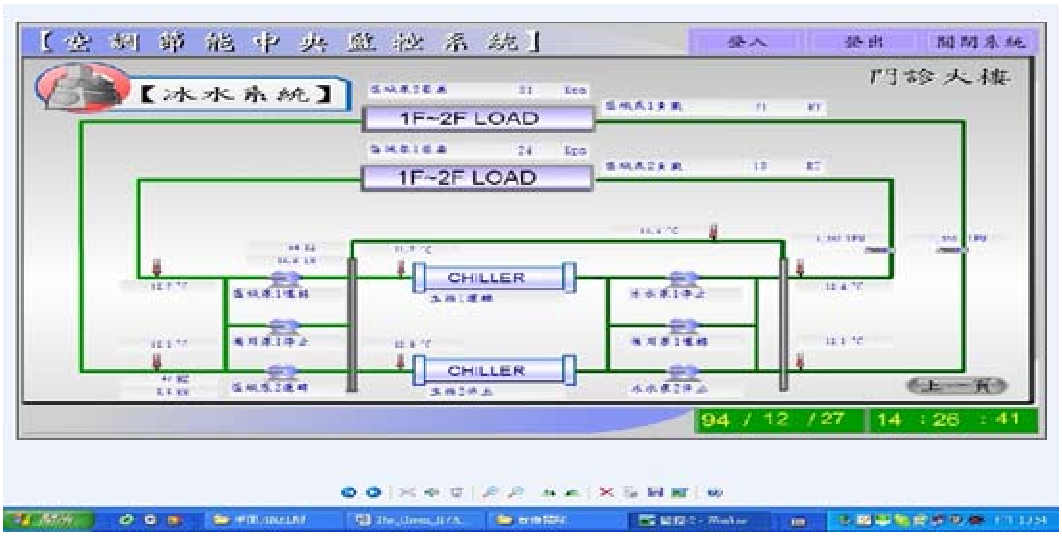

Figure 3 A typical mixing problem occurred when system flow is unbalanced causing cyclic performance defect

The VWV system, instead, lower the pump speed when the demand is low, and solves this problem totally and energy-efficiently and in a simple way. As the horse power of a pump is in cubic proportion to its speed, tremendous power is thus saved this way. Figure 4a and 4b indicated the commissioning process in tuning up the optimal pressure differential settings for the VWV system through the newly-established BEMS (Building Energy Management System) remotely from through the internet.

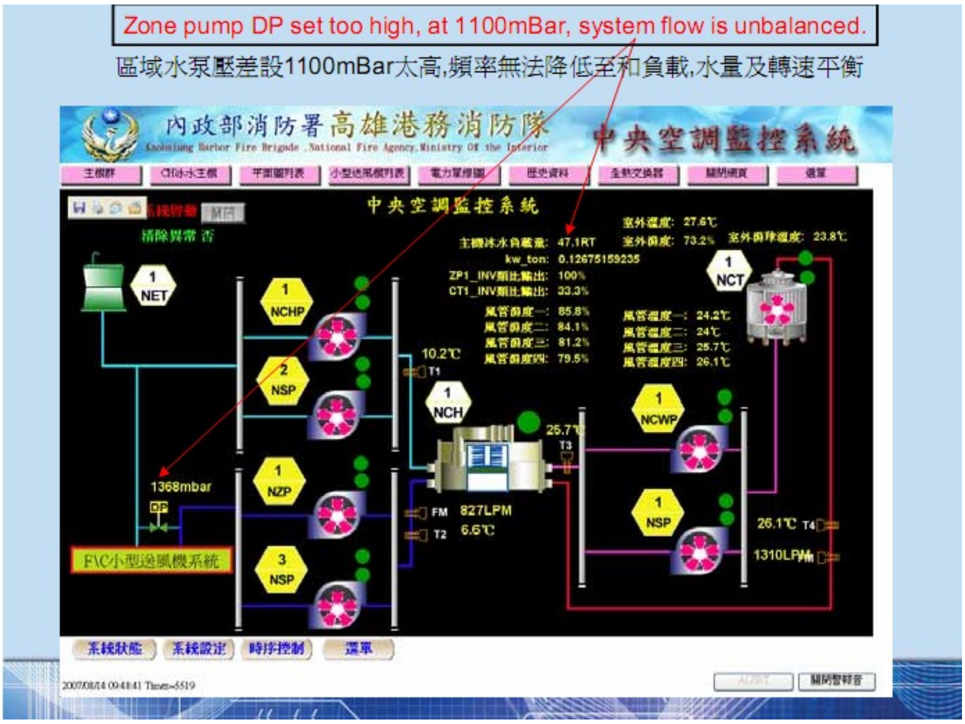

Figure 4a Before commissioning, the pressure differential across the zone pump was set too high, causing system hydraulic unbalances

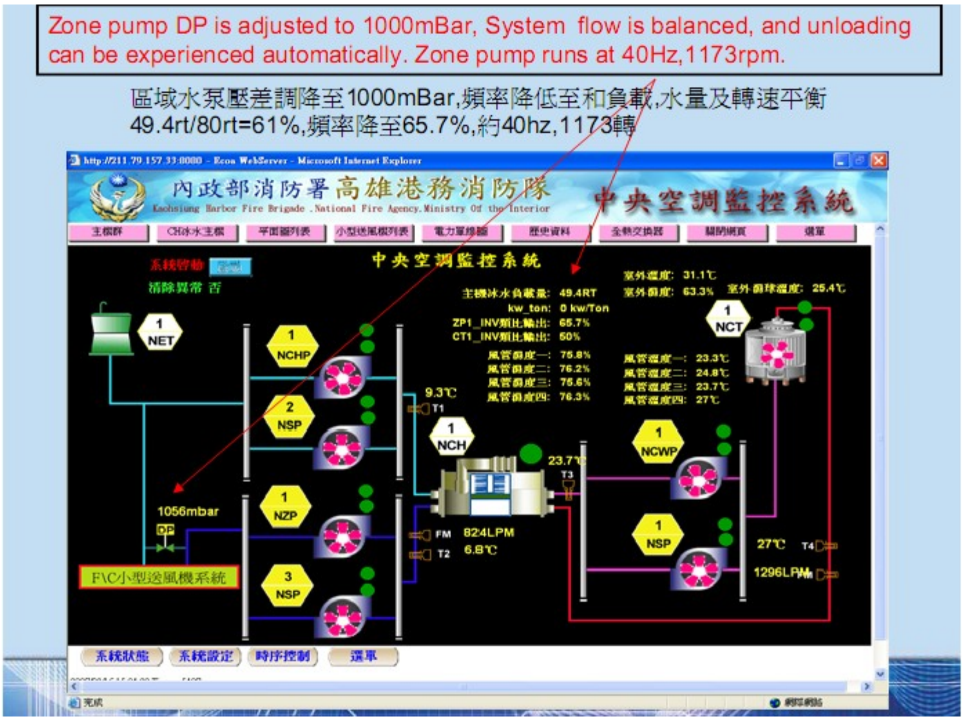

Figure 4b After renovation, pressure differential was reduced, system balance can be maintained. Zone pumps were running at 40 Hz, or 1173 rpm. Energy savings was realized.

It is similarly true for the airside VAV systems. In addition, the VAV system can be coupled with a CO_2 sensor to lower the outdoor air supply intelligently. The reason is that all airside equipment of an HVAC system, especially the AHUs (Air Handling Units), were normally sized and designed with peak occupancy assumptions, but which seldom occurred. An VAV system system adjusts its fan speed to coupe with the smaller cooling demand, and thus saves energy without sacrificing thermal comfort.

4. AN OUTSTANDING CASE STUDY --- THE NMMB AQUARIUM PROJECT

4.1 Original System Problems Description

The NMMB aquarium is the most popular marine science museum in this country for educational and recreational purposes. Located inside a national park, the aquarium is constructed along the beach by the Pacific Ocean where the ambient temperature is around 35□ with relative humidity at 85% in the summer. The huge crowd of sight-seers and hot weather introduce heavy cooling load and keep on increasing year by year.

To coup with this cooling demand, a partial ice-storage air-conditioning system had been designed, consisting of three centrifugal chillers with 500 RT capacity each, and an ice-making screw chiller of 400 RT. The ice chiller was designed to operate during the night, taking advantage of the low cost nighttime off-peak power, to produce ice at its evaporator and harvested during each defrost cycle. The tubular ice was then stored in the ice storage tank located at the basement, where it was melted for cooling during the day to shed the on peak power. The ice storage system only shares part of the cooling load with the centrifugal chillers which are running during the day with secondary zone pumps distributing chilled water to the load.

Unfortunately, this ice storage system was not fully functional since its first installation in 1998.The tubular ice, which was accumulated on the evaporator coil, had been experiencing the “ice-bridging” effect and thus causing the ice scraper severely damaged. The ice storage system was completely shut down in 2002 after several attempts to maintain it.

In this study, a challenging engineering approach has been proceeded to revive the system in 2003. An on-site system diagnostics was conducted first to evaluate the central HVAC system performances. Chillers COP and power consumption of the plant were recorded as baselines for comparison. Secondarily, the ice-storage system was renovated, but not totally replaced, which is the main theme of this project. At last, the completely renovated ice storage system had been commissioned and fine-tuned to achieve system optimization. The benefits of this renovation process has been assessed technically and economically to justify its potential for further engineering applications.

4.2 ESTABLISHING THE RENOVATION STRATEGY

Since this original “ice-on-coil” system was not functional at all, emphasis was put on completely modify it into another “ total-freeze-up” ice storage system. For this, it would be necessary to change the ice chiller into a brine chiller. Instead of a direct chiller replacement, which is too costly in this case, an innovative approach had been adapted to replace the original chiller evaporator, which runs on R22 refrigerant in producing chilled water, into a brine evaporator, which exchanges heat with brine consisting of 30% ethylene glycol. The rest of the chiller components remained intact which could save up to 80% of the total cost compared with a direct chiller replacement. Figure 5 shows a snap shot of the newly replaced evaporator with thermal insulation. As brine was used as the new heat exchange medium among the refrigerant, brine, and chilled water, the heat transfer process was further changed from “external-melting” into “internal- melting” , and a plate heat exchanger was added. Figure 6a and 6b indicated this process modification with a schematic diagram.

Figure 5 The renovated ice chiller with its evaporator replaced and turned into a brine chiller in the NMMB project

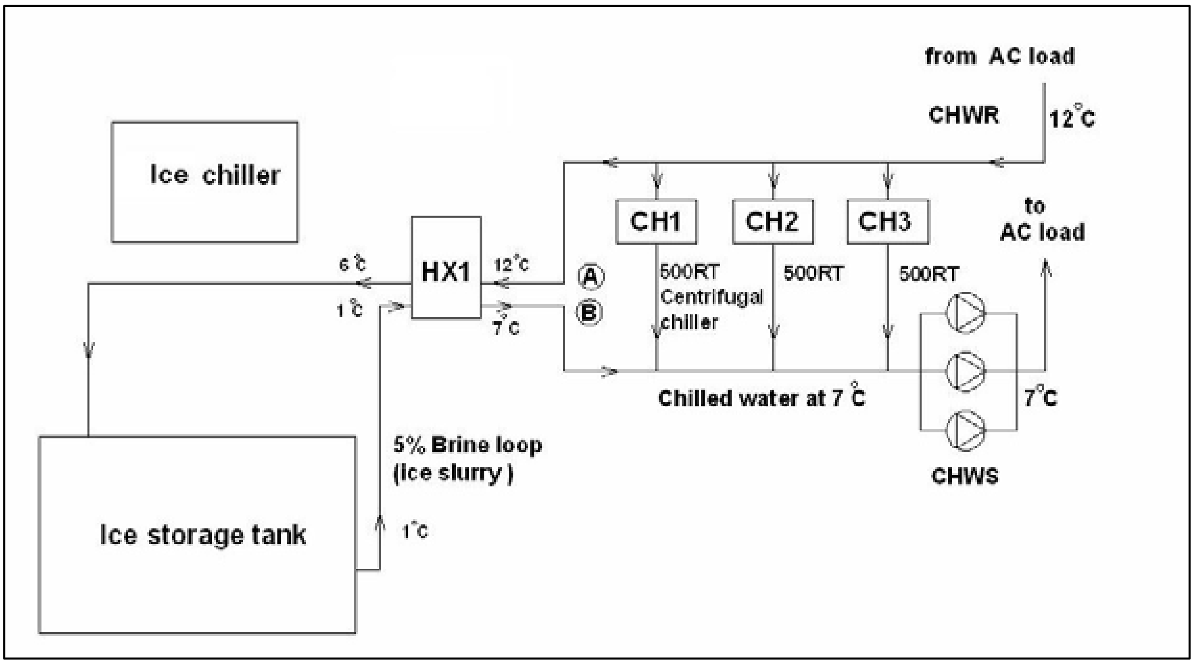

Figure 6a Original Ice Storage AC System under Ice-melting Mode

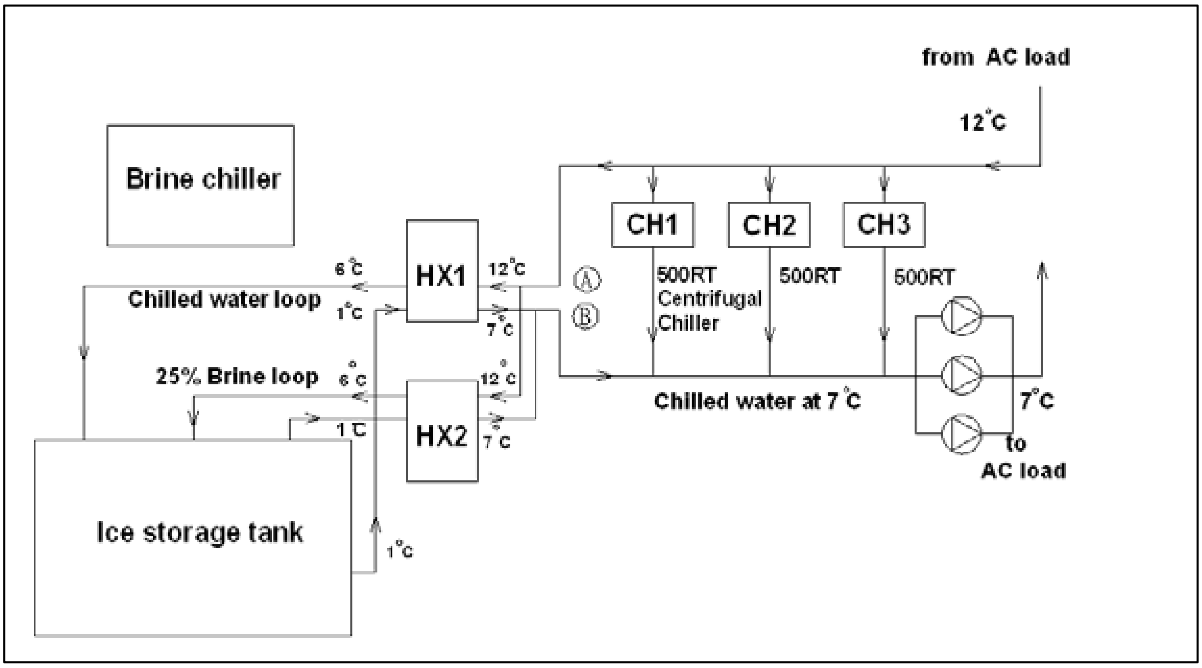

Figure 6b The Renovated Ice Storage System under Ice-melting Mode

4.3 SYSTEM PERFORMANCE VALIDATION UNDER OPTIMAL OPERATION STRATEGY

The revived ice storage system had been operated and audited for one year and compared with original system historical operation data as shown in figure 6 .

In the summer, the strategy is to operate two centrifugal chillers contributing 750 RT shown as curve (3) in figure 6, plus ice-melting providing 250 RT during the day as shown in curve (2). At night, one centrifugal chiller operates plus the ice chiller running under the ice storage mode. On the other hand, the original system operated totally on three centrifugal chillers contributing 1000 RT as shown in curve (1).In other words, curve (1) is now replaced by “curve (2) plus (3)” after renovation. That means, around 25% of the cooling load has been shifted to nighttime in the renovated system paying a much lower power tariff, with an additive 300 RT cooling capacity available ---a double benefit with a minimal renovation investment!.

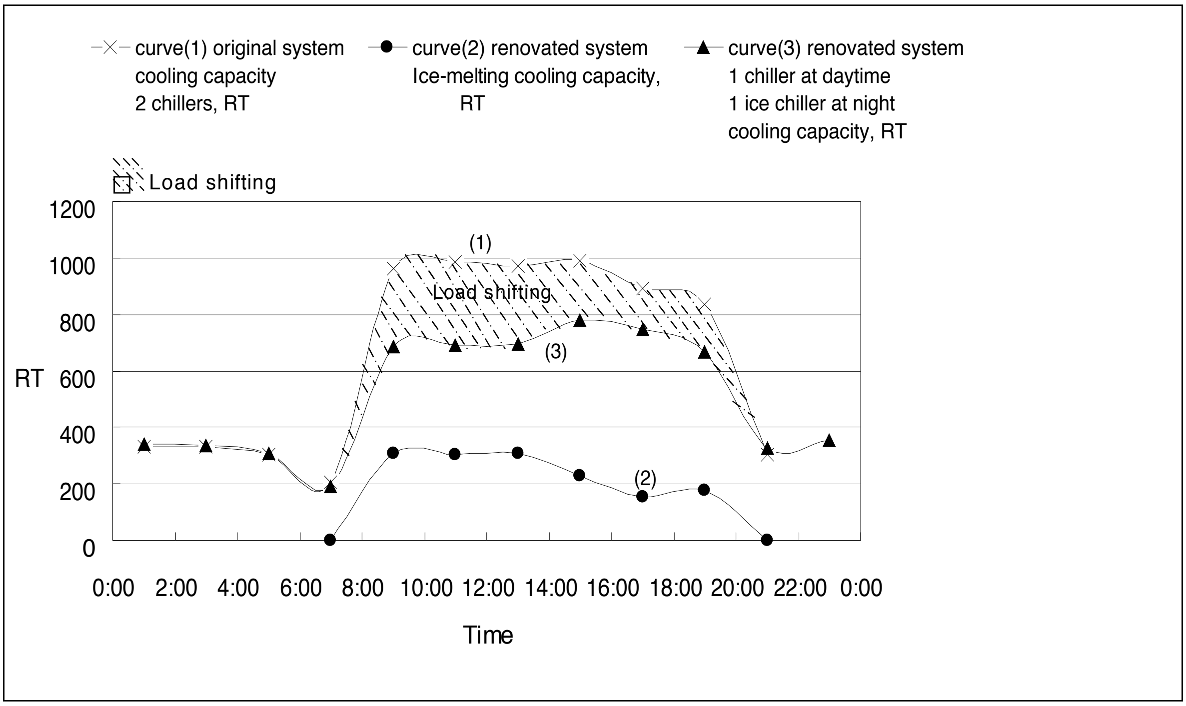

Figure.6 Cooling Output of the Original vs. Renovated System indicating a Significant Load Shifting Effect in a Hot Summer Day

4.4 ECONOMIC ASSESSMENT

The annual ice inventory was recorded in detail and converted into cooling energy stored and released per month. The total cooling capacity released during the year 2004 reached 850,000 RT . The renovated system has been operating smoothly, with ice storage subsystem working at around 80% of its full capacity all the time. There has been no system malfunctioning reported and no system shutdowns, except routine maintenance jobs needed twice a year.

To further assess the economic feasibility, a present worth method using cycle cost analysis has been implemented.

The contracting budget for this renovation project is around 350,000 USD, With the bank prime rate of 4%, in an 25 years life cycle, the calculated payback period is around 8.11 years.

In this NMMB renovation project, the ice storage system has been revived with good thermal performances. The year-long energy auditing revealed that the system provides an extra steady source to meet cooling demand effectively. In the summer, it had successfully shifted 25% of cooling load to off-peak hours. In spring and fall, the load shifting significantly increased to 50%. While in winter, the ice storage system takes the cooling load totally without the necessity to run a chiller. The system runs at around 80% of its full capacity, warrants a steady, reliable and energy-efficient operation.

5. CONCLUSIONS

The Overall renovation research program has obtained significant energy savings effect during these 5 years operation.

For example, the total renovation engineering budget for the year 2003 was 228,000,000 NT (6,846,000 USD), with annual operation cost savings of 46,273,465 NT (1,389,000 USD) realized, the payback is around 5.2 years. While for the year of 2004, the total engineering budget was 93,000,000 NT (2,792,000 USD), with annual operation cost savings of 14,777,338NT (443,753 USD) realized, the payback is around 6.3 years.

The success of this program encourages the MOI Taiwan to launch a Phase II program, and further focusing on fine tuning and commissioning. Successful result is expected after 4 more years.

6. Acknowledgement

The support and sponsoring of this program from the Architecture and Building Research Institute, Ministry of the Interior, Taiwan is highly appreciated.

Thermomodernisation of public buildings conducted in accordance with the conditions of sustainable development STEP

Aleksander Panek, Dr.Eng.
Jerzy Sowa, Dr.Eng.

Faculty of Environmental Engineering, Warsaw University of Technology, Poland, apanek@nape.pl

Keywords: Public buildings, energy performance, environmental impact, educational programs and course materials about sustainability

Summary

Thermomodernisation in Poland has already nine years of official record as in 1998 the Act of Thermomodernisation was accepted by the Parliament. During these years many buildings have undergone investments lowering their energy use. The modernizations were related to energy savings and theirs economic efficiency, but not much attention have been paid to sustainability issues, and only the housing sector was the main beneficent. This situation guided to suggestion of the area of research that may help to fill the gap in existing scope of thermomodernisation, also taking into account the mandate provided by the Energy Performance on Buildings Directive 91/2002/EC. Thus, the proposal of STEP research project was accepted in December 2006 by European Economic Area Financial Mechanism aiming at implementation of a better energy performance of public buildings in Poland. General objective of the STEP project is scientific and research support aiming at implementation of a better energy performance fulfilling at the same time the sustainability requirements of public buildings in Poland . The detailed aim is to supply materials and tools helping to undertake decision as to the most efficient choice of technical solutions in new and already existing buildings.

1 Introduction

Over 80 per cent of the EU's oil requirements are imported, and similar levels of natural gas are imported, with over 51 per cent of total energy requirements in Europe coming from abroad. Higher dependence of Poland and other European Union countries on external supply of energy resources shows that actions dedicated to a more effective energy use are very important from the point of view of energy safety as well as due to the fulfillment of Kyoto Protocol.

General objective of the STEP project is scientific and research support aiming at implementation of a better energy performance fulfilling at the same time the sustainability requirements of public buildings in Poland. The detailed aim – is to supply materials and tools helping to undertake decision as to the most efficient choice of technical solutions in new and already existing buildings, which at a later stage will form a database for the change from contemporary construction solutions to those optimised in accordance with the chosen criteria. Public buildings are usually used by local governments and administration to perform the statutory duties such as: education, health and cultural facilities etc. Energy standard of those buildings is low and refitting or modernisations works are very limited. At the same time, these buildings act as a determinant for local construction practices and should be constructed in reference with standards displaying possible use of energy and environment efficient technologies. The energy technologies for residential buildings, being in a scope of thermomodernisation for nine years, are relatively well known, but the sustainability issues were not, so far, taken into considerations. In a case of non-residential even energy use is not deeply investigated. The only requirements related to these buildings are prescriptive and refer to energy losses.

Table 1. The coverage of scope of STEP project vs. buildings types.

Issue	*Residential buildings*	*Non-residential buildings*
Energy effects of thermomodernisation	Method exists	**STEP**
Sustainability related to thermomodernisation	STEP (partly)	**STEP**

The needs settled up by the Directive 91/2002/EC on the Energy Performance of Buildings, impose new demands in front of the owners and facility managers to upgrade the buildings in such a way that they will fulfill new energy performance requirements. Analysis of the Thermomodernisation Program, which has been executed in Poland for the past 9 years, shows that traditional thermomodernisation techniques might be insufficient for the more demanding recent standards and for new issues that nowadays are taken into concern and should respond to the sustainability paradigm.

Additionally, contemporary modernisation should accept as the priority aims - the quality of the indoor environment quality as well as influence of the building on existing natural environment. This increases the need to widen the scope of research to such issues as: artificial lighting and day lighting, emissions indoors and outdoors, productivity of users, management of water and resources, facility management of the building and surrounding site, waste management as well as new architectural solutions. The STEP project plan is executed in the co-operation with Norwegian Technical University of Trondheim (NTNU), with special care taken on such tasks as: day lighting, hybrid ventilation system and Norwegian experiences concerning assessment of impact of buildings in line with conditions of the sustainable development.

The whole project is divided into 12 work packages:

WP0 Management, administration and coordination

WP1 Analysis of the state of art, existing scope of knowledge on the modelling of thermophysical processes and phenomena in public buildings

- WP1.1 Heating
- WP1.2 Ventilation
- WP1.3 Air-conditioning
- WP1.4 Hot Water Preparation
- WP1.5 Day- and artificial lighting
- WP1.6 Choice of external media
- WP1.7 Utilisation of renewable energies and passive solutions in public buildings
- WP1.8 Aquis Communautaire within the scope of new energy requirements in buildings

WP2 Environment – impact of public building

- WP2.1 Consumption of resources
- WP2.2 Quality of indoor environment
- WP2.3 External environmental loads
- WP2.4 Environmental impact assessment of public building

WP3 Education programme and methodology concerning sustainable development in construction

WP4 Building modernisation guidelines. Case study – Building of Faculty of Environmental Engineering, Warsaw University of Technology, Poland

WP5 Analysis of software required for the modelling of the processes discussed in WP 1, update of the software to Polish conditions, preparation of verification and attestation methods. Preparation of calculation algorithms

WP6 An experimental verification of the calculation methods in real conditions. Energy performance of an office building

WP7 Catalogues of the best technological and architectural solutions in public buildings

- WP7.1 Catalogue of the best architectural solutions in public buildings
- WP7.2 Catalogue of the best technological solutions in public buildings

WP8 Preparation of the education materials to be used In faculties and post diploma courses conducted at the Warsaw University of Technology and other didactic centres

WP9 Preparation of a website course concerning the tools supporting the decisions required for the final choice of low energy solutions

WP10 Monitoring of the investment Project within the scope of public building thermomodernisation, financed by the EOG and Norwegian Mechanism

WP11 Promotion and dissemination of the Project’s outcomes.

2 Energy - the most important element of sustainability

The work package 1 consists of 6 parallel sub-tasks and two vertical – integrating the results of first 6. The scope of the tasks is in line with the objectives of the Directive 91/2002/EC that lays down requirements in regards to:

- the general framework for a methodology of calculation of the integrated energy performance of buildings;
- the application of minimum requirements on the energy performance of new buildings;
- the application of minimum requirements on the energy performance of large existing buildings that are subject to major renovation;
- energy certification of buildings; and
- regular inspection of boilers and of air-conditioning systems in buildings and in addition an assessment of the heating installation in which the boilers are more than 15 years old.

The annex to the Directive defines obligatory elements of energy balance to be taken into account in calculation procedure. To support the implementation of Directive, European Commission ordered set of new CEN standards. These standards, all together 32 new items (as reported April 2007 by CEN), are now already accepted or under the Formal Voting stage. However, due to the passed implementation date – 4th of January 2006 - most of the Member States decided to develop own methods of calculation declaring at the same time the use at the maximum possible extend of CEN standards once they will be accepted and adopted. Even standards as such, should be easily adaptable, as they represent the engineering knowledge of the state of the art, they often require so-called national data or other country specific parameters. Such data have to be provided as a result of research. Thus, the WP1 is dedicated to research to support implementation of the Directive in Poland with particular emphasis on public buildings. WP1 provided an answer about the scope of the energy analysis of public buildings, the calculation method, data requirement, performance indicator, and at the integration stage - methodology of setting the requirements and potential use of renewable energy for every purpose of use in the building. Thus the WP1 is divided into 6 sub-tasks related to technical systems in buildings: heating, ventilation, air-conditioning, hot water preparation, day- and artificial lighting, choice of external energy media, and 2 horizontal tasks - one related to use of renewable energy in all building installations mentioned above, the second about harmonisation with CEN in undertaken legal solutions. The example of this activity's results is presented in the work of Panek and Sowa published in Proceedings of CLIMA 2007. The results of WP1 formed a significant support to new (published in April 2008) official project of regulation about the scope and form of energy certificate that implemented mentioned Directive in Poland. The 5R1C simplified hourly calculation method taken from FDIS ISO CEN 13790 has been adopted for calculation. This adaptation is introducing new dimension in analysis of energy demand in Poland as at first time the adequate data is provided in order to perform hourly analysis. So far, by regulations, only monthly balance method has been used. The STEP project helped in preparing climate data, profile of use of buildings data, and the prototype of calculation procedure that can be used by public.

3 Sustainability of public buildings

During the last 19 years considerable research has been focused on the development of systems to assess the environmental performance of buildings, based on different initial assumptions and prepared for different purposes. The best-known existing system is the Building Research Establishment Environmental Assessment Method (BREEAM), developed by BRE and private sector researchers in the U.K. This system provides performance labels suitable for marketing purposes, and has captured increasing interest of the new office building market in the U.K. Many national systems have been developed by different countries world wide as HQE in France, Eco-profile in Norway, Ecoeffect in Sweden, LEED in US, CASBEE in Japan. There is no country in Europe, which does not attempted to develop adaptation of existing or entirely new system. Several other systems (largely inspired by BREEAM and Green Building Challenge initiative) are in various stages of development in Europe and the World. There are also more specialized systems of interest that are more closely tied to Life Cycle Assessment (LCA), including ECO QUANTUM (Netherlands), ECO-PRO (Germany), EQUER (France) and ATHENA (Canada). Several of these systems have gone the next step, to result in a labeling system that indicates clearly the building's approximate performance to end users. In Poland, the environmental assessment sytem e-Audyt was based on a concept of GBTool but adopted to local conditions and tailored to local data availability (Panek, 2002).

Taking into account this situation ISO TC 59 reactivated in 2002 Sub Committee 17 Sustainability in building construction composed of four working groups which elaborated series of standardisation documents related to assessment of buildings :

CD 21932 - Building Construction – Sustainability in Building Construction –Terminology, recommended for Committee Draft.

WD 15392 - Building Construction – Sustainability in Building Construction – General Principles, recommended for Technical Report.

CD 21929 - Building Construction – Sustainability in Building Construction – Sustainability Indicators – Part 1 – Framework for development of indicators for Buildings, recommended for Technical Specification.

CD 21930 - Building Construction – Sustainability in Building Construction – Environmental Declarations of Building Products, recommended for Draft International Standard.

CD 21931 - Building Construction – Sustainability in Building Construction – Framework for Methods for Assessment of Environmental Performance of Construction Works – Part 1 – Buildings, recommended for Technical Specification

In 2004 CEN got the EC mandate M350 for development of horizontal standardized methods for the assessment of the integrated environmental performance of buildings. The goal of the Commission is to provide a method for the voluntary delivery of environmental information that supports the construction of sustainable works including new and existing buildings (not all construction works will be included). These buildings should provide all of the necessary functions to the users whilst minimising their environmental impacts. Following documents are foreseen to be prepared up to 2009:

1. Framework standard for integrated environmental building performance. Framework standard is intended to provide the methodology for the assessment and the subsequent declaration of the integrated environmental performance of complete buildings and construction works.

2. Horizontal standard on the aggregation of LCA results of individual materials into the building, standard that will provide the methodology for the aggregation of materials data or data on components to provide the overall integrated environmental performance of a building.

3. Standard on the LCA methodology for building products/materials, standard will be based on the ISO TC 59 SC17 standard for the environmental declaration of building products, should provide an answer to the issues beyond the scope of ISO.

4. Standard on the communication format/EPD. This standard should be based on the results of the standard for the LCA methodology for construction products/materials. The outcome of the LCA is one of the communication items of an Environmental Product Declaration.

5. Technical report on the assessment of the environmental performance of the construction process of a building, which will provide LCA-based method for the assessment of the environmental impact of the construction process on relevant scenarios. It should identify which factors should be taken into account and which should not, what climate and what generalisations are acceptable regarding transport, etc. The results should be able to fit in the aggregation step for the integrated environmental performance of complete buildings and construction works.

6. Technical report on the assessment of the environmental performance of the end of life phase process (demolition, recycling, waste treatment processes) of a building and products. The deliverable will be a technical report that provides an LCA-based method for the assessment of the environmental impact of the end-of-life (demolition) process.

7. Technical report on the assessment of issues of building products related to the lifetime of the building (service life, durability, design, maintenance and replacement). The deliverable is a technical report that provides an LCA-based method for the assessment of the environmental impact of the maintenance and repair processes based on relevant scenarios.

The two, above described, standardisation activities formed a basis for the works covered by WP2 Environment. There are three main issues, which are considered in creation of assessment systems. These are environmental impact, indoor environment and impact related to production of building products – every issue is related to separate sub-task. Integration of all of them is a purpose of whole work in WP2.

4 Conclusions

The STEP project is a challenge for the whole team coordinated by Warsaw University of Technology. Within this article only the first two work packages have been presented. The rest altogether 8 meritorious packages will use results from WP 1&2 and will constitute educational framework, textbooks, guidelines and software that will be available for wide public for non-commercial use. The work of WP1&2 are already completed and were very helpful for providing research support to implementation of Energy Performance Directive in Poland.

The work has been supported and performed within a framework of the project PL0077 entitled *Thermomodernisation of public buildings conducted in accordance with the conditions of sustainable development* – STEP, financed by EEA Financial Mechanism. The support is gratefully appreciated

Keywords: sustainable architecture, social aspects, ethics, environmental evaluation methods for buildings.

Summary

The adjective sustainable, both in general and when applied to architecture, involves the consideration of environmental, economic and social aspects. However, advances in research on sustainability in the last decade have confirmed the need to incorporate a new approach to what we understand as basic: Ethics.

The dimensions of current approaches in sustainable architecture widely surpass those usually analysed which are based on time and space. The definition of sustainability in itself, as a link between generations, expands the time coordinate: the research and activity of architecture includes much more than the project itself or a building's useful lifespan. The space coordinate has also widely surpassed the limits that have been used up to now: the idea of thinking globally and acting locally expands the *locus* of architectonic design on to the planet as a whole. These new limits of building horizontally—the whole planet, and vertically—throughout generations to come, makes ethics the base, the fundamental and the field from which we should study sustainability.

First, we must establish the rules that will guide the analysis: Ethics are understood as the study of what is good and bad, proper and improper in accordance with the norms set by society at a given time.

Sustainable architecture and methods of evaluating the environment's behaviour of current buildings is moving towards this field, even though unconsciously. It is important to think about sustainability's reasons and original framework in order to exactly understand what are the aims and scope in which it is developed. The study of sustainability in architecture from an ethical point of view determines the criteria under which the evaluative methods should evolve, noting the ways for proper development.

1. Readopting the meaning of ethics as a concept

At first glance ethics in daily life is understood as a concept applied only to the study of matters on the fringe of human life: the beginning and its origins (cloning, genome, abortion, eugenics, eu-Genesis), or the end and the limits of existence (euthanasia, eu-Thanatos, etc). This is an extreme view, set on the confines of life. However, between these two extremes, humans develop a wide range of life, full of activities and projects that become concrete facts.

The meaning of ethics, from academic definition, is "the branch of philosophy concerning morality and human obligations" (according to Real Academia Española, Dictionary 2001). If morality (or descriptive ethics) describes and studies human customs in each specific moment in history, ethics is the part of philosophy that studies the underlying reasons for these customs. If the description of customs makes up part of morality, a study on "why" and a valuation of this morality would also correspond to the field of ethics. That is, all human activity understood as a custom could and should be an object of study from this point of view. Any human activity is susceptible to being valued and studied in terms of correct or incorrect usage, of what is appropriate or inappropriate. The science or study of making an abode or habitat for a human being is one of these human activities, and an important one at that.

The distinguishing aspect between morality and ethics is an essential difference: Morality adduces "customs," that is, what is common human and social behaviour in a specific moment in time, leading us to a temporal structure. Customs change with time, adapting to their moment in history, surroundings and social complexity; they change and are flexible. Valuating them is thus attained through an understanding of society in time. But a human being also has an unchangeable essential core, which endures and is shared by all human beings throughout all generations and places. In our western culture, our concept of knowledge from Plato, and our Aristotelian reasoning have not lost meaning throughout history; instead they are fundamental to our way of thinking. Their contributions remain, along with the reasoning added by many later intellectuals. This implies an added sense of complexity in this study: knowledge of that which is common in all human beings, and to a specific historical moment.

2. Applied ethics

And what does this have to do with architecture? Can we talk about what is good and bad or reasonable and unreasonable in such an industrialised world submitted to the laws of commerce and the hard, relentless economic and real estate pressures? Can we connect Aristotelian ethics with architecture? Are there stagnate spaces in which philosophical thought is completely absent? Is this study useful to any degree? The response to these questions is yes. The study of general concepts must conclude useful guidelines. Fox (2006) notes this through a definition of different levels of the study of ethics, specifically defined for constructed environments:

- There is a descriptive ethic that studies human behaviour through an observational approach: What do they do, how do they develop behaviours. This description would correspond to what previously was defined as "morality."

- There is standards ethics, which in comparison to the former handles the source of human standards and objectives, through a more philosophical approach in comparison to observation.

- There is a meta-ethics which tries to understand the good and bad, proper and improper, of the purpose, discussion and meaning on what humans are concerned about.

- And finally there is a practical ethic, which applies theoretical reflections in specific contexts, determining how these reflections should be used in specific cases.

With respect to Fox's description of the different focuses on ethics: descriptive, standards, meta-ethics and practical ethics, a comprehensive study should gradually include all four of these levels or phases as applied on construction in order to reach the latter: a practical ethic that provides a guide for specific moments, for our case, this involves the present, with our peculiar historical circumstances and within the context of our society.

3. Aim and application of a classic concept

The aim is purely utilitarian: To have a well-thought out base and a researched theoretical foundation to guide on what to do, how to behave and what decisions to make when confronted up against specific decisions in certain contexts. The problem lies in how to apply such broad, comprehensive and complex concepts like philosophical judgements, how to come up with practical applications and how to carry out the process.

This is where the concept of ethics can be applied to the specific field of architecture. It is about knowing which aspects must be specifically treated within the framework of social relations and behaviours, understanding that we must provide a solution and response to the debate held in our society. These are new problems, since these are new situations, and society is continually changing. With this we hope articulate between the scientific and the common, between theory and practice, between contemplation and action.

For this, and to start the process, we must try to return to the study and origin of the discipline of architecture itself, initially erasing the limits of space and time, taking a step back from the short-sighted view of the daily activity, changing from an immediate focus to a greater dimension in order to understand the meaning of our actions. In order to understand the concepts, it is necessary to return to the origins and definitions.

4. What in architecture can be associated to ethics?

Architecture is understood as the space in which man inhabits and lives his life. Under the title of architecture or architectures in plural, we understand other associated complex activities, like the creation of a city as a collective building and the creation of spaces and environments for human relations. Construction and public works as industrial activities are the practical and technical consequence of this need to provide human beings with a shelter for their life and activities. All of these activities may and should be studied under an ethical point of view. That is, the first or final study of the purposes—why carry out certain human activities.

Architecture ("the art or science of building," according the Merriam-Webster dictionary) is an art for a need, a use, an aim and a purpose. Architecture works with space and light, supporting itself on materials and providing utility. Vitrubio´s *Firmitas, utilitas, venustas* is still valid and lasting. This peculiarity, this practical application of an artistic activity in itself makes it a study of ethics. This is an art, but one requiring responses to questions: For who, for what and how.

We should also distinguish between art and the creator: the architects, those working in this line of work. According to Wasserman et all, (2000), Architecture is 1) the particular places we shape in the landscape for our inhabitation, 2) about their consideration, design and fabrication, end 3) a professional practice. There should be a distinction between the discipline/art and the people as architects, Lagueux (2004) says. This way, the codes or rules of conduct regulating both can be independently studied. On the one hand we would see the reasoning behind the good or not, what is proper or improper in developing art; and on the other hand what is proper or improper in terms of the people's practices. The latter aspect is regulated by the professional codes of conduct that must be applied to the personal relations within a competitive environment and context: Between the professional and his/her client; between professionals themselves, and professionals and the state.

Although the ethical position of the designer is crucial issue as starting point in sustainable design, for this paper we hope to discuss the former aspect: where should architectural theory be directed? The architect's personal or professional behaviour is not discussed here. We will study concepts and criteria that should serve to guide the decision making process involved in the architectural process. The aim is "the moral consideration of architecture", as Levine (2204) says.

5. Different interpretations throughout history

Architecture has always had a conscious ethics that it has been defining throughout historical moments: from the most classic architecture to the latest in architecture. The most primitive societies have created theist, colossal architecture in which the buildings could be either temples or sacrifice places, like Hollier (1992) argues about Bataille thought. There is nothing more descriptive of each period's social structure and morality than that placed in its architecture. The coliseum, the forum, the fortress, the market, the cathedral, the palace…are defining more than just their historical moment, but also a society's beliefs, moral structure and ideology. Studying the ethical purpose of architecture has been the base for modern architecture. Frampton (1980), Pevsner (1951) and Giedion (1976) started their study of 20th Century architecture through the moralist reactions of John Ruskin and William Morris on the growing industrialisation of the 19th century times, which they saw as alienating human beings, while architecture was an element that would elevate human dignity. The driving force behind the rigid architecture of Beaux Arts to modernism is the adaptation and reaction of industrialisation that has changed and regulated a new lifestyle for man. This same industrialsiation would years later be admired by Le Corbusier (1936): "Toute construction (objet d´utilité, unité de logis, moyen de transport, autos, bateaux, avions, etc) répond à des besoins modernes, la forme est dictée par les matériaux, les moyens d´exécution, les machines et une qualité d´esprit qui est la manifestation d`étique d`une époque" Science and techniques have not been the only elements that have modified the architectural process.

Others study the ethical aspects from different points of views. Maybe one of the easiest to approach is the power exhibited, which establishes a way of practicing architecture. The most obvious and crude example is the architecture of powerful dictators and dictatorships. The architectonic language can be used in obvious fashions: oppressive, grandiloquence, imposing. The space in which man lives is his elemental shelter and home, but it is also the collective meeting space, for social relations and joint participation, where relations and situations are established. And for this, the architectonic language can propose, suggest take-in and promote these activities, or reduce, limit, control and even annul or eliminate them. Architecture has technical and functional purpose, but also an expressive one, to create spaces and produce feelings.

This same point of view can give way to confrontational ideological solutions. Dictatorial architecture takes specific stances. Bucharest´s traditional historic quarters were banally and artificially substituted by a single, colossal and megalomaniac institutional building, describing both Ceausescu's dictatorship and its belief and sustenance through the change from a vernacular, anonymous and collective architecture to an imposed and hierarchical form changing the scale of man to annul their sense of participation as citizen's.

From totally opposing ideological positions, but based on the same principles of the power of architecture, the French Internationale Situationniste (from 1958 to 1969) understood the city and space as a place for establishing situations, meetings and forms of free, spontaneous, creative and diverse expression thus establishing a spatial and temporal participation for human relations.

These brief and synthetic examples have been chosen in unique historical moments. From this point of view, architecture is not just a reflection of its time; instead, architecture is creator of its times. The relationship between them (architecture and time) is interconnected, and is established in both directions. Architecture reflects its historical moment, but also makes and creates the space that forms, covers and makes this historical moment visible. Each period's society is defined not only by its advances or technical evolution, but by its determinations, by choosing what is important or by placing priority, thus creating a particular value scale.

Architecture is a functional art that modifies space, making man's shelter into art. This is the discipline that transforms the need for space into the development of an expression. This is an art with a need, a function. This function is carried out through the collective interpretation of people's needs, those that will use the buildings, those who need it. To interpret these needs and adopt to the criteria that society demands at each moment is a necessity and the previous step to making good architecture.

6. Current circumstances

It is not easy to clearly determine what the values of our times are: we live intuitively, collectively, unconscious, without formally declaring them, which are also in continuous evolution. However, there are circumstances that objectively make our times different from the rest, and that have influenced the position we take on our value scale. Society is now confronting challenges it has never had to confront, which require a solution.

The problems of sustainability, arising from the alarms from global warming and the environmental changes and damage, have changed our focus of attention of the problems. While before we did not grant importance to that outside our country's borders, today we understand that this scale is limited. We must expand it; our concept of the limits of space and time must change. The Kyoto treaty and those following have shown that it is useless for a single country, or a small group of countries, to operate independently. On the other hand, the "financial centres" Saskia Sassen (1998) discusses, rewrite the map of economical power. They go beyond countries and continents, through operative networks that function independently, or more appropriately, beyond borders and continents, beyond geographic distribution, in order to determine a non-spatial geography: a "virtual" geography through information networks.

What happens in London is not isolated from what occurs in Baghdad: what happens in Darfur is not disconnected from what occurs in Beijing. The so-called "butterfly effect" describes the interrelation of the cause and effect that go beyond the limited diplomatic, political or economic connections, raising them to a higher scale of possible relationships in space and time. The ease and abundance of communication, both physically and in situ, and virtual or through waves, create a permanent transfer of people, knowledge and information.

The new concept of an ecological footprint, "the amount of biologically productive area (crops, pastures, forests or aquatic ecosystems) needed to regenerate the resources consumed and assimilate the waste produced for a given population with a specific, undefined lifestyle," from Rees and Wackernagel (2001) have provided us with a single figure, in specific units, a resource distribution problem between different societies and countries on the planet. It has shown what societies are using the majority of our common resources. We can no longer be indifferent to not being energy efficient, to the use of certain materials, surpassing energy consumption or building exclusively for a small percentage of the population, etc. We already know the data and all the figures that show the cost this has on the planet.

These new circumstances in constant flux have changed our lifestyle and work, giving a new dimension to our surroundings. That is, the eternal concept of architecture is now given the specific concepts from our times: a holistic or general, complete, universal concept has changed scales. .
Is it advisable to understand the big picture, expand it, expand the conventional margins, and go on from a limited conception of cities installed in our current industrialised welfare society, and take this view to the largest possible spatial scale: the complete planet; and temporally: from one generation to the next.

7. Environmental ethics and environmentalism

The debate on ethics applied to the environment has been called environmental ethics. Its origins can be traced back to Thoreau (19th century), Des Jardins, even Gandhi (20th century), and even further back to Spinoza (17th century). The late 20th century has seen its strongest development. According to Taylor (1986) "Environmental ethics is interested in the moral relations between humans and the natural world. The key ethical principles guiding these relationships define our tasks, obligations and responsibilities, paying attention to the planet's natural environment and the animals and plants living in it." This subject also studies matters concerning environmental problems in solidarity with time (the well-being of future generations) and place (problems the whole planet faces), with the aim of achieving a less unsustainable method of construction throughout the world. The International Sustainable Construction Convention CIB W082 (1998) under titled Sustainable Development and the Future of Construction, already connected these aspects:

"The problems of poverty and underdevelopment or social equity are sometimes part of sustainable construction. In addition to economic prerequisites or social questions, numerous other variables and their importance vary from country to country. Features such density and demography of population, national economy and standard of living, geography and natural hazards, availability of land and water, energy production and supply, the structure of the building sector or the quality of the existing buildings stock, etc., all have a measure of influence and interpretation in national approaches".

The concept is closely tied to what some authors like Raudsepp (2002) have called environmentalism: "Environmentalism is usually operationalised as a certain way of thinking about the environment (beliefs and attitudes concerning nature and human-environment relations) and/or practical way of relating to it (ecological behaviour, e.g. self-restriction in consumption, participation in ecological movements, willingness to sacrifice for environmental quality"

The current view of environmental ethics refers to topics that share specific environmental goals. There are non-anthropocentric concepts (those taking into consideration moral values beyond the mere human interests) and anthropocentric ones (prioritising the individual). Recent environmentalism has focused towards the former. Craig Delancey (2004), in his suggestively titled article "Architecture can save the world: Building and environmental ethics", concludes that from the first point of view, we can reach a well-being for all types of organisms and ecosystems on the planet, at least to some extent. Concepts those are compatible with architectonic practices, according to this same author. Designing and building should benefit all classes of organisms and ecosystems, assuming that even reduced damage is already a relative benefit. Applying this principle to architectonic practice supposes, obviously, certain restrictions, but also new opportunities.

8. Evolution of the study of sustainable architecture

Sustainable architecture—what is equivalent to green architecture, or low-impact architecture in other contexts, is a conscious or unconscious response to the new wave of environmentalism applied to the world of construction. What at first was a reaction to the energy challenges confronting climate change, has gradually become a more complex problem. The study of low energy consumption architecture, as the initial urgent problem to solve, has progressively given way to richer and deeper studies. The first texts in conferences concerning this subject focused on energy efficiency as a paradigm: the aim has been slowly changing, merging with economic criteria and going on to social criteria (including the socio-cultural and historic) as research and evaluative subjects. This expansion and merging of aims has reached public works, infrastructures, construction, terrain interventions and landscape, biodiversity and nature as an entity in itself.

Moreover, the conception of environmentalism in developing countries reaches fairly different aspects, but is also an object of study and research. Our geopolitical and macroeconomic structure has generated an apparent resistance to the phenomena, but the entropy generated by these structures is precisely the cause provoking this environmental consciousness. The concept of sustainable development arose out of necessity. Naturally, environmentalism has expanded into all aspects of this field, just like gas expands throughout its container. The environmental, the origins of the study, was then followed by the economical, and then the social—much like the paradigm: planet, people, profit." The three supports of sustainability that must be united under a general concept. The conceptual triad of environmental, economic and social has become a tetrahedron, which for some authors such Duijvestein (2004) says, the fourth, main vertex is "the project." The geometric analogy of the phenomena must somehow also include the ethical and environmentalist aspects as the concept catalyst.

9. Conclusion

The expansion into these factors has favoured a holistic conception of architecture that inevitably has reached the need for a more essential research into architecture: into the field of ethics. The ethical aspects of architecture are not new to this field. However, when specifically applied to sustainable architecture they are somewhat newer. They do not stop from being steps in a direction that go from the detail to the general concept, from the practical application carried out through an intuitive point of view to a general concept, to underlining reasons, justifications and guidelines. That is, ethical aspects.

The now universally understood sense that architecture is the task of settling the landscape, natural or urban, and that man is no longer the centre of the planet, but just a part of it, in a growing non-anthropocentric culture, imposes a new architectural ethic. What are the current ethical problems? Equity and social justice criteria applied to the planet as a whole, once having excluded the boundaries of space and time. Build for everybody, including everybody throughout the planet, the current inhabitants and the future ones. Build with respect to nature, which encompasses the existence and maintenance of biodiversity, using the scientific support and techniques that are now available.

Sustainable architecture finds its area of performance in the necessary response to the current problems form an environmentalist ethics point of view; Sustainable architecture is not a new paradigm, train of thought or technical speciality. It is the architecture of a period with environmental concerns, and must operate keeping in mind the sensibility of environmental matters; architecture from a period that reinterprets the traditional limits of space and time must capture these concepts and reflect them in its proposals. Each era's architecture has had its own ethic, and our era has its own, with a strong emphasis on environmentalism. And this path is the path architecture must follow, without being obstructed by the entropy of the resistance from our geopolitical and macroeconomic structures.

Summary

Ecological and environmental conditions in and around cities are under pressure: transportation distances grow, protection and qualities diminish, and infrastructures get more complex, less robust and less visible, which result in a decline of sustainable commitment and behaviour of users. Yet, citizens are concerned that environmental degradation is affecting the quality of life in their neighbourhood.

Composite measures of sustainability provide useful insights to the environmental impacts associated with human activities, but, in themselves, are not the solution for abandoning traditional paradigms. Spatial planning must be able to conduct the spatial consequences of these developments. Therefore, it is necessary to look beyond boundaries: not only physical boundaries (between areas or countries), but especially boundaries of the various scale levels of solutions, the interrelated networks, the public space and, particularly, of their reciprocity. It induces the explicitation of the 'urban metabolism' with underlying social needs and the finding of instruments and strategies that allow the spatial planning and renewed infrastructure to fit the changing social objectives, especially as for sustainability, and another way of dealing with "public affairs" better.

The presented approach promotes sustainable management of the environment and its resources through a renewed focus on existing, mostly ignored resources and local 'quality-cascading' (exergy), together with stategic niche planning to improve knowledge on the interactions between natural resources, human activities and environmental impact and in doing so, facilitate continuous urban change. Especially the introduction of solutions on an intermediate scale-level of the neigbourhood or city district offer opportunities.

1. Introduction

Cities are like organisms, sucking in resources and emitting wastes. The larger and more complex they become, the greater the necessity of infrastructures and the greater their dependence on surrounding areas, and last but not least, the greater their vulnerability to change around them. With recent and coming perturbations of the weather due to climate change, as well as constantly increasing global demand of energy, water and materials, this aspect of vulnerability and dependence is becoming essential for sustainability, as the world may be entering a period of scarcity. Therefore, a renewed look on "the urban metabolism" is necessary. There are several strategies to cope with sustainability and the increased dependence and vulnerability. In general due to the urgency it comes down to "effectiveness before efficiency". More specific, two future paths could be determined. Within the globalizing world, centralization through interconnection of sustainable (re)generation and (re)use, connecting sustainable solutions in the different regions, and especially balancing sustainable demand and supply of both hemispheres is one. The other option is exactly the opposite: decentralization, trying to interconnect supply and demand sustainably on smaller scales, near to users and settlements, and therefore near to the origin of environmental problems, ánd potentials (Timmeren, 2008).

The scope of this study is formed by the most important flows related to the first necessities of life, viz. energy and sanitation, which implies energy, water and waste. Systems are called "sanitation systems" (after the French "sanitaire", meaning "health" or "hygiene") if the systems concern the flows dealing with health aspects. In this study, for reasons of the importance of the organic part of the solid waste, we adhere to the general definition of sanitation: waste water systems and solid waste.

The central questions will be how, and especially at what scale level, these "essential flows" in the built-up environment can optimally be made sustainable. The essence of the chosen scale level and role of connecting structures and infrastructures will follow from this.

In practice, it turns out more and more often that the relation between infrastructure (to a lesser degree technical systems) and social needs has been reversed. The newly planned and constructed infrastructure largely drives the social needs and is the result of the balance of power or habits of certain institutions (dominant actors), or "path dependent development".

When we consider the question concerning the various types of infrastructure, whether necessary or not, and their manifestations and scale levels chosen today, it can be established for the sanitation infrastructure and the energy infrastructure that the flows transported within this infrastructure are still characterized by a structure which has been optimized from the viewpoint of efficiency in (centralized) management and of other economic aspects, rather than of far-reaching ecologizing and dematerialization. Hence, looked on from the angle of sustainable development, the infrastructure seems insufficiently efficient. As a result of this inefficiency of the essential (or critical) energy and sanitation flows (water and waste) and the usual large application scale of solutions, the technical infrastructure to be built is not optimally adjusted to the quality as well as the quantity of these flows, seen from an environment-technical point of view.

The presented research is commissioned by the Delft University of Technology (TUD) in the Netherlands as part of the D.I.S.C. Research Programme (Design Integration of Sustainability & Comfort) of the Climate Design & Sustainability chair at the Faculty of Architecture.

2. Permanent Cycles

The presented research attempts to contribute to "cyclic thinking" and "cyclic design" in the (actual) built-up environment, with as little as possible extra work, energy, waste and capital as a starting point. It takes the three-step model by the Dutch authorities concerning sustainable development as a starting point: (1) extending energy consumption; (2) closing of cycles of 'materials / nutrients' and (3) supporting quality / life span of products.

A cycle may be part of one or more ecosystems. Cycles are the key condition for stability in nature to come into existence. In a closed system, matter cannot go beyond its boundaries. In principle, energy can go beyond a system's boundaries (2^{nd} Law of Thermodynamics). Water, nutrients, and other materials, by contrast, having no source of new supplies, are not lost or dissipated but instead are continually recycled.

Usually, ecosystems are defined as parts or areas in a more or less isolated state that are capable of preserving their own balance, always open to influences from outside (Tillman Lyle, 1994). In this study, ecosystems are considered as natural parts of technical systems (e.g., buildings, districts or towns), in their turn being elements (parts) within larger ecosystems. The scope of this study is formed by the most important flows related to the first necessities of life, viz. energy and sanitation, which implies energy, water and waste. The sanitation subflow 'waste' is described as those elements or materials that are left, together with one or more products from a production process or after consumption, and that have no market value in the current market circumstances. By now, waste actually almost always is a product, since it has become to represent an important and increasing market value, and there are markets at regional, national and international levels. Within the area of "water", a sanitation system contains: the entirety of the water chain, viz. the collection, production, distribution and use of drinking-water, the collection and use of rainwater, facilities for toilet water and use of water in housing, the collection, transport and processing of refuse, discharge and/or dumping/reuse. The "urban water cycle" is defined as a cycle, but is not a (closed) cycle: it is part of larger cycles. Drinking-water and waste water form the elements of the so-called "small hydrological cycle" within the "large hydrological cycle". It is not necessary that the small water "cycle" is defined as a closed cycle. It is better to consider it as consisting of various (created and) interrelated "small cycles", including nutrients, energy, carbon, metals. The urban part is only one of the parts in the cycles concerned. Each of these small hydrological "cycles" can be repeated many times, but strictly speaking is not to be defined as a genuine cycle. Then, the objective of sustainability can be set thus: the urban system is not allowed to exhaust or overload the surroundings. In this point of view, it is not necessary for the urban system to be fully autonomous. However, if the created "small cycle" is not closed at an urban level, town and surroundings should be complementary, so that they can minimize, or balance the environmental load together.

Cyclic thinking is often linked up to autonomy and "autarky". Autarky is then defined according to the limited, ecological interpretation of autarkic systems: systems which are closed as regards matter and energy, with the exception of the continuous flow of solar energy. Apart from this, autarky is often linked up to (ecological) holism because of its comprehensiveness. Autonomous concepts in environmental technology and in the building industry (mainly) concern autarkic attempts to subaspects. Here, autonomy is contrasted with "heteronomy". In this study "heteronomy" is used in the limited interpretation of interconnection, and the instictively experienced forced latency, especially applied for the essential networks and services.

3. Private or Public Management of Energy and Sanitation (Infrastructures)

The decision-making concerning the system selection and accompanying infrastructure for the essential facilities, such as energy and sanitation, is often – or too often – established stealthily. Political choices can determine the market hierarchy of changes in the infrastructure, e.g., through the speed of the market opening, policy on competition, price regulation, tax constructions, environmental regulations and supervision. The original objectives and needs of the project will keep slipping further and further to the background, particularly when new (innovative) systems and ways of (sustainable) generation (energy supply) or treatment (waste / output) are introduced, through the investment of effort and time when running through the process and the many interests that come into being. On account of the continuous adjusting of objectives and starting points, and on account of the fragmentation of the moments of decision, decision-making becomes "stealthy".

The argumentation to carry out a project or not changes when criticism on the project (or arguments to not carry out the project) cannot be refuted sufficiently, or when time outruns the arguments. One of the negative effects of stealthy decision-making is "shift of objectives".

The absence of a general theory of sustainability is also a topical problem. Particularly, the role of spatial planning in this respect: the connection between local, communal and global sustainability is characterized by uncertainty, ignorance and inexperience. Too often, developments follow paradigms, which often leads to a development with a fixed end, as an assumed "nec plus ultra". They can lead to an "a priori" brake on attempts to get a better alternative. There is growing consensus that a reductionist command and control approach is perhaps not the most appropriate way of interacting with what is in essence a dynamic complex adaptive living system, a regenerative system, and that resilience and adaptation are factors of urban sustainability as important as (if not more than) conservation, efficiency and equity. This necessitates a quite dramatic mind shift in how cities are viewed and therefor in how spatial planning and design should address to this. Spatial planning must be able to conduct continuously the spatial consequences of developments. Therefore, it is necessary to look beyond boundaries. This does not only concern physical boundaries (between areas, regions or countries), but also boundaries of the various scale levels of solutions, of the interrelated networks, of the public space and, particularly, of their mutuality.

Spatial policy will be able to have a guiding function in a limited way only, since spatial planning is mainly guided by economic interests. In most countries, the general basis for spatial policy nowadays is still too much of a certain pragmatism focused on specialism. The "public interest" is translated into the own scale", a narrow spatial coherence, that is insufficiently characterized by the creation of conditions for the diversity and changeability of society. Private preferences are fundamentally contrary to public wishes. Infrastructure and a certain spatial development at a higher scale level, e.g., that of the region, is often a public wish, a collective good, that should be to the profit of the whole society. Decision-making where collective goods are concerned, should be accomplished in a collective way. Cost-benefit analyses address people as consumers, rather than citizens. Private preferences often differ from public preferences" (Sagoff, 1988).

There is much left to be improved in this matter. First of all, it is the case that many infrastructures are (still) paid out of the general means of the authorities, without there being hardly any incentive to earn back the costs made. Second, there are "external costs" that are often not charged or settled. Finally, costs are still not made to depend on the extent to which the infrastructure or space is used, the so-called "variabilization" of the costs. It is particularly important to consider management aspects of shared spaces and infrastructures, and in some cases charge systems connected to them:

- More clarity is needed with respect to the practical and principal reasons for the preference of private or public management.
- The charges are independent of distance, and the internalization of costs for environmental aspects and reliability of supply will be or will have to be introduced.
- How to handle the (improper) derivation of legal rights from the infrastructure and "public" space, or how to change this.
- The option of so-called "delocalization" as a proposed solution: a shift from responding to local circumstances and making use of them towards having control over the physical conditions. Delocalization is closely interrelated with the "programme design" or the "drawing up of the agenda" of the urban and regional development. It is of particular importance to make spatial interventions leading through the concrete formulation of the commissions and the strategic use of this.
- How to handle the "first mover" problem in spatial development. The sheer risk of specialization in the various professional specialisms is that one loses sight of the entirety, while this is a prerequisite for being able to accept one's responsibility for one's own contribution. Each group, each individual member becomes more functionally dependent on others because of specialization of one's own functions. The "chains of interdependence" branch off and become longer, and, consequently, become less transparent and less verifiable for each individual and each group.

Spatial planning and, within this area, the planning of networks and infrastructures will have to be inspired more by aspects of flexibility and alternative network geometries. This points to the importance of strategic “location development”. One of the background features is that the necessity of extension and/or change of infrastructures become less predictable and involves higher risks (big investments and/or structural changes will not be able to take place so easily, unless collectively supported by several parties). In this, the importance of urban direction and of the guarantee (protection/defence) of specific public services increases. However, the interpretation will differ from the present one, one of the reasons being the so-called “open” economic structures resulting from globalization. Companies break off ties, often historical ones, with national and/or regional authorities. At the same time, however, it is exactly these companies that more and more design the infrastructures and manage logistic chains, and in doing so they control the networks, spatial layout and in the end dependence.

Private property implies heavier supervision (with more rules/bureaucracy) and extra costs for the companies and the supervisor. Therefore, there is some risk of the competition expected to result from the liberalization of public services not leading to lower prices, and not guaranteeing higher reliability of supply and more sustainability. This is mainly caused by strategic behaviour of “key players” (dominant participants), including national authorities and the energy companies concerned on and near the energy market. Take for instance the debate on nuclear power and the role of France with respect to the European electricity supply, but also the natural gas related incidents between Russia and Ukraine. A free-market system is based on a theoretical-economic approach: “Authorities would behave as ideal market superintendents, and players on the market as producers and consumers according to the book.” Reality is more complex: all players show strategic behaviour, with some large concentrations of power ruling the roost as a result. At the international scale level the dilemma of “competition or dominance” plays its role: those countries that behaved “according to the spirit of the letter” of liberalization may become the victims. E.g. with respect to energy supply in Europe, a European market arises with a more or less oligopolistic character, little effective competition and, consequently, few incentives for innovation, real sustainability and permanent cost reduction. In addition to dominance and oligopoly, another important result is that the various processes, that used to be confined within the various borders of the countries or of the regions because of restrictive regulation, can now “march on” to those countries or regions where they can be carried out best, looked at from an angle of business economy. Hence, the processes become “footloose” and authorities (and society) lose their grip of them. This, together with the “economies of scale” and the ongoing centralization of processes, causes more difficulty in preserving the “direction” (sustainability) or in adjusting the processes. It results in an increasing pressure on aspects of “general or public interest”, and a general increase in the pressure of transport and increasing complexity of the connectiveness and heteronomy. Consequently this leads to an increase of the load on infrastructures and environmental load, and to a spatial planning following an unbridled development of infrastructures, with the corresponding negative consequences for liveability, sustainability and “beauty” at various scale levels.

4. Different Network aproach with Alternative Configurations

As stated in the previous chapter, the ecological and spatial conditions of the open areas in and around towns are more and more under pressure. Relatively speaking, distances become larger, technical infrastructures become less visible, whereas traffic infrastructures and technical infrastructures cause impediments more often. This produces inefficiency and irritation for various user groups and stakeholders. When supported and managed well, a spatial planning strategy based on a changing approach starting from the user, whether or not organized into new types of being a commissioner, to be classified is more positively than the usual “issuing do’s and don’ts”. Although the latter should also be a specific part of the new approach in order to guarantee a minimum of guarantees. The main advantage from the built-up environment will then be that it reinforces the aesthetic and functional qualities, improves the entire flexibility of the system, makes use of vulnerable, scarce existing public areas, such as parks, squares and public buildings, and enhances the “readability” of solutions.

An alternative network principle can help break through the relations, that have come about as a result of historical factors, between the internal organization within the administrative organizations themselves and the connections with each other and with the more general social structures in the specific places. Policy seemingly obvious and independent of the paths chosen, and a role of the dominant participants supportive of a paradigm is prevented in this way. Moreover, such a principle has a clear spatial component. The spatial policies of the various national authorities suffice are less and less satisfactory. The systems used mainly at this moment facilitate standard solutions. Moreover, they more and more often lead to lengthy procedures and delays causing the launching tempo, relatively slow as it is, hardly to be able to follow society’s needs, not to mention to guide them. Therefore, a larger differentiation in the planning processes with a closer co-operation between the local, regional and national authorities is argued to be necessary. In this matter, a planning which is more regionally orientated may be the answer to the division between town and country, which is fading away more and more, and the changed organization or geometry of the mutual connections and spatial planning, which has earlier come forward as essential. The concept of “external economies of scale” developed at the beginning of the twentieth century, and the principle of “cumulatively self-reinforcing agglomerations” introduced in 1920 by Marshall could be the basis for this approach (Saxenian, 1994).

Especially the principles of “clustering” and “integrality” (physically and administrative-organizational) are of importance here. Composite measures of sustainability provide useful insights to the environmental impacts associated with human activities, but, in themselves, are not the solution for abandoning traditional paradigms. Finding a new approach to clustering implies a totally different approach of the networks, also described as the pursuit of a different network architecture or geometry on the one hand and different network control or network constitution on the other (Timmeren et al., 2007): In energy supply, there should be more emphasis on increasing the flexibility in the current (infra)structures, including Town and Country Planning in its entirety. The more so since it can be expected that there will not be only one decisive future technology to solve the coming problem(s) concerning security of supply and sustainable development. Especially with respect to energy this asks for a simplification of the processes, products (or rather: services) and parties involved. A larger concentration on integral provision of services, or, in other words, the supply and management of integral packages, offers possibilities. This seems to be reinforced by the (ongoing) liberalization processes. Another solution is having the level of application attune better to the lifestyle and direct surroundings of the users. The desired changed philosophy described has far-reaching consequences for the way in which infrastructures are designed and integrated. It is important to realise that the stability or resilience of networks is directly related to their complexity. Composite measures of sustainability provide useful insights to the environmental impacts associated with human activities, but, in themselves, are not the solution for abandoning traditional paradigms. Resource reduction strategies in close collaboration with urban planners, infrastructure developers, and representatives of key social groups is the basis to achieve environmental improvement, decouple environmental pressures from economic growth, and to restore and develop the functioning of lively neighbourhoods and natural systems in urban regions. This can be supported by an alternative organisation based on decentralized clusters (Timmeren et al., 2007).

5. Introduction of Decentralization and the support of change

The application and fitting in of new decentralized techniques and/or alternative network structures, does not suffice for the accomplishment of sustainable development. Too often there is tension between the mechanisms and the institutions that regulate motivation on behalf of individual or joint wishes. The integration of complementary functions will make or break of the proposed new approach to spatial planning. However, tackling environment-related problems in spatial planning by means of infrastructures often still directed by authorities may be a good start for guarantees of a sustainable arrangement within the various networks and chains. At higher scale levels, many environmental measures still fail through bureaucracy and too large differences in the target groups. Opportunities for a widely supported need for innovation are neglected here, and so is the chance of more significant “sustainable development”, for example through scale invariance. Lately, especially where the essential infrastructures for waste water and energy are concerned, there has been a growing awareness that there should be an end to the unidirectional approach.

In the study presented in this paper (Timmeren, 2008) it was concluded that decentralized systems can only be successful if they are combined with other functions (or supports of structure), and that it is necessary to try and reuse the recycled flows of energy, water and nutrients as close to the (local) solution as possible, or to insert them into the natural system. In this, one might postulate that it is less probable that the optimum scale of the subflows restructured into sustainable cycles will be found at the highest or lowest scale levels. This was supported by Papanek (1995), who claims that one of the central problems is the incorrect level at which ecological design problems are solved. Thus, his proposition that “Nothing big works – Ever!” should be completed with “…and neither do many autonomous small entities”. It is the result of the lack of flexibility and sustainability, and they are caused by the unidirectional development of the level of application. It is not without reason that the word “autarky” originates from “self-sufficiency” that was desired by the level of the Greek “polis”. The polis concerned a flexible reciprocal relation between city and hinterland, centralized and decentralized structures, culture and agriculture. When the balance was broken, new ‘polis’ were founded.

An additional advantage of the use of decentralized clusters is that it offers good possibilities to enhance the necessary transition of product supply to provision of services within the essential flows of energy and sanitation. This is also called: the change from “scale economy” to “economy of scope”. As a result of globalization and individualization, the consumers’ demands are less predictable and less unambiguous, and this is why many companies develop flexible structures of organization and direct-marketing tools. In such an “economy of scope”, clusters of specialized companies collaborate closely in synergistically attuning inputs and outputs and in exchanging knowledge. Because of privatization in the markets of energy processing and waste-disposal, the principle more and more applies to these essential utilities.

Technique influences social life, although this does not go so far as technician sometimes think: we would be able to solve social problems with technical solutions. The problem is that this technology-focused (“techno-fix”) thinking takes too little account of the fact that its introduction almost always involves several unforeseen side effects. In a relative way, our limited knowledge and organization is a problem for the current solutions. The theory has been developed with its basis on yesterday’s challenges, whereas the context has changed substantially. Society is characterized by constant change and transformation.

With respect to this, Röling (2000) claims that survival of mankind is connected with man's talent to change paradigms and to deal with that change effectively (adapted from Kuhn, 1970). This implies the creation of a new dynamic efficiency, an open-end condition as a start rather than a fixed end to work up to. As do Todd (1994) and other ecologists, biologists, urbanists and sociologists (Holling, 1995; Maturana & Varela, 1992; Harper, 2000; Capra, 1996; Tjallingii, 1996), Röling states that "cognition" (perception, emotion/affection and acting) should have a more central role in the current systems and their structures. This goes beyond just "adaptation". It should be taken into account form the moment of the initiative and design. This is also called a "resource-based view", as opposed to the usual "market-based view". Within such a process, the parties relevant to the area can focus on the future, any uncertainties and unexpected incidents, so that they may find alternative possibilities for the design and/or the arrangement, may reveal or promote subconscious strategies and gain experience with the aspect of joint actions. In a way, the process can be compared to the working of a metabolism. Because of an interweaving of sources as well as parties involved at present, advantage can be taken of the chances in a specific living area in a more effective way. The focus is on the incorporation of communities and the principle of "improvisation". Improvisation is "the concertino of action as it unfolds, drawing on available material, cognitive, affective and social resources" (Cunha, 2000).

The issue is how sustainable technology can be promoted within the focus of infrastructures, who is responsible, and how it can optimally fit in with the five phases of cognition. Should it be governed by the authorities or should it be left to the industry and the free-market system? In practice, it appears that the efficiency and competence of organizations to learn from the market or to adapt to it suffer from a lack of "social capital". In the development of buildings or districts and their infrastructures and technical systems and subsystems, parties involved often lack a concrete definition of the abstract notion of "society" and its "social needs" or "suprastructure" (Max Neef, 1991). Various approaches have been developed for this. The most important one within the scope of this paper, is the approach of "niche management" (Kemp et al., 1998). The basis is to realize that "niches" can be created. Niches often generate a set of instruments for setting up a new paradigm or system of techniques. The creation of niches can also take place in a planned way. This is called strategic niche management : "the creation, development and controlled phasing-out of protected spaces for the development and use of promising technologies by means of experimentation, with the aim of (1) learning about the desirability of the new technology, and (2) enhancing the further development and the rate of application of the new technology" (Schot & Rip, 1996). The difference with the more familiar principle of "pilot projects" is that a shelter is built around the new technology in the case of strategic niche management, through which the technology can develop from prototype to an actually applicable technology. Eventually, the technology should work without any protective measures at all.

It is essential to find a strategy and a method for a successful introduction of innovations to the market, even in the case of strategic niche management. It is of importance to find a strategy and a method that support such a process without relying on central authorities too heavily. Support may lie in modernizing the views on the (economic) value of products and services. This is also called the "Eco-efficient Services" strategy (Meijkamp, 2000). In the present "services economy", products and services should only be considered as instruments for the production of what people need. One of the potential advantages is that there will be more emphasis on system-oriented optimizations, rather than purely product- or process-oriented measures.

Critical to the implementation of this option of an approach based on the urban metabolism, or better: of integrated resource management, is knowledge dissemination of low exergy solutions (for all flows considered) including strong feedback systems between the different physical scales (site, neighbourhood, district, city-region). At all times alternatives should be offered. Meanwhile, "reflexibility", the use of the users' critical intelligence and commitment (in an environmental-technical, aesthetic and political or socio-political way) for the design of environmental-technical and spatial processes, can be achieved through the participation of users in the design, the construction and even the management of the built environment (including infrastructures), or parts of it. This goes beyond just social control. The other, often dominant parties involved should realize that the involvement of occupants/ users goes further than just the change itself (design, construction). It is a balanced concept which is interconnected with surrounding projects, in a structure that supports flexible and continuous change processes, is open, and is continuously capable of absorbing corrections through permanent reflection (and learning). A development of an area focused on sustainability had better not follow the ready-made plan, but should be embedded into a structure of flexible and continuous processes of change. This is also called "place making" (Healey, 1998). It should be based on regenerative systems, open to corrections and capable of continuously absorbing changes.

In the increasingly complex interaction of regenerative systems and integration processes it is crucial to appoint a so-called "leading actor". As there is often a lack of creativity, and the leading actor is too far away from the concept for the system to be able to play a good integrating role in the further development and building process, it is a natural decision to appoint the designer in this role. The designer's role, however, is quite different from what they have experienced or interpreted from times immemorial. The difference mainly lies in the type of the co-ordination and the manner of working, which is more like a following way (detailing various alternatives on the basis of, for example, maximization studies), where solutions are highlighted only at a later stage after checking with the various parties/participants; this as opposed to the (conventional) advancing of solutions. In addition to this, instruments focused on decision-making are necessary, so that people will not be stuck in endless discussion or design phases.

When started as a niche, it can be taken as a method of allowing innovations to grow for the purpose of a more structural and large-scale use. The starting points of the restructuring processes from the industry, known as “empowerment” and “business process re-engineering”, are of interest. On the one hand a more market-oriented attitude should be taken as its starting point, on the other a more local, bio-climatical or surroundings-oriented way of organizing. The background for this is the global transformation of economies from being focused on “mass production” to a focus on “tailor-made for the masses” (economy of scope). Particularly inspired by liberalization processes, there is now almost only attention for the first aspect within the essential flows in the built-up environment and their infrastructures. The second aspect (surroundings-oriented attitude) implies a larger and a more structural change, and offers better opportunities for innovation and further-reaching sustainability (at several scale levels) based more on the actual specific urban metabolism. It also addresses to the increasing demand for user-specific, “on-site” solutions.

6. Conclusions

One could state that the infrastructure of the essential (or critical) flows, due to its ‘path-dependent’, long term character, importance of network geometry and the existence of a limited number of dominant actors per network or flow, is determinative to what degree a project -varying in scale from a (part of a) building to a city or region- will or can be sustainable. Especially the wastewater infrastructure and the energy infrastructure can be characterised by transported flows that are not drawn up out of ongoing ‘ecologisation’ and dematerialisation but out of efficiency in central management and other economical factors. There is rising concern for the complexity of structures, aging of existing (technical) infrastructures and, within the increasingly heterogeneous networks, even several places of congestion. The development can be qualified for being ‘path-dependent’: as for the essential flows this means a ‘centralisation paradigm’, resulting most of the times in solutions that still include mixing of different (sub) qualities; i.e. are not based on the sustainable approach of cascading- and exergy principles. From the point of view of sustainability the technical infrastructure and with it urban development therefore seems to be insufficiently efficient. Within this process of path-dependent development, the existing infrastructures therefore can be considered as a growing restriction for sustainable interventions on lower scales, and therefore sustainable development.

In current central infrastructures of energy as well as wastewater flows, the possibilities of an alternative network layout are not or not sufficiently taken into account. More and more connections are made between the various networks and sub networks in gas and electricity networks, but this occurs because of considerations of capacity and economic (business) perspectives, rather than on the basis of the principle of network geometry. Consequently, there is a direct interest for large-scale central networks to have subsystems as a decentralized clusters included into the complex network. Because of the principle of self-organization, the latter also offers the possibility and the guarantees for being able to make local decisions with respect to, for example, further-reaching sustainability without abandoning the principle of scale size (“economies of scale”). Systems within decentralized planning concepts may lead to networks, complex or not, with a more strongly decentralized network structure with part of the networks performing relatively autonomously. These may support flexible planning concepts in town and country planning.

Differentiation and urban flexibility (i.e. for buildings and infrastructures) are pre-conditions for anticipating long-term uncertainties, due to liberalisation processes, rising complexities and mis-use or even sabotage. Sustainable starting-points are suppressed more and more by these changes. However, at the same time especially the intermediate scales can start up the necessary process of transformation towards real sustainable development, for it takes the best of two worlds. At present however, technical infrastructures still are leading to urban development, often even to the suprastructure of society. The strategically or even random integration of decentralised clusters (which preferably approach sustainable generated autonomy) in interconnected centralised networks will help to improve the resilience, flexibility, security and sustainability of the overall network. At present mostly only the dependence of decentralized systems on centralized systems -in general for reasons of storage and/or backup- have been put forward. However, especially in case of ongoing interconnection, centralization and liberalization, both future paths for sustainable development, the ‘economies of scale’ and the ‘scale economy’, or “autonomy” and “heteronomy” need one another mutually. Apart from that, the issue of a more precise attribution of costs to specific customers or transactions (which becomes more and more important as complexity decreases with ongoing liberalization) may be solved or may easier be solved. The postulated changed urban planning and related network philosophy in this is the cascading use of resources, where high-grade flows are used in high-grade processes and residual waste flows are used in lower-grade processes, thus making the most efficient use of the initial value of a resource. This so called low exergy approach taken here is inspired by the urban metabolism based on natural ecosystems, where processes run on the available (usually low exergy) resource flows. This approach is thus in line with the Industrial Ecology and regenerative design thinking of taking nature as a role model. Low exergy design and ecological approaches can strengthen the systems, methods and tools used for organizing, operating and supervising the urban environment and will minimize the negative impacts of urban areas on ecological cycles at all levels, creating efficient urban systems and livable cities. A life-cycle approach and planning based on ‘place-making’ is mandatory here in order to capture all relevant environmental effects to ensure an overall optimisation of resource use at all times.

A STUDY OF SOCIAL ASPECTS WITHIN AN ENVIRONMENTAL ETHIC IN ARCHITECTURE

Justo GARCÍA-NAVARRO (1)
María-Jesús GONZÁLEZ DÍAZ (2)

[1] Construction and Rural Roads, Polytechnic University of Madrid, Spain justo.gnavarro@upm.es
[2] Construction and Rural Roads, Polytechnic University of Madrid, Spain mjgonzalez@arquinex.es

Keywords: sustainable construction, social, ethic, holistic approach.

Summary

Sustainability is the joint consideration of environmental, economic and social factors. While there is already a methodological *corpus* on environmental and economic aspects, research on social aspects is still lacking, especially in the field of construction.

These social matters as applied to the world of sustainable construction need to be specified: the group of social issues is too vague. Therefore, a basis on which to act is to be found and needs to be defined. This involves an understanding of the aspects which must be specifically treated within the framework of social relations and behaviours in sustainable architecture.

In order to achieve this, we have begun by compiling all the already existent basic definitions that hold the theoretical base of a sustainable building. For example, what the social aspects are, strictly speaking, and what their positions are, if any, in the field of environmental ethics. These basic definitions are then developed in more specific aims, framing the field of study and marking out fields on which to act as the basis for defining indicators.

Secondly, the fields of study within a social understanding have been extracted from the different existing evaluation methods for buildings environmental behaviour (for example, analysing in what general fields the applicable indicators are defined: those relative to user's health, mobility, etc.).

These indicators have then been studied in terms of their range, universal scope and field of action, and later compared with the basic definitions. This has helped to determine if the indicators are adequate, sufficient, and adjusted to ensure compliance with the social aspects that conform a sustainable building.

With the observation and analysis of these criteria, the empty fields, lacks and deficiencies that must be overcome in environmental evaluation methods, in order to holistically understand sustainable buildings have been stated: this holistic understanding is one of the necessary steps for obtaining an environmental ethic.

1. Present status. Sustainability as a concept

The term "sustainable" has reached a wide spreading in later years in different fields, with practical results in the construction sector and mainly in the architectural field. Nevertheless, for the consolidation and development of the process, it is necessary to search the meaning and specify the concept of "green" buildings and the benefits these buildings can bring. This particular task should be orientated, not only towards the general public but also and more specially so, towards the professionals implied as agents and from whom the development and fulfilment of these plans depend.

The first issue is to define what building sustainability is. There are several initiatives, social movements, organizations and working groups which have the mark of sustainable building and indeed, a great number of different approaches can be identified.

The reality offered to the architectural professional is drawn from too many alternatives which have created a confusing situation. This unclear and imprecise state adds up to the one created in other spheres but also with a great influence in the construction field: that is, the frequent outrageous architectural construction presence in the media and the overwhelming use of the "sustainable" adjective in non-scientific environments such as publicity, marketing, or in general in the mass media. Therefore, the difficulty to come up with an appropriate, precise definition of "sustainable building" has become an international problem and its scope is thus global.

The first initiatives and organized groups working on the issue of a "green" building (see the following sources identified later) started to join together efforts a decade ago. At the beginning, several studies on energetic topics were carried out, directed towards a consumption reduction and an energetic efficiency. (Gay et all, 1997), (Banham, 1997) Later, some economic and different factors and categories were also considered (Graham 1997) (Beetstra, 1997) and finally sustainability was defined as the integration of environmental, economic and social factors, according to Takemasa (2005) and Ulrich von Weizsäcker (2005). As a result of this, there have been a prolific number of surveys approaching environmental and economic aspects, whereas studies concerning the social studies in sustainability present a confusing state (Guy et all, 2007).

2. Difficulty in establishing indicators

The unclear situation of sustainability conformed by the three aspects –environmental, economic and social--, is further increased by the difficult situation originated by the information spreading and the lack of accuracy in the terms being used. An objective perspective for selecting the sustainable buildings needs to unavoidably focus on these three indicators. A quite clear agreement exists over the environmental and economic indicators, supported by technical surveys based on the building environmental assessment methods. An indicator is a parameter capable of providing relevant information regarding a specific phenomenon. It has to be simple so as to be easily used; it needs to be able of quantifying in order to establish comparisons, and it should be capable of communicating the needed information. Therefore, the indexes used are a combination of the values obtained by the element on the precise indicator so as to measure the variable.

Regarding the environmental and economic aspects there is quite an agreement. As an example, we can take the indicator of the energy used for a building maintenance in a geographic location and with a specific building typology. The 15 kw/m2 indicator obtained for passive houses (Passivhaus Project, 2007) in the district of Kronsberg in Hannover, Germany, indicates results higher than 50 kwm2 per year obtained by other buildings in the same sector. At the same time these results can be compared with the ones obtained in Spanish typological constructions. The period of economic return of the investment used for the improvement of the building thermal insulation is in fact an economic indicator. There is clearly an agreement in the appraisal of the benefits obtained by these indicators. The CO_2 emission produced by the manufacture of the materials employed in constructing a building of a specific type can also be another indicator. The potable water supply per inhabitant per day can become also an indicator regarding the scarce water resources of our societies. The application of these indicators is direct, rational and comparable. Nevertheless, it is very difficult to come up with a definition for an equivalent of these quantifications in the social aspects. Indeed, the questions remain clearly unanswered: what are the social indicators? What do they have to measure? On which concepts should they be applied to, or studied? And even more; is it possible to reflect, in a comparable way, the object to be measured, the scope and the results of these "social" criteria? What criteria can be taken as a common base so as to establish those criteria?

3. Aims of the indicators establishment

The primary aim of this proposal is to establish a common base among all these multiple approaches of the so called "sustainable architecture" in order to create a ground on which to specify, analyze and define the indicators integrating the aspects, and paying special attention to social determiners.

For this reason, in this study the following operations have been established:

- A selection of main resources, keeping in mind the broad spreading in the different fields.
- A compilation of definitions, their analysis, selection and systematized comparison of the gathered information.
- Establishing unifying criteria proposed for the completion and methodology to use the new indicators (system).

The working hypotheses stated at the beginning are the following:

- The assumption of the variety of points of view in sustainable architecture; the complexity of architecture allows several approaches.
- The difficulty a field such as building encompasses, with multiple and varied users.

- The variables, probable qualitative rather than quantitative, that social aspects include and which are fairly difficult to express in objective terms or with a certain degree of subjectivity implied in the process.

4. Basis and sources of knowledge

To reach an integral interpretation of the phenomenon, the different sources of knowledge should be clearly known and analyzed in detail. In the present state, sustainable architecture is a term used and even adapted in many different areas. Some of the sectors in which this term has become a landmark are commented hereafter. At the same time these sources define, in a direct or indirect way, their own idea of what sustainable architecture represents where the social indicators defining the concept are implicit.

4.1. HABITAT program of United Nations

The HABITAT program of United Nations and the International Community periodically organizes the Contest of Good practices. It has, as the main goal, to strengthen society and political awareness toward the improvement of the citizens' life conditions from a perspective of sustainable development. It works in agreement with the principles stated at the Second UN Conference on Human Settlements, Habitat 1, and the Dubai Declaration, ratified at the Special Session of the UN General Assembly , Istambul+5, celebrated in June 2001. Probably, this is the organization which more directly analyzes and awards initiatives with a clear "social" approach applied both to constructive and urban practices, developing a system on objective indicators of social issues within the integral concept of sustainability.

Regarding this, the Habitat Committee recognizes as Good Practices the following requirements, also drawn at the previously referred Dubai Declaration:

- To have a demonstrable and real improvement in the life conditions of the people.
- To be the result of a joint work among different sectors acting and living in the city: administration, citizens through their associations, and the private sector in general.
- To be socially, culturally, economically and environmentally sustainable and durable.
- To contribute to the strengthening of the community and its organization capacity.
- To specially consider the resolution of social exclusion problems, due to gender, cultural, ethic or economic reasons.

In the last of these callings, for 2008, the following areas of studies are stated; all of them strongly supported on socially bounded criteria:

- Housing area, in which concepts such as ecological dwellings, energetic saving and rehabilitations are included. Special attention is paid to problems such as rent problems, physical, economic and social accessibility for disadvantaged groups.

- Area of sustainable land and urban planning development. This section values improvements in the urban, physical, economic and social environments for all sorts of collective medium such as neighbourhoods, cities, tourist locations as well as their rehabilitations. It includes the land and urban planning which considers the accessibility and the design for all communities, the functional balance and the improvement of amenities.

- Specific area of gender and fight against social exclusion. It studies and values the initiatives which reduce specific problems of gender, migration and cultural diversity.

- Specific area of sustainable management of natural resources. It studies solutions and initiatives which promote a more efficient energy production, consumption reduction, renewable energies, and recycling. It also deals with the recuperation of contaminated grounds and the study of the water cycle.

- Area of the city and its natural environment; focusing on present and specific problems, such as ecotourism and new enterprise initiatives.

- Area of transport and accessibility, studying the specific problems of gender and disabled.

- Area of urban governs, insisting on issues of management and valuing solutions for gender specific problems.

4.2. Consolidated international private initiatives of scientific character: iiSBE

The iiSBE, acronym for *International Initiative for a Sustainable Built Environment,* has a recognized international acclaim. Among the great quantity of technical information found within it, the research referring to social aspects in the sustainable construction has not yet reached enough development, and specially not so in the case of health and air quality inside buildings. In the academic program of the International Conference SB05 held in Tokyo, areas normally related to sustainable construction (such as environmental assessment, building evaluation, case studies, urban and regional context and construction agents), were analyzed and for the first time ethical aspects regarding sustainable construction were also included. This shows how the scope of the different areas affected by the term sustainability in building are being enlarged and go beyond the merely technical aspects, moving towards a more complete, integrated concept of architecture. These ethical aspects focus in the relation between human beings and nature, and within it, the impact of the architectural professional in its surroundings. The need for ethical codes in relation to the performance of all the actors involved in the constructive process through learnt lessons and education aims was also highlighted.

4.3. Methods for building environmental assessment

These methods allow to establish objective comparisons between different buildings, in such a way that the ones with a “smaller environmental impact” can be chosen, and it will be possible then to give them the trademark of “sustainable building”. The different strategies of the environmental impact studies are well known for all the phases of the life cycle building –design, construction, maintenance and demolition--, regarding energy and resources use and specific environmental impacts.

The main methods or those which have been widely used are further described (Sangster, W. 2006.) All of them recognize, in their declaration of intentions, the economic, social and environmental benefits of a way of constructing which causes smaller impact to the environment. This leads to considering these practices as key factor for the upkeeping of the planet’s health, and a clear improvement of the products themselves together with the profits for the users.

These methods are the LEED (USA), BREAM (UK) , Green Globe (Canada y USA), Green Star (Australia), CASBEE (Japan), SBTool (originally from Canada using tools which have been regionalized and adapted in many countries such as Spain, Italy, Argentina, etc).

These systems assess environmental impacts through study fields or categories. As an example, the CASBEE method presents the following four areas: energetic efficiency, resource efficiency, as well as local and interior environment. Other methods include up to 9 areas of study, as in the case of the BREEAM: management, use of energy, health and user’s wellbeing, pollution, transport, use of solar energy, materials and use of water.

The fields of study refer mainly to environmental issues. None of these methods includes a study area specifically oriented towards social themes with concrete social indicators. However, they also include topics which clearly surpass the environmental issues, and they are related to more subjective issues: LEED includes design innovation and quality in the process; BREAM includes health and wellbeing; Green Globe, Green Star and CASBEE assess the quality of interior air as a study category; SBtool also refers to the quality in service, and transport indicators as well as distance to points of social relevance.

An important issue not to be forgotten due to its great transcendence is the new orientation these methods are undergoing; more precisely, SBTool of iiSBE which is going through a conceptual change where basically the impacts are measured and the reduction is assessed. The values given to each of the impacts are assigned regarding the priorities of each country and the local and global importance each one of them has. This new orientation is technically supported by the standardization efforts of CEN and ISO, and is also considered by the national norms (in the case of Spain, CTE and CALENDER)

Therefore the scientific precision of the process is enlarged, since it is not any longer based on the addition of the means from areas, criteria and categories but it needs a consensus on a more subjective basis. At the same time, it will allow for the self assessment by any of the implied agents in the construction and exploitation processes.

4.4. Reknown and highly qualified architecture

The spreading of “sustainability” in the field of architecture is done in the media through several sources. Since it is not a traditional or fixed subject in any educational cycle, and it is of quite recent development, and it appears in an area where a great ignorance prevails, the way it shows in the media and way this appearance is done has a great influence. Some architects known by their brilliant works and by their support to sustainable architecture have been of great importance for the wide spreading of sustainable architecture. Their opinions, including the contrary or opposed, have also contributed to the raise of the concept of sustainability.

These architectures, called by their authors “sustainable”, are represented as models for the public who accepts them as such without questioning this issue or posing any criticism. In fact, this would not have happened regarding other more technical aspects or other disciplines more studied by architecture. The works and even the opinions of architects such as Norman Foster, Renzo Piano, Richard Rogers, Shigeru Ban, Ken-Yeang, as well as other Spanish architects have a great impact on the general public, but even greater one on the younger generation of architects. A similar situation can be observed with well known international competition or contests, such as the Holcim Awards, or the Aga Khan Awards among others, in which sustainability and the solution to social and integration problems are part of their value. However, it is necessary to extract from this discourse the concept of sustainability, especially when the term is applied to these types of buildings in which their iconic character surpasses any kind of critical architectural analysis.

In relation to this, it is necessary to comment the different approaches these architectures hold regarding the social content. Guy and Farmer (2001) identify six different positions in where the social interest is a predominant idea when this specific context is considered as one of them. The logical premises of sustainable architecture, according to these authors are the eco-technique, eco-centric, eco-aesthetic, eco-cultural, eco-health and eco-social.

In the opposite side of the professional prestige, but also with an important incidence is the excessive marketing of some commercial products –included not only in buildings, but also within urban units and complex tourist complexes—which use the term “sustainable” as a commercial call in order to capture environmentally conscious clients, although with a great technical lack of knowledge. There is not yet an objective way or recognized mark to identify these initiatives as “sustainable”, which can be internalized by all the members, in a similar way to what has been done with other evaluation systems of scientific research.

4.5. Non-state spontaneous initiatives of collective participation character

A different vision in sustainable architecture, much more committed with the practical daily life and the social compromise, is the one developed by some organizations, associations, foundations, non-governmental and independent groups. Some of them have been founded by spontaneous efforts of people in the rural environment and are based on the agriculture practice, removed from any conventional commercial circuits. This is for example the case of the “ecoaldeas” (ecovillages), (RIE, Iberian Web of ecovillages) which have organized sustainable dwellings, considering ecological aspects apart from social, economic and cultural ones, and where green architecture is developed. They promote a horizontal development of strong social content opposed to the commercial structures.

Other initiatives have based their efforts in the recuperation of the heritage and the conservation of almost abandoned traditional techniques. As an example, the use of the soil as constructive material has been recuperated due to social, environmental reason, and because it represents a tradition and it is compatible with the surroundings where the constructions are inserted. Examples of this practice are: Centroterra, Arquiterra, Proterra, Interacción (Navapalos Foundation), Craterre (France), Terra Cruda (Italy), Modern Lehmbau (Germany) etc, which have brought up discussion forums, studies, documentation groups or research in different countries. These initiatives are not completely strange to the legacy of those American alternative movements from the 60’s, with the self-sufficient, imaginative, self-accomplished and isolated proposals such as the ones described in the film “Counter Communities”. The work of sustainable architecture performed within these initiatives has a strong social, practical character, and is self-sufficient to a great extend, far from the conventional industrialized systems.

4.6. Grouped Standardized Organizations

The main organizations are:

- International Standard Organization ISO and its committee devoted to sustainable construction (ISO/TC59/SC17 *“Building construction/ Sustainability in building construction”*)

- In a European setting, the committee CEN/TC350 *“Sustainability in construction works”* as a result of Mandate of the European Commission to CEN (*Standardisation Mandate to CEN “Development of horizontal standardized methods for the assessment of the integrated environmental performance of buildings”*).

- In Spain, the organization responsible for standardization, AENOR (Spanish Association for Standardization and Certification) created at the end of 2003, a working group on Sustainable Construction, within the AEN/CTN41 “Construction” committee, which later changed into AEN/CTN41/SC9 “Sustainable Construction” and has recently become an independent standardization committee by the name of AEN/CTN198 “Sustainability in Construction”. Other normalization groups are AEC (Spanish Association for quality) and ENAC (Notional Entity for Standardization).

As can be seen, the interest in developing standardizing projects is increasing. In this sense, the European program LENSE (Methodology Development towards a Label for Environmental, Social and Economic Building), is working in this direction on the three categories mentioned. These categories --environment, social and economic-- present a whole range of main subtopics including: safety, health, comfort, user’s wellbeing, functionality, social values (equality, accessibility, privacy, working conditions, and boundary properties), cultural heritage (architecture, image and history) and ethical values (orientated towards an honest purchase, punctual payment and acquisition criteria). Therefore, the field of valuable criteria has been noticeably broadened with more complete new concepts.

5. Conclusions

It is obvious that those sources of knowledge provide, each one, with a different face of the architectural fact. One general view of all those sources is necessary. HABITAT program of United Nations offers a merely social structure; Private initiatives of scientific character, such as iiSBE, have a technical and numeral approach to subjective items; Methods for building environmental assessment show a whole view, but have a great difficulty in catching the design parameters; Highly qualified architecture is not very environmentally rigorous, shows a scarcity of critics, and sometimes contains too much marketing; Non-state spontaneous initiatives of collective participation character are too poor artistically and technically; and Grouped Standardized Organizations have a particular items, not focused on the standard certification, and are very far away to catch the whole symbols and languages of the complexity of architecture. Nevertheless, all of them contribute to understand the whole concept, and to establish rules for more accurate definition of social aspects of sustainable architecture.

So, taking the working hypotheses stated at the beginning into account, that is, the variety of points of view of sustainable architecture, the complexity of architecture allows several approaches, and the difficulty to express in objective terms, it is possible to obtain some concept systematisation. Although what has previously been said is merely an approximation in which the indicators for an assessment are not clearly determined too, the social dimension of sustainability is suggested through the groupings in some performance fields such as:

- Social aspects of the built environment: urban mixture, mixed use of land, accessibility to basic means of transport including the transport in leisure and culture areas, availability of green areas and social segregation.

- Land use (for example, density since it contributes to the wellbeing of the inhabitant etc.).

- Impact of the building on the built heritage, cultural heritage or on the social structure of a specific environment (for example, the one related to Nimby, Not In My Back Yard which describes the adverse reactions of some of the neighbourhoods to certain type of constructions).

- Aspects referred to the process: user’s participation in the process, capacity to encourage a good relation among neighbours, quality to support social cohesion, consideration of the different social groups in the design of common areas, etc.

- Universality and integration of the human diversity, regarding capacities (psychic, functional, sensory disabled), ages, sexes, social status, religious and cultural situations etc.

- Health and comfort aspects of the users, referred to humidity conditions, temperature, interior air quality, and safety (home safety and safety in the workplace, fire, risk or dangerous situations, etc)

- Safety for the workers during the preparation and building construction, during the manufacture of the construction materials, etc. Although the normative is not directly treated, there are references towards it.

- Aspects referred to the circumstances of building acquisition, whether it is of contractual, economic, financial or of purchase capacity type.

- Aspects related to the environment from the point of view of the user: quality of architecture, relation with the traditional and artistic inherited heritage, etc.

It is quite clear that the study of the social aspects broadens and that it includes integral aspects of building. This wide field evidences the interrelation between primary environmental, economic and social aspects as a requirement for a sustainable valorisation and needs to be considered from a global perspective; a final holistic approach towards an integral project is necessary so that it shows the complete shelter and habitat of the human beings, that is, the essence of architecture.

ANALYSIS OF PASSIVE COOLING EFFECT OF VEGETATION AND A CANOPY THROUGH FIELD OBSERVATIONS IN THE SUMMER

Keywords: radiant environment, passive cooling, solar shading effect, thermal comfort, heat island

Summary

In the last century or two, the increase in man's influence on the urban environment, such as the concentration of energy, and artificial factors, such as buildings and the heat characteristics of surface covering materials, has brought changes to city climates. Urban climate needs to be determined by many different factors, such as the use of various artificial buildings' surface materials on a building scale. The passive cooling effect has been recognized as the most effective alternative at natural cooling. This is a study of the passive cooling effects of three outdoor solar shading facilities: trees, a pergola with wisteria vine growing on it; and a steel framed canopy, all of which are expected to provide cool spots in the summer. Field observations of measuring the thermal environment of selected facilities are executed. The thermal environment measuring was categorized as short wave radiation, long wave radiation, net radiation, globe temperature, and surface temperature measured by an infrared camera. The heat transfer mechanism was analyzed with overall data from the field measurements. The results from this study are as follows; 1) The radiation balance measured on the shaded surface under the canopy was 17%(86 W/㎡) of the unshaded surface radiation balance(511 W/㎡). This clearly supports the theory of the natural passive cooling effect under the shade. 2) At 3 o'clock in the afternoon, a surface temperature comparison between the vegetation (the tree and the vine) and the canopy was performed. The surface temperature of the vegetation was same as the air temperature and that of the canopy was 5 ℃ higher than the air temperature. It is believed that the main factor that causes those differences in temperature is vegetation transpiration. 3) As the results from this study could be used as fundamental data for reducing the heat island, and continuous research on this subject is needed.

1. Introduction

As the city's overcrowding and centralizing is deepening, the increase in man-made arrangements, due to the concentration of energy, and artificial factors, such as buildings and the heat characteristics of surface covering materials, a decrease in vegetation, and wind directions affected by building structures, all act in concert to create a unique urban thermal environment. This urban environment is highly affected by the heat characteristics of building exteriors. Other factors, such as the characteristics of the buildings' exterior materials, planning the vegetation in the outdoor spaces, the planning of the building arrangement in consideration of the wind environment—all directly affect the urban thermal environment.

In consideration of the natural heat convection function, applying the passive cooling environment controlling method is the best possible alternative for a building's exterior space.

In this study, the outdoor solar shading facilities (trees, pergola with wisteria vine and canopy) are selected and analyzed for their passive cooling effects in the cool spots in the summer by observing the experimental objects' thermal environments, while focusing mainly on radiant environment and temperature.

The observations of the experimental object's thermal environment measuring were categorized as: short wave radiation, long wave radiation, net radiation, globe temperature, and surface temperature measured by infrared camera. The experimental objects and their surrounding area's heat transfer mechanisms are analyzed with overall data from the field measurement.

The result of this study is ultimately for a moderation of the thermal environment around the outer space of the building structure and it could be used as fundamental data to evaluate quantitatively for trees and the shading structure's spot cooling effect.

2. The outline of experiment

2.1 Space for experiment and methods of measurement

The experiment spaces are shown in Figure 1. The three popular outdoor solar shading facilities such as trees, pergola with wisteria vine, and a steel frame canopy were chosen as experimental spaces. The tree located in the grass garden is a zelkova tree, 7 m in height and 8m in width. The pergola with the wisteria vine is covered the steel frame, which is 7 m (length) ×5 m (width) ×2.4 m (height). The size of the steel frame canopy is 4 m (length) ×4 m (width) ×2.7 m (height) and is made of white Teflon.

a) tree *b) pergola with wisteria vine* *c) canopy*

Figure 1 The experiment spaces

The location of the measurement points were selected on each experimental object as the shaded area and the unshaded area to measure air temperature, surface temperature, globe temperature, relative humidities, wind velocity, infrared radiation temperature, and both long and short wave radiation. Among the radiant environment measurements, long wave radiation is measured on each experimental object, one by one, due to the difficulties in supplying the measuring device.

2.2 Experiment conditions

The conditions set for the experiment and the measurements of the representative day are shown in Table 1. The experiment conditions were set up to measure the thermal environment and radiation balance of the each experimental object's lower part, including the shaded area and the unshaded area.

The experiment was conducted from the 12th to the 15th and the 27th to the 28th of August in 2005. During the fine weather conditions of August 12th to 15th, the 13th of August was chosen as the representative day and analyzed. In this study, the measurement of the thermal environment was taken at the height of 0.8 m. On both the27th and the 28th of August, a long wave radiation measurement was added to be observed and analyzed. To measure the shape factor of each experimental object, a fisheye lens was used. The calculated shape factors are as follows: trees, 0.73 (73%), Pergola with wisteria vine, 0.77 (77%), and canopy, 0.58 (58%). The shape factor of the pergola with wisteria vine measured the highest and the shape factor of the canopy measured the lowest.

Table 1 The weather condition of the representative day

Experiment condition	Experiment day	Representative day	Temperature[℃]			Globe temperature[℃]			Relative humidity[%]		Wind speed[m/s]		
			Max	Min	Aver.	Max	Min	Aver.	Max	Min	Max	Min	Ave.

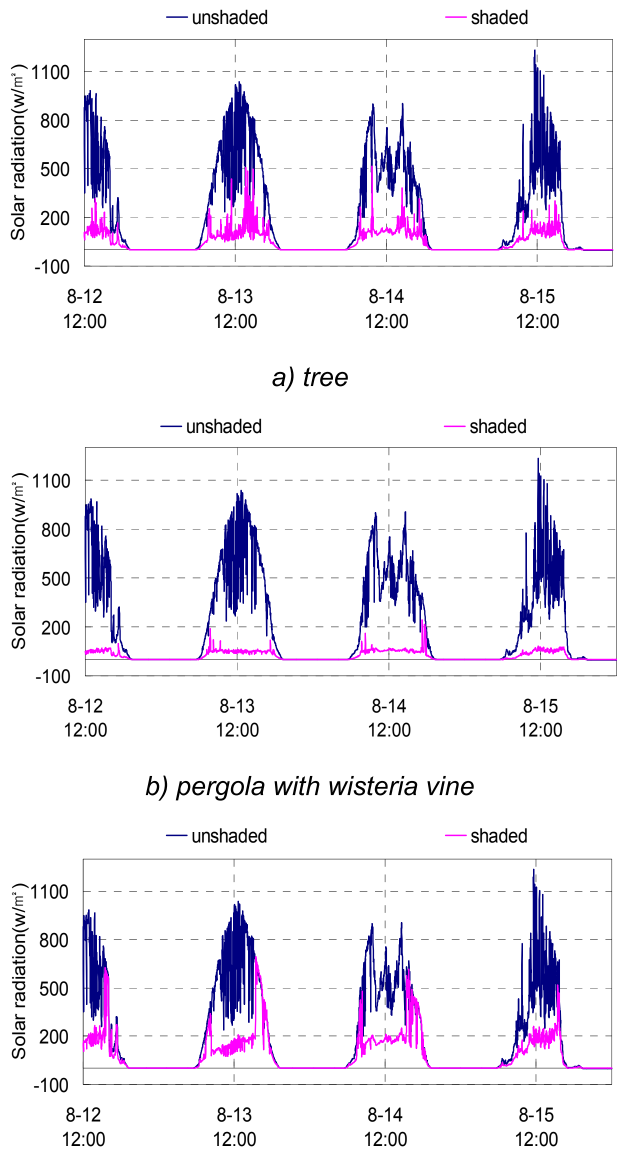
3. Analysis of experimental results and examinations

3.1 Solar radiation, relative humidity, wind velocity distribution

The distribution of solar radiation is shown in figure 2. The maximum value of solar radiation was 1,000 W/㎡ on the representative day. The value of solar radiation under the shaded area of the tree was about 60~120 W/㎡; under the pergola with wisteria vine was 40~60 W/㎡; and under the canopy was 80~200 W/㎡ (Figure 2). Around noon time, from 11:30 to 12:30, each experimental object's shaded area's solar radiation

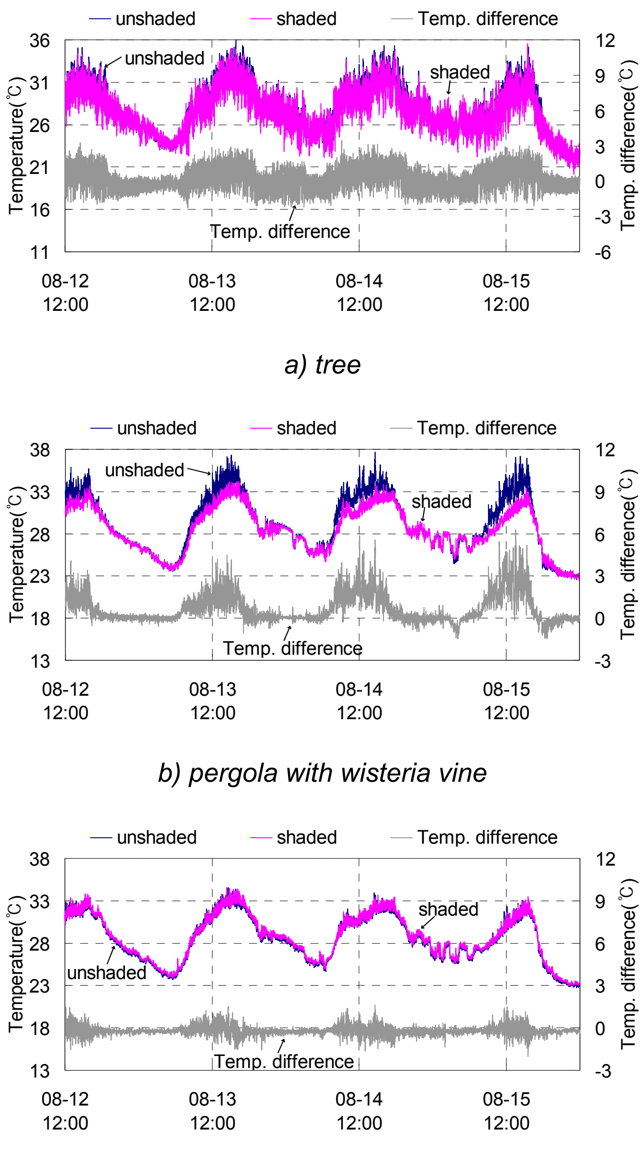


a) tree

b) pergola with wisteria vine

c) canopy

Figure 2 Distribution of solar radiation



a) tree

b) pergola with wisteria vine

c) canopy

Figure 3 Air temperature (Shaded and unshaded area)

was compared with their unshaded areas' solar radiation (1 hr average: 601 W/㎡) as follows: trees 15%(88 W/㎡), Pergola with wisteria vine 8%(48 W/㎡) and canopy 22%(129 W/㎡) (Figure 2).

According to the result, the Pergola with the wisteria vine had the highest shading effect over the solar radiation, while the canopy had the lowest. These results were derived from the interaction of the multi vegetation structure (leaves) with the higher radiation shading rates, the canopy's shading structure (white), and the reflection effect of the solar radiation and the low shape factor.

The representative relative humidity was 47~95% and the humidity difference between the tree's shaded and unshaded areas was at most 8%. The maximum wind velocity on the representative day was 3.4 m/s, with an average of 0.7 m/s, the experiment had been conducted under a low wind velocity condition.

3.2 Temperature distribution

3.2.1 Outdoor temperature

The experimental objects' shaded and unshaded areas' air temperatures are shown in figure 3. At around 05:40, the tree's unshaded area's air temperature on the representative day (13TH of August) had the lowest temperature of the day - (23.7 ℃) , while at around 15:50, it had the highest temperature of the day, at (35.2 ℃). The pergola with wisteria vine's unshaded area's air temperature was the lowest, at 23.9 ℃, at around 05:40, while its highest temperature (36.6 ℃) was measured at around 15:10. The canopy's

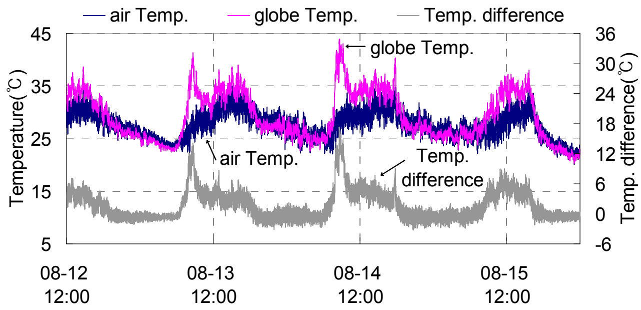
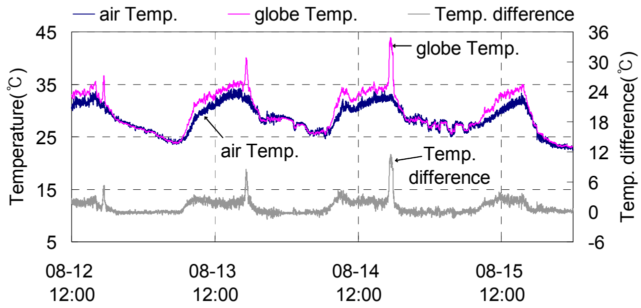
c) canopy

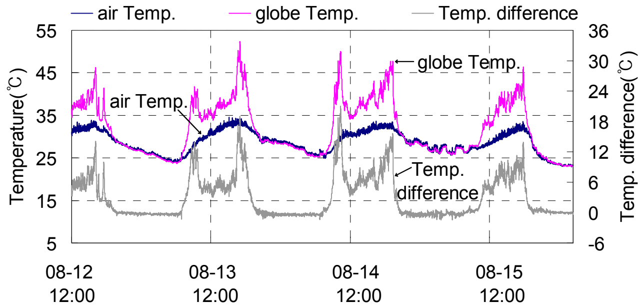
Figure 4 Globe temperature (shaded and unshaded area)



a) tree



b) pergola with wisteria vine



c) canopy

Figure 5 Globe and air temperature (unshaded area)

unshaded area's air temperature was measured at its lowest (23.8 ℃) at around 05:40 and its highest temperature (34.5 ℃) came at around 14:40. The pattern of the temperature changes was similar. The temperature difference between the shaded and unshaded areas in the Pergola with the wisteria vine was higher than between the tree's 2 areas. Compared to the tree and the canopy, the Pergola with the wisteria vine had the highest difference in air temperature, and the canopy had the least temperature differences (Figure 3). However, the air temperature measurement of each experimental object at 0.8 m high and 1.5 m high did not show any particular differences. Therefore, it is not mentioned in this study.

3.2.2 Globe temperature

The measurement of globe temperature, which is the incorporation of the radiant component around the experimental object's shaded and unshaded areas and the convection component in the surrounding air, is shown in Figure 4, 5 and table 2. To compare and analyze the experimental objects' shaded and unshaded areas' globe temperature changes under the equal conditions, the experiment was taken between 10:00 and 15:00, when the altitude of the sun is high and the shade is formed stably.

First of all, the globe temperature for the tree's unshaded area, where the solar radiation is directly affected, ranged from 33.2 to 50.2 ℃(average 42.6 ℃), while for the shaded area, it ranged from 28.7 to 38.5 ℃ (average 33.2 ℃). The tree's shaded area had little temperature variation as the temperature difference in the unshaded area was measured as 17 ℃ and the shaded area as 9.8 ℃. There was a temperature difference of 4.5~11.7 ℃ between the tree's shaded area and its unshaded area. The average temperature difference of 9.4 ℃ was measured (Table 2, Figure 4 a)).

The temperature of the Pergola with wisteria vine's unshaded area ranged from 36.6~50.1 ℃ (average 44.5 ℃) while in the shaded area, it ranged from 31.6~35.5 ℃ (average 33.4 ℃). Compared to the tree, its

Table 2 Temperature of representative day

Experimental object	Experimental areas	Globe temperature changes [℃]	Average[℃]		
			Globe temp.	Air temp.	Temp. difference
Tree	unshaded	33.2~50.2	42.6	-	-
	shaded	28.7~38.5	33.2	30.2	3.0
	difference	4.5~11.7	9.4	-	-
Pergola with wisteria vine	unshaded	36.6~50.1	44.5	-	-
	shaded	31.6~35.5	33.4	31.7	1.7
	difference	5.0~14.6	11.1	-	-
Canopy	unshaded	35.4~48.2	41.4	-	-
	shaded	34.1~40.8	36.6	31.8	4.8
	difference	1.3~7.4	4.8	-	-

unshaded area's average globe temperature was 2 ℃ higher, while the shaded area was only 0.2 ℃ higher (Table 2, Figure 5 b)). Finally, the canopy's unshaded area ranged from 35.4~48.2 ℃ (average 41.4 ℃), while in the shaded area it ranged from 34.1~40.8 ℃ (average 36.6 ℃). Unlike the other experimental objects, the canopy's unshaded area's average globe temperature difference was 3 ℃ lower but its temperature in the shaded area was more than 3 ℃ higher. The difference in globe temperature verified that the passive cooling effect of the shading structure (the canopy) was not effective (Table 2, Figure 4 c)).

In the comparison of the air temperature and the globe temperature, the little temperature differences both in the shaded area of the tree and the Pergola with wisteria vine were measured at 3.0 ℃ and 1.7 ℃ respectively. On the other hand, there was a relatively big difference of 4.8 ℃ in the canopy's shaded area compared to the vegetation (tree and Pergola) (Figure 5). This is a result of the reflection of the radiation energy of canopy.

3.2.3 The surface temperature of the objects

The experimental objects' surface temperatures were measured using an infrared radiation camera at the hours of 06:00, 11:00, 13:00, 15:00, and 22:00. The surface temperature reached its highest at 15:00. The surface temperatures of the vegetation (trees and Pergola with wisteria vine) were the same as the air temperatures, while the canopy's surface temperature was 5 ℃ higher than the air temperature. The temperature difference is a result of the differences in heat characteristics between artificial materials and vegetation. This can be explained as the cooling effect of the transpiration of the vegetation. On the other hand, the surface temperature of the canopy measured at dawn (06:00) was lower than that for the vegetation. The surface temperature after sunset (22:00) was similar to that measured at 06:00. The surface temperature of the canopy showed that it was high during the days and low at night.

3.3 Radiation environment

The graph of the short wave radiation and the net radiation of the experimental object's unshaded area measured on 28th of August. On this day, the radiation balance (short wave radiation, long wave radiation, net radiation) of each experimental object's shaded and unshaded areas were measured and analyzed and are shown in Table 3.

3.3.1 Short wave radiation

In observing the value of the downward short wave radiation of each object, the canopy had a value of 154 W/㎡, ahead of all the other objects' values. The upward component of the shortwave radiation was 82 W/㎡, the highest value of all the other objects. Its difference was 72 W/㎡ and it was verified that the canopy observed the most of the short wave radiation. The albedo in the tree's unshaded area was calculated as 0.30(=249÷838), as shown in table 3. The value of the albedo in the canopy was high, as its reflection rate affected influentially as it was in white color unlike the vegetation which was in green color.

3.3.2 Long wave radiation and net radiation

In the same manner as the short wave radiation analysis in the previous section of 3.3.1, the long wave radiation radiated by the surface temperature of the object measured highest in the canopy, as the result of the fact that the surface temperature of the canopy was higher than the other experimental objects.

On the contrary, the vegetation (trees and Pergola with wisteria vine) had a relatively low surface temperature compared to the canopy; therefore, the long wave radiation measurement was also low.

In the section on the overall radiation rate in table 3, "▼mark" represents the direction of the overall radiation balance according to the results of the calculations. As above, the value of the overall radiation balance (net radiation) implies the surrounding area of the objects' radiation energy value. As a result, the calculated radiation in the unshaded area of the tree, at 511 W/㎡, was much higher than that in the canopy, at 86 W/㎡. The reason for the low radiation value of the canopy's shaded area of 86 W/㎡ was because the downward short wave radiation (154 W/㎡) was lower than the tree's unshaded area's radiation (838 W/㎡). Moreover,

Table 3 The result of radiation environment

Experimental object	Direction	Short wave radiation [W/㎡]	Long wave radiation [W/㎡]	Net radiation [W/㎡]
Tree (shaded)	downward	84	459	543
	upward	32	460	492
	difference	▼ 52	▲ 1	▼ 51
	total	116	919	1,035
Pergola with wisteria vine (shaded)	downward	25	476	501
	upward	22	463	485
	difference	▼ 3	▼ 13	▼ 16
	total	47	939	986
Canopy (shaded)	downward	154	500	654
	upward	82	486	568
	difference	▼ 72	▼ 14	▼ 86
	total	236	986	1,222
Unshaded	downward	838	431	1,269
	upward	249	509	758
	difference	▼ 589	▲ 78	▼ 511
	total	1,087	940	2,027

"▲,▼" represents the direction of the radiation

as to the total value of the short wave radiation, the tree's unshaded area measured at 1,087 W/㎡, while the Pergola with wisteria vine's shaded area was 47 W/㎡; therefore, the variation difference was 1,040 W/㎡. On the other hand, in the long wave radiation, the canopy's shaded area was measured at 986 W/㎡, the tree's shaded area was measured as 919 W/㎡, showing a difference of only 67 W/㎡; therefore, the measurements of the long wave radiation showed that, it was not depends on the objects.

The overall value of the long wave radiation of the canopy measured the highest, at 986 W/㎡, as its surface temperature was relatively higher than the other objects (vegetation). This because there was no transpiration in the canopy, like there was with the vegetation, and also because it is made of artificial materials.

4. Results

1. In comparing the air temperatures and the globe temperatures under the objects' shaded areas, the canopy, which has a higher reflection rate than the vegetation, showed the biggest difference in temperature values. It is believed that the main reason for this was that there is a higher reflection rate in white than in vegetation, which is green.

2. The surface temperature reached the highest at 15:00. The surface temperature of the vegetation (trees and Pergola with wisteria vine) was approximately same as the air temperature while the canopy's surface temperature was 5℃ higher than the air temperature. The temperature difference results from the differences in heat characteristics between artificial materials and vegetation. This cooling effect can be explained by the transpiration of the vegetation.

3. The radiation balance measured on the shaded surface under the canopy was 17%(86 W/㎡) of the unshaded surface radiation balance(511 W/㎡). This clearly supports the theory of the natural passive cooling effect under the shade

4. The overall value of the long wave radiation of the canopy measured the highest, at 986 W/㎡, as its surface temperature was relatively higher than that of the other objects (vegetation). This, and the fact that it's made of artificial materials, is the reason there was no transpiration in the canopy, unlike in the stratified vegetation, and therefore less of a passive cooling effect from the canopy.

Keywords：the elderly, living environment, public housing

Summary

Regardless of developed or newly industrialized countries, the phenomenon of “old age less offspring” has become a trend for future population development. According to relevant studies in Taiwan, living style and living intentions of the elderly are aimed at “aging in place”. Hence, the current living environment of the elderly has become an important issue. In addition, residents of public housing in Taiwan are mostly veterans. Initially, community planning of public housing and design regulations in Taiwan emphasized “cross-generation life demands”. However, whether this intended design was actually implemented is yet to be confirmed. Therefore, we used six public housing developments as research subjects to examine the current conditions for the living environments of the elderly.

1. Introduction

Currently, the aging population is higher than 15% in West European countries, compared with Japan at 20% in June 2006. In July 1993, the aging population in Taiwan exceeded over 7%, and Taiwan formally became an “aging society”. At the end of 2006, it reached 10% with an aging index of 55.2%, indicating Taiwan is facing an unavoidable aging problem. Furthermore, according to the survey, the aging population will reach 14% by 2017, only 24 years to go from 7% to 14%, which is equivalent with the pace in Japan. Compared with other developed countries, it is obvious that Taiwan has less time for preparation; hence, living arrangements for an aging society is a topic that demands active confrontation.

Studies conducted in Taiwan show that, living style and living intentions for the elderly are mainly based on “aging in place”. Therefore, from this perspective, we selected six public housing buildings in Taiwan as research subjects to examine living environment usage and functional requirements. The purpose of this study includes; 1) establish “review framework of living environments for the elderly; 2) review living environments for the existing elderly in public housing; 3) suggest methods to improve living environments of public housing for the elderly.

2. Research method

According to literature review, this study divided the living environments into: “indoor environment”, “building environment”, “community environment”, and “urban environment” for discussion. Based on the data concerning the aging phenomenon and corresponding living environment designs for the elderly, functional requirements for elderly living environments include: 1) safety, 2) health, 3) convenience, 4) comfort, and 5) assessment of welfare, as shown in Fig. 1. Referring to regulation standards and data information for elderly housing, we established evaluation factors and criteria for each item of the “Questionnaire on current situations for elderly living environments”, and conducted survey with the objective “Questionnaire on current situations for elderly living environments” and subjective ”Questionnaire on elderly living environments”. We also compared and analyzed survey results of all public housing communities in order to understand facility differences in different stages. From the perspective of the elderly, suggestions on points of attention and improvement regarding public buildings and living environments were proposed for use as reference in future planning, design, and improvements.

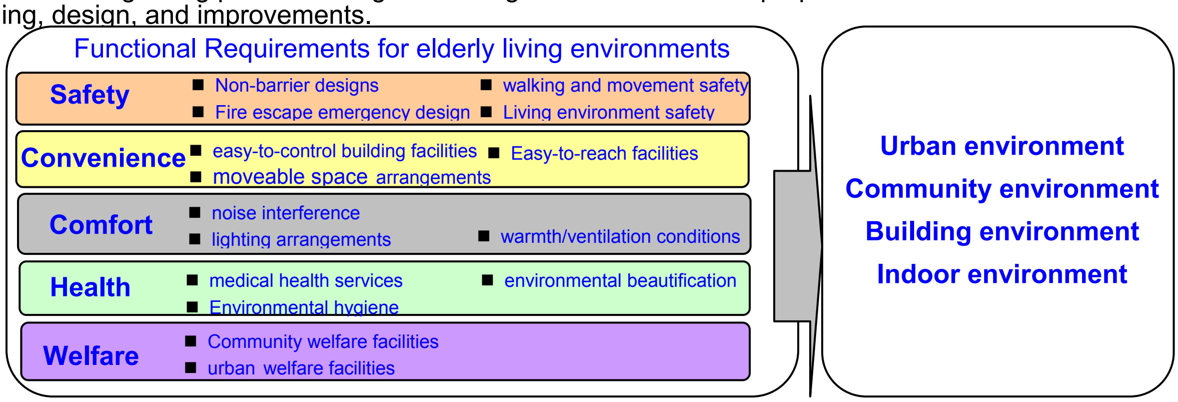

Fig. 1 Review Framework for elderly living environments

3. Research Subjects

3.1 Case study

Existing public housing in Taiwan can be roughly divided into three stages based on the date of its construction: Initial stage(stage1), Development stage(stage2), and Transition stage(stage3). Two public housing developments, in three stages were chosen for this study, and analyzed from aspects of indoor environment, building environment, community environment, and urban environment. The case profiles are shown in Table 1.

Table 1 Basic Data of Survey Cases

	CASE 1	CASE 2	CASE 3	CASE 4	CASE 5	CASE 6
Periods	Initial stage(stage1) (1975--1981)		Development stage(stage2) (1982--1991)		Transition stage(stage3) (1992~2008)

3.2 Basic information of the interviewees

This study conducted in-person interview with community residents over the age of 65, and a total of 295 effective questionnaires were rendered. In addition, five households were chosen for an indoor environmental survey for every case. The surveyed interviewees included 51.21% female, 48.79% male, 30.31% with elementary education background, uneducated was 25.09%. The following statistics indicate the general living styles of the elderly in Taiwan with source of living expenses including: self-support (41.78%), followed by from children (33.56%); most elderly (and spouse) are living with their children (59.85%), and a low percentage is living alone. It reflects the common living style of elderly in Taiwan. The ideal living style considered by elderly is “living with children”, which highlights the importance of “at-home living environments for the elderly”.

4. Results Analysis

4.1 Satisfaction with entire living environment

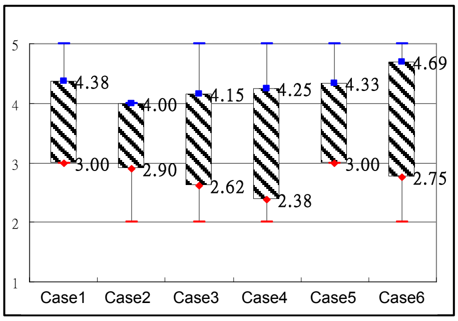
In terms of overall indoor environment satisfaction, the average community satisfaction is as follows: the average satisfaction in Case 1 has an increasing trend, indicating that living environment design is more concerned in buildings built in recent years. The building environment showed no significant trend, and the satisfaction varies according to the public housing community planning, among which, Case 4 ranked the lowest. Community environment satisfaction is affected by entire community planning, arrangement, and size of public facilities/space; among which,,community satisfaction in the transition stage(stage3) is higher. There is little difference of urban environment satisfaction among all cases, as shown in Figs. 2~5.

4-2 Review for the elderly living environment functions

4.2.1 Safety review

(a) Review of no-barrier designs

The width of indoor living room entrance is smaller than the width of the average wheelchair, there are 2cm or higher doorsills at the entrances of living room, kitchen, bathroom, and balcony in most cases. Only cases since early transition stage(stage3) are design with sloping path for disabled; and the self-built sloping path have not met the needs of elderly in terms of slope, height of armrests, and extensions. For building less than five stories, all five cases have not equipped with elevator facility, which causes daily inconvenience of vertical movement for the elderly.



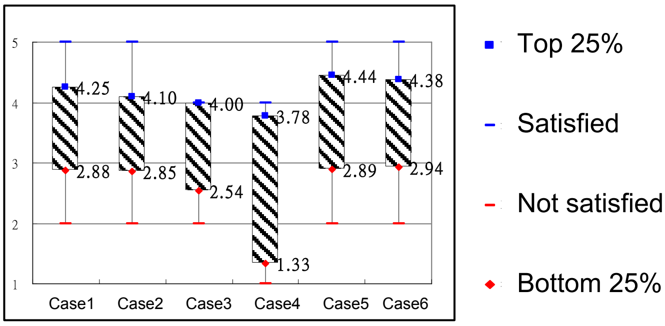


Fig. 2 Indoor environment satisfaction *Fig. 3 Building environment satisfaction*

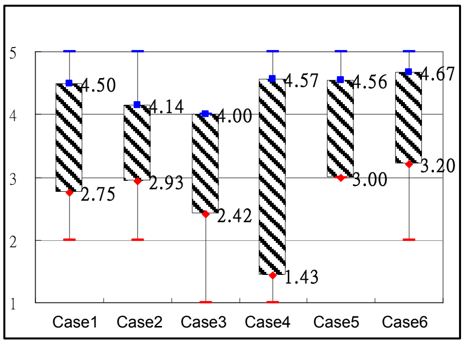

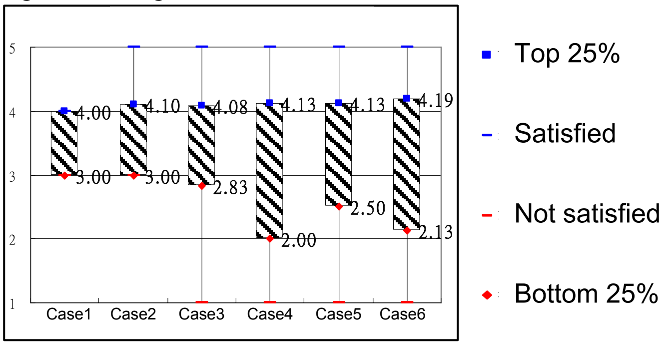

Fig. 4 Community environment satisfaction *Fig. 5 Urban environment satisfaction*

(b) Review of fire escapes and emergency designs

Fire alarms and automatic sprinklers must be added in kitchens and bedrooms to ensure the safety of the elderly. In addition, the survey found that the most needed facility is “automatic gas disconnection device” in elderly homes, as shown in Figure 6. It shows the importance and need for household fire safety for the elderly.

The building fire safety survey indicated that following the progress and practice of new regulations, fire safety facilities such as fire distinguishers and fire alarms have already been improved and installed. Emergency lighting equipments have been installed since the development stage(stage2); since the transition stage(stage3), emergency broadcasting system has been installed.

(c) Review of walking and movement safety

The survey results showed that there are no handrails installed in front porch and bedroom for elderly at home The elderly consider the bathroom to be the most accident-prone indoor space, but only 4 elderly households (13.33%) have installed handrails by the side of the toilet and bathtub. Regarding flooring and tiles, slip-proof porcelain tiles are largely used in bathroom and kitchen in all cases. In addition, a local survey of indoor accident rates showed that the bathroom (38.28%) is the highest, followed by the living room (21.09%), the bedroom (17.19%), and the dining room (9.38%).

(d) Review of living environment safety

Regarding safety facilities, there was no emergency call device in any of the cases. For the cases in the initial stage (Cases 1 and 2), there are no cold/hot labels on bathroom faucets, which is a cause of danger to the elderly.

For achieving safety in elderly living environments, survey results showed that the three areas that require the most indoor improvements are bathroom (27.6%), living room (20.36%), and bedroom (17.65%), as shown in Figure 7. Individual items needed for improvement include: (1) living room: size of space, slip-proof materials, doorsills removed; (2) dining room: size of space, slip-proof materials, improved lighting; (3) kitchen: gas leakage detectors, size of space, slip-proof materials; (4) bedroom: size of space, handrails added, air conditioner heater added; (5) bathroom: size of space, slip-proof materials, handrail added. Regarding the buildings that have the greatest need of improvements, all buildings that were built in earlier days or seldom repaired have higher demands for improvements.

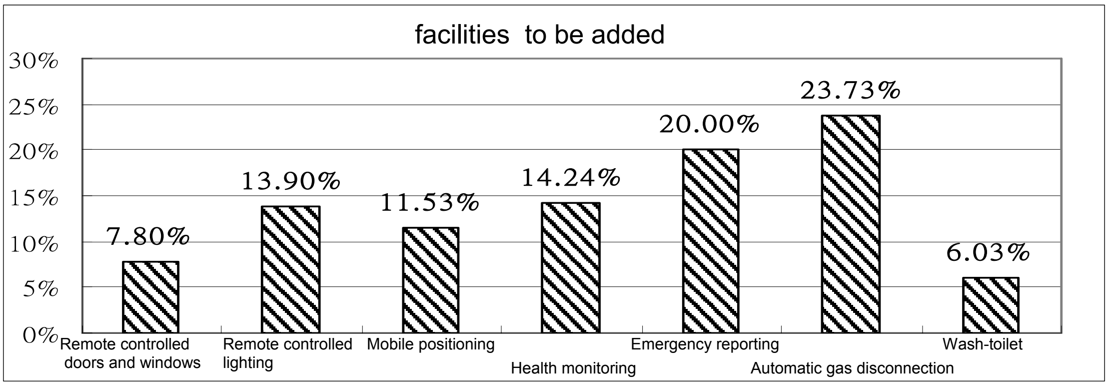

Fig.6 The most-needed indoor facility

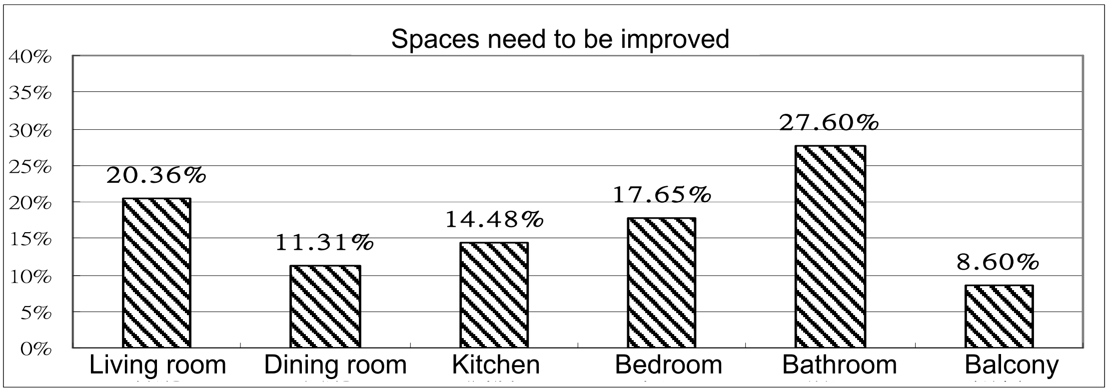

Fig. 7 Necessary renovations of indoor spaces

4.2.2 Convenience Review

(a) Review of easy-to-control building facilities

In all cases, bathrooms have horizontal pull-style windows with a higher-than-average windowsill standard (>140cm). Doors and screens are inward/outward open style with higher than the standard of 85~90cm distance measuring between the floor and handle. Handle style is a rotary lock, which causes inconvenience for the elderly. Regarding the height of light switches, the ideal height is 90~105cm from the floor; yet in the survey, we found the height of most indoor switches in community building is 110~125cm. The ideal height between floor and switch is 70~90cm. This survey found that the average height for switches in living rooms and bedrooms is 30~35cm, 100~140cm for kitchen, and 110~135cm for the bathroom.

Regarding facility cleaning and maintenance, as shown in Figure 8, there is a very high percentage of self-maintenance addressing water pipe blockages for elderly residents. In Cases 3~6, nearly 60% elderly residents would replace light bulbs on their own, and among the self-cleaning items, cleaning air conditioner filters is the highest because the cleaning frequency is rather low.

(b) Review of moveable space arrangements

In terms of indoor master bedroom space, 50% of the cases have less than the ideal standard of 12 ㎡ (Case 1:11.34 ㎡; Case 3: 11.70 ㎡; Case 5:10.88 ㎡) of floor space. For indoor bathrooms, 60.38% of the elderly do not have a bathroom because the master bedroom is used by children or grandchildren.

In shared stairs and halls, all cases meet the standard of over 140cm (radius for wheelchair rotation) to ensure a convenient entrance for elderly in wheelchairs. Regarding separate lanes for pedestrians and cars, all cases adopt separate lane design. In terms of satisfaction on community outdoor hallways, Case 4 has the lowest satisfaction level due to its poor hallway design and motorbike parking, which have caused problems for other residents and serious access problems for the elderly.

(c) Review of easy-to-reach living facilities

"Usage frequency" and "convenience" for urban facilities are the main topics for review. In terms of usage frequency, these are generally categorized as "economical living facilities", "medical health facilities", and "cultural recreational facilities". The detailed classifications are as follows: 1) park/green space, 2) traditional/supermarkets, 3) hospital/clinic, 4) dining facilities, and 5) post office/financial institutions. The uses of cultural recreation and social welfare facilities are comparatively lower.

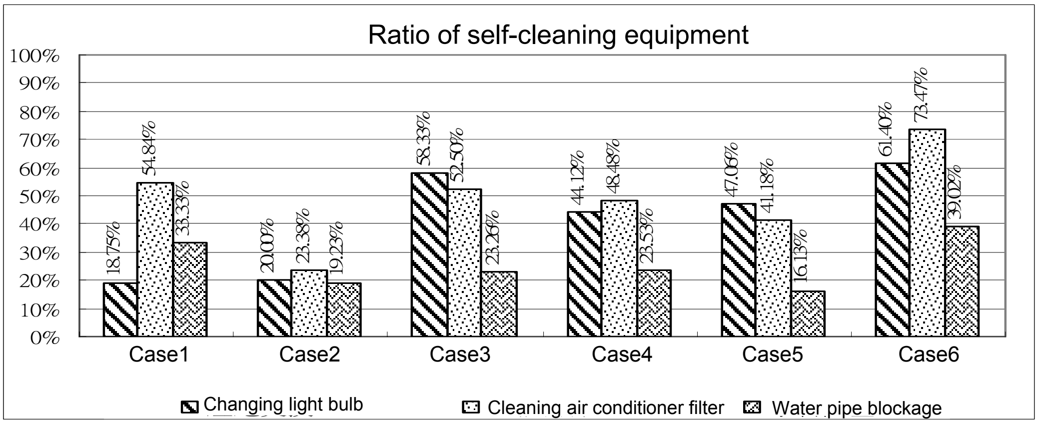

Fig. 8 Percentages for case facility self maintenance

4.2.3 Review of comfort

(a) Review of noise interference

Dissatisfaction on noise interference is much higher than any other items in every case. The effect of outdoor traffic noise is apparent in all cases, as shown in Fig. 9.

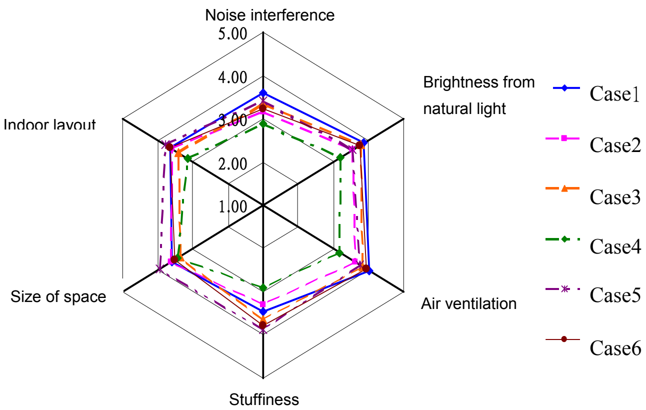
(b) Review of lighting arrangements

The satisfaction on indoor lighting is affected by the overall layout of the community and surface planning and design. Among all surveyed cases, Case 4 has the worst satisfaction due to its closed architectural design.

(c) Review of warmth/ventilation conditions

For building cases in our survey, most buildings face south and north, except for Case 3. Residents are generally satisfied with indoor muggy conditions. In Case 4, the satisfaction is lower because the community has no separation of buildings and open ground like other communities, and is located in an alley surrounded by crowded and narrow building structures, which lead to muggy conditions. In the survey of air conditioning facility installations, no heating facilities are installed in elderly households, the need for heating facilities is lower for the elderly living in southern Taiwan. Regarding air conditioning, there are 67.86% elderly having air conditioning installed in the bedroom.

The satisfaction on air circulation in each case is above average. Among them, there is higher satisfaction on indoor ventilation in Case 6 and Case 1. Although there is over 20 years of gap the construction period of the two building cases, the architectural designs adopted individual building-plan layout, which created better indoor ventilation. Case 4 has the lowest satisfaction due to its enclosed architectural style, which causes ventilation problems. This shows the importance of “planning and design” for residential physical environments, as shown in Fig. 10.



5:Very satisfied 4：Satisfied 3：Fair 2：Not satisfied
1： Very dissatisfied

Fig. 9 Satisfaction survey of case study for indoor environment satisfaction

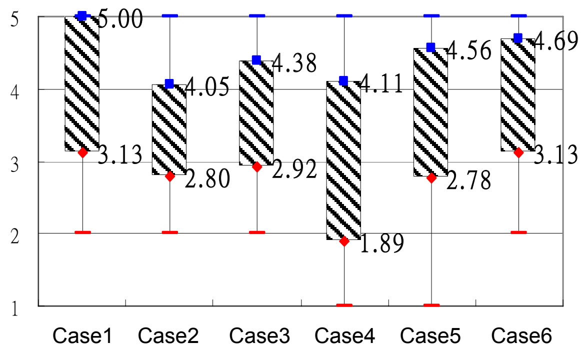


Fig. 10 Satisfaction on indoor air circulation

4.2.4 Health review

(a) Review of medical health services

The survey found health issues ranking the second highest, only after safety issues, for the elderly. Facilities expected by the elderly include health-monitoring equipment (14.24%), as shown in Figure 11. As to community environment, most elderly consider medical stations as the most needed (26.80%) in public spaces of the community. Currently, three community cases are providing simple blood pressure measuring services. In urban environment, hospital/clinic usage for the elderly is higher, with an average of 1~2 visits per month, it also includes 70% elderly who visit 3~4 times per month, indicating the importance of medical facilities for the elderly. The transportation time needed to reach hospitals and clinics is approximately 5~15 minutes, with over 80% of the elderly able to reach hospitals within 30 minutes, showing it is commonly used in the area.

(b) Review of environmental hygiene

The survey showed that waste and garbage disposal in all communities, for all building cases, are collected by garbage truck, except for the garbage disposal services in Case 6. Survey results indicated that 30.38% of the elderly think garbage disposal service is necessary and should be provided, as shown in Fig. 12. In addition, 12% of the elderly think stores in the community affect community living and cause environmental problems.

(c) Review of environmental beautification

In terms of satisfaction on outdoor recreational space, the elderly generally expressed satisfaction. Case 4 showed the lowest satisfaction because the community has very limited outdoor recreational space and green plantation, and is floored with tiles, as shown in Fig. 13. For other cases, centralized open recreational space is provided, indicating that proper community layout design and sufficient outdoor recreational space are essential to meet the needs of the elderly.

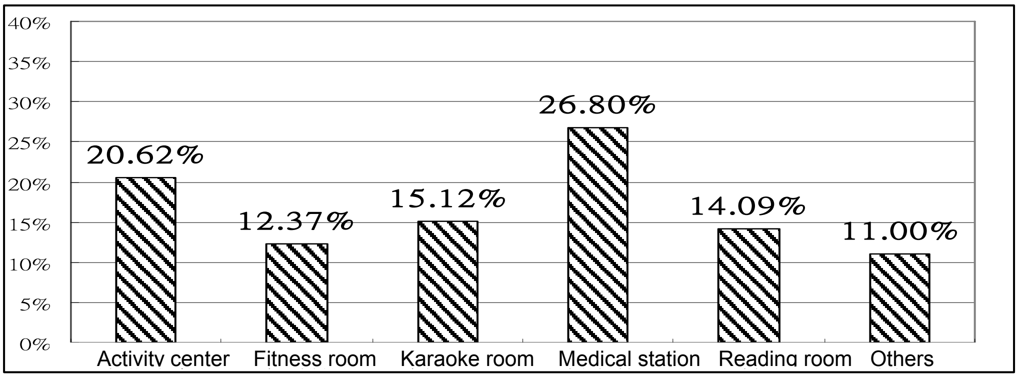

Fig. 11 Public spaces desired to be added

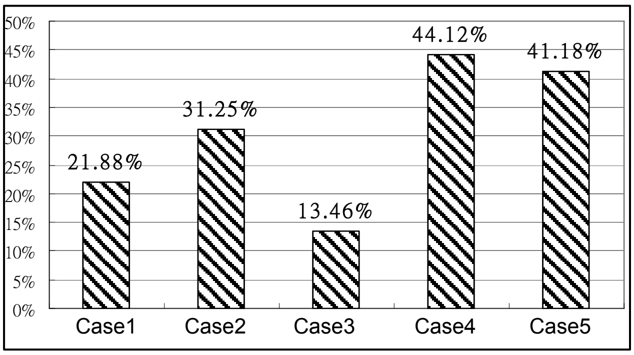

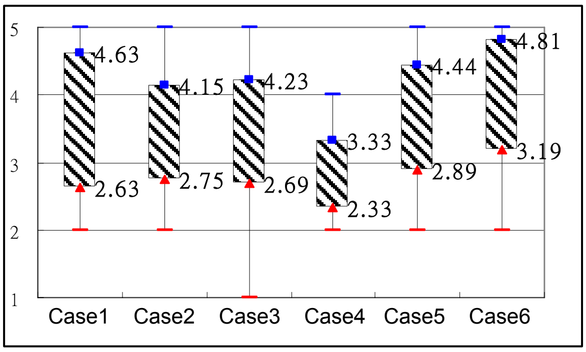

Fig. 12 Percentage of the demand of waste disposal services

Fig. 13 Outdoor recreational services

4.2.5 Review of welfare

(a) Review of community welfare facility participation

The survey showed that only Case 6 has provided community meal delivery services. Using space in community centers to provide the elderly with less expensive and convenient meals have resulted in a positive feedback. Among other cases, there are 20.12% hoping to have meal services in the community. In terms of community activity participation, besides personal preference, promotion by the community committees is an important factor. In the transition stage(stage3), the community committee is more active, and organizes more activities, thus, the activity satisfaction and participation levels are higher, as shown in Fig. 14.

(b) Review of urban welfare facilities

As shown in the survey, the elder usage of urban cultural and welfare facilities is limited, among which, about 80% elderly never visited library, art museum or elder activity center. The usage rage of daycare institutions and art class/elder school is very low, as high as over 90% elder living in public housing never visited these facilities. The usage of urban facilities is as shown in Fig. 15.

	Case1	Case2	Case3	Case4	Case5	Case6
Never	34.38%	66.20%	34.69%	62.50%	35.29%	13.33%
Seldom	34.38%	28.17%	26.53%	25.00%	20.59%	30.00%
Occasionally	21.88%	28.17%	20.41%	6.25%	14.71%	25.00%
Frequently	9.38%	12.68%	18.37%	6.25%	29.41%	31.67%

5. Conclusions

5-1 Establish "Review Framework for the elderly living environments"

Based on literature reviews, this study focused on living environment function requirements for the elderly to establish a review framework. This framework is divided into five aspects: 1) safety, 2) health, 3) convenience, 4) comfort, and 5) welfare. Then, it focused on "indoor environment", "building environment", "community environment" and "urban environment" for assessment.

5-2 Review the living environments for the elderly in current public housing

According to the survey of "Review framework for the elderly living environments", six existing public housing developments in different stages were surveyed, in order to understand the current usage and demands on the five function in elderly living environments.

5-3 Recommended improvements of living environments for public housing for the elderly

According to the survey results, safety functions for the current public housing living environments should be recommended. In terms of space, bathroom renovation should be considered; followed by living room. As to facilities, emergency call equipment and fire alarms should be added to provide a safe living environment for the elderly.

Keywords: climate change, water resources, agricultural production, floating vegetation.

Summary

After the Industrial Revolution, the Earth's greenhouse gases continue to grow denser. In recent years, all parts of the world are experiencing high temperature, serious flood and drought disaster. The climate change becomes drastically faster and threatens human's survival and evolution. This research focuses on these points and proposes a concrete operation for "□-field planning" and "floating field farming" plans. These attempt to penetrate the agricultural fields in order to improve the existing irrigation system, increase the land ability for flood detention and rain buffer enhances, increase the area of evapotranspiration in square measure to reduce the environmental temperature, preserve the retention time of the fresh water on land, advance the water self-supplying ratio in farming land for agriculture, as well as decrease the influence of climate change on the agricultural production and overcome the challenge of hot climate and flood in the future. This study designed a "floating field system" to proceed with the experiment using the pool of the Symbiosphere 1 Center of Archilife Research Foundation. The elementary experiment provides a feasible method for planting vegetation on water through floating fields, which need neither good weather condition nor irrigation but still grow plants as well. In conclusion, this study believes that in order to overcome the damages brought by climate change, the floating-field system of planting vegetation is a feasible method.

1. Introduction

Recently, the global climate change has been very sudden. Many meteorological data consistently break record. Different places in the world continuously encounter surprisingly high temperature and serious water drought. The greenhouse gasses continue to become denser. The climate change has become more and more drastic. Therefore, there is a need to consider adjustments for the living system of the future generation due to climate change, whereby the relationship of water resources processing and constructions is aligned. This will influence the regional disaster prevention and the resource recycling efficiency. Agricultural production is becoming more and more inseparable to the global natural resource, water. Therefore, this paper attempts to discuss the possible problems caused by climate change, and proposes a corresponding strategy to sustain the continuity of a better living system.

In the recent 100 years, Taiwan has a tendency to become warmer. Also, the average increase warmth is the double the world's average. Taiwan has consistently encounter days without rain. Since 50 years, the average

4 days has also increased to 10 days. The threat of drought has become more evident. We can already anticipate that the future climate and the change of water resources strongly endanger our existence. Facing these challenges – water preservation, agricultural production guarantee, with the inclusion of increasing micro culture adjustment – are unavoidable. How to solve the problems will influence Taiwan's future. We believe that in order to contest the challenges of hot climate and flood prevention in the future, we need to increase regional transpiration. We use this transpiration to lower the region's environment temperature, increase fresh water maintenance in the land, increase the land's flood detention and water preservation capabilities, increase self-sufficient rate of the irrigation water and decrease the water pressure. Thus, we propose change in land utilization and agricultural methods. This is to change the originally fixed agricultural thinking towards land. We use water's floating system to decrease the climate change influence to agricultural production. We also propose "[illegible]-field planning" agricultural plan and "floating field farming" plans agriculture cultivation concept to reach a stable regional micro climate and water resources. Also, when tackling this environmental climate change, we will be able to sustain the agriculture production ability to reduce the loss and disaster. But, to concretely execute the concept above, we first need to consider how to execute the floating field cultivation. Hence, this study tried designing numerous floating fields to experiment. Undergoing related experimental observation experience, we unceasingly find design economic efficiency which would ease the plants on the floating field system. While facing the problem of climate change, we design a new agricultural system that pursues a set that confer to efficiency, safety, technology-adequate, convenience and economically sustainable.

2. Climate Change Challenge

Base on the 2007 Intergovernmental Panel on Climate Change (IPCC) United Nations annual report, the carbon dioxide density in our atmosphere has increased from the pre-1750 Industrial Revolution of 280ppm to 379ppm in 2005. Analysis of carbon dioxide in the ancient Antarctic ice showed that at no point in the past 650,000 years did levels approach today's carbon dioxide concentrations of around 380 parts per million (ppm). If the discharge of greenhouse gases is to maintain at the present standard, the whole world will be warmer and even create a bigger climate system change. According to the report, this will initiate drought, famine, sea level increase and more frequent poor weather. From this, we can see that the pressure on mankind brought by global climate changes will increase and not decrease and moreover will be harder to prevent. Facing the problems of global warming doesn't only involve the lessening of greenhouse gases but more importantly the possible frequenting of climate change and decreasing of future disaster loss and survival/development of mankind under the circumstances.

2. 1 Main Issue on Climate Change

This ponders on facing the warming trend and believed that the way to achieve the regional temperature and microclimate modulations considerations are essential in the future. In addition, the surface evaporation hastens as the temperature increases. This leads to the problems of drought, extreme rainfall, flood and agricultural production problems simultaneously brought about by the insufficiency of water resources. Also, this study believes that the countermeasures are "water" related; hence agricultural development strategies are vital. The evapotranspiration of water can modulate microclimate change temperature. Water also provides for the growth of all things on earth, maintains the ecosystem and biodiversity. Plants and animals also rely on water for their cultivation and growth. The growth of plants also provides carbon dioxide which is a good thing. Therefore, the maintenance of nature requires an abundant supply of water. Naturally, water is still an essential part of mankind. Food, which is brought by agricultural development, also needs water abundance. All in all, the role of water can't be fully explained by words.

However, since agriculture cultivation accounts for over seven-tenths of Taiwan's water usage; once a shortage of water supply occurs, it will have the first effect on irrigation needs. Thus, to analyze the problem of water resources in the future, diverting sufficient water for irrigation must first be considered. As a result of Taiwan's various agriculture property divisions and of course, "water ownership" is debatable and complicated, it is necessary to first establish a proper irrigation system in order to face the challenges of water shortage. In addition, we must also consider that under extreme tendency of rainfall can we maintain agriculture production and lessen agriculture losses. Integrating the above considerations, this research proposes a concrete countermeasure and method of agriculture developments.

3. Concrete Methods and Strategies

In the future, mankind must face the serious climate change that gets worse every day and the potential problems brought by water preservation and agricultural development. Thus, we must consider how to improve land utilization and agriculture methods, increase regional ability to face extreme climate condition, efficiently use the limited agriculture lands and water resources. On this, this study proposed a concrete strategy of "回-field planning" and "floating field farming" plans. Although the floating field system is still in the experiment stage in a small pool, but it is believed that the future floating system development will move with the accumulated experimental results. We can start from a small ecological circular system and expand to a bigger system. From the small experimental pool, we can develop the results to a bigger region's agriculture developments, increase the region's production and resource utilization, decrease the natural environmental burden, face a more efficient symbiotic cycle development.

3.1 Agricultural Planning Strategy

This research proposes using the square-field as a unit and having a 4-shape water storage hole like in Figure (see Figure 1). Therefore the planned land shows the Chinese character "回" which means return. Thus, it complements the idea of naturally returning the water to the land for storage. Hence, we call this plan as the "回" or "return" to field plan. For water storage area, depth for rainstorm, runoff, flood amount, needed flood detention pond and evapotranspiration and seepage, we pushed through with planning the design where on can either choose double, triple or quadruple layer. The more layers, the more flexible the water storage can be. The channel between the fields can serve as water detention ponds during rainy seasons. This will decrease the burden of the regional drainage system, decrease the tendency of river overflow and at the same time, this can provide the necessary water amount for irrigation ahead of time and prevent possible water shortage. Also, because the water quality needed for agriculture is relatively lower than for domestic needs, the usual grey water and the rainwater system's collected water can be asked to be collected and would lessen the pressure given to the reservoir dam and lower the risk of water shortage for agriculture purposes. In addition, the growing plants and vegetation would help absorb the water nutrients, lessen environment burden, decrease water pollution, increase regional cycle efficiency and increase the regional environmental self-clean capabilities.

However if water will not flow for a long time, there is a chance for it to become stagnant. Therefore, in order to include the use of aeration, we consider using the solar energy and learning how to use the machine in breeding fishes to dissolve the oxygen and thus avoid water being stagnant. In addition for the water pond to become a floating field, it can also be a place to raise ducks, geese and fishes and thus increase the land's usage and products. The above layer of floating field can be used to raise herbs and the lower layer can be used as a place to raise animals such as geese, ducks and fishes. This will initiate a food chain system. With regards to the problems of culicid, fishes feeding on worms can be raised in the pond or plants feeding on worms can be raised on the floating fields.

Moreover, on the borders of the field, windbreaks can be planted to lessen the possible effects of strong winds to the fields and floating fields. Usually, the stored water of [illegible]-fields are used on floating fields and for those other fields, they can use the reservoir's water during dry season. Most of the time, the increase of water level can be used on the cultivation of floating fields. Hence, this will help prevent flood and problems caused by monstrous rain. Naturally, the floating fields must also consider their own distinction; because of their arrangement, management and convenience of harvest must all be taken into their consideration.

The establishment of this system must anticipate increasing the ability to retain water, reduce the burden on water conservation, flood retention on rainy seasons, enough water for agriculture during dry seasons, maintain the usual evapotranspiration capabilities, increase the microclimate modulation ability and lower the regional warming. This must also be able to make sure of the land's production, reduce the after-effect of natural calamities and reduce the usual burden on farmers to worry about water. This must be a multi-functional system.

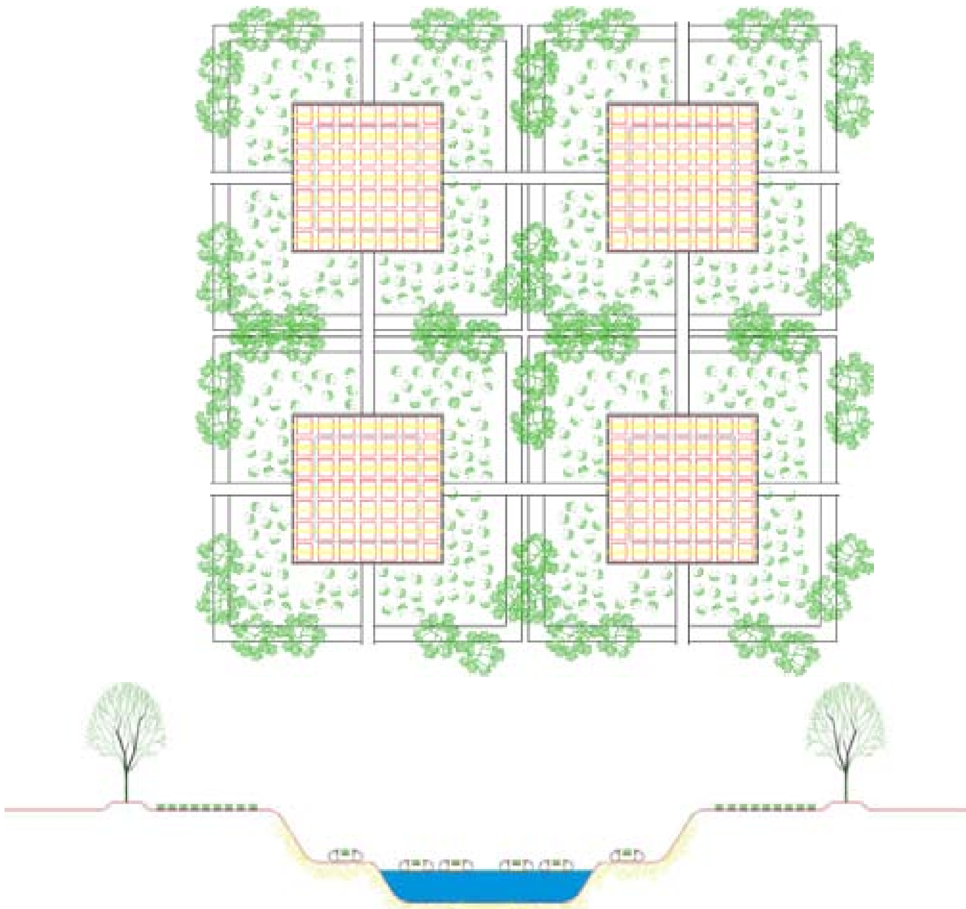

Figure 1 「□-field」 surface and sections

3.2 A Discussion on the Floating Fields Method and Initial Experimental Results

Because of the agricultural cultivation system nowadays, only a few possess aquatic cultivation experience and therefore does not fully satisfy the needs of this research. Therefore, this study tried to design a floating fields system. Before designing, we tried harder to have an understanding of each floating island all over the world. While reviewing the past literatures, observation includes that the functions of floating islands include ecology functions, embankment abilities, water purification abilities, landscape functions and at the least agricultural production abilities. (Will, 1970; Fager, 1975; Hoeger, 1988; Nunnally, 1987; Nakamura, 1997). And since most of the plants' nutrients originate mostly from water, aquatic plants must be more cultivated. This study also hopes that the floating fields can be used as a grain production and system and would also be able to suit the growth of different land and aquatic plants. Therefore, the designed floating field of this paper primarily uses soil and partly uses water as the origin of plant nutrients. In addition, the past floating islands' usage concern very minimal regional warming or microclimate modulation considerations. The less it is on the issues of water shortage concerns and grain production considerations.

Because of the different usage and challenges, this research proposes an aquatic floating fields system so as to have a segment for floating islands development. This therefore clarifies the taken agriculture challenge of floating field system development. Based on the reasons above, this study tried designing different forms of floating field units to experiment (see Figure 2). After two years of being in the water pool of Archilife Symbiosphere I Center, the preliminary experimental results showed that flexibility must be present in the floating fields used on plants. (Chen, 2006; Chen, 2007) Even though winter and summer seasons, rainfall and typhoon were experienced during the plating time, the plants were able to grow well and were able to even avoid watering service.

In order to face the future challenges of natural disasters, lessen agricultural losses and maintain the agricultural production abilities, floating fields cultivation is a feasible agricultural production method. However, because of the limitation of researchers and budget insufficiency in this present research, the results of small regional experimental grounds may be applied to a bigger ground in the future. This way, the development will be more evident.

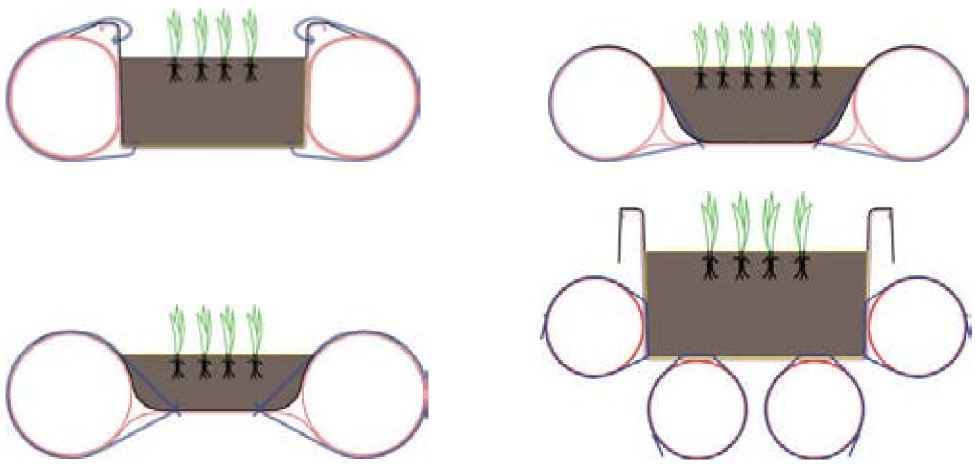

Figure 2 Different Floating Fields Sections

3.3 Floating Field System Design Unitization and Future Developments

After long-term experimentation, this research proposes uniting the floating field system design (see Figure 3). It is mainly to focus on the plants' convenience. Because they are planted on the water surface, if the unit is too big, the transportation and soil change will be of serious work. Using unitization and standardization, most of the labor work can be substituted by automated machines. No matter it is to fill the soil, change soil or ease the soil and so on, the automated machine will be able to handle these. Also, unitization can make its own adjustment basing on different plant demand, seasonal/climactic conditions. It can also change the plant box materials, shape of opening side (see figure 4), permeability, soil fertility, waterlogged depth and carry on with modifying the control to the suitable physiochemical conditions for a living organisms. It will also be providing multi-plant growth condition, preventing the system to plant unitize. Naturally, multi-plant has another advantage in preventing the problems of pests. Another, aside from eluding the necessary watering, the aquatic plants can also lower the need for agricultural cultivation processed water. The result nutrients therefore will be hastily dissolved and loss. Also, when the habitat humidity of microorganisms always changes, it might create problems. When the soil fertility can be prolonged, especially the habitat stability of microorganism, it can multiply the microorganism and help with the plant's growth. In addition, because the system can anytime support the water needs of plants, even the moisture content and absorption content can be contained. Also, undergoing evaporation, the water temperature would adjust, creating a more steady temperature that will benefit plant growth. Therefore, the anticipated unit time and unit area must be able to compare with the natural ones. Only the above particular problem should indeed go for a further experimentation.

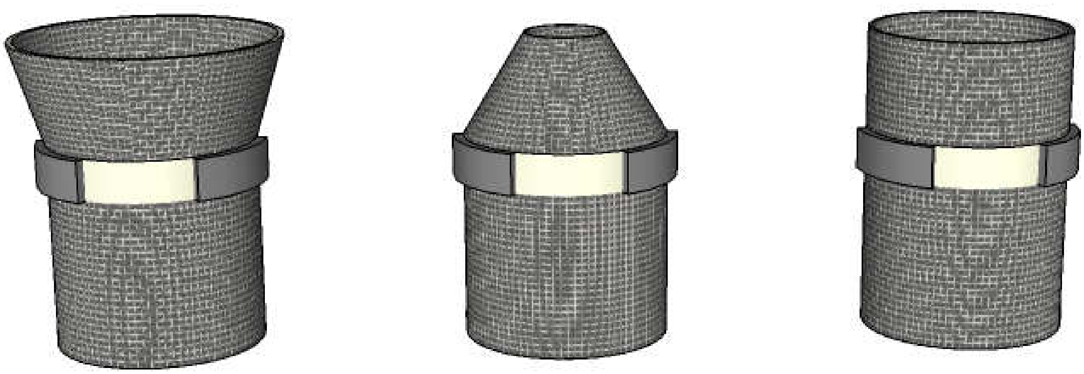

Figure 4 Planting boxes with different design in shape of opening side

4. Conclusions

Along with global warming, the future mankind will face the threat of climate change trend that becomes worse everyday. This study proposes "□-field planning" and "floating field farming" plans attempts to have changes in land utilization and agricultural methods to reach a stabilized regional micro climate water resource and under the environmental climate change, the agricultural production ability can be maintained and lower the losses and disasters. The study responds to this and tries to design various floating field system and proceed with experiment. Different crops are planted for long-term observation. Going through the preliminary experiments, the aquatic plants will be able to show feasibility and elude the need for manual watering. The growing of plants and climate looks to be good and in fact, it has undergone experimentation in four different seasons. Another, the study designed a new floating field unit that attempts to be the future floating agriculture, change soil, harvest, integrate industrial production, lower the need for manual work, lower production cost and will be able to provide an efficient and convenient agriculture system. These experiments have undergone preliminary tests and have shown feasibility. Although related designs still have rooms for improvement, but we believe that from the accumulation of the experimental results, the floating field system will be able to expand different agriculture fields in the future and establish a more efficient symbiotic cycle.

NEUTRALISING A FACULTY: VICTORIA UNIVERSITY'S CARBON NEUTRAL FACULTY OF ARCHITECTURE AND DESIGN

Maibritt PEDERSEN ZARI

School of Architecture, Victoria University, Wellington, New Zealand, maibritt.pedersen@vuw.ac.nz

Keywords: green house gas, carbon neutral, education, tertiary, emissions reduction.

Summary

International research suggests that the built environment may be responsible for approximately a third of global carbon emissions. It is therefore particularly appropriate that Victoria University's Faculty of Architecture and Design, in Wellington, New Zealand has taken the significant step of becoming the Southern Hemisphere's first carbon neutral campus, and the world's first carbon neutral Faculty of Architecture and Design. This is part of the Faculty's long term commitment to sustainability in the built environment and is consistent with a growing international movement calling for Architecture Schools to be carbon neutral by 2010.

The process and opportunities that enabled the Faculty to become carbon neutral in May 2008 are outlined, including the preparation of a greenhouse gas emissions inventory, an emissions reduction and management plan and the audit and accreditation process. The successes and difficulties inherent in the approach taken are examined.

As well as reduced environmental impact, this paper analyses further significant anticipated benefits of the Faculty of Architecture and Design's carbon neutral status, including opportunities to publish research and enhance the reputation of the Faculty and the significant opportunities arising for the development of new teaching tools and methods. Involvement and participation by students in reduction plans and the facilitation of a forum for debate and discussion about the future of carbon trading markets are also elaborated on.

It is anticipated that the process undertaken by Victoria University of Wellington's Faculty of Architecture and Design could be used as an example by other educational institutions moving towards becoming carbon neutral. It is posited that reducing and offsetting carbon emissions in academic institutions, particularly those responsible for the education of new generations of built environment professionals, could become an important part of the creation of a built environment that is better able to address mitigating the causes of climate change.

1. Introduction

Climate change will affect many aspects of life and has well documented social, economic and environmental impacts (Stern 2006; Chapman, Boston, and Schwass 2006). Public awareness of this and with it Government directives to address climate change issues, have increased significantly in the last two years in New Zealand and in many other countries. Coupled with this is the growing realisation that the global built environment contributes significantly to the causes of climate change through construction and demolition practices, but most significantly through operational and embodied energy (O'Connell 2003; Alcorn 2003; Lend Lease Corporation, et al, 2007). Built environment professionals and designers will have to address reducing greenhouse gas emissions in the future as well as find solutions to adapting to many of the changes that will come about through climate change (Camilleri, Jaques, and Isaacs 2001). O'Connell (2003) points out that *'current projections indicate New Zealand buildings will potentially suffer significant impacts this century.., the direct and indirect costs of which may be very high*'.

Many of the negative human impacts on climate and ecosystems have been described as a failure in design rather than available technology (Orr 2002; McDonough and Braungart 2002). Lowe (2000) estimates for example that reductions of 80% in carbon emissions form the built environment are possible using current technologies. It is appropriate then that Victoria University of Wellington's Faculty of Architecture and Design is addressing climate change issues in part by reducing and offsetting greenhouse gas emissions. This is consistent with a growing international movement calling for Architecture Schools to be carbon neutral by 2010 (Architecture 2030 2008). The Faculty will be a pilot for the rest of Victoria University of Wellington (VUW) in assessing the feasibility of ongoing and future greenhouse gas (GHG) offsetting and emissions reduction planning for the university's other four campuses.

The Faculty of Architecture and Design participated in Landcare Research's carboNZero programme to achieve certification, and obtained international Gold Standard carbon credits through a sponsorship agreement, to offset GHG emissions. These credits are sourced from Meridian Energy's wind farm projects in New Zealand[1].

2. The Carbon Neutrality Debate

It is acknowledged that voluntary carbon offsetting and trading is still in its infancy in New Zealand but that this is growing rapidly internationally (Bellassen and Leguet 2007). The difficulties with 'carbon neutrality' achieved through offsets are acknowledged in their role as a potential green washing mechanism. Harris (2007) points out that *'despite its positive attributes… the role of offsetting should be only temporary, creating much needed early emissions reductions and generating awareness, whilst being only a small part of a much wider and longer term global effort to tackle climate change*.'

For this reason the Faculty consider it prudent to use participation in the carboNZero programme primarily as a platform to plan for and instigate significant GHG emission reductions. Offsetting is considered to be the final step in a plan that seeks to avoid, then reduce and finally offset emissions. 'Carbon neutrality' also provides a valuable forum to discuss and raise awareness of the issues of climate change that effect in the case of the Faculty of Architecture and Design: the built environment; tertiary education and research; and New Zealand. It is the intention of the Faculty of Architecture and Design to combine carboNZero certification with a range of additional sustainability initiatives and research already existing and proposed for the Faculty. This is in line wide a wider strategy to move towards becoming a leading educational institution for environmentally sustainable design.

3. Opportunity for Engagement in Climate Change Issues

The Faculty deciding to become carbon neutral and then making this a reality was a long and somewhat complicated process. This is briefly described below in chronological order.

3.1 Initial Steps: A Carbon Neutral Course

Since 1997, the School of Architecture has offered a specialist elective course in Sustainable Architecture. More than a third of the second year cohort of architecture students elected to take this course in 2007. This course is open to all students in the University beyond first year and is designed to give an introduction to the philosophy, concepts and ideas of sustainable and regenerative architecture. The objective is to enable students to incorporate these ideas into further study and into their practice of architecture, design, building science and related fields.

In late 2006, the course coordinator began to investigate opportunities to engage the students in debate on carbon trading and carbon neutrality as part of the educational programme concerned with climate change. The decision was made to explore the possibility of the course becoming carbon neutral through both emissions reduction and offset.

Initial calculations for the course were made by sourcing university records for energy use (gas and electricity) and estimating the proportion of these figures that the course was responsible for. Assumptions were also made for commuting by establishing distances of student and staff residences from the campus. Paper use and field trip emissions were calculated from the previous year's course.

New Zealand based online carbon calculators and emissions multipliers were used[2] and compared to come up with an estimated carbon emissions amount for the course. These online calculators use different factors and methods, and are not consistent with each other or with international calculators (Bottrill 2007). In light of this, the highest estimate was used. A figure of just under 2 tones of carbon equivalent emissions was reached for the course of 50 students.

3.1.1 Determining Offset Options

Several avenues were explored in determining an appropriate method for reducing and offsetting GHG emissions. Because making the course carbon neutral was intended to be an educational exercise for the students involved, it was thought that involving them in the offsetting part of carbon neutrality might be appropriate. For this reason, carbon sequestration through tree planting was initially investigated. Both the Greater Wellington Regional Council, which offers a corporate volunteer programme to plant trees in community group planting areas, and a local non-governmental forest regeneration scheme [3] were approached for tree planting possibilities. While both were willing to have students plant trees for them, the framework for measuring the carbon sequestration potential and ensuring the continuation of the planted areas was not in place. Although research has been done in New Zealand and internationally defining methods for calculating carbon stored in trees and forests (Landcare Research 2006; Brown 2002), it was thought that tree planting in projects not specifically dedicated to carbon sequestration would be problematic and would not be a robust method of carbon offset. It was also difficult to calculate how many trees and of which species would be suitable in a local context.

[1] For a full description see http://www.meridianenergy.co.nz/AboutUs/Emissions+trading.htm and Appleyard (2004).
[2] CarboNZero, NIWA, BRANZ.
[3] Manawa Karioi Trust

A search was made for other Tertiary institutions that had attempted a similar project to ascertain best international practice. Newcastle University launched their first carbon neutral degree course in 2006 (Newcastle University Press Office 2006). Personal correspondence between the two institutions helped to define the best way to progress with carbon neutrality. The potential problems with tree planting were discussed and the need for engagement with recognised carbon offset and certification programs established (Broderick 2006). A recommendation to source credits from Gold Standard projects was made.

The Gold Standard is a certification scheme that registers projects in the Clean Development Mechanism (CDM), Joint Implementation (JI) and voluntary offset markets and is endorsed and supported by 51 non-governmental and charitable organisations. The projects accepted by the Gold Standard Foundation for registration must be *'clearly additional, involve local stakeholders in their design and show transparently how they will contribute to sustainable development'* (The Gold Standard 2006). Independent validation and verification of the projects also takes place. Being *'clearly additional'* refers to a project could not take place without the sale of its carbon emissions reduction credit in a carbon market (Bellassen and Leguet 2007). Gold Standard accepts only energy efficiency or renewable energy projects and is not open to forestry projects, due mostly to the problem of the impermanence of forests (Bellassen and Leguet 2007). Few projects have achieved the grade for Gold Standard to date, but the number is increasing rapidly (Harris 2007). The Gold Standard (2006) point out that Gold Standard verified projects are selected because they provide additional benefits (social, economic or environmental) beyond just emissions reduction *'lest offsetting become a zero sum game where emissions are reduced in one place while they continue in another'.*

In New Zealand, Meridian Energy supplies Gold Standard third party verified emission reductions (VERs) carbon credits from their wind farms in Te Apiti and White Hill. These projects were among the first registered with the Gold Standard, and are the only New Zealand source of Gold Standard credits. The decision was made that using these credits would mean that some of the uncertainty with forest offsets would be avoided and importantly that the highest standard of international carbon credits would be met (Bumpus 2007). It was decided this method of offset was more relevant to students of architecture and design, who will in part be responsible for the energy performance of the built environment and will be making decisions about energy sources and energy efficient design and technologies in the future. It was also thought that approaching a local New Zealand carbon credit provider would be more desirable that sourcing credits from another country.

3.1.2 Securing Carbon Credits – A Sponsorship Agreement

Meridian Energy were approached in March 2007 to explore sponsorship potentials, and were positive about providing their Gold Standard carbon credits to offset the course's emissions. To increase the educational and research collaboration potential of the sponsorship agreement for both parties, it was agreed that a Memorandum of Understanding (MoU) would be drawn up between the Faculty of Architecture and Design and new Meridian Energy subsidiary Right House. Right House specialises in energy conservation and energy efficiency in the residential sector[4]. This relationship began in 2007 with Meridian and Right House participating in various courses in the Faculty on critique panels and offering guest lectures where appropriate. The MoU was formally signed in on the 31st of March 2008.

3.2 Expanding the Scope: A Carbon Neutral Faculty

Senior Faculty management and academic staff were involved during sponsorship negotiations with Meridian Energy. After learning that a sponsorship agreement was possible, the decision was made to try to expand the project to include not only one course, but the entire Faculty. Several initiatives to strengthen and expand the capacity of the Faculty to deliver a high standard of education in sustainable architecture and design had already begun, including development and expansion of compulsory and senior aspects of the sustainability programme, and significantly increasing staff numbers with specialties in aspects of sustainability. Addressing the problems of climate change, through engaging in the carboNZero programme was seen as being a suitable addition to these set of initiatives. Between April and September of 2007, the sponsorship agreement with Meridian Energy was expanded and agreed to in principle.

Victoria University's Faculty of Architecture and Design is made up of the School of Architecture (architecture, building science, landscape architecture and interior architecture programmes) and the School of Design (digital media and industrial design programmes). The Faculty is housed separately from the rest of Victoria University on the Te Aro Campus, located in central Wellington, New Zealand. Two connected building facilities make up the campus, which houses lecture theatres, design studios and computer suites, a workshop, library, offices, and exhibition space. Approximately 1200 students are enrolled in courses in the Faculty and more than 100 academic, general and technical staff are employed.

3.2.1 Calculating the Faculty's Emissions

Faculty wide emissions were calculated by analysing external records and internal accounting records. Direct emissions sources (termed scope one) were identified as gas (used for boilers) and vehicle fleet (consisting of one diesel van). Indirect emissions (scope two and three) included the hiring of vehicles (buses

[4] http://www.righthouse.co.nz/

for field trips), flights (both international and national), and waste. Electricity for the Faculty is supplied by Meridian Energy, 100% of which is generated by wind and hydro sources[5]. Meridian Energy themselves went through the carboNZero programme in 2007 and were New Zealand's first certified carboNZero energy company (Meridian Energy 2007). Electricity use was measured therefore for the Faculty, but was not recorded as requiring offset. This was a requirement by Meridian Energy in the sponsorship agreement and was agreed to by carboNZero to avoid double counting of emissions. Increasing energy effieciency was however included in the GHG Emissions Reduction Plan. Because the Faculty began GHG calculations in 2007, 2006 was initially used as the base line year. Total emissions for the Faculty were calculated to be equivalent to 192 tones of carbon.

3.2.2 Certifying the Faculty's Carbon Neutral Status

To ensure the most robust and transparent process of reducing and offsetting GHG emissions, it became apparent that the Faculty would have to obtain certification of carbon neutrality from an independent organisation. This was a requirement of the Meridian Energy sponsorship agreement to ensure that the process had integrity, and would be robust under scrutiny. Certification would also ensure that calculations were correct and that procedures in planning for reductions and offsets met international best practice based upon a rigorous, third party verified process.

There is currently only one organisation that is able to certify individuals, organisations or events as carbon neutral in New Zealand. The carboNZero programme was established by Landcare Research, a Crown Research Institution in 2001, after more than a decade of climate change and GHG reduction research[6]. Initial quotes were obtained from the carboNZero programme and from Pricewaterhouse Coopers for a third party audit in March and April of 2007.

3.3 Final Goal: A Carbon Neutral University?

During the negotiation and recalculation period to enable to whole Faculty to become carbon neutral, funding was sought from the central university. At this time however, the university's Environmental Committee also submitted a proposal for central university funding for the entire university to become carbon neutral. While this initially held up the process for the Faculty, valuable research into emissions across the university was conducted by URS consulting (commissioned by the Environmental Committee), which was then able to be used by the Faculty. The proposal for the whole University to engage with carboNZero was unsuccessful; however a decision was made to grant funding to the Faculty, so they could act as a test pilot for going through the carboNZero process, and committing to GHG reductions, on the condition that going through the carboNZero process be run as a research project.

4. Time delays and unexpected issues

Initial timelines for the project anticipated that by September of 2007, the Faculty would have completed all requirements for certification and would be able to claim carboNZero status. Several delays in the process made this impossible. Final quotes and contract agreements for the Faculty from the carboNZero programme were held up due to the possibility of the entire University becoming carbon neutral. If this proposal had been successful, this would have included the Faculty of Architecture and Design, making the process of the Faculty becoming carbon neutral redundant. Once it was established that funding for the entire university to become carbon neutral was not obtainable, progress on the Faculty going through the carboNZero process resumed.

The six month period between the initial quote for Faculty participation in the carboNZero programme and the final quote meant that a substantial increase occurred in projected costs. This required further funding to be sought from central university funds, which added to the length of the process. Because of these delays, it became apparent that certification would not be achieved in 2007, but rather 2008. The 2006 base line year for emissions measurement had to be changed therefore to 2007.

In January of 2008 after all of the major issues had been rectified, the Faculty was in a position to engage with all parties in the carboNZero programme. A three month time period to redo the inventory for the 2007 year and draw up the Emissions Reduction Plan and Greenhouse Gas Emissions Inventory Report was agreed to by all parties (as illustrated in Figure 1).

After a re-calculation of emissions for 2007 a new figure 341 tonnes was arrived at. Additional emissions sources that were included in the 2007 inventory were the use of taxis, rental cars and industrial gases used in the workshop. The increase from 2006 figures was accounted for by increases in the scope of the inventory, changes in emissions factors, changes in calculation methods, and actual increases in emissions. This meant that the sponsorship agreement of providing carbon credits to offset 200 tones of carbon emissions had to be expanded once more, leading to further time delays.

[5] In 2007, 68% of all electricity available for purchase by consumers in New Zealand was generated from renewable sources including hydro, wind, geothermal, and biomass. This figure was 65% in 2006 (Statistics New Zealand 2008).
[6] http://www.carbonzero.co.nz/index.asp

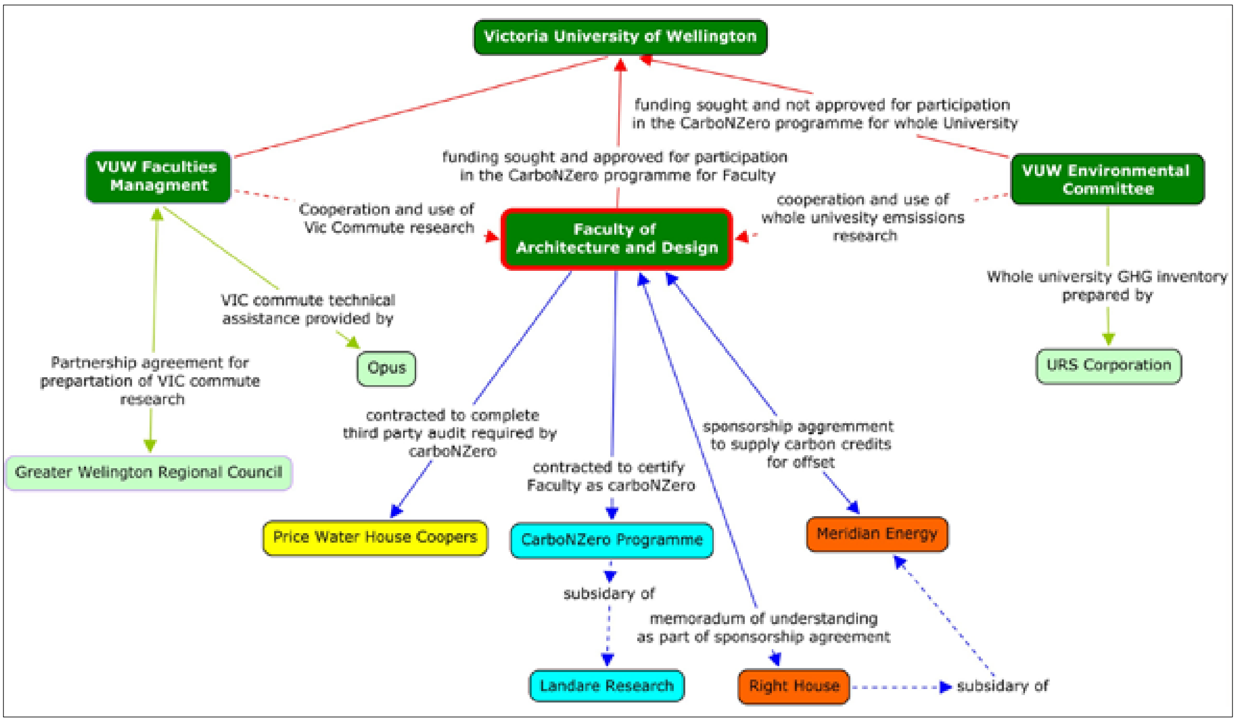

Figure 1 Participants in VUW Faculty of Architecture and Design's carboNZero Process.

5. The carboNZero Process

The carboNZero process involved six steps:

5.1 Measure - understand and measure GHG emissions

The Faculty prepared a 2007 Greenhouse Gas Inventory in February of 2008. The process of sourcing data for the GHG inventory was at times difficult, exacerbated by a lack of reporting and record keeping structure for GHG emissions. Most external records such as those for gas and electricity consumed, diesel purchased for the van and flights purchased from the university's travel agent were easy to obtain. Records of hiring cars and buses for field trips were more difficult to obtain. Calculating waste was also difficult and several qualified assumptions were made by Landcare Research.

Research commissioned by the university's Environmental Committee on university wide emissions contributed to the Faculty's inventory. The inventory was handed to carboNZero, who produced the emissions calculations based on most recent emissions factors and checked all the data for accuracy and made sure no emissions were left out. A Greenhouse Gas Emissions Inventory Report was completed in mid April 2008[7]. The purpose of the report was to document direct and indirect greenhouse gas emissions from the Faculty of Architecture and Design and was prepared in accordance to International Standard ISO 14064-1:2006, (Technical Committee ISO/TC 207 2006) and the GHG Protocol for Corporate Accounting and Reporting (WRI-WBCSD, 2004) in order to meet carboNZero certification procedures.

5.2 Manage - make a commitment to manage and reduce emissions

The Faculty prepared a Greenhouse Gas Emissions Reduction Plan in April 2008[7]. This incorporated comments and suggestions by interested staff, included several student initiatives to reduce GHG emissions in the Faculty, and involved negotiations and advice from the university Facilities Management Team. The objectives of the plan were to: demonstrate management commitment to reducing GHG emissions; maintain and introduce effective GHG emissions accounting procedures; target both the most significant and the easiest to address emissions; and to target reduction of emissions that are significant, but considered to be outside the scope of the Faculty's operations.

Major emissions were identified as the burning of gas which is used in boilers (41% of total emissions requiring offset); GHG emissions from decomposition and transportation of waste (32% of total emissions requiring offset); and the burning of fossil fuels used in international flights (26% of total emissions requiring offset). Student and staff commuting, although not included in the inventory, due to the difficulties in accurately measuring the emissions from this source (Buttazzoni and Zyla 2005), were targeted in several ways in the management reduction plan. A Victoria University of Wellington travel plan (Vic Commute) was

---

[7] GHG Emissions Inventory Report and GHG Emissions Reduction Plan are available from the author upon request.

prepared as an internal university document[8]. It estimated commuting emissions by conducting a survey in 2007. Faculties Management used these same results to estimate that student and staff commuting could be responsible for an additional 130 tonnes of emissions for the Faculty of Architecture and Design. This would equate to approximately 28% of total emissions if it were included.

5.3 External Audit - conducted by an approved qualified auditor
The third party audit of the GHG Emissions Inventory Report was carried out by Pricewaterhouse Coopers in June of 2008. Several suggestions were made to ensure that the report was accurate and adhered to international best practice.

5.4 Mitigate - offset or mitigate remaining or unavoidable emissions
Meridian Energy organised the retirement of carbon credits though the M-co company to meet the requirements of the carboNZero process. This ensured that the credits were cancelled in a maintained independent register and that they could not be on sold in the future. The credits supplied to the Faculty were a combination of 2006 and 2007 Gold Standard credits.

5.5 Certification - verify mitigation step and issue certificate
Landcare Research provided the certification of the Faculty's carboNZero status after the first four steps were completed in June 2008.

5.6 Marketing - communicate achieving carboNZero certification
Public announcements of the Faculty's carbon neutral status were made in June 2008, to coincide with Internation World Environment Day. Meridian Energy and the Faculty co-operated in media announcements. Case studies and further information about the Faculty's carboNZero status were posted onto the university and carboNZero websites[9].

6. Benefits of a Carbon Neutral status

It is the intention of the Faculty to quantify benefits of becoming carbon neutral, where possible, after a year period. There are a number of anticipated benefits that can be discussed here that ultimately made the project more attractive for allocation of funding by central university, and allowed it to proceed.

6.1 Environmental Benefits

The primary benefit and justification of the Faculty participating in the carboNZero programme is the reduction of GHG emissions in mitigating the causes of climate change. Through the carboNZero certification progress, a detailed GHG Emissions Reduction Plan must be put into action. It is anticipated that this will result in tangible GHG emissions reductions in the Faculty that could have environmental benefits that go beyond Faculty boundaries.

If a university wide commitment is made to reduce and offset carbon emissions, after a successful trial period conducted by the Faculty of Architecture and Design, significant emissions reduction may occur across the entire university. The carboNZero programme has acknowledged that the Faculty is the first educational institution to go through the programme in New Zealand and as such sets a benchmark.

6.2 Social and Cultural Benefits

As the Faculty of Architecture and Design embarks on strengthening its capability to deliver sustainable design education, it is important that its own conduct is bought into line with what it teaches. By being an early adopter of voluntary carbon offset and GHG emissions reduction measures, the university is able to take a leadership role on climate change in a New Zealand context. This provides a platform to bring attention to climate change issues in a positive forum, to debate or normalise the idea of voluntary GHG emissions reduction planning, and potentially to enhance the reputation of both the University and Meridian energy.

The potential to involve students in projects to reduce emissions further and to facilitate debate and discussion about carbon trading and climate change in general has been taken, and will be developed further during the year trial period. The main building on the campus is already set up to be an educational tool and is studied in depth by building science students in particular. Students in the Sustainable Architecture course devised GHG emissions reduction schemes for the Faculty and implemented them where possible in 2007. Some of these ideas and projects were included in the Faculty GHG Emissions Reduction Plan. The potential to involve more students will be developed in 2008 and 2009. This may include: involvement in projects to reduce emissions further; participation in monitoring and measurement

[8] Available from http://www.victoria.ac.nz/fm/services/vic-commute.aspx
[9] Available from http://www.carbonzero.co.nz/members/organisations_certified.asp#VUW and http://www.victoria.ac.nz/architecture/

associated with such projects; participation in GHG inventory data collection and management; and participation in debate and discussion about carbon trading.

6.3 Economic Benefits

The reduction of gas use, paper use, international flights, and waste produced in accordance with the Faculty's GHG Emissions Reduction Plan is expected to have tangible economic benefits for the Faculty and University alongside the anticipated environmental benefits. Preparing for managing GHG emissions while it is still voluntary will likely be less costly than leaving it until institutions such as universities are regulated to take account of their GHG emissions.

It is expected that unique research opportunities will arise from a carbon neutral status. With increased monitoring and more accurate records it is anticipated that students and academic staff alike will be able to analyse results and carry out additional research projects. It is possible that academic research papers would subsequently be published in international journals or conference proceedings. The Memorandum of Understanding between the Faculty and Right House, a subsidiary of Meridian Energy is also expected to herald research opportunities for both parties. Improving and cementing the Faculty's reputation as a leader in sustainable design and architectural education and research may bring further economic benefits by attracting high achieving students and staff.

7. Recommendations and Findings

The conclusion to be drawn from the experience of the author is that although all parties in the process were willing to make a carbon neutral Faculty of Architecture and Design a reality, it took substantial time and effort for all groups to be clear about the process involved and to fulfil their parts. This is due in part to steep learning curves for the Victoria University and for the Faculty of Architecture and Design, and rapid changes in the carboNZero programme, and carbon trading in general during the time period. It is clear that it is important to carefully define the scope of the project first to avoid delays caused by recalculation of emissions and sourcing funding. Other significant delays were caused by rapid changes in how GHG emissions are measured and offset, and the costs of certification.

The commitment of senior management to the process was important in the Faculty obtaining carboNZero certification. In larger organisations, having a dedicated and resourced team to source required data, write the necessary reports and coordinate communication and record keeping is seen to be a crucial part of an efficient process. Although a number of parties are necessarily involved in the process, making the coordination of the project more complex, several beneficial relationships have been formed and a success of the process has been using participation in the carboNZero programme as both and educational and research opportunity for students and staff.

The efforts of the Faculty of Architecture and Design to move towards carboNZero certification were not made public for some time while negotiations were taking place. Once the plans were discussed with a wider group of staff and students, opportunities for wider engagement were taken. In inviting staff in particular to participate in the GHG Emissions Reduction Planning, greater 'buy in' was thought to have occurred. Students that participated in designing and implementing initiatives to reduce GHG emissions in the Faculty in late 2007 also commented on the positive experience of practical engagement in reducing the causes of climate change.

8. Conclusion

The process of becoming certified carbon neutral was longer than initially planned for and significant delays occurred during the process for Victoria University's Faculty of Architecture and Design. By clarifying the decisions that were made and outlining the process that was undertaken, it is anticipated that other intuitions or organisations may avoid some if the same time delays.

Along with the environmental benefits of reducing GHG emissions, it is clear that engaging in carbon reduction and offset measures will have significant additional benefits for the Faculty in terms of educational, research and marketing potentials. Economically, the benefits are expected to be longer term.

It remains to be seen if the significant efforts that the Faculty have and will go to in reducing GHG emissions will result in a net reduction, or reduction in intensity (per student), of GHG emissions. The opportunity to be leaders in addressing climate change in the built environment however, sends a clear signal to students, staff and the public alike that working towards mitigating the causes of climate change is considered to be important by Victoria's Faculty of Architecture and Design as a design and built environment educational institution.

[2] Department of Architecture, Seoul National University, Seoul, S. Korea
[3] School of Architecture, Yeungnam University, Gyeongsan, Gyeongbuk, S. Korea

Keywords: residential building, cooling, package air-conditioner, indoor-unit type, thermal environment

Summary

This study was conducted as a preliminary study to establish energy-efficient installment standards for individual-unit air conditioning system in residential buildings in Korea. Therefore, this study examined current air conditioning status and related problems in residential buildings, and selected currently the most common package air-conditioner type, the indoor-unit type of package air-conditioner. Based on this, this study performed a numerical analysis to compare and analyze the thermal environment across each type of indoor-unit package air-conditioners.

1. Introduction

As worldwide discussion for sustainable development is actively in motion in these days, variety of effort on environmental protection is also in motion around developed countries. Keeping pace with this effort, Korea is also searching for various solutions. Among the buildings that consume near the two thirds of energy, however, residential buildings explosively increase energy consumption for heating and cooling as living standard arises, which causes many problems.

Korea has considered only heating system in design and construction of residential building with the consideration of air-conditioning system almost excluded due to the temperature characteristics of short cooling season and the Korean life style. Therefore, the resident individually installs a package air-conditioner for their own depending on their affordability and need after construction is completed. For this reason, there are no standards for energy consumption and design in case of air-conditioning system.

In addition, many construction companies were competitively looking for ‘brand’ and ‘luxury’ buildings in their business, constructing many high-rise residential buildings. The increased load from heating and cooling due to the trend of tall buildings and air-tightness in residential buildings accelerated energy consumption in residential buildings. For this, the number of house that installs air-conditioned cooling system increased abruptly raising various individual and national problems.

Hence, this study is a preliminary study to establish energy-efficient installment standards for individual-unit air-conditioning system in residential buildings, and intends to compare and analyze the indoor thermal environment across the different types of indoor-unit package air-conditioner. For this purpose, this study examines the current status of air-conditioning and its related problems in residential buildings in Korea, and selected a most common indoor-unit type of package air-conditioner. Based on this, this study performed a numerical analysis to compare and analyze the thermal environment across each type of indoor-unit package air-conditioners.

2. Air-Conditioning System in Residential Buildings in Korea

2.1 Current Status of Air-Conditioning in Residential Buildings

Korea is geographically located to the east of Europe-Asia continent, between 33.6°~43.1°N latitude, middle range, and in temperate climate zone. The CDD (cooling degree-day) and the HDD (heating degree-day) in Korea in 2006 was 721 degree-days and 2525 degree-days, respectively, which indicates that the portion of air-conditioning in buildings is relatively low by 30% compared to that of heating. Because of this and Korean life style, only heating system has been considered with cooling system excluded since past in designing and constructing residential buildings in Korea. Hence, the resident individually installs and uses individual-unit air-conditioning system depending on his/her ability and needs.

2.2 Problems in Individual-Unit Air-Conditioning by Package Air-Conditioner

2.2.1 National problem

In the past, when the residents needed air-conditioning in the residential building, they did natural ventilation and put up with some unpleasant feelings. However, the ratio of apartment house increased more and more, and recently many high-rise buildings were constructed, as the results of which the heating and cooling load in the residential building increased. Moreover, as the need for pleasant and comfortable residential environment increases due to increased living standards, air-conditioner occupies the position of living necessity.

Korea power exchange (2006) was reported that the penetration rate of air-conditioner was 0.02 per house in 1985 and kept increasing year by year to 0.48 per house in 2006, which is 14.29% of increase to 0.42 in 2004 showing steep increase rate

Air-conditioning system using package air-conditioner uses electricity for the power for the compressor. Therefore, the penetration increase of highly electric energy-dependent air-conditioner leads to the increase of electricity consumption. In addition, it leads to the increase of maximum power demand and the decrease of power reserve rate in summer season, which becomes a social issue. Moreover, it causes high increase of power demand in summer season that induces increase in investment expense for expansion of power generation plant and decrease in the usage rate of power supply facilities, which becomes a factor that decrease the effectiveness of national power supply system. These increase in power demand and decrease in effectiveness in power supply system result in increase of CO_2 emission due to the increase of primary energy to produce electrical energy.

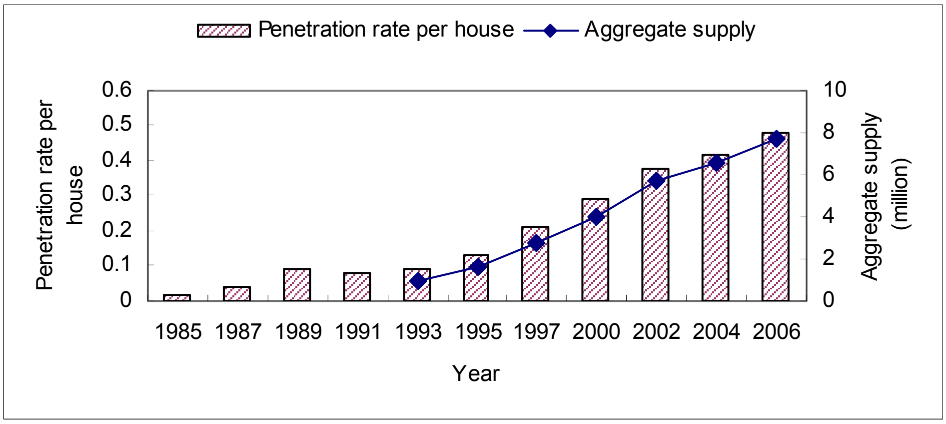

Figure 1 Annual changes of aggregate supply and holding rate of package air-conditioner in Korea

2.2.2 Personal problem

Progressive tax is applied to the electric charge for household in Korea in which the charge is weighted as the amount of use increases. Therefore, when a household operates a package air-conditioner during cooling season, it should pay the weighted charge in which the electric charge for the package air-conditioner is added to the ordinary electric charge. For example, if a house hold consumes 300KW per a month on average, the electric charge for it is 39 960 won (about 42 USD) calculated by the usual method as of February, 2008. However, if the household uses a package air-conditioner that consumes 2KWh for 8 hours per a day and 30 days per a month during summer air-conditioning period, the total amount of electricity consumed for a month is 780KWh, and the household should pay 326 600 won (about 344 USD), 286 640 won (about 302 USD) more than when it does not use a package air-conditioner. Consequently, it charges 8.2 times more despite it is weighted charge for only 2.6 times of actual amount of electricity consumed.

Such burden of energy expense acts as a negative factor for the users to operate air-conditioning system although it is equipped when they need it. While the penetration of air-conditioner increases at high rate year by year, the increase rate of electricity consumption for air-conditioner in 2006 was only 0.6% compared to that of 2004. However, during the same period, the increase rate of electricity consumption for electric fan was 9.54%. This results from the fact that although requirements for cooling increased due to seasonal factors, they used more electric fans alternatively to air-conditioner for the burden of energy expense.

The phenomenon caused by the burden of air-conditioning energy expense also influenced on the installation location and operation time of air-conditioner. The installation location of air-conditioner in Korea is mostly limited to the living room in which all family members gathers. As for the operation time, the ratio of the households that restrictively operates air-conditioner between 7 p.m. to 9 p.m. when all family members gathers together is very high.

Another problem caused by the burden of energy expense is the indoor air quality. Users tend not to ventilate while package air-conditioner is on operation in order to prevent temperature rise due to the induction of warmer outside air. This operation pattern causes many negative problems such as contamination of indoor air and air-conditioning it is due to no ventilation during air-conditioner operation.

2.3 Change in the Types of Indoor-Unit of Air-Conditioning System

The fist air-conditioner mass production began in late 1960s. Since ever, air-conditioning system has developed in a variety way according to consumers' need for bigger cooling capacity, premium, and multi-function product. The types of indoor-unit of air-conditioning system can be divided into the window type of 1st generation, wall mounted type of 2nd generation, Floor standing type of 3rd generation, and the ceiling cassette type of 4th generation, and the characteristics of each type are as such in the table 1. In recent, most of houses use a package air-conditioner with one of wall mounted type, Floor standing type, and ceiling cassette type.

Table 1 Changes in the types of indoor-unit of air-conditioning system

Period	Indoor-unit type	Characteristics
1st generation (Late 1960s)	Window type	Attached to window as indoor unit and our door unit are combined as one unit
2nd generation (Late 1970s)	Wall mounted type	Embellished outlook and began to be used as an interior design factor
3rd generation (Mid 1980s)	Floor standing Type	Most commonly used and large cooling capacity
4th generation (Late 1990s)	Ceiling cassette type	Improved design and space usability by installing on ceiling

3 Brief Overview of CFD Analysis for Thermal Environment Analysis

3.1 Target Space for Analysis

The common size and shape of Korean house was selected as the target space for CFD numerical analysis as shown in figure 2. The target space was also limited to living room area considering the fact that the most common installation place is living room. In addition, since living room area is generally connected to the kitchen and other adjacent rooms through aisle spaciously, the adjacent open area was also included in the target space to examine the interaction effect of the other adjacent open area with the living room. The target space was 7.1m(W) × 8.1m(D) × 2.3m(H), the total floor area of 36.6m^2.

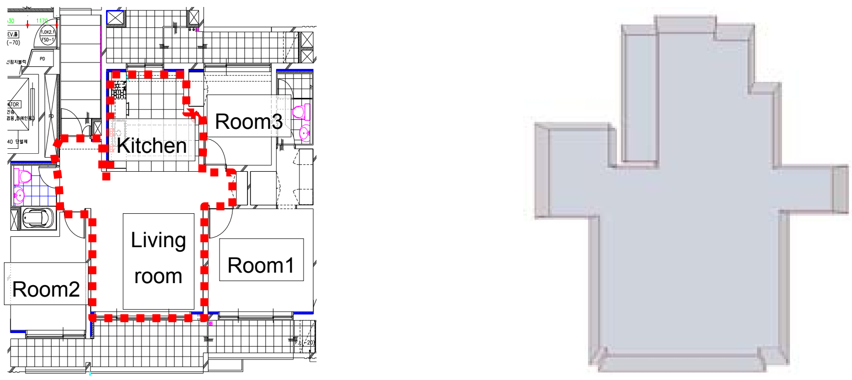

Figure 2 CFD Floor plan and modeling of the target space for analysis

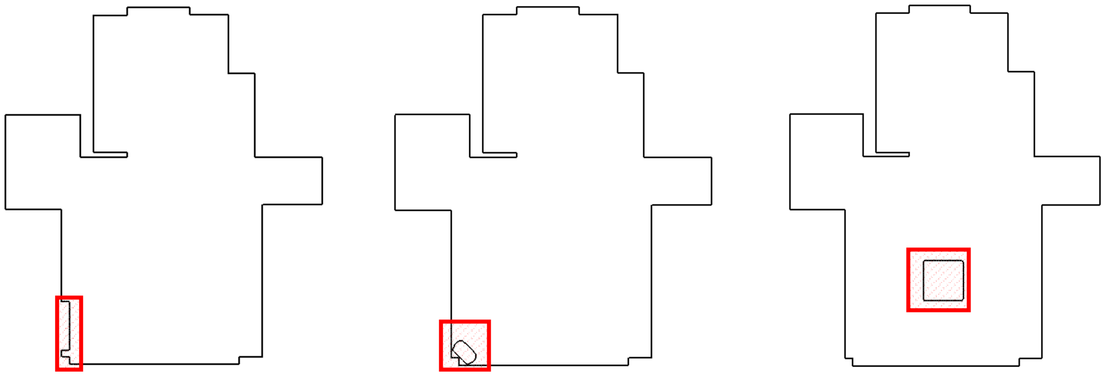
3.2 Case for Analysis

The analysis was performed by making figural copies of wall mounted type, floor standing type, and the ceiling cassette type installed. An individual package air-conditioner consists of indoor-unit and out-door unit. As for the arrangement of the indoor-unit and outdoor unit, the outdoor-unit is generally installed at terrace and the indoor-unit is installed in the living room near the terrace in order to increase the effectiveness of installation and the efficiency of air-conditioning by shortening the length of refrigerants pipe. The installation place for indoor-unit and outdoor-unit for each case is as following in figure 3.

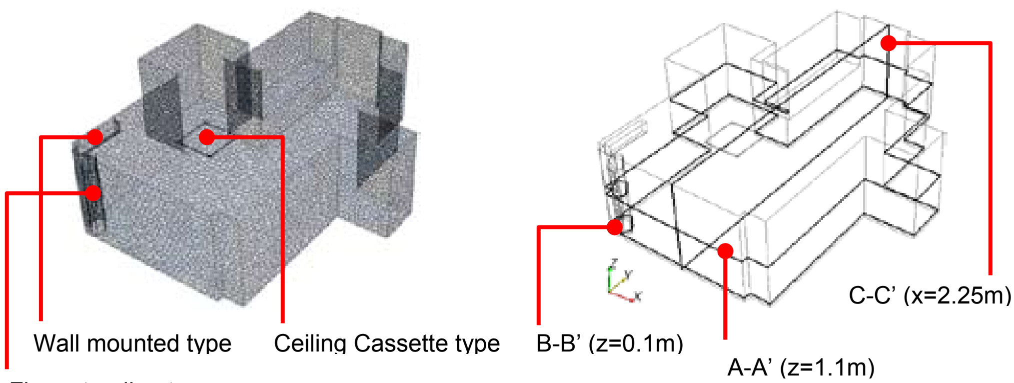


(a) Case1: Wall mounted type (b) Case2: Floor standing type (c) Case3: Ceiling cassette type

Figure 3 Case for CFD numerical analysis

3.3 Mesh for CFD Analysis

Polyhedral mesh was used for the space division for CFD numerical analysis. Different depending on case, the total volume was divided by 60 000 elements, and the surface was divided by 400 000 elements.



(a) Mesh for CFD analysis (b) Analysis section

Figure 4 Mesh for CFD analysis and the analysis section

3.4 Numerical Analysis Model for CFD & Boundary Conditions

Standard k-ε turbulence model of STAR-CCM+ was used for the CFD numerical analysis, and the boundary conditions of the CFD numerical analysis are shown in table 2.

Indoor thermal environment according to the changes of indoor-unit types for all cases was examined at equivalent supply air temperature and volume condition by fixing the volume and the temperature at equivalent level. Assuming that the target space was located in the middle floor, and the adjacent rooms were also air-conditioned by the equivalent temperature condition to the target space, the wall was set as adiabatic. The windows of the living room and the kitchen were the areas in contact with outside air and set as 309.3K for the outside temperature and 3W/m^{2}K for the heat transfer coefficient. The heat transfer of human body was set based on the 70W (sensible heat) for 1.1met for an adult man to make the total 234.5W of a foursome family, one male adult, one female adult, and two children. In addition, assuming the heating rate from basic electric home appliances was 100W, total of 334.5W of heating was evenly distributed on about 15.7m^2 of the living room floor on plane figure. Heating from lights was set as 15W/m^2 from the ceiling.

Table 2 Boundary conditions of CFD

Wall		Body and equipments load (①)	• Body convective heat transfer: 234.5W 1) Male: 70.0W (100%) 2) Female: 59.5W (85%) 3) Childs: 52.5W (75%)×2(person) • Equipments: 100W
		Lighting load (②)	• 15W/m^2
		Convection (③, ④)	• Outdoor temperature: 309.3K • Heat transfer coefficient: 3W/m^{2}K

		Case1	Case2	Case3
Air-conditioning	Supply air	• Volume: 0.2m^3/s • Temperature: 291K • Velocity: 2.4m/s • Size: 0.98m×0.085m • Direction: Downward 15° • Turbulence intensity: 10%	• Volume: 0.2m^3/s • Temperature: 291K • Velocity: 1.9m/s • Size: 0.44m×0.24m • Direction: Upward 30° • Turbulence intensity: 10%	• Volume: 0.2m^3/s • Temperature: 291K • Velocity: 1.7m/s • Size: 0.42m×0.07m×4 • Direction: Downward 30° • Turbulence intensity: 10%
	Return air	• Size: 1.09m×0.11m	• Size: 0.07m×0.86m×2	• Size: 0.46m×0.46m

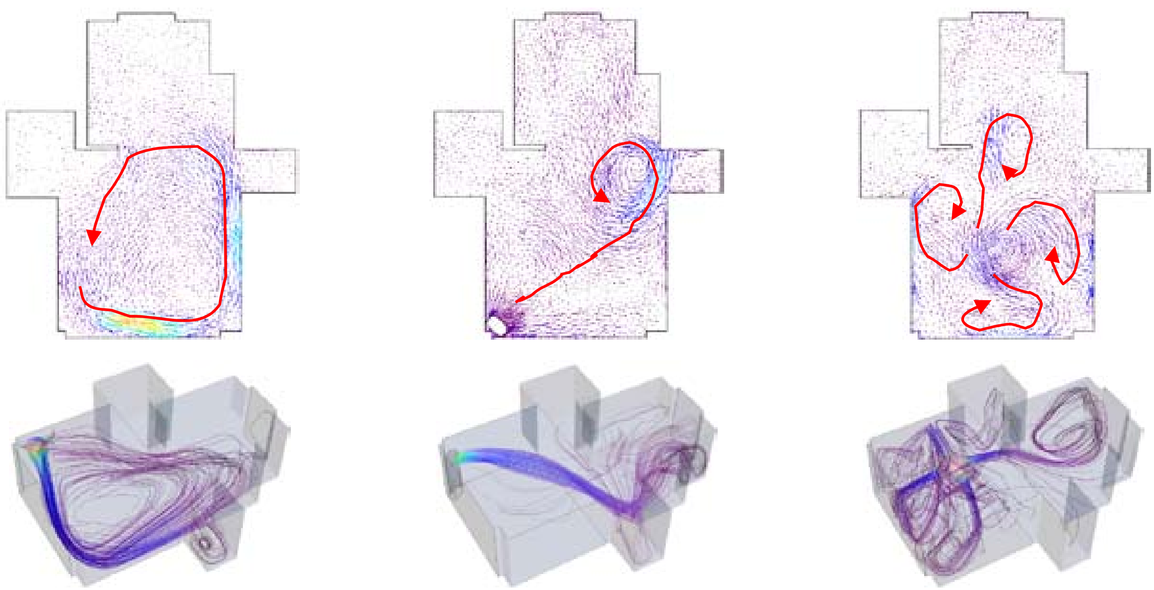
3.5 Analysis Method for Evaluation of Indoor Thermal Environment

The efficiency of indoor air-conditioning was comparatively analyzed for the indoor thermal environment factors in air current field, temperature distribution, and velocity distribution formed between 0.1m and 1.1m from the floor when equivalent supply of volume and temperature was extracted. The evaluation target range was limited to living room area.

4 Analysis of the CFD Numerical Analysis Results

4.1 Air Current Field

For Case1 to which the wall mounted type was applied, the air extracted from the distributor descended right after extraction due to extraction angle and density difference from around-air, and moved through the left-side living room window. The descending air progressed to the direction of the distributor and moved to the kitchen, an open space, through the surface of the walls opposed to the distributor. For Case1, current air field which circulated around the whole kitchen and the living room through the floor was formed.



(a) Case1 : Wall mounted type (b) Case2 : Floor standing type (c) Case3 : Ceiling cassette type

Figure 5 Velocity vectors of A-A' (z=1.1m) section across each case and streamline of the chilled air extracted from the distributor

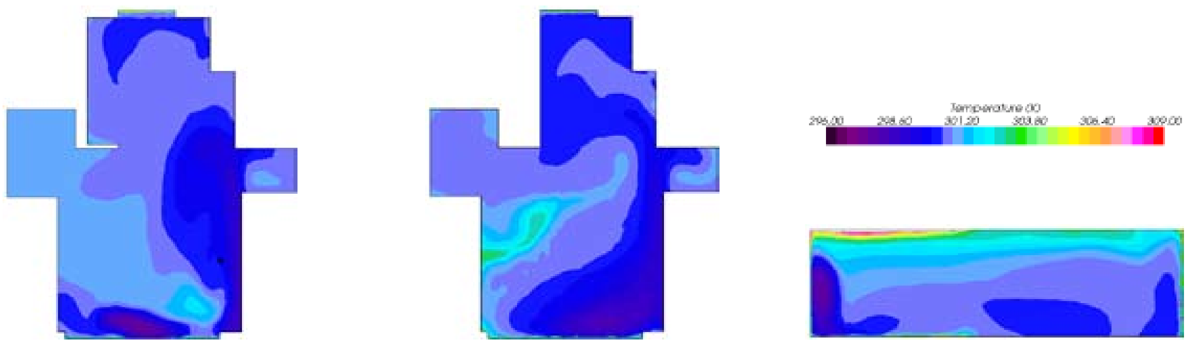
For Case2 to which the floor standing type was applied, the extracted air moved relatively far away through the ceiling and hit the walls of the aisle connecting to the adjacent rooms to form current air field spiraling and scattering around.

For Case3 to which the ceiling cassette type was applied, the four-way extracted air flowed through ceiling toward the distributor and hit the opposed walls to form abruptly descending air current field. Case3 shows the formation of living room-limited air current field due to the fact that cooled air was extracted from various directions with lower wind speed compared to other cases.

4.2 Temperature Distribution

4.2.1 Case1 (wall mounted type)

For the wall mounted type, the chilled air extracted from the distributor was distributed centered on the opposed walls to the direction of the distributor. The pattern for temperature distribution area between 0.1m and 1.1m was formed in a similar fashion. In addition, due to the cool air distribution grounded on the floor, the low temperature zone at 0.1m was formed relatively broad. The temperature at the living room window and the opposed walls at which the cool air arrived earlier was formed low. However, the temperature for the air current that came into the return circulating throughout the kitchen was formed higher than adjacent areas because it was mixed with the air in the around area. The average temperature for living area at the height of 1.1m, breathing height on seat, was 300.5K. The average temperature of 0.1m was 300.2K formed similar to 1.1m because while the range of relatively lower temperature than 1.1m was wide, the temperature for the area that the cool air did not directly reach was formed high.

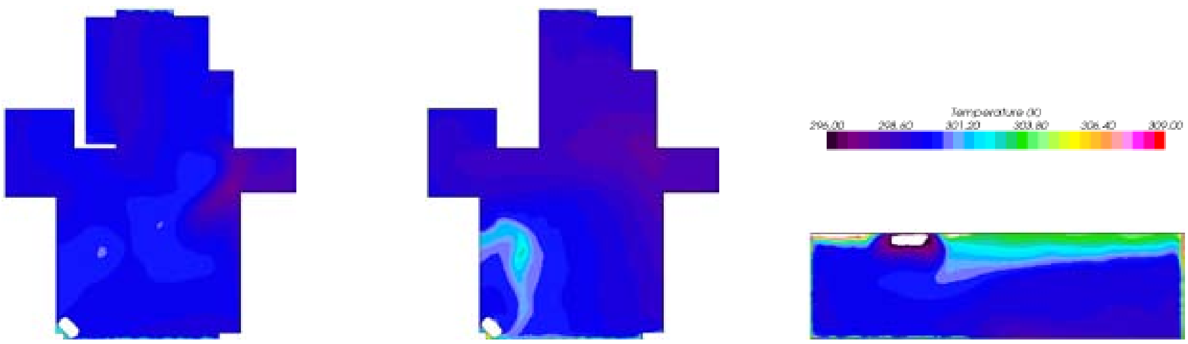


(a) A-A' section (z=1.1m) (b) B-B' section (z=0.1m) (c) C-C' section (x=2.25m)

Figure 6 Temperature distribution of Case1

4.2.2 Case2 (floor standing type)

For the floor standing type, the temperature distribution for the section of 1.1m and 0.1m was evenly distributed across the whole area. Only the area around the air-conditioner formed a zone that showed higher temperature by 2K than surrounding area. The average living room at 1.1m and 0.1m was 299.8K and 299.7K, respectively, which was relatively lower than case1 by 0.6~0.7K. In addition, Case2 showed lower and even temperature distribution than case 1. It is judged to result from the fact the first air unmixed with surrounding second air reached more at the occupied zone since the location of the distributor was closer to the occupied zone than Case1.

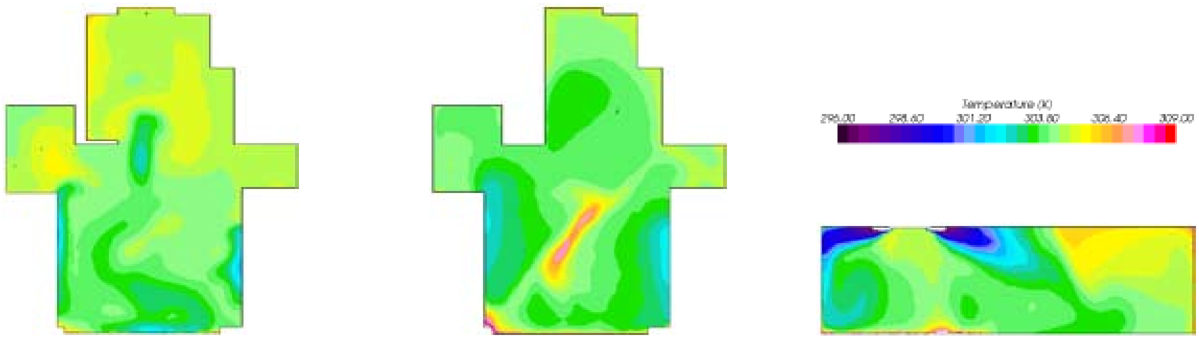


(a) A-A' section (z=1.1m) (b) B-B' section (z=0.1m) (c) C-C' section (x=2.25m)

Figure 7 Temperature distribution of Case2

4.2.3 Case3 (ceiling cassette type)

For the ceiling cassette type, the average living room temperature for 1.1m and 0.1m was 303.9K and 303.7K, respectively. These were the temperature above Case1 and Case2 by about 4K. Case3 had narrower distributor and lower extraction velocity than Case1 and case2 since it had many distributors. In addition, the distributor was located on the ceiling so that it was located farthest from the occupied zone. Therefore, before the extracted chilled air from the distributor was mixed with surrounding hot air before it reached the lower part of the occupied zone, it did not effectively remove the air-conditioning load in the occupied zone.



(a) A-A' section (z=1.1m) (b) B-B' section (z=0.1m) (c) C-C' section (x=2.25m)

Figure 8 Temperature distribution of Case 3

4.3 Distribution of Velocity

The velocity scalar of 1.1m across each Case was shown in figure 9. For the wall mounted type, the velocity of the extracted air current was formed relatively high at 1.2m/s. The velocity around the walls forming air current was formed high as well. The average velocity in the living room was 0.25m/s

For the floor standing type, the velocity around the corner opposed to the living room at which the extracted air current reached first was formed high, and generally the current velocity at the location diagonal to the distributor was formed high. The average velocity in the living room area was 0.13m/s, lowest among the three cases.

For the ceiling cassette type, the velocity was formed evenly and actively around the living room in which the indoor-unit was installed as extracted to various directions from the distributor. Therefore, the air current in the living room area was most even and finest among all the three cases. The average velocity in the living room area was 0.18m/s.

Figure 10 shows the velocity area beyond 0.25m/s of the A-A' section (z=1.1m). For the ceiling cassette type, the velocity area beyond 0.25m/s was formed broadly around the walls in the living room. On the contrary, the velocity in the living room for the floor standing type remained under 0.25m/s except the corner of the living room opposed to the distributor. For the ceiling cassette type, the four-way extraction directions from the distributors and the vertical below the indoor-unit installation place formed the velocity area beyond 0.25m/s. The area beyond velocity 0.25m/s is very likely to cause partial unpleasant feelings due to draft.

Figure 10 Area beyond velocity 0.25m/s of A-A' (z=1.1m) section across each case

5 Conclusion

As a preliminary study to establish the standards for energy-efficient installation of individual air-conditioning system, this study comparatively examined the thermal environment across the types of indoor-unit through CFD analysis. The results are as following:

1) Examining the average temperature formed in the occupied zone around the living room, the ceiling cassette type formed higher than other types by 4K, which indicates that it does not effectively remove the cooling load in the indoor occupied zone. For the wall mounted type and the floor standing type, the average temperature for the occupied zone was formed lower by 0.6~0.7K for the floor standing type. In addition, the floor standing type was relatively better in the evenness of temperature distribution.

2) The average velocity in the occupied zone around the living room was 0.25m/s for the wall mounted type, 0.13m/s for the floor standing type, and 0.18m/s for the ceiling cassette type. As for the evenness of velocity distribution, the ceiling cassette type showed even distribution in the living room area due to the variously directed extraction from the distributor. Examining the area in which the velocity went beyond 0.25m/s to be likely to show partial unpleasant feelings, the floor standing type was the best among all the types.

3) The reason that the package air-conditioner consumes high amount of energy is that the compressor consumes a great amount of electric power. Therefore, the compressor would not be operated as much as possible to reduce the electricity consumption. For this, the indoor temperature should be set higher. From this perspective, the worst energy-efficient type is the ceiling cassette type, and the best is the floor standing type.

Managing the Built Environment – The Facilities Management Industry's role in delivering connected, viable, liveable Built Environments.

Jonathan MCCORMICK

Managing Director- Brookfield Multiplex Services Pty Ltd

Chair- Sustainability Working Group, Facilities Management Action Agenda

Ref. SB291

Summary

The role of the Facilities Management Industry in managing the Built Environment is not widely understood or appreciated. There is very little recognition of the possible contribution the Industry can make in making the built environment more sustainable, particular in respect of the existing built environment. The focus of many government and corporate policies is on new buildings and refurbishment. This is supported, using energy efficiency as an example, in the OECD's Environmentally Sustainable Buildings; Challenges and Policies document which states "This concentration of policy implementation on the new building sector can be justified, to some extent by the fact that energy performance of buildings is largely fixed at the time of new construction." There is a fundamental flaw in this argument as it assumes that all new buildings will be operated at the optimum design level (which is indeed, somewhat fixed at the time of new construction). However, evidence suggests that a majority of buildings (both old and new) do not currently operate at their optimum design levels. There are a number of possible contributing factors to this sub-optimal performance, but a key contributing factor is the standard of facilities management.

Consequently, the anecdotal evidence also suggests that improvements of in excess of 20% could be achieved in the sustainability performance of much of the existing built environment through better facilities management practices with little or no requirement for capital expenditure. Again using energy efficiency as the example, a 20% improvement across the non-residential component of the built environment alone could generate up to a 2% reduction in Australia's total contribution to greenhouse gas emissions.

As an industry, Facilities Managers must promote their role in sustainability to a wider audience and hence improve this audience's understanding of the facilities manager's role. Facilities Managers must improve their understanding of sustainability through better education and training and deliver demonstrable improvements in environmental sustainability across the built environment.

This is the challenge that must be taken up by the Facilities Management Industry to deliver connected, viable, liveable Built Environments.

1. Managing the Built Environment

"Managing the Built Environment" was the title given to the Facilities Management Action Agenda (FMAA) sponsored by the Australian Federal Government and supported by industry over the period from August 2005 until April 2008. Its vision for the Australian facilities management industry was "to be the foremost contributor to a productive and sustainable built environment through excellent and innovative management of facilities services" [1]. Twenty actions were developed including four specifically relating to sustainability;

Action 14 Promote the role of facilities management in responding to increased demand for corporate accountability associated with sustainability performance.

Action 15 Promote the role of the facilities management industry in key industry and government forums addressing sustainability.

Action 15 Use the data portal [FMAA] proposed to disseminate sustainability information.

Action 17 Develop a 'business case' model that highlights the costs and benefits of embracing sustainable practices in the use and management of materials; energy; water; waste and indoor environmental quality with a particular focus on workplace productivity.

In addressing the above 4 actions as part of the FMAA Sustainability Working Group it became very apparent there was little understanding of the facilities management industry and the role it must play in delivering sustainable built environments.

At the holistic level, Governments can legislate and Corporations and individuals can adopt sustainable policies. Architects, engineers and builders can design and build new 'green' buildings or refurbish existing buildings to enable better sustainable performance but this does **not** deliver sustainable performance in the built environment. It provides the tools for improved performance, but it is the facilities manager who must used these tools effectively to deliver optimum sustainable performance.

In Paul Bannister's 2003 review of energy use benchmarks for class 5 commercial buildings (offices)[2] a key finding as to why computer simulations results differed significantly from actual building data was that "real buildings suffer from a range of operational issues that impact upon building efficiency above and beyond the impact of design". It is these operational issues that are in a large part the responsibility of the facilities manager of either the owner and/or user of the building. The impact of these operational issues was not quantified, but a telling statistic is that less than 25% of buildings designed to a specific ABGR (Australian Building Greenhouse Rating) level were not operating at that level at the time of the report. This is even more concerning given that these new 'green' buildings had generally been given the necessary tools to perform. What about the existing built environment? How well is it currently performing against its original design intent given that it makes up in excess of 98% of stock, with the other 2 % being currently under construction or refurbished?

Various other reports have identified the opportunity of improving the existing built environment sustainability performance, but very few have focussed and quantified the impact that facilities management has in this area. For example the Parramatta CBD Greenhouse Leaders Project[3] (2005) acknowledges the contribution from "improved housekeeping" (a euphemism for better facilities management) but does not quantify the improvement and generally focuses on technical solution improvements. This is also evident in the more recent CIE Report[4] (2007) which addresses "Capitalising on the building sector's potential to lessen the costs of broad based GHG emissions cut". It reports that "the building sector as a whole could reduce its share of CHG emissions by 30-35% per cent whilst accommodating growth in the overall number of buildings by 2050". Again the focus is on investment in energy efficiency technology and does not address the potential risk of not having an industry skilled enough to manage effectively that technology nor does it address the even greater opportunity of combining improved management with this greater investment in technology.

On the other hand, Orjan Lundberg[5] (2008) has attempted to link the management of buildings to environmental impacts and concludes that "there is a relationship between the environmental performance of a building and the way it is managed. However, to be able to quantify and qualify that relationship, some modifications to the research design are necessary", which neatly sums up the general understanding of the impact the Facilities Management Industry has on the delivering sustainable built environments.

2. Barriers to delivering Sustainable Built Environments in the Facilities Management Industry

There are numerous barriers to delivering sustainable built environments in the Facilities Management Industry including;

1. Facilities management is not currently recognised by the Federal Government as a profession;
2. There have not been undergraduate degrees available in Facilities Management until recently in Australia and hence most people entering the profession do so as a "second career";
3. There is still little or no understanding of the Industry at the school leavers level, but the Industry's ability to deliver real sustainability improvements could be used to attract younger people into the Industry;
4. The remuneration paid to most facilities managers is not commensurate with the skill level required to deliver sustainable outcomes;
5. The property sector's continued focus on design attributes as opposed to actual performance. There needs to be a significant paradigm shift in the industry where stakeholders are rewarded for actual performance of the built environment not just its design potential;
6. Accredited designs need to be correlated with actual performance data, and the root cause of any gap analysed and addressed; and
7. Lack of basic sustainability education for practicing facilities managers.

It is the strong belief of the Author of this paper that in relation to Point 7 above, if one hundredth of the investment in any building refurbishment is made in providing basic sustainability education to practicing facilities managers, you will see a ten fold improvement in sustainable building outcomes over and above what is delivered by the actual refurbishment alone. Taking energy efficiency as an example, the return on investment in education and training can be significantly higher than that provided by investment in refurbishment of technology.

3. Industry Initiatives to deliver Sustainable Built Environments

As part of the FMAA, there are a number of specific initiatives been undertaken to address a number of the barriers highlighted above. Generally, the FMAA Sustainability Working Group has been actively promoting the role of the facilities management industry across many government and industry forums over the past three years.

The industry has supported the emergence of a number of undergraduate degrees in Facilities Management and in tandem has developed a strategy to "market" the industry to school leavers.

Specifically "Sustainable Operations Guidelines for Facilities Management" [6] have been developed by the FMAA Sustainability Working Group to provide operational facilities managers with a simple and relevant reference document on "how to" deliver sustainable built environments.

In conjunction with the University of Sydney and UNE Partnership, an innovative, industry led, education and training programme is being developed specifically for operational facilities managers with defined work related sustainability improvements as part of the key deliverables.

The industry continues to engage with the Federal Government in relation to the proposed Green Building Fund to ensure taxpayers funds are spent proportionately on what will provide a lasting legacy through improved education and training rather than a "one off" technological fix (which is unlikely to provide the expected benefits for all the reasons outlined in Section 2).

Conclusion

The Facilities Management Industry clearly has a role to play in delivering connected viable liveable built environments. What is needed is greater recognition and clear understanding of this role by all stakeholders so that the Industry can be developed to realise the full potential of its ability to deliver improved performance across the entire built environment.

Relying on design and technological improvements ***alone*** does not equate to delivering sustainable performance in the built environment.

Australia must invest in education for the facilities management industry as this is clearly the "lowest hanging fruit" available to produce material improvements to the sustainability performance of the built environment.

MAINSTREAMING SUSTAINABLE HOUSING: POLICIES AND PROGRAMS THAT WORK

Caitlin McGee[1]
Emma Partridge[1], Naomi Carrard[1], Geoff Milne[1]

[1] Institute for Sustainable Futures, University of Technology, Sydney, Australia; caitlin.mcgee@uts.edu.au, geoffrey.milne@uts.edu.au, emma.partridge@uts.edu.au, naomi.carrard@uts.edu.au

Keywords: sustainable housing, policy, consumers, industry, home buyers, social research

Summary

This paper draws on the findings of research by the Institute for Sustainable Futures (ISF) for the Queensland Environment Protection Agency (QEPA) into attitudes towards sustainable housing. The aim of the research was to examine what drives housing provision and choice from both the housing industry and consumer perspectives, and how sustainability fits within this picture. The research also aimed to demonstrate how this understanding can better inform sustainable housing policy. The research found that for consumers, cost and lifestyle are the most powerful drivers of housing choice. For industry the drivers for action (from product supply and service delivery to building practices) are profit and market edge, both of which are largely driven by perceived consumer demand. There is a significant mismatch between the perceptions of consumers and industry in that each group perceives the other as lacking commitment to advancing sustainability in the housing sector. The study underlined the value of social research in informing sustainable housing policy in the mainstream housing market in order to ensure that these drivers and conflicts are addressed.

1. Introduction – the importance of social research for sustainable housing policy

Governments around the world have implemented a wide range of policies to encourage and underpin the uptake of sustainable housing, covering the full complement of regulatory, fiscal and educational measures. These have had varying degrees of success, and sometimes unexpected and even undesired outcomes.

Currently, much of the research undertaken prior to policy implementation focuses on technical and financial analysis, with little effort put into finding out and understanding what motivates consumers and industry. However, when it comes to what drives action, it is as likely – if not more likely – to be structural or attitudinal factors as technical or financial ones.

If sustainable housing policies are to be effective and supported by both consumers and industry in the mainstream housing sector, there is a need to research and respond to the perceptions and attitudes of the intended recipients. Policy is more robust and effective if it aligns with people's existing drivers for change, while anticipating and addressing barriers to uptake. Even the apparently more predictable regulatory measures can fail to achieve desired outcomes if they are not grounded in an understanding of these drivers.

This paper presents the results of research conducted by the Institute for Sustainable Futures (ISF) for the Queensland Environment Protection Agency (QEPA) on consumer and industry perceptions of sustainable housing. A review of previous research on perceptions of sustainable housing establishes common themes and key questions for investigation. The results of new research conducted in Brisbane for the QEPA are then described, building on themes and issues evident in the literature. The research findings are then used to create a framework for policy to progress sustainable housing.

2. The QEPA project

The project that the Institute for Sustainable Futures (ISF) undertook for the Queensland Environment Protection Agency (QEPA) consisted of two main components; a research element, using primary and secondary research to investigate building industry and consumer perceptions of sustainable housing; and a policy development component, using the findings of the research to inform the development and analysis of a series of policy options. The research included some examination of the social aspects of sustainable housing such as accessibility and health, however the main focus of the research was the environmental aspects of sustainable housing. The research component of this work consisted of three parts:

- A literature review (described in section 2 below)
- Empirical social reseach, comprising:
  - A series of telephone and face-to-face interviews with key stakeholders
  - Two surveys conducted with visitors to the *HIA Home & Building Expo 2006,* held at the Brisbane Convention & Exhibition Centre from 4 – 7 May 2006 (hereafter referred to as the 'Brisbane Expo survey'). One survey targeted consumers (382 responses), while a smaller survey was aimed at building industry members (142 responses)

The policy development component consisted of three stages:

- Development of a suite of potential policy measures and instruments (informed by the research)

- A stakeholder workshop to present and seek feedback on the research findings and the potential policy measures and their likely impacts
- Refinement of the policy proposals using the workshop outcomes and including an analysis of the costs, benefits and risks associated with each option

These were focused on new housing, but many of the findings would be equally applicable to the home renovation market.

The results of the literature review are discussed in section 2 below, and the findings of the emprical social research summarised in section 3. Section 4 then goes on to explain how the research phases of this work were used to inform policy development.

2. Previous research on consumer and industry perceptions

Previous research into awareness of sustainable housing has produced conflicted results, with literature divided on the extent to which consumers are aware of and interested in sustainability in the residential sector. A number of studies indicate a general lack of awareness and resistance to sustainable housing based on a perception that sustainable housing is less aesthetically attractive and has a lower resale value than traditional housing (see for example, Minnery et al. 2003 cited in Buys et al. 2005; Buys et al. 2004; Clark 2001). A Queensland Department of Housing study identified a relatively low consumer awareness of sustainable housing issues and found that there was little education or information provided to them (Colmar Brunton 2004). Interviews with 421 consumers from Melbourne and Sydney found that only 47% had even heard of ‘green’ buildings (Trilogy Property Pulse 2005 cited in Iyer-Raniga et al. 2007). Gold Coast water identified lack of awareness as a barrier to the successful uptake of its water efficiency program, evidenced by questions from consumers such as “Will this really save water?” “What does the rating system mean?” and “Which appliance do I buy?” (GHD 2005).

However many Australian and international studies contradict these analyses and there is evidence that consumers are becoming not only more aware of sustainable housing, but more interested and convinced of its value. A US study of consumer approaches to green home buying found that half the market were interested in sustainable buildings, with energy efficiency, indoor air quality and water efficiency the most valued features (Johnston 2001, cited in Iyer-Raniga et al. 2007). Similarly, research undertaken in Melbourne by Trilogy Property Pulse (cited in Iyer-Raniga et al. 2007) found that 85% of 421 survey respondents believed that future developments should be ‘environmentally friendly’ or ‘green’. A survey conducted for the Sustainable Energy Authority Victoria (SEAV) found that of a group of display home visitors interested in a household energy rating, 25% indicated energy use would significantly influence their choice of home (Allen Consulting Group 2002, cited in Kam 2005).

Despite increasing awareness of and support for sustainable housing, much of the literature reports that action is lagging behind expressed intentions. While consumers feel positively about sustainability, these positive attitudes often do not translate into action. This is because consumers do not consider sustainable features in isolation, but in relation to other more significant and often conflicting drivers. As a result, actual uptake of sustainable housing elements – unless regulation mandates implementation – does not match people’s expressed support for sustainability as a principle.

The relatively low voluntary uptake of sustainable housing is reported anecdotally and supported by a number of studies. Ambrose et al. (2005) note that uptake of energy efficient design in the residential sector has rarely been voluntary and has primarily followed advances in regulation including amendments to the Building Code of Australia. This is reinforced by Buys et al. (2005), who note that despite increasing consumer awareness about the importance of reducing energy consumption, the uptake of sustainable housing designs and smart technologies remains relatively low. Of 50 homes surveyed by Brisbane City Council about energy efficiency (Brisbane City Council 2002), over half did not consider natural ventilation and more than a third did not consider eaves or window shading. A survey of 3,304 Queensland householders in 2005 found that only 7% use solar hot water systems, with 85.5% using electricity for hot water (OESR 2005).

Cost is the most commonly cited reason for low uptake of sustainable housing (for example Iyer-Raniga 2007; Yudelson 2004 cited in Kam 2005). This is interesting in light of apparent increasing support for sustainable housing. Sibley (2004) suggests that cost is not so much a *motivator* as a *barrier*. Rather than driving consumer choices, cost is a limiting factor for those consumers unable to afford particular initiatives. This implies that cost is a secondary – albeit important – consideration: consumers identify preferred sustainability initiatives first and consider affordability (and consequently rule out particular options) second.

Lack of industry support is also cited as an important barrier to consumer uptake of sustainable housing and a perception exists amongst consumers that the urban development industry generally lacks awareness of sustainable housing. Of 421 Melbourne and Sydney consumers interviewed, 60-70% believed that developers are not interested in the environment (Trilogy Property Pulse 2005 cited in Iyer-Raniga et al. 2007). A Melbourne study of environmentally conscious buyers found that only 3% of 300 people surveyed had received information on environmentally friendly housing from their builder or architect (Sibley 2004).

This forms a significant barrier to wide uptake of sustainable design features, as consumers naturally tend to rely on advice from industry when making choices about house design and construction.

Interestingly, while consumers believe industry has little interest in sustainable housing, the perception from industry is that it is lack of consumer demand that is preventing mainstream adoption of innovative design. In a survey of housing industry representatives in South East Queensland, respondents believed that consumer expectations centre on comfort, lifestyle and resale (HIA 2005). They perceived a general consumer ignorance regarding sustainability issues, and said that whilst they had a role in educating consumers they could only take this up to a point. There was also the perception that consumers would not pay more for sustainable housing (which conflicts to some extent with the consumer literature). The consensus was that without consumer demand industry is not in a position to deliver sustainable housing.

3. Results of new social research on attitudes to sustainable housing in Queensland

The new social research undertaken by ISF for the QEPA explores perceptions of sustainable housing among consumers and industry, and builds on themes and issues evident in the literature described above. Results from this research provide insights into both consumer and industry perceptions of issues relating to sustainable housing. The study also helps understand some of the behaviours and choices that both groups display in response to these issues. The findings of this research are summarised below.

3.1 Consumers

Consumers have a range of perceptions about sustainable housing, some of which support and some of which inhibit the uptake of sustainable housing features, products and services. The study suggests that people feel positive about sustainability and sustainable housing at a conceptual level, as something they aspire to. For example, almost 80 per cent of survey respondents agreed that 'it's important to do the right thing' in the context of sustainable housing. Respondents were also convinced that sustainable housing has the potential to offer them a number of different personal benefits. Almost 65 per cent thought that it could improve their lifestyle, over half thought it could save them money and half thought it could improve the value of their house. Respondents also ranked sustainability highly compared to other factors. In response to the survey question *what is most important to you when buying, building or renovating a home?* respondents ranked environmentally friendliness third overall (below comfort/lifestyle and resale value) when given a list of eight criteria. These results suggest that consumers are predisposed to view sustainable housing positively – at least at the conceptual level. They also have high levels of intent to implement sustainability features. The survey asked whether people had, or intended to, implement a range of specific features (such as rainwater tanks, energy or water efficient fixtures and passive/low energy heating and cooling and so on), and among those who had not already implemented these features the proportion who intended to do so in the future was at least 40 per cent for each of the features. The elements that the highest numbers of people intended to include in the future were rainwater tanks (69 per cent) and energy efficient fixtures (60 per cent).

However, despite positive general perceptions and good intentions, there are also barriers for consumers that may prevent them from translating intent into action, behaviour and purchasing choices. Overall, the biggest barrier to implementing sustainability elements is cost. Perceptions about the cost of sustainable housing tend to be negative – that is, the belief that 'sustainability costs more' is fairly common. This can be seen in two aspects of the research findings. In the survey, when consumers were asked about implementation barriers in relation to a diverse range of sustainability aspects, 'added cost' was consistently named as the biggest barrier. In the stakeholder interviews, the perception that consumers are largely driven by cost was very common. As one interviewee put it, "*Consumers want [sustainability] as a bonus but they don't want to pay for it".* Many interviewees noted that not only are consumers driven by cost, but they also tend to have a narrow, or short-term view of what constitutes 'cost'. It was thought that many were only interested in comparing up-front costs – few considered running costs, or the savings that could be made over time by using more sustainable features. As one person said, "*most consumers base their decisions on "what can I afford right now?"*

The ISF survey found that many people do see sustainability as something that has the potential to save them money over time. For example over half the consumers surveyed thought sustainability could potentially save them money or add value to their home. Further, when offered a choice of factors that might encourage them to implement elements of sustainable housing, 'savings on energy and water bills' was overwhelmingly the highest ranked answer.

It is worth policy makers noting this positive cost-related perception, and where possible building on it, by stressing the potential for cost savings over time (for example, through lower bills) and for added asset value. However, while worth pursuing, the potential for this approach may be somewhat limited. Stakeholder interviewees suggested that most consumers still consider cost predominantly in relation to upfront costs and asset/resale value, and that ongoing or running costs are secondary and much less important considerations for most consumers.

Insufficient knowledge is also a barrier, with one in five survey respondents stating that they did not know enough about sustainable housing. However, interviewees generally thought that consumers have become more aware in recent years, particularly in relation to environmental issues:

In general, people are more concerned and smarter about the issues

The consumer base is more educated and more wanting of a greater intersection with sustainability.

Awareness is across a broader cross-section of the population now.

One interviewee suggested that younger people in particular are showing higher levels of awareness, and that their views may be quite influential in the future:

The generations coming through are far more educated about this whole process than their parents were.

However, many of the interviewees suggested that there is a marked difference between what consumers say about sustainability, and what they actually do when it comes to housing choice.

If I just did a general survey of the public out there, you'd get an overwhelming response that, 'yep this [sustainable housing] *is good'. But you target the people who are about to build and spend the money; you'll get a totally different answer.*

This apparent gap between general attitudes and actions was a key theme of the research, and it is perhaps explained by the fact that consumers are motivated by other important drivers. These certainly include cost, as just discussed, but also important are what might be referred to as 'lifestyle' factors. When asked what was most important to them in their home, 'comfort and lifestyle' was by far the most highly ranked criteria overall, and was also the most popular criteria, with far more respondents ranking it first than any other.

'Lifestyle' is a loose term, used here to refer to a range of factors that are commonly expressed by consumers. 'Lifestyle' factors are most often expressed in terms of comfort and convenience, and can also relate to other aspects like aesthetics, status and the size of the home. The desire to be sustainable can be easily overridden by these considerations. On the face of it, consumer perceptions linking sustainability and the lifestyle driver tend to be largely positive. For example, 65% of consumers surveyed in this research believed that sustainability could improve their lifestyle, and almost none saw sustainability as a lifestyle compromise. However these attitudinal results (particularly the latter) should be interpreted with some caution. The link between this 'lifestyle' driver and cost is difficult to measure, particularly because consumers are less likely to admit to attitudes that conflict with their stated desire to 'do the right thing'. Nevertheless, translating those positive attitudes into action, particularly when it means compromising on comfort or lifestyle, proves challenging for many.

However, while it is true that actions do not always live up to attitudes, and consumers are not keen to 'compromise' comfort or lifestyle, it appears that consumers do at least have a positive perception of sustainability in relation to lifestyle. This indicates the potential for a greater emphasis on the lifestyle benefits of sustainable housing to be used as a policy lever.

3.2 Industry

What emerged from the research as the key drivers for industry when it comes to decisions about sustainable housing were the need to make a profit and the desire to develop or retain a 'market edge' over competitors. These drivers are strongly influenced by perceptions about two things, firstly consumer demand, and secondly the cost and risk of any given action. Perceptions of how sustainability relates to these two drivers are predominantly quite negative, particularly in the mainstream of the housing industry.

Some aspects of industry perceptions and drivers are best understood with reference to certain characteristics of the mainstream housing industry, for it is the particular nature of the industry that appears to influence industry perceptions about the possibilities of sustainable housing. Firstly, the industry is relatively segmented, with different segments playing different and well-defined roles. This means that many industry players are focused fairly narrowly on their own role in the building process, rather than on the 'bigger picture' and their relationships with other segments of the industry. This is illustrated by the fact that 40 per cent of industry respondents to the ISF survey said that the main barrier to implementation of sustainability is that it is often not specified 'upstream' in the process. This appears to mean that individual players 'downstream' feel they have little control or influence over it. The second relevant characteristic of the housing industry, in particular the project home sector, is that it is highly standardised and relies on certain designs, processes, relationships and supply chains that have been gradually developed and refined over time. There are large perceived (and possibly actual) costs and risks in changing these standard ways of working in order to incorporate more sustainability initiatives. Further, in a buoyant market, this is seen as an unnecessary 'experiment'.

Changing housing designs and product supply chains is seen as a significant financial investment, with no guarantee of a financial return. Even if the will to show leadership and change current practice exists on an individual level, it can be constrained by other factors including organisational reluctance, lack of knowledge, insufficient skills or lack of access to training

Another significant finding is that the housing industry is heavily influenced by perceptions of consumer demand. A message that came through very strongly in the interviews was that the industry is highly consumer driven. Many people noted that industry members will only act on sustainability if they see a consumer demand for them to do so:

Our industry is driven by what people ask for, rather than what we give them.

Furthermore, it seems to be a common perception amongst industry members that there is little consumer demand for sustainability, and without such demand, the industry cannot respond. There was a feeling among some people however, that this perception was quite limited, and that if the industry were more proactive on sustainability issues then perhaps consumers would respond:

It's definitely in the hands of the developer or the builder [to stimulate demand]

They [the industry] *don't actually realise that it's a chicken and egg argument.*

However, others thought that change in industry ultimately must be driven by consumer demand, and that it is the responsibility of governments to educate consumers and create a demand (and hence a market) for sustainability in the housing industry. In this sense, the high degree to which the industry sees itself as demand driven can potentially be positive:

If the public can create the demand, change within the industry tends to flow on very, very quickly.

In general however, and particularly in the 'mainstream' project home market, levels of consumer interest in and demand for sustainability are thought by industry to be low, or even in some cases, non-existent:

Nobody comes into our office and says, "I want the most environmentally friendly house that you've got". Nobody does that. The environment for our customers is way off their radar.

The consumers aren't asking us for choices.

Customers come to us and say, "I want the most amount of house I can get for the least amount of money, and I want it to be big, and I want it to be functional; I want the kids to have big bedrooms".

The main reason for the lack of consumer demand is perceived to be cost of sustainable housing, and the fact that consumers do not see it as an immediate benefit:

Would [consumers] *pay an extra thousand dollars knowing that it's going to take them ten years to get that thousand dollars back? No.*

If you want people to be environmentally friendly you have to make it instant and you have to make it not cost any more.

Industry perceives cost to be a major driver for consumers, and sees the challenge with sustainable housing to be marketing it in a way that addresses this:

We've got to find a way to target the sustainable housing at the hip pocket because that's where you're going to get the people in.

Further, many interviewees thought that most consumers have not yet reached the point where the issues of sustainability is personally relevant and important to them.

The industry perception of limited consumer demand relates strongly to the profit and market edge drivers. Clearly many industry members are aware of the consumer 'attitude-action gap' discussed above. They feel that while consumers have positive intentions about sustainability, when it comes to implementation their behaviour may not reflect this, and it is their behaviour that industry pays attention to. As a result while the industry is aware of increasing consumer interest in sustainability it is seen as fairly marginal, and certainly not as a key factor that drives decision making. In particular, industry does not believe that consumers are willing to pay more for sustainability. For these reasons, sustainability is not generally seen as a useful differentiator for business. It can even be seen as having the potential to compromise profit and market edge in cost sensitive markets such as the project home market.

The perception that sustainability adds cost was a predominant industry view among the survey respondents. Cost was the most commonly identified barrier to implementing sustainability features, with between 14 and 34 per cent of respondents naming cost as a barrier, depending on the feature.

This perception may be compounded by the typical tendency to treat sustainability as an 'add on' rather than as integral to the house, and therefore to view the costs as additional to the cost of a 'standard' house. It is also affected by levels of knowledge – some industry members, like some consumers, may only be aware of the larger more costly features (such as rainwater tanks and solar cells), and not immediately think of the range of low or no-extra-cost features (such as solar passive design and orientation, or water efficient tapware). Lastly the perception that sustainability adds cost may be related to the lack of experience and skill in incorporating sustainability elements, and the view that 'skilling up' to do things differently will be a time consuming and costly process.

Finally, it is also important to acknowledge that there is a perception predominant in mainstream industry that there is no *need* to change practice. This can be the result of individual lack of interest in sustainability, inertia or attachment to the status quo, or of people not feeling a sense of personal responsibility for change.

There are however, some sectors of industry that hold a more positive view about sustainability. In the ISF survey, almost half the industry respondents thought that sustainability was a way of 'adding value' for their clients, and over a third saw it as potentially adding value to their business. Others are beginning to see sustainability as a marketing tool, or a means of giving their business a 'market edge', particularly if they can target consumers who are both more aware of the issues and capable of making more sustainable choices (although there is a perception that these are likely to be the more educated and wealthier consumers rather than those in the 'mainstream', or project housing markets). Some also suggest that sustainability has the potential to improve efficiency and risk management in the industry, by promoting better integration and cooperation between currently fragmented players. Finally, there are industry members, although they are in a minority, who are highly committed to the principle of sustainable housing and are 'leading the way' by actively seeking information, exploring options, and developing and trialing new ways of working. The positive examples being set by these motivated individuals can be highly influential within the industry, as they have the potential to inspire others to start moving in a new direction. Building on these more positive perceptions may be a useful approach to the development of sustainable housing policy that seeks to get larger numbers of industry members 'on board'.

There may also be a need to focus on particular segments of the industry. It was notable that builders were viewed by other industry respondents as being less open to change and in some cases playing a 'change resistor' role. Builders tended to be viewed as quite resistant to addressing sustainability issues, particularly where doing so is optional – in other words, where it means taking action beyond compliance with building code requirements. As one interviewee said:

> *The builders, as a general rule, will only be compliant. They'll do the minimum they have to, and they'll fight tooth and nail against anything that's likely to add any more effort and more challenges for them, or more money to the job.*

Part of the reason for this may be that builders are already working to narrow margins, particularly in the first home buyer market. This means that any additional costs of sustainable elements may be seen as difficult to absorb.

It seems that many builders may see themselves as having a limited role in sustainability innovation because they are mainly implementers of other people's designs and requests, and 'change followers' (responding to new directions set by customers, architects and developers). However, there is some evidence to suggest that this is not the case, and that builders can actually exercise a high degree of influence over whether or not sustainable features are chosen (for example Brisbane City Council, 2005). This suggests that if builders were to change their standard offerings to include more sustainable options, consumers may well just accept the new and different inclusions. Product suppliers, subcontractors and sales people were also identified as change followers rather than leaders. It appears that there is substantial scope to work with these various industry groups to help them better understand the level of influence they have, and the potential role that they could play in the change process.

4. Implications of social research for sustainable housing policy

This section discusses the implications of the research findings discussed above for housing policy, and shows how the findings were translated into policy recommendations for the state of Queensland.

The research ISF conducted in this area is based on the firm belief that a 'technical solution' will never deliver sustainability on its own, rather there is a critical need to consider the social dimensions of the issue, and design policy in response. Social research is extremely valuable in identifying the key drivers and corresponding perceptions of the target audience for a given policy, and provides a knowledge base that can inform policy development. In the case of sustainable housing policy, strategies that are based on an appreciation of the target audience's existing drivers and perceptions, and that counter negative aspects and build on positive ones have the best chance of being supported and therefore effective.

4.1 Translating social research into policy

Figure 1 (right) shows the research and policy development process used in this project. The first step was a review of relevant local and international literature, from which research findings were collated and further questions were raised. These findings were tested specifically for Queensland through surveys conducted at the Brisbane Home Show, which collected mostly quantitative data from a statistically significant sample of consumers and industry practitioners. Survey questions were designed to test the previous findings, explore relationships between certain findings and examine some of the

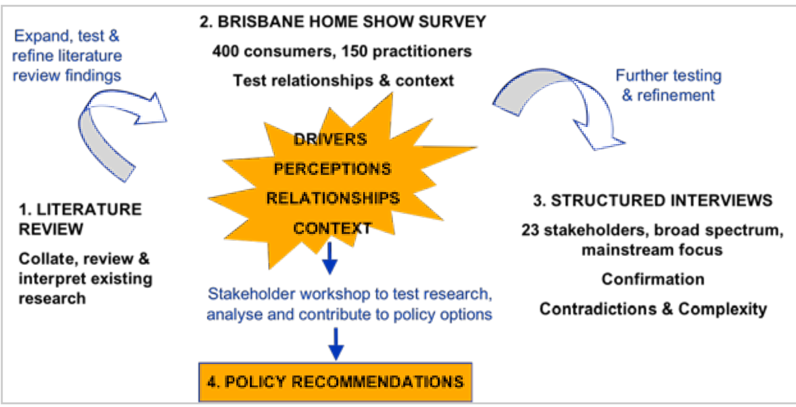

Figure 1 Process for social research and policy development

unanswered questions raised by the previous literature review, for example, "How do perceptions vary based on the specific aspect of sustainability being considered?" and "Is there indeed a gap between attitude and action?" The third and final stage in the social research involved structured interviews with a diverse and carefully selected sample of stakeholders to further test the findings and explore in more detail the complexity and contradictions raised in previous stages of the research.

Then, the drivers and perceptions identified in the research were mapped and translated into potential policy aims. A workshop with key stakeholders from government and the housing industry was held to discuss and further develop policy aims and potential instruments.

Figure 2 Translating drivers into policy (extract)

DRIVERS	PERCEPTIONS	POLICY AIMS	POTENTIAL POLICY INSTRUMENTS
Example drivers: Profit Market edge Cost Resale	Costs more upfront (consumer and industry perception) Limited consumer demand (industry perception)	Reduce upfront costs of sustainable housing	Low interest loan (specific items, or entire home/ renovation) Rebates for sustainable products Fast tracked approvals processes for sustainable developments Development bonuses/ concessions for sustainable developments
	Doesn't add value (consumer and industry perception)	Increase asset/ resale value of sustainable housing	Sustainability rating tool for homes Point of sale disclosure of sustainability performance Home valuation standards that incorporate sustainability
	Compromises market edge (industry perception) (Note: this is a particularly strong perception the in cost constrained project home market)	Improve industry practice in sustainability without compromising market edge (Note: project homes constitute approximately 80% of new housing in South East Queensland)	Voluntary partnership program with project home builders to review designs and supply chain

Figure 2 (above) is an extract of a larger table that shows how drivers and related perceptions were mapped and translated into potential policy aims and instruments. This extract uses money-related drivers (profit, market edge, cost and resale) as an example. For consumers, these money-related drivers primarily relate to capital costs and resale value, and are accompanied by perceptions that sustainable housing costs more upfront and doesn't add value to their property. For the housing industry, drivers relate to market edge and profit, and are accompanied by the perception that consumers aren't interested in sustainability and therefore any cost increase due to sustainability will diminish market edge and profit. This perception was particularly prevalent in the cost-constrained project home market, which attracts a significant proportion of first home buyers and constitutes around 80% of new home sales in the populous and rapidly developing South East Queensland region.

The policy aims were directly translated from drivers and perceptions. This alignment ensures that the policy aims leverage drivers and any positive perceptions, as well as addressing negative perceptions. The policy aims were then used to develop appropriate policy instruments, in collaboration with a number of key government and housing industry stakeholders.

5. Conclusion

Currently much of the research prior to policy implementation focuses on the technical and financial barriers, with little effort put into finding out what will motivate consumers and the industry to take the desired action. However, our research suggests that barriers and drivers are often as much structural or attitudinal as they are technical or financial, if not more so.

If policy is to be effective, there is a need to research and respond to the perceptions and attitudes of the range of intended recipients. Policy is more robust and effective if it aligns with the drivers for change while addressing the barriers. Social research is needed to identify the drivers that can be used to support policy development and implementation, and is a way of indirectly involving recipients (in this case, consumers and the housing industry) in the policy development process.

Furthermore, the intent and implications of policy measures, especially regulatory measures, must be communicated to both consumers and industry. That way technical and fiscal solutions chosen will be well received, which is essential to facilitate implementation and ensure acceptance and uptake.

Until issues related to consumer and industry attitudes and perceptions are addressed by the development of policy that is informed by in-depth social research, the implementation of sustainable housing policies is likely to be difficult, uptake may be lower than expected, and policy may even have undesired outcomes.

Summary

"Sustainable Design Laboratory" (SDL), is a unique research facility that was established by Sekisui House Ltd. in 2006 to propose a more environmentally friendly lifestyle through houses that coexist with nature instead of challenging it. SDL has built an experimental house that is suitable for an urban environment. It was designed with consideration for the environment by utilizing natural energy, and it incorporates ancient practices and modern technology at the same time.

There are two fundamental concepts of the SDL research; The first one is "Learn from the trees"; We want to create houses that depend on, and use, the sustainable energy of nature, as trees do. The second concept is "Learn from traditional Japanese houses"; Use natural energy to mitigate the effects of heat and cold as people did in earlier times. People can feel and enjoy the four seasons.

1. Concept & Planning

The building is located in Kunitachi City, in Tokyo Japan (Figure 1). Figure 2 is the floor plan and Figure 3 is an elevation view of the building. Table 1 shows an outline of the building. It is a heavy steel-frame structure with a 2story *engawa* (Japanese sunroom) of wooden construction attached on its south side, forming a doubleskin structure made of glass and *shoji (sliding doors made of a wood frame and Japanese paper)*.

The environmental concept of this building is the reduction of energy consumption and comfortable living through a hybrid-technology house (Fig. 4). In Japan, four distinct seasons bring hot, humid summers and cold, dry winters. In the summer, this building reduces the cooling load with well-controlled ventilation. In the winter it lowers the heating load by incorporating solar heat. The balance of utilizing nature and modern technology is thus called a hybrid-technology. The keys to achieving this balance are the "*engawa* space" and "ventilation skylights".

The Japanese house should be suited to the climate and environment of Japan. The concept guiding this design was a desire for it to be a home where people can feel the changing of all four seasons.

2. ELEMENTS

2.1 PENTHOUSE

The planning of the house included a simulation of a three-dimensional airflow (Figure 5). In Kunitachi, in the summer, south winds blow frequently during the daytime. The pressure distribution map provided a hint on where to locate the windows in the design.

Ventilation skylights equipped with a SWINDOW were installed in the penthouse. A simulation showed that the wind speed on the roof was high. It was designed to take advantage of the wake effect, which exhausts heat from inside the building. Square, octagonal and other shapes were studied (Fig. 6), with a hexagonal shape finally being selected.

Photos 2 and 3 show the SWINDOWs. The SWINDOWs on the windward side are closed so that negative pressure forms, on the leeward side, thus drawing out the wind; Opening the downstairs windows creates a natural upward airflow through the SWINDOWs.

Figure 7 shows how air is exhausted from the penthouse during the summer. The figure shows the wind speed inside the penthouse, the outside wind speed and the temperature difference between the first story and the penthouse. It shows that during the daytime the outside wind produces negative pressure just outside of the SWINDOW, which in turn causes the inside air to be exhausted. The ventilation is also facilitated by the temperature difference. It shows that during the night, only negative pressure causes ventilation because there is no temperature difference inside the building.

2.2 Double Skin

The *shoji* is the inner skin of a double skinned structure in this house. The space between the windows and the *shoji* is called “*engawa*” in Japanese. The *engawa* can be used to enlarge room space by opening the *shoji*. To give people in this space a feeling of being outdoors, it is completely enclosed by a glass ceiling and glass walls (Fig. 17).

Because the *engawa* faces south, shade must be provided to block the sunlight during the summer, but during the winter the *engawa* helps warm the inside air. Figure 9 shows the temperature in the second floor bedroom during the winter. For the first day, the temperature is shown for when the *shoji* was closed. For the second day, the air in the *engawa* warmed up and the *shoji* was opened at 10 o’clock. The warm air in the *engawa* is allowed to move into the bedrooms, keeping the temperature at 20ºC for five hours. This saves heating energy.

Photo 6 Blocking Sunlight (summer)

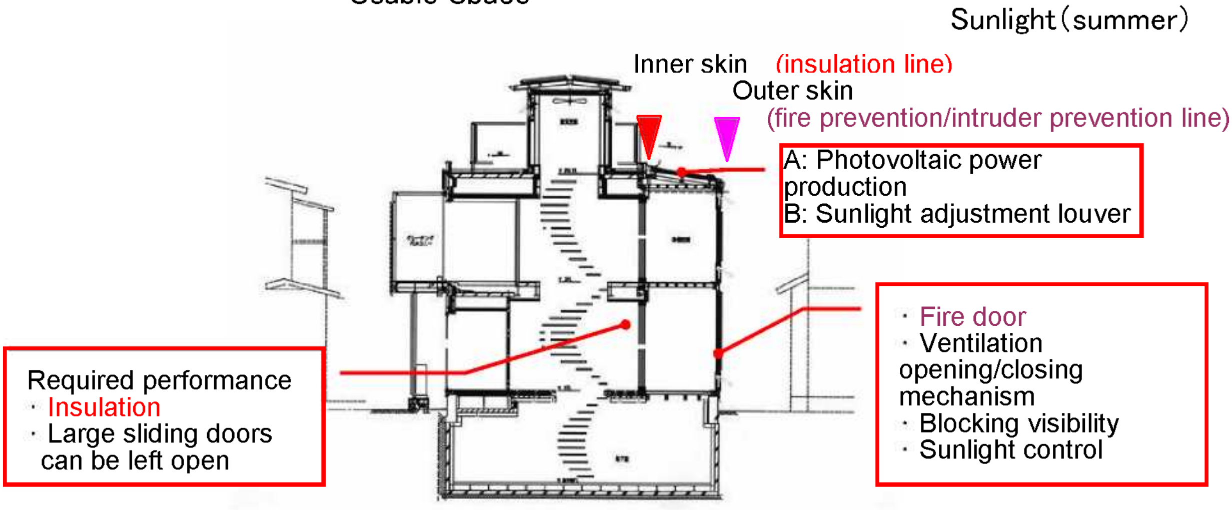

Fig 8 Schematic Diagram of Double Skin Mechanism

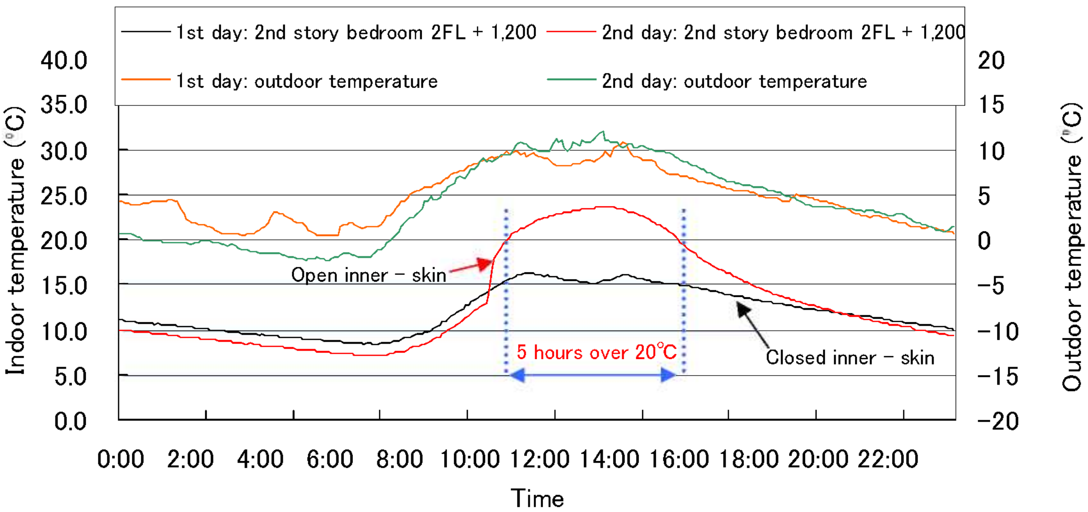

Fig 9 Intake of Warm Air During the Winter

2.3 Sunlight blocking screen

Photo 7 shows how this screen is both a thin membrane solar panel as well as a sunlight blocker. The skylight opens as shown in Photo 8. It opens from the top rather than the bottom, which is normal for a rainwater barrier. It is meant to exhaust heat without allowing hot wind to enter from the south side. It is designed so that warm air can be purged at night.

Photo 9 shows well water being sprayed on the top of the skylight to cool it down (5L/min). Figure 10 shows the temperature when water is sprayed on the skylight. Before spraying, its surface temperature was about 60ºC. Within one hour of spraying it, the surface temperature was down to about 40ºC. It lowers the surface temperature while the sound of the water makes the residents feel cool, allowing them to enjoy a pleasant daily life.

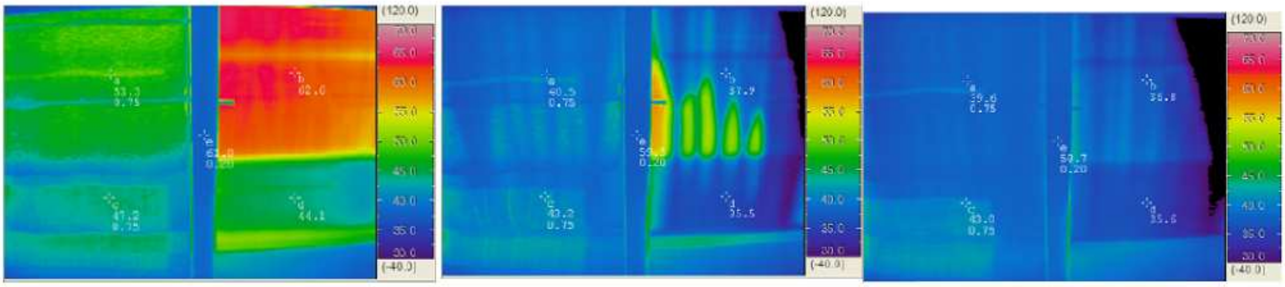
Photo 8 Heat Exhaust from the Skylight

Photo 9 Opening the Skylight



1. Before spraying 2. 30 minutes of spraying 3. 60 minutes of spraying

Fig–10 Spraying Time and Temperature

2.4 Control technologies

This house was not consciously designed as an IT home; The sensing technologies were added as a supplementary feature. They measure the inside/outside temperature, humidity, and ppm of CO_2 (Photos 10&11). They monitor the condition of the air and allow for both manual and automatic opening/closing of the windows as needed.

The airflow through the open windows was simulated in the design stage, verifying that when the upper windows are open, air is discharged. Even when it is hot and the air conditioner must be on so that people can fall asleep, after the outside air cools down late at night, the air conditioner shuts off and outside air is taken in. The operation of the windows can be set to several different modes, depending on the daily life patterns of residents. For example, a mode to provide comfort in the second-floor bedrooms at night is called "the night air mode". Figure 11 shows a PMV evaluation of the night air mode in the summer. This reveals that conditions are comfortable, even when dawn approaches and the air conditioning is off.

Photo 12 is a view of a bed pushed out into the *engawa* space during the day. This allows the bed to absorb the sunlight and dry out so that residents can sleep in warm beds in the winter. The beds are also equipped to accurately measure people's respiration and pulse.

2.5 Environmental performance evaluation, *CASBEE for homes* (detached single family) (Comprehensive Assessment System for Building Environmental Efficiency)

CASBEE is a tool developed by industry and government to be used to comprehensively evaluate the environmental performance of a building. This single-family home edition of CASBEE was completed in September 2007.
CASBEE for home is used to evaluate 54 points of the house and its environment. It provides an overall score, and the house is rated in one of five different levels based on that score (Table 2).
The results of using it to evaluate the Sustainable Design Laboratory are reported (Fig.12). This building achieved a 5.6-point score, and is ranked “S”, the highest rank.

Table 2 Five evaluations levels

Rank code	Evaluation	Rank
S	Excellent	★★★★★
A	Very good	★★★★
B+	Good	★★★
B-	Fainx	★★
C	Poor	★

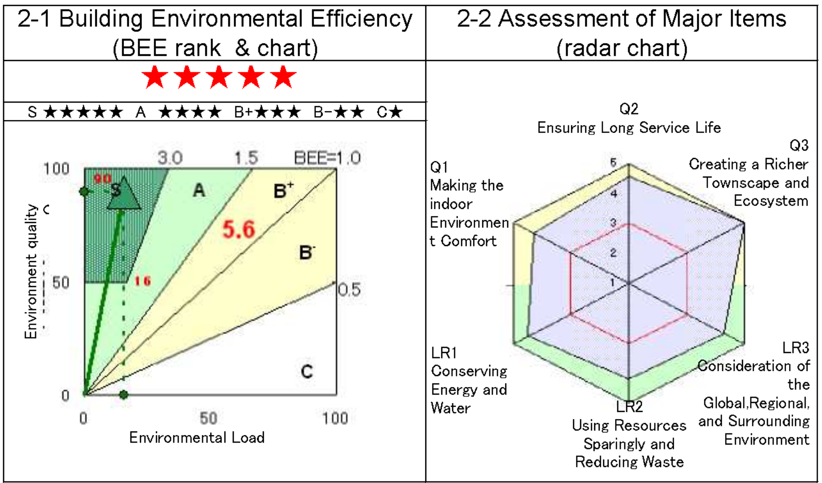

Fig 12 Evaluation Rank

3. Summing up

Guided by the ideas, “Learn from traditional Japanese houses” and “Learn from trees”, we have developed a house suited to modern lifestyles.

The following points have been discovered through experiments carried out on this project:
1. An increase in comfort of interior room environments is realized by the ventilation effect of a penthouse
2. The effectiveness of *engawa* (blocking sunlight, drawing in warm air, conserving energy)
3. Interior temperature is reduced by spraying water on skylights
4. The effectiveness of “opening mode”
5. Achievement of the highest rank of CASBEE.

The following points are considered to be future challenges:
1. Trial occupancy testing
2. Measurement of the effectiveness of night purges
3. Installation of cool tubes in basements
4. Evaluation of the contribution to comfort by extremely low-speed air movement

WHAT IS A "GREEN" BUILDING ACCORDING TO DIFFERENT ASSESSMENT TOOLS?

Marita Wallhagen, PhD student, Architect SAR/MSA[1]
Mauritz Glaumann, Professor, Architect SAR/MSA[1]
Ulla Westerberg, Ph D, Architect SAR/MSA[1]

Key words: green building, sustainable building, environmental assessment, environmental indicator, weighting, environmental management, building design, assessment tool

Summary

Environmental assessment tools for buildings are rapidly developing in many countries. All of them claim that they measure "greenness" or "sustainability" of buildings, i.e. if maximum scores are awarded a building is sustainable in some respect. But so far there is no consensus on the interpretation of "green" or "sustainable" in terms of criteria and indicators.

This article explores if different tools point in different directions regarding "green" building design. It also investigates characteristics of assessment tools and consequences of different approaches.

Three distinctly different assessment tools, LEED-NC, Code for Sustainable Homes (CSH) and EcoEffect have been selected. They have three core assessment areas in common, namely Energy, Indoor Environment and Materials & Waste. The content however is different.

The tools have been compared with respect to aim, content and aggregation. They have been tested on a new multi storey residential building. Assessments within the core areas were compared. Measures to improve the overall judgement were explored. The diverging result raises the question how to design environmentally relevant and practically useful assessment tools for buildings.

1. Introduction

Building environmental assessment tools, have emerged to provide an objective evaluation of resource use, ecological loadings and indoor environmental quality (Cole, 2005). Much work has been done to develop a tool that predicts, calculates and estimates one or more environmental performance characteristics of a building (Sundkvist et al, 2006). These tools present different ways to define criteria for "green" building" They bring together a large number of environmental issues and aggregate them into overall judgments. What issues the tools address and give priority to indirect or direct might influence environmental building policies, design and building practices. Assessment methodologies play multiple roles; understanding the impact of buildings on natural systems, marketing "green" buildings, addressing sustainability (Cole, 2005), help decision makers and politicians, and being tools for environmental management primarily in architectural projects. What picture the tools mediate to their users influences "green" building designs. This may contribute to setting the agenda in a similar way as trade magazines and mass media (Gluch and Stenberg, 2006).

Environmental assessment tools consist of a number of indicators and criteria. Some also include life-cycle assessment (LCA) methodology (Assefa et al, 2007). Important for the outcome of the assessment are choice of indicators, measurement scales, aggregation and classification criteria. However the basis for these choices, which always are a balance between theoretical and practical aspects, is seldom presented in tool descriptions (Malmqvist, Glaumann, 2006). A lack of theoretic and systematic approach and a mix of different kinds of indicators make tool comparisons difficult as well as understanding what a final award means in terms of environmental impact.

2. Objective and delimitation

The objective with this paper is to compare different methodologies for environmental assessment of buildings and to explore in which direction they push new "green" building designs.

3. Methodology

Three completely different environmental assessments tools have been select to illustrate fundamental differences. These tools have been compared with respect to a limited number of aspects, namely; *aim, content* and *aggregation.* At last they have been applied on a new multi storey residential building to illustrate the differences between the tools.

The tools chosen for comparison are LEED®-NC, Leadership in Energy and Environmental Design for New Construction version 2.2, (USBC, 2005), Code for Sustainable Homes (DCLG, 2007) and EcoEffect (Assefa et al, 2007). The tools differ, in a number of ways, for example regarding where they are developed, for home they are developed, the methodology they use and the way they are used. The two first tools are internationally well-known and well documented. Besides being different EcoEffect is chosen because it is the one that we have the greatest experience from.

4. Method comparison

4.1 Different Aims

LEED is developed by U.S. Green Building Council (USGBC) committees with the aim to promote "green" design. It is argued that "Green design not only makes a positive impact on public health and the environment, it also reduces operating costs, enhances building and organizational marketability, potentially increases occupant productivity, and helps create a sustainable community" (USGBC, 2005). USGBC (2005) claims that LEED is "consensus-based, market-driven, based on accepted energy and environmental principles, balancing between established practices and emerging concepts."

Code for Sustainable Homes (CSH) is the first tool in the process of becoming a code (DCLG, 2008). It is a further development of the BRE's EcoHomes© scheme. "Adoption of the Code is intended to encourage continuous improvement in sustainable home building." The driving force behind establishing a code for sustainable building seems to be the wish of the British Government to act on climate change in combination with the fact that BRE (Building Research Establishment), has extensive experience with voluntary schemes in this field.

EcoEffect is an assessment tool developed by a group of researchers in Sweden. The task was to develop an holistic environmental evaluation method not a national classification system: The formulated objective was twofold: "1) to quantitatively describe environmental and health impact from real estate and the built environment 2) to provide a basis for comparison and decision making that can lead to reduced environmental impact. The method primarily target decision makers within the planning, designing and management of the built environment". (Sundkvist et al, 2006; Glaumann, Malmqvist, 2004)

LEED is voluntary and very market oriented. CHS involves the authorities and intends to integrate environmental assessment into the building code. EcoEffect is neither commercial as LEED, nor institutionalised as CSH. Focus is on methodology and understanding the significance of different types of environmental impacts.

4.2 Different content

All the tools have the areas Energy, Materials and Indoor Environment in common, but the content still vary a lot. Besides assessing issues related to these core areas LEED gives credits related to the issues: Water, Design Innovation and Site. CSH also specifically assess Water, Waste, Management and Ecology. EcoEffect includes Site assessment and calculation of Life Cycle Costs. The tools also measures issues differently. To be able to compare them we have ranged similar criteria and indicators under common areas (Table 1.). Only the issues within the core areas are presented in this paper.

4.2.1 Energy

About ¼ of the assessments in all the tools are devoted to energy. LEED (Table 1.) assesses energy performance, green power and management. CSH assesses CO_2 emissions for energy use and specific energy saving technical solutions. EcoEffect takes only the detrimental side of energy use into account assessing its associated negative emissions and depletion of resources. EcoEffect then uses a linear scale without a defined endpoint, which cannot be easily transferred to scores. Another difference between the tools is that CSH also assess the energy performance of white goods.

Table 1. Addressed issues and available scores or scale within the three areas; Energy, Indoor Environment and Material & Waste.

AREA		ASSESSED ISSUE	ASSESSMENT METHOD		
			LEED	CSH	EcoEffect
ENERGY	Energy use	Minimum Energy Performance	Mandatory		
		Optimize Energy Performance/ Energy cost savings	10		
	Kind of energy	On-Site Renewable Energy	3		
		Green Electrical Power	1		
		Resource depletion			Calculated
	Emissions	Low or Zero Carbon Technologies		2	
		Dwelling emission rate (CO_2)		15 /Mand.	
		Life cycle emissions from energy use			Calculated
	Technical solutions	Internal lighting		2	
		Drying space		1	
		Energy labelled white goods		2	
		External lighting		2	
		Home Office		1	
		Building fabric (Heat Loss Parameter)		2	
		Cycle storage		2	
	Management	Commissioning of the Building Energy Systems	1/ Mand		
		Measurement and verification	1		
		Available scores for this area	**16**	**29**	-
		Fraction of totally available scores	**23%**	**25%**	-
INDOOR ENVIRONMENT	Air quality	Air quality in general			0-3
		Minimum IAQ Performance	Mandatory		
		Environmental Tobacco Smoke (ETS) Control	Mandatory		
		Outdoor Air Delivery Monitoring	1		
		Increased Ventilation	1		
		Low-Emitting Materials	4

		Rapidly Renewable Materials	1		
		Available scores in this area	**14**	**35**	-
		Fraction of totally available scores	**20%**	**34%**	-

4.2.2 Indoor Environment

LEED covers Air Quality, Thermal Comfort, Daylight and Management of Indoor Air Quality but surprisingly not Noise. CSH addresses Noise, Daylight and the three features; Privacy, “Lifetime homes” and “Home user guide” measured in terms of accessibility, adaptability and information. EcoEffect assesses; Air Quality, Thermal Comfort, Noise, Solar Access and Daylight, Radon Legionella and Electric and Magnetic fields. EcoEffect has an inverted scale, i.e. high scores here mean risk for inconvenience.

4.2.3 Material and waste

LEED is very much focused on reuse and recycling. Typically credits are given for reuse and recycling without taking into account that the reduction of environmental impact vary with material, (for example between recovery of aluminium and wood). Other LEED issues are; Household Waste, Local Materials and Rapidly Renewable Materials.

CSH is concentrated to environmental impact from production of building materials and responsible sourcing but do also cover household waste. Material is about 1/3 of all assessed issues in CSH, compared to 1/5 in LEED. Concerning material EcoEffect evaluate negative environmental impacts from the production phase of used building materials. Reuse and recycling is rewarded by decreased emission, from processing, and material depletion.

Hazardous Substances is not addressed in LEED. In CSH and EcoEffect primarily toxic emissions from the materials and their production are covered by the LCA of the materials. Thus none of the tools assess the issue embedded hazardous substances. Even though hazardous substances are one of the most prominent sub-themes of "environmental impact" according to the building sector in Sweden (e.g. Swedish Environmental Advisory Council, 2000; The Ecocycle Council, 2007). The Swedish focus on hazardous substances has also been observed in other studies (e.g. Stenberg and Räisänen, 2004).

4.3 Differences in weighting and aggregation

All environmental assessment tools weight and aggregate results differently. According to Lee et al. (2002) weighting is the heart of all assessment schemes since it will dominate the final valuation of an assessed building. However, according to Grace K.C. Ding, (2008) there is at present neither a consensus-based approach nor a satisfactory method to guide the assignment of weightings. There are a number of techniques to set weights in a systematic way (Andresen, 1999).

Within LEED 69 points are available within 58 assessed issues organized in six assessment categories. Some indicator are of a *procedural nature*, rewarding procedures and behaviour, like following a certain control plan, in contrast to *performance indicators*, which directly measure performance like amount of energy used for heating. Often there are optional ways to receive a point. Normally one point is available per issue except for two energy indicators, where more points can be gained (10 for "Optimization of Energy Performance" and 3 for "On Site Renewable Energy", Table 1). This means that the points have the same "environmental" value and are tradable, with the exception of a few mandatory aspects. The awarded points are added and the total score tells which of four final rewards the building get (certified, silver, gold, platinum). The basis for assigning a certain number of points to an issue is not described. This aggregation system is simple and easily understood, but the environmental meaning of the final score is hazy (Humbert, 2007).

In CHS 104 credits can be awarded within 9 categories (Table 1). A total of 34 issues are assessed and the value of each issue varies between 1-15 credits (per issue), some mandatory while most tradable. Most assessed issues gives at maximum 1-4 credits, except the issues Dwelling Emission Rate and Environmental Impact of Materials, which can give up to 15 credits (Table 1). Each category has a weighting factor, which emanates from a survey among international "experts" and a consultation with industry representatives. Energy has a category weight of 1,26 while Materials only have 0, 33, which in reality says that the environmental value of energy scores are almost four times larger than those for materials. The sum of the credits results in a character represented by 1-6 stars. Since the aggregation is done by varying the credits per issue and by weighting the categories the meaning of the result is difficult to perceive. Special for CSH is that it evaluates dwellings and not buildings. A rating of a building is composed of the ratings for its dwellings. The final rating is achieved when the building has been erected and used to make sure that the performance complies with the intentions and the points received at the design stage.

The final rating in EcoEffect consists of results regarding external impacts and internal impacts. External impacts include energy and materials use. The basis is a life-cycle approach and equivalents for seven impact categories are calculated mainly using internationally well-known calculation algorithms. The external impact is measured per designed number of building users and divided by the corresponding value per capita in the country, i.e. in the end showing a percentage. This favours efficient space use, which is important from an environmental point of view (Wilson and Boehland, 2005). For each impact category weights have been established by estimating the potential harm the endpoint problems within each category might cause people. (Assefa et al, 2007). The assessment is based on the total amount of energy and materials used per resident or user.

Internal impacts cover indoor and outdoor problems on the property. Targets are categorized in 5 categories and assessed through risk assessment at the design stage considering 54 issues. The final assessment is completed at earliest one year after building completion. It is then based on a couple of measurements in the building along with a user questionnaire. A scale with four steps (0-3) is applied, punishing poor measurement results and discomfort. Originally there was an expert weighting system in three levels which is now being exchanged to disability/discomfort scale developed as an extension of the DALY (Disability Adjusted Life Years) system (Malmqvist, Glaumann, 2006).

EcoEffect is quite comprehensive and the aggregated values, although systematically applied, may be difficult to understand for a layman.

5. Case study

To illustrate differences in practical use and assessment result the three tools have been tested on a new residential building under construction, Gronskar, Stockholm, i.e. complete drawings and descriptions are available but no real performance data. No environmental assessment tools were used during the design. The results in the areas; Energy, Indoor environment and Material & Waste are presented. The EcoEffect results, which not are received in points or credits, are shown in relation to a reference building, built in 1990 in the same region. LEED and CSH scores are presented in relation to the maximum possible score.

General information about the test building, GRONSKAR,
Gross area: 2893 m^2, 32 apartments, 8 storeys, Energy use for heating and hot water 80 kWh/m^2,yr. Energy supply: District heating and a heat pump on exhaust air.
Structure: Prefabricated concrete elements with an insulation of polystyrene.
Average U-value is 0,46 W/m^2,K, (window U-value is 1,3 W/m^2,K)

5.1 Energy use

With LEED Gronskar receive 9 of 16 points on energy (i.e. corresponding to 56%). 6 of 10 available points are gained for energy optimization. Primarily due to the heat pump on exhaust air since the envelope is not exceptionally well insulated. No points are gained for on site renewable energy which corresponds to ~20% of the available points. Measures needed to gain all the 10 available points correspond to about 150m^2 solar collectors for 50% of the hot water or lowering the average U-value by ~20%, i.e. from 0,46 to 0, 37 W/m^3K. The first option also gives maximal points for renewables. Since LEED uses *cost indicators* for energy the solar collectors don't give any credits since they are more expensive than district heating for hot water. The option left is to lower the U-value, which would influence the construction of the building.

In CSH 16 credits are given out of 29 for energy, (i.e. corresponding to 55%). The CO_2 emissions per year are compared with emissions from a reference dwelling which has the same size, fixed U-values and is heated by gas. Gronskar uses 80 kWh/m^2,yr. while the reference building uses 146 kWh/m^2,yr mainly because it lacks the heat pump. Gronskar emits about twenty times less CO_2 compared to the reference building because district heating fed by bio fuel emits very little CO_2.

The remaining 3 points Gronskar gained for energy saving fittings and "home office" which implies certain space and support of electricity and telecommunication. More energy points are available for improved envelope, labelled white goods, drying space, bicycle storage etc. The last two and "home office" can be called *potential indicators* since they award possibilities to reduce the environmental impact, which may not happen. Energy saving technical solutions are credited at the same time as low overall energy use, which might lead to *double counting*, i.e. crediting both energy saving measures and overall energy use. Normally Gronskar could also receive two additional points for the heat pump which is considered as a low carbon energy technology. But in this case the heat pump gives no CO_2, reduction according to our calculations, because the Swedish electricity mix emits much more CO_2 than the district heat. To improve the scores it would be better to exchange the heat pump with district heating and receiving more scores for low CO_2 emissions.

In EcoEffect, energy use is evaluated by measuring resource depletion and emissions influencing a number of effect categories. Although Gronskar uses 70% more electricity pr m^2 (the heat pump) than the reference building the overall energy use is 40% less than for the reference building which is also heated with district heating. The result is that the impact from emissions is only slightly larger for Gronskar. The largest impacts come from nutrification and radioactivity (nuclear waste from nuclear power). Contribution to nutrification origins to 70% from Swedish electricity mix and to 30% from the Stockholm district heating. Changing the heat pump here would only give a small reduction of environmental impact so the signal from EcoEffect is primarily to reduce the heat losses, i.e. improve insulation of the building envelop.

5.2 Indoor environment

Gronskar receives 12 out of 15 points (corresponding to 80%) in LEED, 6 credits out of 12 credits (corresponding to 71%) in CSH and is 30% better than reference values in EcoEffect, i.e. is good on indoor environment in all methods. The indoor indicators are different in all methods except from daylight, which still is calculated differently.

In LEED ventilation is the most dominant issue with 6 of the 15 points and two mandatory requirements: Air Quality in general and Minimum IAQ Performance. To receive a higher score Gronskar would have to meet the criteria for emissions from adhesives, sealants, paints and coatings. Low content of hazardous substances in building materials has been an important goal in the design, but emissions have not been measured. LEED is the only method, which uses indicators for management and control systems. Here Gronskar receives 4 out of 5 points because of the used management and control system. More documentation of specific measures and procedures would be needed to be able to gain the fifth point.

Air quality, ventilation and thermal comfort are not included in CSH. The tool uses a wider definition of sustainable building and includes social issues like “Private Space” and “Lifetime Home”. Lifetime Home contains a number of criteria, which all have to be met. Gronskar misses 4 lifetime home points because the buildings electric sockets are not placed at the right height. CSH also gives 3 credits for a “home user guide”, which is a specific document that is missing. Further more sound insulation is included in the assessment. To get the 4 available credits better sound insulation would be necessary.

EcoEffect addresses Air Quality, Ventilation, Thermal Comfort and Sound Environment. In EcoEffect Gronskar gets a rather high score in all these areas. The indoor environmental issues that are linked to comfort and health are included in the indoor environment area and Electric environment and Legionnaires disease are also included here. The scores for solar access and daylight are low because many dwellings face north. Directing balconies and some rooms in other directions would be needed to attain better scores.

5.3 Material and waste

Gronskar receives low scores in all the tools. In the category Material and Waste there was a wide variation in the type of indicators and criteria used. With LEED Gronskar received 4 out of 14 points (39%), with CSH it was estimated that it would receive 18 out of 35 credits (54%). The latest version of “Green Guide” and the Mat 1 and Mat 2 calculator tool, all necessary for the rating, were not available to other than approved CHS and BREEAM assessors.

With LEED the project doesn’t earn many credits because the lack of reused or recycled content. 7 points out of 14 can be gained in this category. There are also three mandatory criteria - Storage & Collection of Recyclables, Construction Activity Pollution Prevention and Fundamental Refrigerant Management. Using FSC, (Forest Stewardship Council) certified wood and local and rapidly renewable materials would also be needed to get the maximum scores.

The main targets in CSH are using materials with low environmental impact that are responsibly sourced.The low score with CSH primarily depends on the estimated high environmental impact from the used materials. The criteria for the indicator “Responsible Sourcing” was not met exactly as the method demanded EMS Certification and a third party control. Moreover the wood used was not FSC certified. For Household Waste Storage and Construction Waste Gronskar received high scores. The industrialized building processes applied minimize construction waste.

With EcoEffect the indicator for emissions from production of building materials was eight times higher than for the reference building and the indicator for resource use was twice as large as for the reference building. These high values are explained by the comparatively high use of concrete, steel and polystyrene, which demands a lot of energy for production and thus giving emissions. EcoEffect doesn’t assess means to recover household waste during operation as in LEED and CSH.

6. Concluding discussion

A “green” building according to LEED has a commissioned and cost optimized energy system and on site renewable energy. Low-emitting materials are used and management and control systems applied to secure a good indoor environment. Building materials are preferably reused, recycled and regional. Schemes for waste and pollution prevention are used.

CSH’s “green” building has low CO_2 emissions from energy use and specific technical solutions to reduce the households energy use. The walls and slabs are sound insulated and rooms daylit. The building is adopted for disabled and home office. Responsibly sourced building materials with low environmental impact are used and constructions and household waste is taken care of.

“Green” building according to EcoEffect has low energy use produced with low environmental impact. The indoor environment is designed to have good air quality, thermal comfort, daylight, sunlight and sound isolation and to prevent, electromagnetic fields, radon and legionnaires’ disease. Building materials with low environmental impact from production and transport are used and measures are taken for simplifying future recovery. The layout plan is designed for efficient use of space.

Further characteristics of the tools are summarised in Table 2. The differences in aim may influence the market penetration, Table 2. Official back up probably will become a strong incentive to use CHS for residential buildings, LEED is used by “green” forerunners and EcoEffect is mostly used for educational purposes. The dissemination is not a consequence of the content of the tools or their applicability but rather which forces push them into the market.

Table 2. Summary of significant characteristics of the tools

		LEED	CSH	EcoEffect
Aim	*Practical use*	Commercial tool	Policy tool	Analytical tool
	Environmental focus	Environmental sustainability	Climate change, (CO2)	Decreased emissions and depletion.
Content	*Energy*	Quantity and cost of energy use. Technical solutions	Quantity and quality of energy use. Technical solutions	Quantity and quality of energy use.
	Materials and waste	Quality and cost of materials use Recycling	Quality of materials used. Waste management	Quantity and quality of materials used
	Indoor environment	Air quality, Thermal comfort Daylight. Management	Noise, Daylight Management	Air quality, Noise, Daylight, Thermal comfort.,
Assessment & Aggregation	*Energy & materials*	Indicators, criteria	Indicators, criteria	Calculations
	Indoor environment	Indicators, criteria	Indicators, criteria	Indicators, criteria
	Within categories	Scores added	Scores added	Calculated equivalents for energy and materials, Indoor environment weighted
	Between categories	Scores added	Weighted	Weighted and added
	No of assessed issues	58	34	18
	No of final scores	1	1	2

The tools use different methods for measuring and different methodology for aggregating. For example regarding indoor environment both LEED and CSH awards good management for the building in operation while EcoEffect for this purpose relies on questionnaires. The basis for assigning scores for different issues and setting weights seems quite arbitrary in all three tools apart from the damage based weights in EcoEffect. The more issues involved in the weighting procedure the less influence is given to each indicator. A higher weight of one indicator means a lower of another. Finally, adding scores and weighting categories makes the meaning of the result difficult to understand. In this respect LEED, which is purely additive, is easier to understand.

The case study of Gronskar shows that the tools push the design of “green building” in different directions. CSH signals that the heat pump should be exchanged for district heating, since the tool concentrates on CO_2 emissions. Bicycle sheds and laundry lines and other technical solutions could be used to gain more scores for Energy in CSH. In LEED use of local and renewable energy sources are awarded, but since energy cost is decisive in this case solar collectors would probably mean too expensive scores. EcoEffect advocates better U-values and low emission fuels for heating, like the district heating in Stockholm. The huge quantity of concrete and expanded polystyrene insulation would have been avoided with EcoEffect and CSH. Applying LEED it would have been more important to use recycled concrete and insulation. Being a commercial tool may be the reason why LEED puts relatively more weight on the indoor environment and consequently might have produced a better indoor environment than CSH. EcoEffect would have influenced the architect to orientate the north facing balconies to a sunny direction. This exemplifies cultural and geographic differences between the places where the methods have been developed.

It is obvious that a technique encouraged by one tool is not always the best way to reduce environmental impacts according to another. A complete environmental assessment of a building ought to consider the whole life cycle, just like environmental assessments of products or services (Finnveden, 2000). The result of this comparison shows that the concept of “green building” is far from universal. The diverging result raises the question how to design environmentally relevant and practically useful assessment tools for buildings.

Summary

This research is to improve, Taiwan's high temperature and high humidity climate environment located at the subtropics area. This study proposes an appropriate opening design and implementation method for buildings in Taiwan, with the aim to improve such environment. The subject of this study was a three-floor atrium-style building, and 8 residential units were investigated. The two-sided openings were formed by shutters and glass, and could be categorized into 4 models. The research method was numerical simulation and field measurement. The numerical simulation divides into three criteria field ranges of three scales, in order to understand the wind flow situation surrounding the buildings. The simulation results and measurements were approximate. Also, the measuring results on temperatures and relative humidity inside the units showed that two-sided shutters are more effective to dissipate heat at night in summer than two-sided glass windows are. In winter, full-closed openings with small gaps could make the indoor temperature 2°C higher than the outdoor temperature, and the relative humidity could reduce by 10%. If there are furniture and heat source inside, the indoor temperature can be 1~2°C higher, and relative humidity can be 3~8% lower. Based on the results, this study proposed the window-opening ways are suitable for summer and winter, and discussed the wind guide effect after installing vertical deflector outside of the opening to improve the natural ventilation effect. In accordance with simulated results, after installing the vertical deflector, its average ACH can increase approximately 260% when the wind direction is parallel to the external windows. Also when the wind direction with the building stand the surface becomes 45°, and the angle of vertical wind deflectors (P=0° ~ 22.5°) is advantageous to the indoor airflow field evenly, however, with the vertical wind deflectors at 67.5°, there is a reduction in DR (draft rating).

1. Introduction

Many studies in the past pointed out that the indoor temperature and humidity significantly affects people's health and their working efficiency. The outer layers of a building, like the cells on the surfaces of foliages, have the functions of adjusting the air flows, temperature and humidity. The Opening Design of a building greatly impacts the indoor environment conditions in this high temperature and high humidity weather climate of Taiwan. Based on the premise of energy conservation, many studies investigating on the ways to improve the efficiency of natural ventilation are very popular in Taiwan. The objective of these studies is to maintain a healthy and comfortable indoor environment.

Based on the theory of ventilation, Cross ventilation has very good ventilation performance. Some studies (Chiang, 1999, Chiang et al, 2005) pointed out that one-sided opening space is very effective in ventilation by changing window opening patterns and by utilizing the thermal buoyancy principle. However, the use of natural ventilation is still not easy because factors such as the outside winds, building distribution and height in the practical environment. Therefore, in order to understand the effects of natural ventilation on indoor environment, we must understand the external environment conditions such as wind direction, wind speed, wind temperature, etc. However, data such as these are difficult to obtain. The majority of data are obtained from the weather station of the Central Weather Bureau located in the vicinity of the base building. But these data do not represent the actual wind situations around the base building.

In this study, a three-floor atrium-style building (Symbiosphere No.1) located at Fulong, a city in the northeast corner of Taiwan, was used as the research target. A long-term climate monitoring stations was set up at this base building. From data obtained from 1999 to 2001, it is shown that the general weather around the base is as follows: It is hot in summer and cold in winter, and it has distinct different temperatures for the four seasons. The highest temperature in summer is on the “Solar Term” called "DaShu- Great Heat ", the lowest temperature is on the “Solar Term” called “LiChun- Beginning Spring”. The temperature difference between these two is 17.3 °C. There are 25% of the 24 Solar Terms in a year with high temperature over 28 °C (from late June to early September). There are 37.5% of the 24 Solar Terms in a year with low temperature lower than 20 °C (from early December to early April next year). Since Taiwan is an island, its climate is generally humid. Fulong has high humidity (relative humidity is above 70%) all year long, especially in spring and winter. Its relative humidity is over 80% for 2/3 of a year (early October to early May next year). Mainly influenced by the monsoon wind, terrain and the sea-land wind, the local wind roughly is Northwest, North or Northeast in winter and mainly Southeast wind in summer as shown in Figure 1.

In summary, the main objective of this study is to propose the building opening designs to maintain a healthy and comfortable living environment according to the wind characteristics around the base.

2. Steps and Method

This study is divided into the following three stages:

2.1 Study of the wind environment around the base

Numerical simulations and field measurements of the wind environments around the base were used to explore the difficulties in using natural ventilation. In order to thoroughly understand the airflow changes around the base building, simulations of three field ranges of different scales were performed in the study, as shown in Table 1. These three are: simulation of wide range valley terrain (large range), simulation of field range around the base building (medium range), and simulation of air flows inside the building (small range).

Table 1 The descriptions of the numerical simulations of the three field ranges of different scales.

Field Range	Large Range	Medium Range	Small Range
Definition	The whole valley terrain in Fulong area	Terrains and buildings around the base building	The base building (Symbiophere No.1)
Model Picture			Photo			

2.2 Study of the temperature and humidity conditions in the resident units

The field measurement method was used to measure temperature and relative humidity in eight resident units in the base building. Based on daylight utilization and ventilation, four two-sided opening models were created by mixing the shutters and openable windows, as shown in Figure 2 and 3, in order to understand the indoor temperature and relative humidity conditions under the extreme weather (extreme cold or extreme hot).

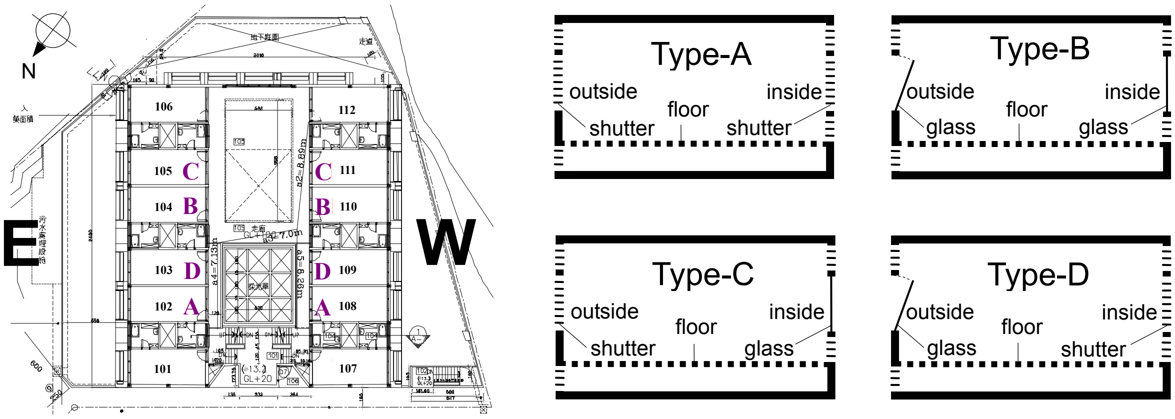

Figure 2 The positions of the eight resident units and the four two-sided opening *models in Symbiosphere No.1.*

(1) Outside shutter *(2) Outside transparent glass* *(3) Inside shutter* *(4) Inside foggy glass*

Figure 3 The types of shutters and glass at the openings.

2.3 The improved design of the opening model

The numerical simulation methods were used to further analyze the situation of the base and resident units to identify the solutions of increasing the efficiency of natural ventilation. The numerical simulation used in this study is the Reynolds-Averaged Navier-Stokes (RANS) simulation method. It analyzed the flow fields inside and outside of the building, and established basic assumptions for the computational domain, as shown in table 2.

Table 2 The basic assumptions for the numerical simulation in this study.

Basic Assumptions	
1. Steady State flow (wind speed, pressure)	5. Do not consider the roughness of the wall
2. Turbulence Flow	6. Use Wall Function
3. Do not consider the influence of Gravity	7. 3D Cartesian Coordinate
4. The speed field on the wall is assumed to be zero	8. Incompressible Flow

The turbulent transfer model selected is the widely used standard k-ε model. This model has good predictability for the mean velocity of the natural convection, and the required calculation time is also shorter (Chen, 1995). The average governing equation about the continuous, momentum and turbulence scale k and ε is shown in equation (1).

$$\underbrace{\frac{\partial(\rho\phi)}{\partial t}}_{transient}+\underbrace{\nabla\cdot\left(\rho\vec{V}\phi\right)}_{convection}=\underbrace{\nabla\cdot\left(\Gamma_{\phi}\nabla\phi\right)}_{diffusion}+\underbrace{S_{\phi}}_{source} \quad (1)$$

In equation (1), ϕ represents 1, u, v, w, k, ε, and source, S_{ϕ} has different descriptions for different equations. Convection and diffusion are the same in all motion equations. Γ_{ϕ} represents diffusion coefficient for quantity variables and the effective viscous coefficient for velocity variables.

In order to understand the ventilation effects, this study evaluates the ventilation rate (air changes per hour). The air changes per hour (ACH) is defined as the number of times a volume equivalent to the room volume are replaced per hour as shown in equation (2), where *Q* is the ventilation volume (m^3); *V* is the room volume (m^3), *T* is the ventilation time (hr).

$$ACH = \frac{Q}{V \times T} \qquad (2)$$

Since under natural ventilations, the ventilation rates are influenced by external environmental factors such as the outdoor wind speed and wind directions, therefore by merely looking at the magnitudes of the measurements provides no common basis for evaluation. Hence, in this study, the ACH was converted under different conditions to dimensionless air change increase rates and compared them. The calculation equation is shown in equation (3) where $Q_{normalize}$ is the air change increase rate (%); Q_e is for ACH with vertical deflectors; Q_c is ACH without vertical deflector.

$$Q_{normalize} = \frac{Q_e - Q_c}{Q_c} \qquad (3)$$

3. Results

3.1 Analysis of the simulation results of the wind environment around the base

Figure 4, 5 depict the numerical simulation results for the summer and winter wind fields of large range. From the flow structure it can be found that in summer, wind mostly comes from the Southeast, and in winter, it comes from the North as predicted. However, the simulation results also show very detailed changes in the flow field. The wind speed is significantly lower on the Eastern side of the building in summer (Figure 4), on the contrary, its wind speed is higher in winter. The wind speed on the North side is also high because of the air compression (Figure 5). The South side is the main static area both in summer and winter.

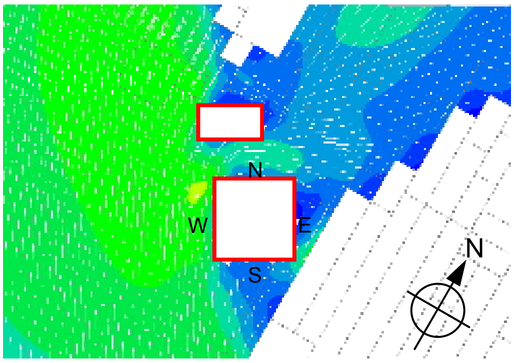

Figure 4 Simulation results for wind fields in summer (Large range model).

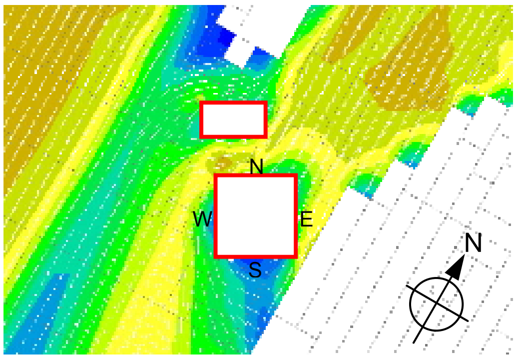

Figure 5 Simulation results for wind fields in winter (Large range model).

To exam the accuracy of the simulation results, the simulated values of wind speeds were compared with the field measurements of those. From the simulation results of the wind field around Symbiosphere No.1, five (A~E) places that have dramatic changes of wind speed, and some places surrounding the Symbiosphere No.1 were selected to measure wind speeds. Those places surrounding the Symbiosphere No.1 include five measurement points E1~E5, on the East side because the wind on that side is stronger affecting by the terrain, and three measuring points individually on the remaining three sides W, S, N.

The results of the comparisons on the A~E points are shown in Figure 6. On places A and B, there are larger differences where measured wind speeds are lower than the simulated values. But on the others (C, D, E), the simulation results and the field measurements are consistent. The results of the comparisons of the wind speeds on the places around the Symbiosphere No.1 are shown in Figure 7. The results from the large-scale simulation have larger differences than those from the medium-scale simulation, especially shown on the points (E1~E4) on the East side. The correlation coefficient between the medium-scale simulations and measurements can reach to 0.89. It demonstrates that the medium-scale simulation can more approach the real situations.

In addition, the accuracies of the simulation results are different on locations with different heights. The comparison of large-scale simulation results from the height of 5m and 13m show that the latter has higher correlation as shown in Figure 8.

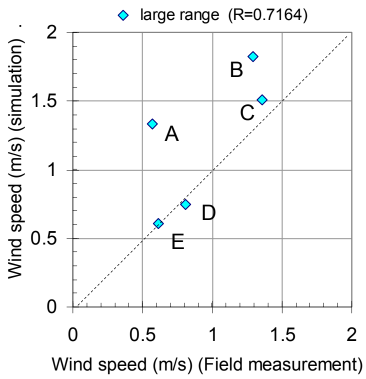

Figure 6
Comparison of the simulation results and the field measurements (A~E).

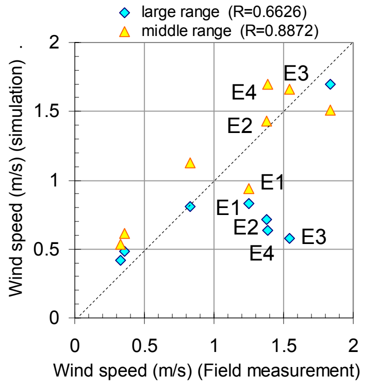

Figure 7
Comparison of the simulation results and the field measurements, large range vs. medium range (E1~E5,S,W,N).

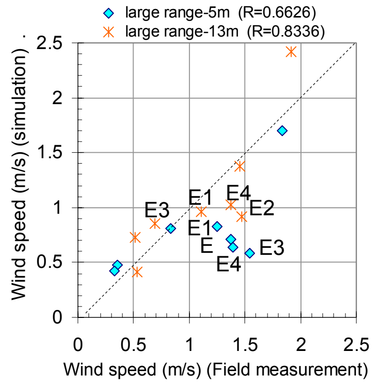

Figure 8
Comparison of the simulation results and the field measurements at different heights (E1~E5,S,W,N).

The medium-scale simulation can also model the very small air flow changes surrounding the base building. Figure 9 and 10 are the simulation results for the air flows in summer and winter respectively. It shows that in both summer and winter, the air flows are closely in parallel to the window surface. With respect to the ventilation needs for different seasons, we extremely need indoor natural ventilation to dissipate the heat for summer. However, Figure 9 shows that, in summer, there are some small air flows getting indoor in resident units on the West side and the air flows are not noticeable in the resident units on the East side. Hence the effects of heat dissipation are limited. In order to let air get indoor more effectively, installing the some deflector at opening is necessary to change wind direction. For the analysis of the impacts of installing vertical wind deflectors to natural ventilation using small-scale simulation, please see 3.3.

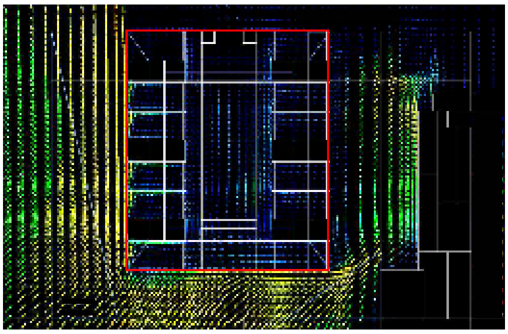

Figure 9 The simulation results for wind fields in summer using medium range.

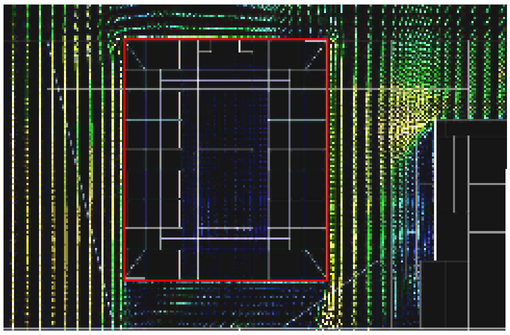

Figure 10 The simulation results for wind fields in winter using medium range.

3.2. Measurement results of the temperature and relative humidity in resident units

3.2.1 Measurements of the temperature and relative humidity in summer

The temperature and relative humidity were measured in summer at the Solar Term: Great Heat and in winter at the Solar Term: Beginning Spring - the extreme climates of these two seasons (extreme cold or extreme hot). Whether the windows are open or closed depends on the need of the season, it is open for summer, closed for winter.

In the area of temperature, due to the fact that sometimes the ventilation during the higher temperatures in the day time not only has no benefit to reduce the indoor temperature, but also cause a great deal of heat to get into the interior of a building, hence ventilation cooling is mainly performed at night time. Figure 11 is the changes of the indoor temperatures in the resident unit, Type-A, during Great Heat. It shows that when the outdoor temperature plunged at night, the indoor temperature of the Type-A will also droop sharply. The indoor temperature is only higher than the outdoor temperature by an average of 0.81 °C. However, the effects of other types of night time ventilation for heat dissipation are less significant. The temperatures of Type-B, Type-C, and Type-D are higher than the outdoor temperature by 0.87, 0.98, 1.08 °C respectively.

In the area of relative humidity, the relative humidity decreases because of the higher temperature for the day, so to prevent high humidity at night is our main goal. Figure 12 shows that the difference is larger between indoor and outdoor relative humidity for Type-A. The indoor relative humidity is lower than that of the outdoor by an average of 6.53%. The differences between indoor and outdoor humidity for Type-D also can reach an average of 5.53%. Type-B and Type-C are less effective in lowering the humidity than Type-A and Type-D. The differences between indoor and outdoor humidity for Type-B and Type-C are only 3.38% and 4.02% respectively.

The test results during Beginning Spring show that every opening model is somehow effective for thermal and humidity insulation, with the indoor temperature higher than that of the outdoor by about 2 to 3°C and the indoor relative humidity less than that of the outdoor by about 10%. Take Type-C for example, the impacts of the indoor furniture and heat source are shown in Figure 13 and 14. The indoor temperature for the unit with furniture and heat sources is higher for about 1 to 2°C. In other words, it is maintained at 17 to 18°C, about 4°C higher than the outdoor temperature (13 ~ 14°C). The relative humidity of the unit with furniture and heat sources is maintained at 65 ~ 70%, about 3 to 8% lower, or approximately 15% lower than that of the outdoor humidity of 80 ~ 85%.

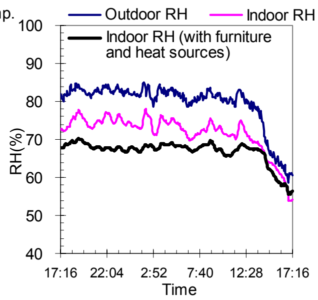

Figure 14
The RH changes in the resident unit, Type-C (Beginning Spring).

3.3 Simulation results for the improved opening model

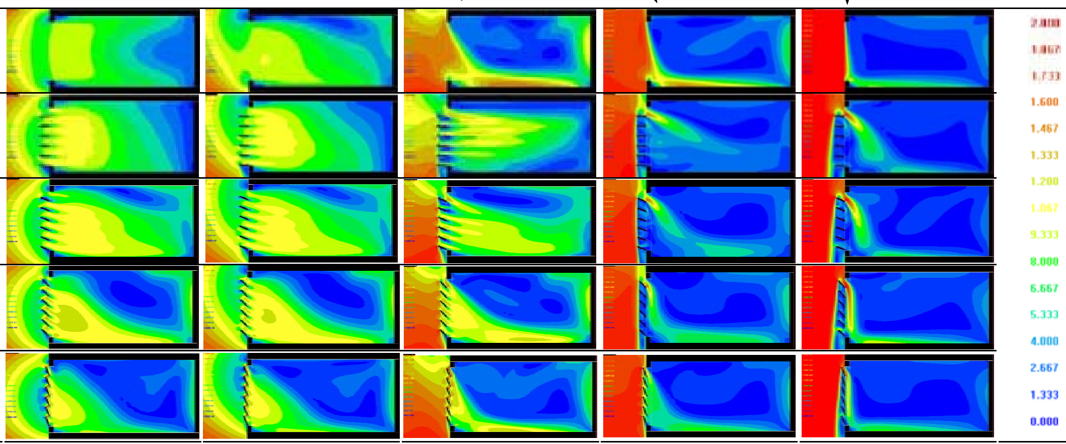
3.3.1 Numerical simulation results

From the small-scale simulation (as shown in Table 3), we can see that when the wind direction S is 45 ~ 90 degrees, the outside air entering the room would cause the higher speed air flow concentrate on the edge of the walls. This will make the wind speed lower in the middle of the room because the airs can not be distributed uniformly in the room. As a result, large areas of "Dead Zones" tend to develop in the room.

Table 3 also shows that if the angel P of the vertical wind deflectors is set to 0 or 22.5 degrees, air flow can spread more evenly to the living space through the wind deflectors to improve the problem of uneven distribution of flow velocity. The improvement is the most significant when the wind direction S is 45 degrees. The improvement is less effective when the angel P of the vertical wind deflectors is larger than 45 degrees. But at these angles, the wind deflectors have the ability to reduce the wind speed. Especially the wind speed was reduced significantly when the angle P of the vertical wind deflectors is 67.5 degrees, the indoor draft rating DR is thus lower.

Table 3 The comparison of the indoor air flows.

Opening Model		Wind Direction (S) 0°	22.5°	45°	67.5°	90°	Unit m/s
Without Vertical Deflector							
Angle of Vertical Deflector (P)	0°						
	22.5°						
	45°						
	67.5°						



3.3.2 The analysis of the Air Changes per Hour (ACH)

In addition, installing vertical wind deflectors improve indoor ventilation when the wind direction is parallel to the external windows. It can be seen from Table 4 that when the outdoor wind speed is 0.5 m/s, after installing the vertical wind deflectors of 0 degrees, ACH increased from 2.9 to 9.2. The greater the wind speed, the more increase in the ACH. When the wind speed is 2.0 m/s, the ACH increased from 10 to 38. The difference in ACH is not significant with different wind deflector angles, especially when the wind speeds are low.

Table 4 The comparison of the ACHs with and without the vertical wind deflectors.

V	0.5 m/s					1.0 m/s					1.5 m/s					2.0 m/s				
P(°)	Non	0	22.5	45	67.5	Non	0	22.5	45	67.5	Non	0	22.5	45	67.5	Non	0	22.5	45	67.5
S = 90° (ACH)	2.9	9.2	10	10	9.0	5.1	19	19	20	18	7.7	28	29	31	26	10	38	38	41	35

Annotation: V: Wind speed, P: Wind deflector angle, S: Wind direction, Non: Without vertical deflector, ACH (Unit:h^{-1})

Following the discussion above, the equation (3) was used to calculate the air change increase rate ($Q_{normalize}$) at various wind deflector angles under different wind speeds as shown in Figure 15. The ACHs of the rooms with installed different wind deflector angles has an average increase of about 260 percent than those without the deflector.

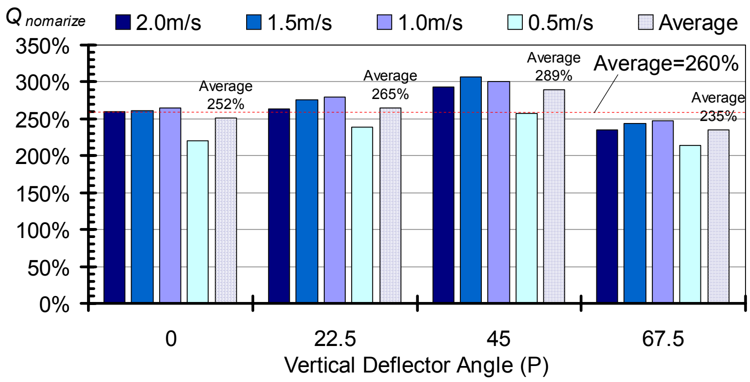


Figure 15 The air change increase rate for vertical wind deflectors with different angles (S = 90°).

4. Discussions

4.1 The necessity and the difficulties of the numerical simulation of different scales

Large-scale simulations help us understand the wind environment change in the area. However, since this model is rough so it affects the accuracy of the simulation. Like some objects including trees, bushes on the ground were not built in the model could cause the simulation values higher than the real values. Furthermore, as shown in Figure 8, that the errors are larger at heights closer to the ground maybe is impacted by the terrain because the complete landscape could not be modeled. These problem can solved either by setting more roughness on the ground in the model, but the values of the settings may vary for difference cases, or by narrowing the domain of simulation, and increasing the details in the model. In the second case of medium-scale simulations, the model gradually approaches the true situation and can show micro-environment wind changes in the base to achieve a more accurate simulation results. However, the impact could be significant if the transformations of the boundary conditions of simulations of different scales in the numerical simulation are not performed correctly.

4.2 Comparison of four opening models

4.2.1 Reductions of the temperature and humidity in summer

With respect to indoor cooling, Type-A has the advantages. The main reason is that inside and outside openings of Type-A are all shutters. Cross-ventilation can be formed to reduce the temperature rapidly. Especially when the temperature rises in the afternoon, a lot of ventilation makes people feel more comfortable. Other types of cooling effect are less significant because the open area is not large enough so the ventilation is not adequate.

With respect to indoor humidity reduction, Type-A can remove moisture by ventilation because of the larger open areas. The indoor relative humidity of Type-D is lower because its glass outside prevents external moisture from getting into the room. On the other hand, Type-B and Type-C are less effective than Type-A and Type-D for removing moisture because their ventilations are inadequate and they allow more external moistures to enter inside.

4.2.2 Maintain temperature and reduce humidity in winter

In winter, even the resident units with shutters on both sides are effective in maintaining temperature and reducing humidity mainly because the window frames are hermetically treated which block the majority of heat loss and moistures entering. The ventilation relies on the gaps on the floor alone. In addition, rooms with furniture and heat sources are more effective in maintaining temperature and reducing humidity. The heat sources (such as computers, people, lights, etc.) provide heat to raise the indoor temperature and lower relative humidity. Other factors of influence are the ability of the furniture to absorb moisture and the shutters to block the transfer of heats to outside. The proper and simple window-opening ways for summer and winter is suggested as shown in Table 5 based on the above analysis.

Table 5 Suggestions on the window-opening ways in summer and winter for Symbiosphere No.1.

Season	Time	East Side		West Side	
		Outside	Inside	Outside	Inside
Summer	Day	All Open or Half Open, All Open in the afternoon	All Open	All Open or Half Open, All Open in the afternoon	All Open
	Night	All Open	All Open	All Open	All Open
Winter	Day	All Closed	All Closed	All Closed	All Closed
	Night	All Closed	All Closed	All Closed	All Closed

4.3 Discussion on the angles of the vertical wind deflectors

We can see from the cross-section of the flow field shown in Table 3 that although the vertical wind deflectors can deflect the air indoor, but air flows accelerated when it passed through the shrunk openings and may cause greater wind draft to the staff indoors. Hence, the adjustable vertical wind deflectors are more suitable both for indoor ventilation and comfort. It can be adjusted according to the wind changes in the external environment.

Because feeling of the wind draft for humans is inversely proportional to the temperature, proportional to the wind speed, so improving ventilation should be more considered when the temperature is high or wind speed is low. The angle P of the vertical wind deflectors should be smaller in these situations. When the temperature is low or the wind speed is high, the impact of the wind draft needs to be more considered, so the angle P of the vertical wind deflectors should be larger.

Furthermore, when this study investigate the impacts of the vertical wind deflectors on natural ventilations, it sets limits on the five kinds of designated wind directions, four kinds of wind speeds (0 to 2 m/s) and four kinds of wind deflector angles (separated by 22.5 degrees). We will conduct more in-depth researches in the future with other conditions.

5. Conclusions

In this study, micro-environment wind field and indoor temperature of the real room are used to investigate which opening models benefit natural ventilation. By using numerical simulations of different scales, the monitored data obtained from the weather stations are converted to more detailed wind flow situations around the base buildings. Assisted by the investigation on the indoor temperature and humidity, the conclusion is that, the two-side shutters is more effective than the two-side glass windows in using night time ventilation to dissipate heat in summer. When they are all closed except some small gaps, the indoor temperature is higher than the outdoor temperature by about 2 °C, the relative humidity is reduced by 10%. With furniture and heat sources, indoor temperature can be further raised by 1 to 2 °C and relative humidity dropped by another 3 to 8%. This study also proposed the window-opening way suitable for summer and winter. When the wind direction is parallel to the external windows, the average ACH increases about 260% with the installation of vertical wind deflectors. When the wind direction with the building becomes 45 degrees, the wind deflector angel set between 0° to 22.5° (P = 0° to 22.5°) is advantageous to the indoor airflow field evenly. When wind deflector angle is 67.5° (P = 67.5°), it can reduce wind speed and help lower the draft rate DR. Therefore, respect to the Taiwan's subtropical climate, installing vertical wind deflectors with the appropriate angles at openings of the building has noticeable improvement in natural ventilation.

A CRITICAL EVALUATION OF THE GREEN MARK SCHEME FOR NON AIR-CONDITIONED BUILDINGS IN SINGAPORE

Uma Maheswaran, Ph.D[1]

[1] Department of Architecture, National University of Singapore, Singapore, akicrum@nus.edu.sg

Keywords: Green Mark scheme, Sustainability, Green Building, architect, Performance specifications

Summary

Green Building Design has been interlaced in to the larger agenda of sustainability and it has already been shown that working with the idea of Green Design is closely related to issues involving environmentalism, energy efficiency and economy. Buildings can no longer be seen as independent entities with architects as the master control, without adequately factoring the symbiotic contribution they have with the surrounding environment. Green Building Rating Systems such as LEED and BREEAM have been developed in the past and are constantly being reviewed and refined over the years in order to assess the performance of buildings. Studies show that the buildings that have achieved awards under these systems generally perform in a much more efficient way than others. In line with its European and American counterparts, the Building and Construction Authority of Singapore introduced Green Mark Assessment for air-conditioned buildings in 2005, in an attempt to draw the attention of the construction industry towards developing an awareness on develop pay more attention to its impact on the environment. Green Mark assessment scheme went through its first revision in the year 2006 and its modified version for residential buildings has also been released at the same time. This paper attempts to compare the newly developed Green Mark Scheme with respect to other major green building rating schemes with the aim of critically discussing the role of an architect in contributing to the design of a true green building as emphasized through these rating systems. It is necessary to approach the topic with an universal bias towards sustainability and energy efficiency in order to highlight the critical need from the profession to be aware of the potential directions of progress in to a future green society.

1. Background

Sustainable architecture is not a style to be blindly followed or replicated without meaningful interventions. It is a holistic design approach which takes into account all aspects of the building that will affect and be affected by the environment. It is the harmonious integration of technology and natural habitat, with minimum negative impact on the living environment. As the number of buildings bearing the tag of sustainability increases, it is essential for the building industry to understand how well or poorly they perform, in order to access the degree of implementation. This information would also allow cross communications between the regulators, architects, engineers, contractors, clients and end users, and benchmark progress in improving performance. Green building rating systems are thus developed as a way to evaluate the performance of buildings across a board range of environmental considerations against an explicit set of criteria. Rating systems such as Leadership in Energy and Environmental Design (LEED, http://www.usgbc.org/DisplayPage.aspx?CategoryID=19) in US, British Research Establishment Environmental Assessment Method (BREEAM, http://www.breeam.org/) in UK, though established only in the 1990s, have been responsible for the surging number of buildings that are more environmentally friendly. Throughout the world, countries have shown great interest in learning, adopting and developing their own set of rating systems, which would be unique to the local climate, environment and economic context. There are about 21 countries using various types of rating systems throughout the world currently. The increase in the awareness of the building rating systems towards reducing the negative impacts on the environment and the dependence on the finite availability of non-renewable resources, is thus gaining importance in influencing the building industry to play a major role in creating a sustainable city.

2. A prelude to existing green building rating systems

BREEAM, British Research Establishment Environmental Assessment Method, was developed by the British Research Establishment and introduced in 1990. It was the first building rating system to assess the environmental performance and impact of buildings with the longest track record. It is also responsible for the certification of many environmental buildings both locally and abroad. BREEM has a wide coverage of buildings such as offices, homes, industrial units, retail units and schools. BREEAM Offices 2005 generally focuses on the following categories of building design and life cycle performance including management, health and well-being, energy, transport, water, materials, land use, ecology and pollution.

U.S. Green Building Council (USGBC) was formed in 1993 and launched the first version of Leadership in Energy and Environment Design (LEED) after five years of intense research work on existing building matrix and rating systems. It is a voluntary, consensus-based, market driven building rating system based on existing proven technology. It evaluates the total performance of buildings from an overall environmental perspective over a building's life cycle. For each category, a number of pre-requisites and credits with specific design performance criteria exist. Design Projects and buildings need to fulfill the pre-requisites in the respective categories in order to qualify for assessment. Although pre-requisites do not award points, it is essential that they are met first, irrespective of whether other credits requirements are fulfilled, to enable the whole design process to be properly addressed.

Green Building Council of Australia (GBCA), formed in 2002, is a non-profit, national organization that has major support from both the government and industry players. Green Star environmental rating system (http://www.gbca.org.au/green-star/) was launched in 2003 with aims to reduce the environmental impact of buildings, improve occupant health and productivity and archive real cost-saving, while showcasing the innovation in sustainable practice. Green Star has tapped on the rich experiences of the other two and has been fast in developing different Green Star Rating Tools catering to specific types of buildings. And like USGBC and BRE, GBCA also offer courses for interested individuals and organizations to be a registered Green Star Accredited Professional upon passing.

The point distribution profile of BREEAM evidently shows that the percentage of the number of points available in BREEAM is relatively evenly distributed with the highest being the Management category at 16%. However, only for the categories of Land Use and Water, the percentages are much lower at 3% and 9.8% respectively.

3. Introduction to the Green Mark assessment scheme

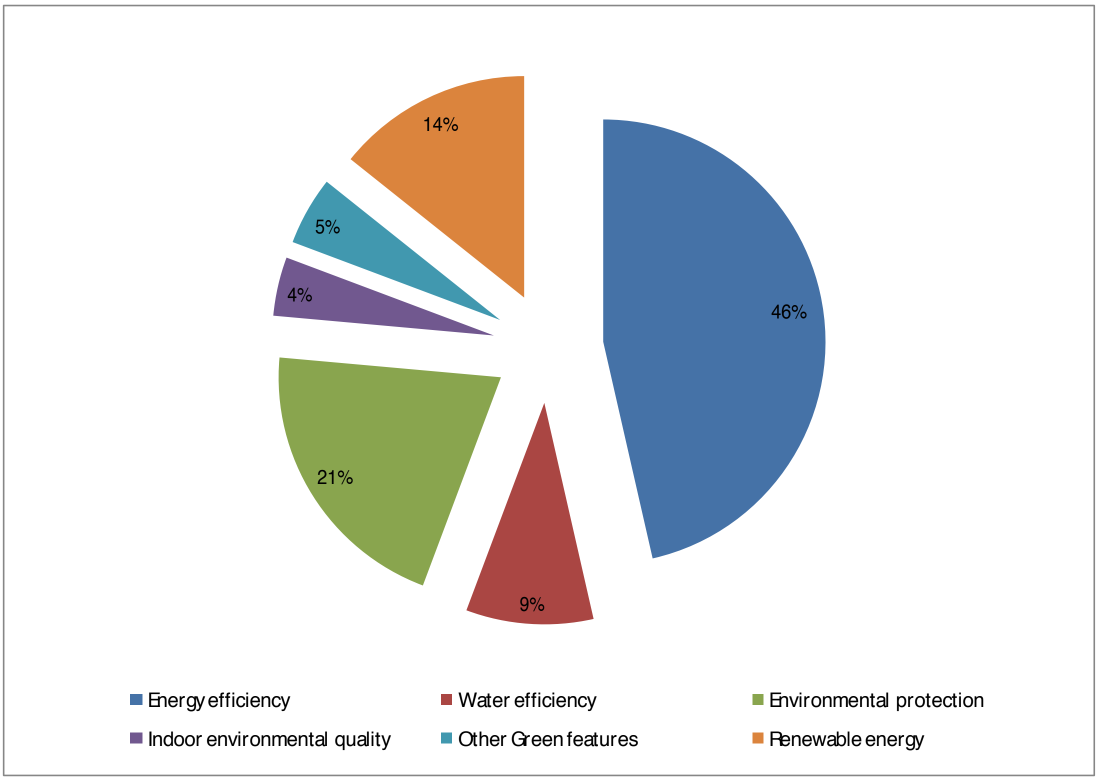

Figure 1 Schematic distribution of different green aspects of a design in the Green mark labeling scheme, Singapore

Green Mark Scheme (http://www.greenmark.sg/public/greenmark/en.html) was introduced in the lines of its western rating systems in the year 2005. The current version 3.0 has been just released in April 2008 and has developed leaps from where it originated. For typical residential as well as a non-residential building, there are five categories in Green Mark namely, Energy Efficiency, Water Efficiency, Environmental Protection, Indoor Environmental quality and Other green features. Figure 1 clearly identifies the structural decomposition of the Green mark evaluation criteria. 35% of the point allocation has been made to the aspect of "Energy efficiency". Green Mark encourages designers to take into account essential factors such as site ecology, local culture and infrastructure and integrate them with the building design. This would optimize the use of existing or/and natural features and minimize the negative impact on the environment. In terms of material selection, besides the conventional aspects like costs, performance and aesthetics, environmental friendliness and health issues are also being assessed in a Green Design. The revised version of Green mark has an additional set of criteria including conservation and restoration ideas, CONQUAS score that impinges on overall quality of the construction and public transport accessibility that would in turn encourage the public to use bus and MRT services compared to the use of private cars. With such comprehensive considerations, the particular site can be potentially deployed in a more environmental responsible manner while promoting sustainable utilization of resources.

In terms of energy efficiency, optimization of the performance of each of the building's components and systems both individually and in interaction with other energy consuming systems has been the prime objective. Such design integration, together with energy efficient technologies, can provide significant returns for building owners. Efficient facade design and the use of energy efficient features are the two key scoring elements in the revised Green Mark assessment criteria. Energy efficiency also includes the use of renewable resource technology that helps to reduce the reliance on non-renewable energy, and the pollution involved in consumption. Use of gardens and landscaping in building designs helps to reduce the cooling load and the urban heat island effect and this aspect has been insisted through the addition of "Green Plot ratio" in the revised version. Besides the control of quality of water, the level of consumption also needs to be monitored as it contributes significantly to a building operation cost. Suitable choices of water efficient equipments, fittings and fixtures can help to minimize water wastage. Proper storage and use of recycled water for non-potable usage could be encouraged to further reduce the consumption of water in a building. Innovative rainwater harvesting systems could also be integrated into the building design to provide additional source of water.

Green Design not only aims to reduce the amount of resources consumed by buildings and the negative impact generated, it also pays attention to improving the total quality of the indoor environment. Components in indoor environment quality consist of thermal comfort, acceptable air quality, visual comfort and appropriate acoustical level. Increase the overall quality of indoor environment would improve the quality of the workspace and boost the productivity of the occupants. Green Mark encourages the incorporation of innovative design strategies, technologies and construction methods for building projects. Such innovations which exceed the current benchmark set by the authority could bring about significant impact on improving the performance of buildings and promote the concept of sustainability. In order to aid the process of familiarizing the industry to the concept of green building design, a guide to supplement the assessment criteria of the building has also been developed.

4. Architect's contribution in aiding green building Design – A Green Mark perspective

Although the contribution of a particular profession in designing, developing and constructing a green building is debatable from a conceptual perspective, it is equally important to understand that architects play the first cut, key role in developing a green society. Hence, it is necessary to motivate the professionals to take up their role in achieving a truly efficient and green building design. A number of prescriptive requirements under Green Mark scheme currently have very high involvement from the architect's side. The following are the key components under which architects can play a vital role in obtaining a Green Mark certification for a residential building

4.1 Energy efficiency category under Green mark scheme

1. RB 1-1: Residential Envelope Transmittance Value (RETV) calculations

   Calculation and Optimization of Residential Envelope Transmittance Value (RETV)

   a. RETV depends on five parameters:
      i. Building Geometry and facade orientation
      ii. Window to wall ratio
      iii. Material of the wall
      iv. Glass type and thermal properties
      v. External Shading provided on the facade

   b. The value of RETV is evidently dependent on an architect's decision as an engineer has very little control over these listed parameters. However, in Singapore's current practice, these technical numbers are computed and optimized through engineers and this process is often resulting in either thickening of walls (to decrease U-value of the wall, by increasing the resistance offered by the thermal mass) or by darkening the glass (to reduce the Shading coefficient of glass).

   c. The computation and optimization of RETV values could result in up to **15 points** in both residential and non-residential buildings.

2. RB 1-2: Dwelling Unit Indoor comfort:

   This clause controls the selection of air conditioning system and gives a choice to an architect to opt for natural ventilation. The points awarded for a naturally ventilated building against an air conditioned building depends on the following three aspects:

   a. Building layout design: this is primarily decided by the architect and the decision of orienting the building right as well as providing fenestrations in the right facade orientations would give a building up to 6 maximum points.

   b. Achieving true cross ventilation is the second aspect that could provide the building with another 6 points. Cross ventilation in the building depends on the orientation of the openings to the prevailing wind direction, prevailing wind speed, depth of the floor plate and the size and position of the inlet and outlets for the air flow.

c. These factors clearly are either completely external or contingent upon the decision made by architects. Hence, an architect could be considered as solely responsible for these 6 points.

d. The third requirement on calculating and optimizing ventilation potential is currently handled by consultants in the field, although the inputs are primarily from an architect.

e. On a whole, it could be assumed that an architect actively contributes to about **12 points** of the total 16 points under this clause.

3. RB 1-3: Natural Ventilation in Common Areas:

   Provision of natural ventilation in common areas of a buildings is another decision made jointly often by the architects in terms of their spatial requirements in consultation with the client's requirements. The attempt to make such a naturally ventilated space also lies in the hands of an architect. Considering the architect plays a significant role in deciding the type of space (Air-conditioned vs. Naturally ventilated), the points resulting from the same (RB1-3) are to be shared equally between the clients and the architects (i.e. **1 point each**).

4. RB 1- 4: Lighting

   Computation and optimization of artificial lighting is usually not attempted by architects. However, optimization of artificial lighting through implementation of day lighting has a significant architect's role. In Singapore's condition, where the direct sunlight is not desirable and only diffused lighting is to be harvested, it is only feasible to achieve a 3 m deep penetration through the spaces and this in turn has a definite impact when we decide on the floor plate size and depth. In addition, perimeter glare is another pertinent problem in Singapore and hence, the treatment of the facade to curtail perimeter glare and to redirect natural lighting to deeper interiors could be a possible strategy that would save on the artificial lighting demand required. In all cases, an architect plays an equal role as that of an electrical engineer to optimize lighting budget and hence could be considered vital for gaining up to **6 points** under this clause.

5. RB 1-5: Ventilation in Car parking
   Car parks designed with natural ventilation is again a joint decision process between four different parties namely the client, the architect, M&E engineer and fire consultant. Apart at times, safety consultants also play a vital role in deciding the same when there are possible threats to lives (terrorism, etc.). Hence, the maximum point of 8 is to be apportioned amidst 4 key consultants including the client. An architect is able to contribute through this design (12 m from an opening maximum is the required regulation for naturally ventilating the car park, if the car park is in the basement) to a maximum of **2 points**.

6. RB 1-6: Lifts

   The architect has no control over the mechanical specifications and selection of a lift. Hence, he plays a negligible role in deciding the energy saving parameters of the lift.

7. RB 1-7: Energy efficient features

   Feature based points was considered as an ineffective means of rating a scheme. However, In the current version of the Green mark, energy efficiency features have been further classified in to high impact items and low impact items. Some of these features are designed and incorporated by an architect. For instance, implementation of light redirecting devices, wind directional devices, new technology test bedding (cool paints, phase change materials, etc.) are driven by the designers. However, domain experts handle the design and incorporation with due collaboration from designers. Hence, the architects could have a 10 – 20% role in effectively implementing these systems in place. The apportionment of points is also based on the same figures above and hence, of the total 7 points under this clause, an architect can be considered vital in scoring a maximum of **2 points**.

8. RB 1-8: Renewable energy

   Solar energy is the prime source of renewable energy in Singapore. Singapore's island wide average wind speed is around 3 m/s (www.nea.gov.sg) and hence, harvesting wind at low heights is almost impossible. Hence, mostly Solar cells and BIPV systems are the commonly considered renewable strategies. Although these strategies are commonly considered, there is reluctance because of the prices from the client's side. The client plays a vital role in deciding the use of solar energy and an architect supports its implementation in to the design. Thus, an architect's intention of incorporating the system in to his design brings a contribution from his side. This could be considered as contributing to about 25% of the total bonus points which is **5 points.**

Thus, under the domain of energy efficiency, an architect plays a confident contribution in scoring the maximum allowed score of **38 points** and a bonus of about **5 points**, giving the signal towards the basic green mark certification to the building.

4.2 Water Efficiency

The role of an architect under this topic only comes under the clause RB 2-3 where the concept of rain water harvesting systems come in to picture. Rain water harvesting has been very little practiced in Singapore as the country had no real demands of conserving water until recent days. Today, Singapore consumes about 300 million gallons of water per day, which is equivalent to about 500 Olympic-sized swimming pools of water. By 2011, we will consume about one-third more. To meet this growing demand for water, PUB will expand our water catchment and continue to develop other water sources such as NEWater and desalinated water (http://www.pub.gov.sg/Marina/about.htm). This awareness to conserve water is only in the recent times and attempts are only happening at the macro level. Hence, bringing in to rainwater harvesting in to the individual building design is considered a good starting strategy for designers to adopt. This **carries 2 points** when the architects make provisions for an effective rainwater harvesting system and utilize the water for irrigation purposes.

4.3 Environmental protection

1. **RB 3-1 Sustainable Construction**

   Efficient regulation of concrete as a key building material with the use of Concrete Usage Index (CUI, which is defined as the volume of concrete used per unit area) is a key factor that would require an architect's participation. The designer needs to decide on the material composition in order to realize their design intention. Concrete has conventionally provided an architect a dream platform to realize unimaginable spans, unsupported lengths and structural integrity. Restricting the use of concrete truly requires an architect understands and support and this parameter would very much determine the resulting design solution. The computation and optimization of CUI provides 4 points and this is jointly contributed both by a structural designer and an architect. Hence, there is an equal share to an architect resulting in **2 points.**

2. RB 3-2: Greenery

   Greenery Provision (GnP) is calculated by considering the 3D volume of spaces covered by the plants. The provision of greenery in a building is decided by an architect to match his design intentions and is jointly executed by architects in conjunction with landscape specialists. Hence, of the maximum allowed 6 points, an architect's spatial provision carries a 30% weightage to be further designed, developed and detailed by landscape specialists who hold 70% of the total score. Hence, in terms of an architect's contribution**, 2 points** could be claimed.

The other categories of the Green mark scheme do have contributions from an architect, however, not extensively. Provision of bicycle parking lots (1 point), Appropriate location of refuse areas to reduce airborne contamination (1 point), Provision of natural ventilation in wet areas (1 point), reduction of noise levels (0.5 point), provisions for other green features (3 points) have roles played by an architect. However, there are specialist consultants involved in the same and hence the role of an architect is diluted a lot.

5. Key findings

The exploration of a single rating scheme at this micro-level is extremely necessary with the global concern on sustainable built environment from the following scenario:

The building industry is headed and lead by the creative group of professionals, the architects and in most cases, the design related decisions are taken and executed in line with the architect's thoughts. Hence, in order to drive the industry towards a green building practice, the concept of going green is to be assimilated in the minds of these designers. If the understanding of how they could participate does not strike their minds, it would be difficult for them to play their parts in creating a green built environment. There is also a definite misconception amidst industry players that green building design is a lot of additional work and it involves expert simulations and computer programs. The presented rating tools are simplifying the requirements as start-up incentives and hence it is necessary for the industry to understand and appreciate the same.

The study exploration on analyzing green mark scheme clearly reveals that approximately 50% of the total green mark score is dependent upon an architect's decision and this clearly elucidates the importance of the role of this team player in building a green society.

Keywords: sustainable, constructed environment, building.

Summary

In this work, the historical dialectic method is used to analyze the creative process in the constructed environment. The paper relates that creative process with the historical moment starting from the period of the beginning of century XX. This period is marked by the rational thought, where the man believes in the man believes in its capacity to control whole the causes. The researches and great progresses of engineering allow that the technology culture can be used in the creative process of the constructed environment in the levels of materials, buildings and cities. The perception of the consequences of this model of development promotes the discussion of the technological paradigm. In the contemporary reality the conscientious thought indicates our incapacity to control the consequences of the development of the current model. We have the uncertainty of the future and we search for a model of sustainable development. In some countries, the influence for the new cultural context and new paradigm of sustainable development does that the actual creative process of the environment constructed be object of experimentations for sustainability. The article believes that is necessary to make a synthesis in the sustainable construction theories. One way for it is to consider a theory of selection of five points in some levels of the constructed environment. The five points would be: correct conception; correct consumption of energy; correct water consumption; correct constituent and correct end. The levels of the constructed environment would be related to the correct constituent: cities are constituted by buildings; buildings are constituted by construction materials; and materials of construction are constituted by substances cousins. The theory of selection of five points believes in a virtuous chain in process for sustainable construction.

1. The historical dialectic.

The theory of the historical change (MARX) considers that each moment of progress is the synthesis of two preceding and conflicting trends. This theory of historical change is based on a method of thought developed for Hegel that is named dialectic method. The principles of this method are the thesis and the antithesis. The thesis is an affirmation or a situation initially given. The antithesis is an opposition to the thesis. The synthesis appears like a consequence of the conflict between thesis and antithesis. The synthesis is a new situation that have inside of itself resultant elements of this shock. Then, the synthesis becomes a new thesis that contrasts with a new antithesis generating a new synthesis, in a continuous process.

The historical moment of the search for the sustainable development can be interpreted under the optics of the historical dialectic. The current model of development of our civilization, characterized by the consumerism, increasing consumption of energy and natural resources and increase of the generation of residues, clearly presents a conflict with the antithesis of the ambient reality of climatic changes and exhaustion of the energy and natural resources. Of the conflict of these two situations, it is necessary to search a synthesis that would contain elements of the thesis and antithesis.

Our current model of development is an affirmative thesis that is denied for the antithesis of the exhaustion of the natural resources and climatic changes. The negation (ambient situation) of the affirmation (consumerism) implies in stopping the consumption of resources and energy, and the emission pollutant. The transformation of the negation in a affirmation is inadequate for solution of the problem. Our society cannot simply to stop of consuming. Moreover, the consequenc of the current model can have it become irreversible, fact that science calls of “point of in return”.

New actions are necessary, a dialectic change, where through the negation of the negation, let us reach a new situation, that it suppresses and it contains, at the same time, elements of the thesis and antithesis. The negation of the thesis and antithesis, or doble negation, becomes a superior positive proposal, a new thesis. Thesis that is not simply the addition of the characteristics of the consumerism and the ambient situation, but a new model of development, that changes the current paradigm.

The dialectic also considers that a situation is as part of another one. To understand synthesis of the conflict, the whole X+Y, it is necessary to understand subject X that it is part of subject Y, and subject Y. Therefore, the search for the agreement of the new model of sustainable development passes for the understanding of the model of current consumption and our ambient situation.

2. Actual historical moment - Thesis and antithesis

Our historical moment can be analyzed from the period of the beginning of century XX. This period is marked by the rational thought, where the man believes in its capacity to control whole the causes. This thought can be understood as a result of the industrial revolution of the half of century XIX. This introduces the machine and a technological certainty. The culture of the technology is used in the creative process of the constructed environment, with experimentations and research and great advance of engineering, in the levels of the materials, buildings and cities. New techniques, like reinforced concrete, and concepts, like functional archictecture, international style and cities gardens, appear. These techniques fed the technological culture. The technological certainty paradigm began to be questioned when the consequences of this model of development was noticed. In the contemporary reality we have a conscientious thought, in which the man perceives its incapacity to control the consequences of the development of the current model. We have the uncertainty of the future and we search of a model of sustainable development.

In this context, the term sustainable dominate great part of the speech of the most different subjects of the society. Many times the term is used to reinforce the old philosophical desire of a more human society. However, the sustainable must be understood as the welfare with the social, economic and ambient balance. The human vision of the society also worries about the welfare state and ambient. However, a differentiation is necessary for the constant relevance that sustainable has been reaching in this historical moment. Inside of this historical revision, our interest is to stand out the importance of the constructed environment in the process, that is, the sustainable construction.

In some countries, the actual creative process of the environment constructed, influenced for the new cultural context and new paradigm of sustainable development, presents, experimentations and researches for sustentability in the constructed environment. The development of the civil construction level is a indicator of economic development and social growth, and it varies of country for country. The sustainable in the constructed environment is also. Infrastructure, building, pavement, water and energy supply are products of the construction industry that reflect the degree of economic development of each country. A traditional process of construction worry about costs, quality and time. In the new paradigm of century XXI, the construction must consider the natural resources, the biodiversity and the pollutant emissions. This occurs because the construction generates a great ambient impact as consequence of the consume of tons of natural resources. It also pollutes the environment directly, when it generates residues due the mistakes and wastefulnesses, and indirectly, when it consumes products whose manufacture pollutes the environment. The contribution of the construction sector for the ambient impact still can be bigger if it is considered that during its useful life the construction consumes energy and water to remain itself, and that, after the use, it generate dump. The ambient impacts of the civil construction are for long stated period.

According to Kibert (Agenda 21, 2000) the sustainable construction would given for the creation and responsible administration of an environment of healthful construction, based on ecological principles and efficient resources. However, to reach the sustainable construction, is also necessary to approach social-cultural and economic dimensions (figure 1).

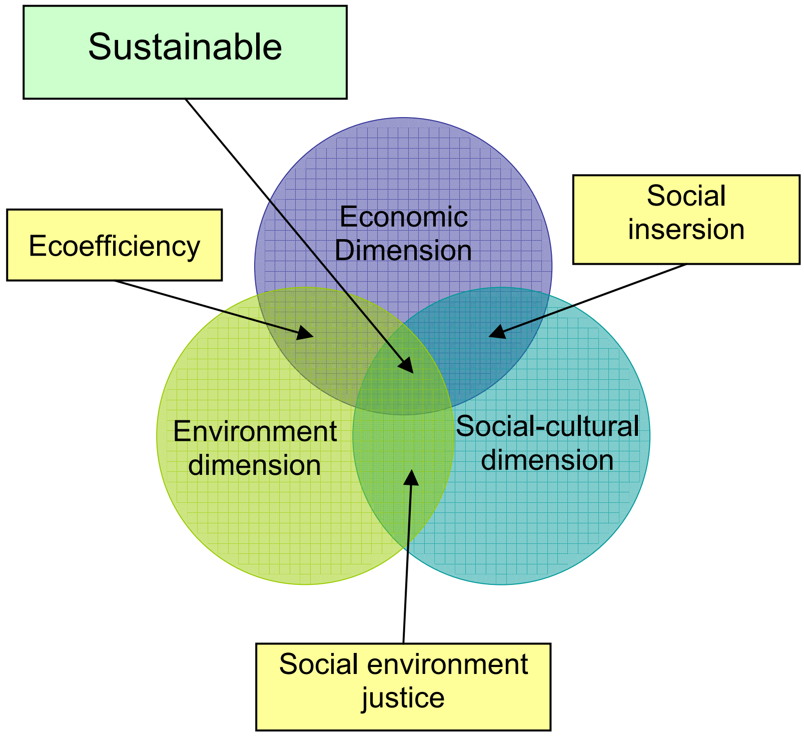

Figure 1 – Sustainable dimension

3. Prompt boarding of goals of sustainable in constructed environment – Synthesis.

The creation of a model of sustainable in the constructed environment is complex because involves action in different space levels and different sectors of the society. The complexity of the constructed environment takes the researchers to propose simplified models based on personal perceptions. In this way, they are induced only to notice the elements for interpretation that was chosen unconsciously. They not perceive other elements that would be important in the complex system. The relationships inside of the system are not noticed also, and the synthesis is harmed.

A prompt boarding facilitates the perception of the elements that the mind eventually are not considerate when it was exposed to the complex system whole. This prompt boarding can be defined as a reduction of the complexity of the system. The perception, interpretation prompt of the elements of the system allow to understand the relations and functions of it, and they allow the synthesis and the understanding the complex system in whole.

This prompt boarding must consider the concept of constructed environment in its totality and fluidity. The concept of the creative process for a sustainable construction does not have to be static. The synthesis of the creative process must allow that we have different and even contradictory perspectives as how to make a sustainable construction. A concept with flexible boarding allows to consider all the parts of the whole constructed environment. The parts of the constructed environment, as for example its scales, are parts one of the others. Therefore, we cannot conceive a sustainable building, as something separate of its construction materials or its locality. Some scales of the constructed environment are related. The synthesis of the creative process for a sustainable construction must consider this influence between some scales.

For the prompt boarding we can have goals for some scales of the constructed environment. These goals must have a positive influence. The goals must be flexible to allow adequate actions to some existing realities. The article suggests the following goals:

• Correct Conception, with social, cultural, economic and environment considerações.

• Correct consumption of energy, with the search of lesser consumption of energy and minor generation of residues for the existing necessity.

• Correct water consumption, with the search of lesser water consumption for the existing necessity and not water contamination.

• Correct constituent, with use component and constituent that searchs the five goals suggested.

• Correct end, with the search of the biggest durability for the existing necessity and destination with a correct conception when it will not be useful.

The positive influence in some levels of the constructed environment would be given by the goal of correct constituent. Cities are constituted by buildings, buildings constituted by construction materials, and construction materials constituted by cousins. The search for the correct constituent in these some levels, would bring a virtuous chain in the creative process for sustainable in the constructed environment (figure 2).

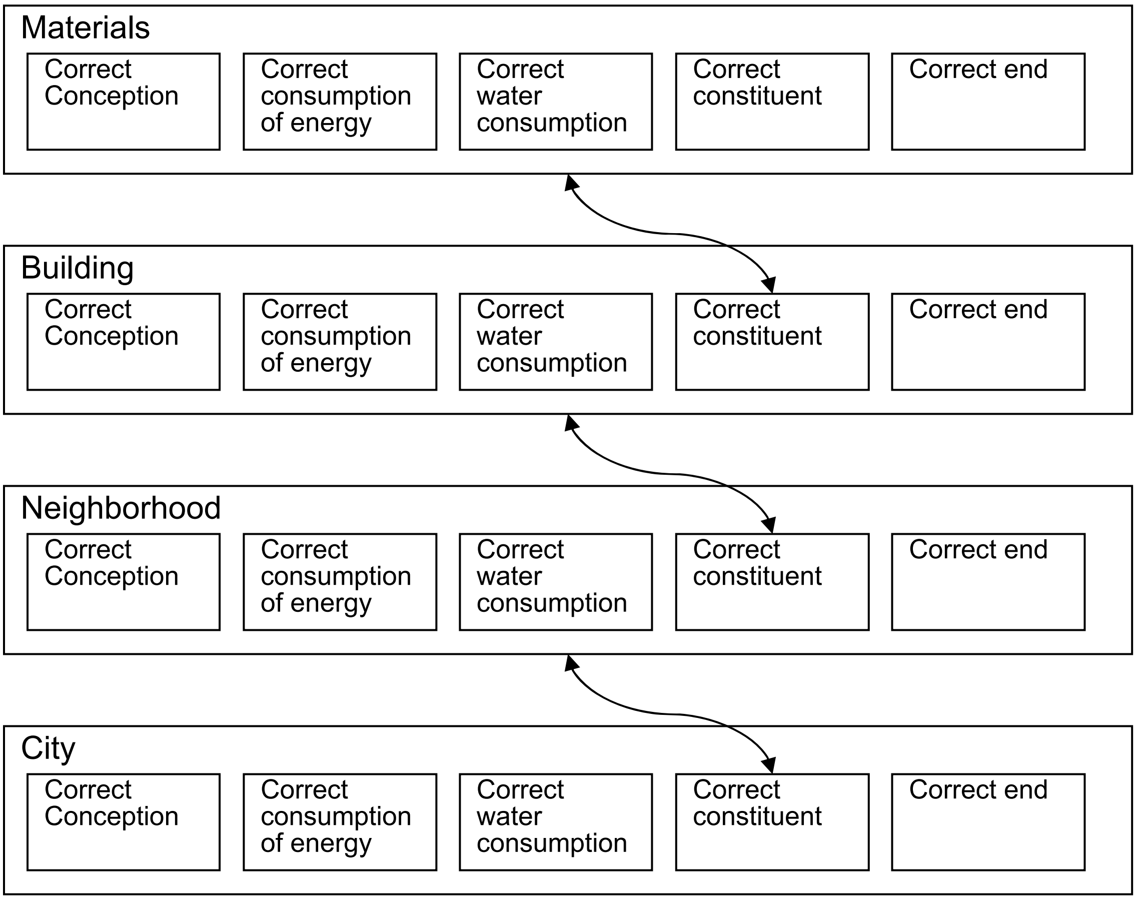

figure 2 - The positive influence in levels of the constructed environment.

Keywords: solar heating, socio-technical approach, implementation, actors, planning, simulation, load profile, system solution

Summary

The solar collector technology is well developed and cost-effective. Why is then solar heating not more widely used? In this study a socio-technical system approach is applied to identify some of the obstacles to increased use of solar heating. The main focus is on the planning process of buildings and heating systems, the influence of user behaviour and different combined system solutions for large-scale and small-scale heating respectively. Parts of four different projects in the topic are presented to show the complexity of the issue, which has to be understood to reach wider implementation of solar heating. The importance of user-friendly and well-functioning planning tools as well as easily installed and operated system solutions are addressed. Increased knowledge and communication in all actor groups are also recurring concerns.

The solar heating development has to adjust the focus from only improving the technological properties of the components to also put effort on attracting the user. Not only energy output or investment cost is decisive for whether a solar heating system is installed or not. To overcome the obstacles and reach success solar heating has to be seen in the wider social context it is actually part of.

1. Introduction

Energy demand in buildings should always in the first place be minimized, but there will always remain a need of energy supply for appliances, space heating and hot water. To meet the requirement of being sustainable the energy supply must come from renewable energy sources. Solar energy is a vast resource of renewable energy that today is used only to a small extent for heating and electricity production. Thermal solar collectors for hot water production have been markedly developed since the 1970's and the technique to utilize solar radiation for heating is today well developed and has reached cost effectiveness. But if the systems are both technically well developed and cost-effective, why is solar heating not more widely used? The reasons are many and of different nature and in order to grasp the complexity we apply a socio-technical framework to solar heating in this study.

The following report is based on a PhD thesis work under completion that comprises a socio-technical evaluation of domestic solar heating using Sweden as a case study. The objective is to identify technical and social obstacles for a wide implementation of solar heating. The study focuses on problems that arise in the building planning process, installation and utilization of solar heating systems. The study does not cover all obstacles that can possibly appear in those stages, but more highlights a few important issues in each stage. We address the importance of good planning tools for dimensioning solar thermal systems, easy-to-install systems for solar collectors combined with an auxiliary heat source and heat storage issues that influences the final contribution of solar heat in the total heating system.

Below, the technical solar heating system and the present development of the systems are first discussed before introducing the extended system view, including both technical and social aspects of solar heating. Three main issues are then discussed; the importance of planning tools, the influence of hot water use on the dimensioning of a system and the auxiliary heating system. Finally, the importance of applying a socio-technical frame of references is argued.

2. The technical solar heating systems

Traditionally, when speaking of solar heating a pure technical system is considered; the solar collectors, storage tank, circulation pump, auxiliary heat source, heat exchangers and supply loops being the main components. One of the studies presented in this report is based on interviews with actors within the solar and pellet industries (see further in section 3.3.2). According to some of the informants solar heating systems are often presented in very *technical* and complex ways, showing detailed technical schemes. They even claim this to be a reason for low selling rates of solar collector systems. Development of solar heating systems has mostly been focused on increasing the solar yield in the collector or the efficiency of the system. Some solar collector retailers, however, argue that this is not what the costumers are interested in; that some few extra kilowatt hours over the year do not make a considerable difference when choosing a heating system. The costumers are rather interested in a well-functioning, aesthetically attractive and easily operated system. The development should therefore rather be directed to the issues that concern the potential costumer to achieve increased sale rates.

The development of solar collector technology has however moved in that direction; efforts are made to develop units that are both easy to install and easy to operate by the end-user. The number of components and operational options open to the end-user are reduced to secure optimal operational conditions. This is applied both to solar heating systems and combined system solutions, such as solar and wood pellet systems presented below. By this approach the manufacturers hope to offer easily operated and robust systems and thereby attract costumers to a larger extent. This shows the importance of including a social dimension in the system and we will in the following define the solar heating system as a socio-technical system when analysing implementation of such systems.

3. Extended solar heating system – a socio-technical system approach

Figure 1 shows additional social components connected to the technical system, which altogether constitutes the socio-technical system. A system is in this case considered comprising a set of components interacting with each other through connections. What is not influenced by the system is considered belonging to the environment (not shown in the figure), but the environment still influences the system (Churchman, 1968). Consequently, by this system view users and other actors, which were previously regarded as belonging to the surroundings and not being influenced by the technical system, are now considered parts of the system and intimately interacting with the technology.

In this study four main sub-issues have been studied; the planning process through building simulation tools (including components such as *architects* and *constructors*), the utilization of the solar heating system by modelling hot water profiles from people's statements about their activities (*user*), system solutions with different auxiliary systems by evaluation of a large solar heating pilot plant as well as investigation of the present Swedish market for small-scale solar and pellet heating systems (*installers, building companies, user, market, government, industry*).

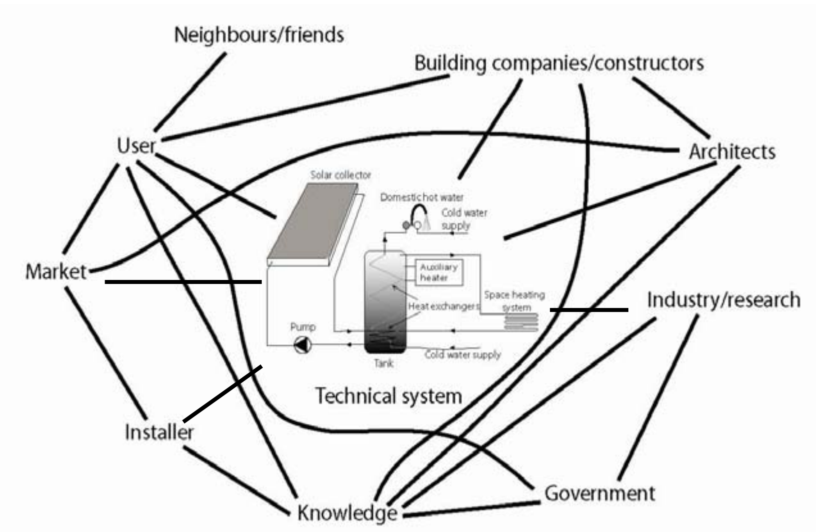

Figure 1 A socio-technical system view of solar heating, including both technical and social components.

3.1 The planning process – simulation tools for solar system dimensioning

Numerical models for calculating energy demand of a building are often used in the planning of new buildings or retrofitting of existing ones. Similarly, for dimensioning a solar heating system, models are used before erecting a solar collector plant. Such system simulations are of high importance to the architect, the builder, the entrepreneurs and other actors taking part in the planning process. The prerequisite for simulations being valuable in the planning is however that they deliver reliable results. This in turns requires simulation tools based on validated system models.

The need of well-functioning and user-friendly simulation tools for buildings has even increased the last years due to a directive on energy use in buildings from the European Parliament and Council from 2002 (Cox et al, 2002). It claims that energy certificates for buildings should be introduced in all member countries. The certificates shall show the energy performance of a building, but also supply proposals for cost-effective measures to improve the present performance. To serve this purpose several simulation tools have been developed to estimate the energy balance of buildings.

At present, planning buildings with solar heating often requires two different simulation tools, one that simulates the energy balance of the building and one simulating the performance of the solar collector system. That puts a lot of responsibility on the planners, to be able to handle different simulation tools, but also to compare and use the results from both programs in relation to each other. This makes the planning both complicated and cumbersome. A more easily managed alternative would be one simulation tool handling both different types of buildings and various installation systems.

Very few building simulation tools offer the choice to include solar heating systems in the model for calculation of energy supply. When investigating the market of commercial building simulation tools frequently used by planners in Sweden, it was found that only one of them (at that time, since 2007 there is at least one more similar simulation tool available) had an option to include solar heating. This simulation program was used to calculate the monthly solar energy contribution to space heating and hot tap water for an average new-built single-family house with a solar collector system of 12 m^2 and a water heat storage of 1 000 litres. The result was compared with results obtained with simulation tools that are specialized on solar collector systems, but also with experimental measurements on a real system. The solar heating systems and heat loads were comparable in size in all system models as well as in the real system. The results showed that the commercial building simulation tool severely underestimated the solar energy contribution as shown in Figure 2.

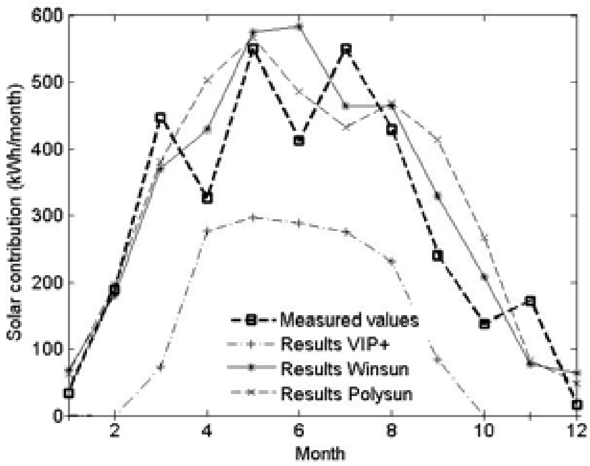

Figure 2 Simulation results from three different simulation tools as well as measured solar heating contribution for a solar combi-system in Sweden. The results from the building simulation tool VIP+ 4.0 deviate significantly from the others.

The deviating result for solar gain obtained in the building simulation originated from the tank model used in the program. The model only accounts heat of the set temperature in the tank, but in storage tanks used in solar heating systems heat of lower temperature is also accumulated for pre-heating (Lundh et al, 2007c). The results, however, show the importance of correct system models that are also validated against real operating systems. If this type of simulation tools is used in the planning process, resulting in extremely low solar energy contributions, solar collector systems will probably not be chosen because of low cost effectiveness. Building simulation tools with supply system models must be easy to use by the planner, not requiring professional competence in each area, but they also have to generate realistic estimations. The results must be reliable to thereby constitute the base for rational decision-making during the planning process.

3.2 User behaviour – hot water profiles

The planning and dimensioning of small solar heating systems (i.e. for single-family houses) is performed by the installer, mainly based on experience and rules of thumb. When planning for larger systems simulations are often used for determining system sizes. In both cases, the daily hot water demand is crucial in order to obtain the proper system sizes. Simulation tools for solar heating systems are often equipped with default daily pattern of hot water use, which can be adjusted to a chosen total daily consumption level, but which can not be changed in the time-resolved pattern. This section presents results from a study where hot water use was modelled for individual households based on time use data. This enables use of significantly diverse behaviours as time-resolved hot water loads and thereby also investigation on how different behaviour influences the solar contribution through the hot water use.

It has been shown in Krause (2003) that the heating cost of a large solar collector system can be considerably underestimated if it is dimensioned for too high hot water consumptions, while the difference in cost is small if the hot water use is underestimated. However, not only the total load, but also the distribution of the daily load has been shown to influence the solar utilization. In Jordan et al (2000) hot water profiles were constructed from statistical means on hot water, based on empirical studies from Germany and Switzerland. System simulations with the statistical load profiles showed a reduction in solar fraction (the fraction of the total heating demand covered by solar energy) by more than three percentage units compared to the default hot water draw-off pattern often used in simulation tools. Jordan's profiles were also used in Frei et al (2000) to investigate the influence on solar tap water systems. The difference in performance due to the type of draw-off pattern shows that solar heating does not only depend on the technology but also on how it is used; that the hot water user pattern actually influences the solar heating system.

In this study a model for translating time use data from so called time diaries into hot water demand was developed, which is jointly reported with a model for generating electricity load profiles in Widén et al (2008). The model is based on a pilot study on time use, which was performed by Statistics Sweden in autumn 1996. It comprises 464 persons living in 179 different households in apartments and detached houses. All family members older than ten years wrote time diaries, where they recorded all activities and the time spent on them, for one weekday and one weekend day. The time resolution in the time diaries are mainly five minutes intervals, which therefore serves as the basic resolution in the load profiles as well.

The model can generate load profiles with different time resolution, for single persons, single households or groups of households, for different types of dwellings as well as for different taps. The generated average load profile for a person living in a detached house and an apartment is found in Figure 3a and 3b respectively, while Figure 3c shows the significant deviation in hot water use between different individual households on a weekday. The hypothesis is that the time and amount of hot water use influence the ability to utilize solar heat. By introducing the modelled hot water profiles in dynamic simulations of solar collector systems a more realistic interaction between users and technology can be achieved.

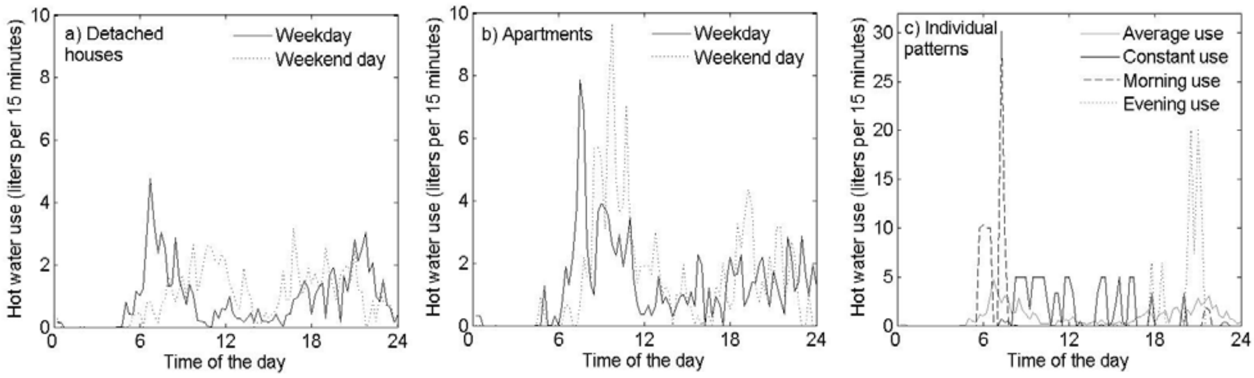

Figure 3 In figure a) the hot water profiles for weekdays and weekend days are shown for an average person living in detached houses. In figure b) the profiles for an average person living in an apartment is shown, while c) presents individual patterns of an average person from three different households showing completely divergent behaviour. (Lundh et al, 2008b)

The generated profiles need not be representative for all households, but constitute improved descriptions of hot water loads compared to the schematic draw-off patterns normally used in simulations. By generating load profiles from time diaries, they are based on people's statements about their activities. That means an order of activities that makes sense to the person that performs them, but it also puts energy use in a larger context of activities.

The main lesson to be learnt from this study so far is that the distribution, but also the amount of hot water use over the day, looks very different between different households. Can the load then be generalised with a certain, significantly simplified, hot water profile and a stereotyped total demand for all households when dimensioning solar heating systems? This is the question at issue in an ongoing continuation of this project which will be reported later.

3.3 Auxiliary system solutions – demonstration and market development

Solar heating systems are mainly of two different types, tap water systems or combi-systems. The tap water system, which only supplies hot water, dominates the world market having a share of more or less 90-100 percent in most countries (Weiss et al, 2002). Combi-systems, on the other hand, supply both hot water and space heating, and constitute 75 percent of the total installed solar systems in Sweden. A solar heating system can however not cover all heating demand in a building, but has to be operated together with an auxiliary system. For example, a combi-system is often dimensioned for a 20-25 percent solar fraction, while a tap water system covers about half of the total hot water demand over a year. To achieve considerably higher solar fractions seasonal storages have to be used. Storage of heat over long periods of time and to a reasonable cost is however not trivial, especially for small systems such as for single-family houses, since long-term storage is associated with high thermal losses. This means that proper system solutions have to be developed. There are several appropriate combinations of heating systems with solar collectors, and two different solutions are presented below; one large-scale solar heating plant with a seasonal storage and one small-scale solution combining solar collectors with another type of renewable energy, biomass in form of wood pellets.

3.3.1 Large-scale solar heating with seasonal storage in rock – 70 percent solar fraction

In 2000 to 2001 a new residential area, Anneberg, was built outside Stockholm in Sweden. It comprises 50 semi-detached and terraced houses, but what makes the area special is the heating system. A total of 2 400 square meters roof-integrated solar collectors have been installed on all south-facing roofs, see Figure 4. This yields an over-production of heat during summer, which is used to heat a 60 000 m^3 rock volume, by leading the heat through 100 boreholes penetrating the ground. The temperature increase can then be utilized for heating buildings and pre-heating hot water during the winter without use of heat pumps, due to the low-temperature floor heating system. Both solar collectors and borehole storages are well-known techniques, but the combination was unique. Previously, mainly large water storages have been used as seasonal storages for solar heat.

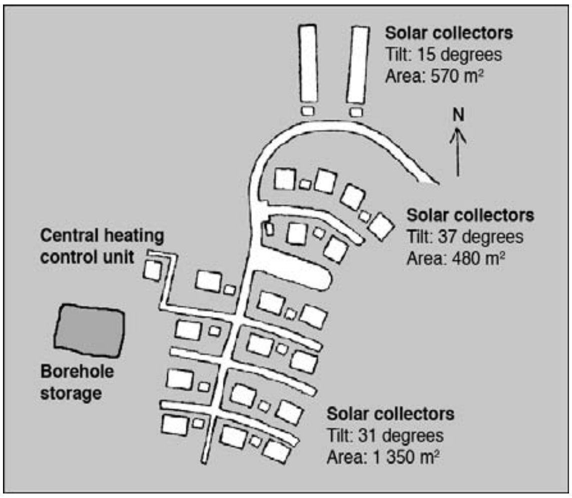

Figure 4 Example of the semi-detached houses in the area Anneberg outside Stockholm is seen to the left (Photo: M. Lundh). The south-facing roofs are covered by flat plate solar collectors. The right figure shows the distribution of buildings, solar collector areas and tilts as well as the location of the storage.

The initial thermal losses from the borehole storage will be large and full capacity will therefore be reached first after three to five years of operation. By utilizing the two techniques of solar collectors and borehole storage the heat demand will be supplied by solar heat to 70 percent under designed steady state conditions. The remaining required heat is supplied by electrical heaters in the floor heating system and in the water heater respectively. An electrical back-up system was chosen due to its simplicity and the small space requirements.

The solar heating system was put into operation in spring 2002, but due to problems both in the collector loop and in the storage loop, equilibrium has not yet been reached. When the solar collector system was tested, some of the pipes in the collector loop were found to be made of plastic, which resulted in an exploding pipe and a water leakage in one of the heating sub-units. The pipes therefore had to be replaced by copper pipes. This caused a delay in operation until autumn 2002. The system was then running without major problems for two years, until a leakage was discovered in the borehole storage. The U-tubes in the boreholes were found to have an inappropriate construction, causing cracking and thereby leakage, and all pipes in the storage loop had to be replaced as well. The system was put back into operation in autumn 2005 and has been running since then.

A first evaluation of the system was performed in 2005. Detailed information about the evaluation is found in Lundh (2007a) and Lundh et al (2008a). An evident supply of solar heat to the households both directly and indirectly via the borehole storage was shown. The system is designed to supply about 9 000 kWh heat per household and year at full capacity. From measurements of the storage discharge during 2003 it was found that an average of about 1 700 kWh heat had been used per residential unit. Moreover, the direct use of solar heat was assumed to be about ten percent of the total collected solar energy, which means another 1 800 kWh per residential unit. In total this means that the solar heating system already the first year contributed with more than one third of the designed heat supply at full capacity. (Lundh et al, 2008a)

What lessons can then be learned from a demonstration project like this? The two major incidents with leakages in the heating system have resulted in the electrical back-up system being the main heat supplier. This, in turn, has caused higher electricity bills than expected by the residents and thereby complaints, since several residents expected reduced costs already after one year of operation. These problems have in some cases led to reduced confidence in the heating system, but also in the property developer. When the indoor temperature, in addition, has been experienced as being too low, the negative attitude has been reinforced. On the other hand, there is an overall positive attitude towards the solar heating system, shown by interviews with residents (Lundh et al 2007b). The understanding of the system being a pilot plant, and thereby acceptance of some initial problems, is wide-spread.

Both technical and social issues connected to knowledge and understanding, have occurred in Anneberg. It is of high importance to engage, inform and discuss the system performance and what to expect from the system with the residents both before and during the operation. By clearer communication, the frustration experienced by the residents in Anneberg, and the speculations caused by lack of information, would probably have been reduced. On the other hand, some of the technical problems in Anneberg were unavoidable, but there are a lot to be learned from the building process (which was not followed at the time). Several problems seem to be a result of lack of global means of control during the building process. For example, diverging instructions for the piping in the heating system resulted in the exploding pipe and the leakage in the solar collector loop. Although many problems have arisen during the project, new system solutions have to be installed and evaluated in reality to show actual potentials as well as difficulties. Computer models can never replace actual demonstration projects if solutions for future energy supply are to be found. Systems have to be built and used by people to achieve knowledge about the actual interaction and performance.

3.3.2 Solar and pellets – an increasing small-scale solution

Seasonal storages are not economically feasible for small-scale solar heating systems for single-family houses, due to the large volume required and the high losses from the relatively small storage. For single-family houses other solutions therefore have to be applied. One system solution that has been introduced on the market recently and that is getting more frequently used is the combined system with solar collectors and a wood pellet boiler.

Both solar heating and heating systems with biomass are sustainable energy suppliers based on renewable energy sources. By combining the two systems even more advantages appear; the solar collector system and the wood pellet boiler complement each other well. A pellets boiler normally operates with a low efficiency and frequent starts and stops during the summer when the load is low (only hot water), while a solar heating system can not supply all heat during the winter. By introducing solar collectors in a pellet heating system the pellet boiler can be turned off completely during summer, while it can operate at a high efficiency in the winter when the load is high, which in total increases the system efficiency. Furthermore, wood pellet is an economically reasonable solution that is easily handled by the user. It may however mainly suit countries with domestic wood assets. Combined systems have been used for some years, but during the last years more and more efforts have been made to develop integrated systems that are easy to install and easy to operate by the user. To study the development of the *concept* of combined solar and pellet heating systems, as well as trying to identify obstacles to increased use, an interview study was performed with ten actors such as manufacturers, retailers, installers and representatives for interest organizations within this business in Sweden during autumn 2007. The material will be further analyzed and reported in detail in future papers.

During the interviews the installers were pointed out as key actors for guiding the consumers in their choice of heating systems. Today, lack of installers willing to install combined systems with solar and pellet is experienced both by installers themselves and by manufacturers. Many installers lack in knowledge, mainly about the solar heating systems, and as one of the informants expressed it “plumbers do not want to climb roofs”; they are unwilling to make this kind of businesses. To make the systems attractive they must however be easily accessed by the consumer. One solution could be to develop standardized systems that are easily and quickly installed, and thereby also changing the attitude among the installers.

On the other hand, very few suppliers are able to deliver complete system solutions. Instead the potential costumer is directed to purchase different components from different companies, which probably discourage many people. An important issue is therefore co-operation. At present, the different actors delivering the different system components often meet first at the installation, which could be too late to enable well-performing heating systems. Collaboration already at the stage of planning would be an important progress. The present system development is however focused on adapting the components to the combined systems, for example by introducing small boilers suitable for an accumulator tank with solar, but also on packaging the systems nicely, offering the costumer (and installer) a simple system with less units and simple operational conditions; systems that the user can understand. The comfort is also highly stressed, not demanding daily commitment from the operator, but also to offer system solutions compatible to other heating systems that are already nicely packed and easily operated.

Identified obstacles to solar and pellet heating were mainly the lack of user focus in the system development; comfort and design have not been the main issues for the manufacturers so far. When no complete combined systems are offered on the market, the consumer is forced to consider an *additional* system. The cost could also constitute an obstacle, while no technical problems were recognized. Due to previous governmental subsidies for converting heating systems, causing a fluctuating Swedish market mainly for pellet boilers, a stable market with long-term governmental decisions and well-established governmental viewpoints in energy supply issues were also pointed out as necessities for success.

Most informants agreed on that combined solar and pellet systems have entered the market during the last two or three years, and that the market share will grow significantly; “it is just a matter of time”. Comfortable standardized, but also cheaper, combined systems, enough number of good and engaged installers to meet the increasing demand, as well as more and better marketing are necessary prerequisites for solar and pellet systems to reach success.

4. Main advantages with an interdisciplinary approach

What are the advantages of extending the system view on solar heating from the traditional view of being purely technical to a *socio-technical* view? Foremost, a solar heating system will always be part of a social context; (developed in the industry or at an academic institution due to decisions taken by a board, financiers or a group of researchers) it will be available on the market, which is governed by several different actors (manufacturers, importers, installers, interest organizations), it is planned by an installer, architect or a construction company and finally it is operated by the users (household members or technical staff). All those stages include *people*. Thus, the solar heating system, or any heating system, can not be considered purely technical. If one of these stages fails, solar heating will not work in a satisfactory way, or in the worst case it will not be installed at all. This in turn can result in bad reputation and in the long run a vicious circle of decreasing number of installations.

By applying a socio-technical approach the technical system is seen in a wider context and connections not only between components within the technical system, but also between components inside and outside the technical systems, can be identified. When applying a research question such as “How can the use of solar thermal systems be increased?” the studied object can not be limited to the devices. To enable identification of obstacles as well as possibilities with solar thermal the wider socio-technical system, that the solar heating system is actually part of, has to be considered. Both advantages and obstacles tend to appear in the connections between the social and technical components, meaning that the issues can often be related to *people* and their knowledge; people’s expectations on the technology and the planners’ expectations on people. Those do not always match. But to understand *why* they do not match the interaction between technology and people have to be investigated.

6. Conclusions

There is not *one* universal solution to reach increased use of solar collector systems. Different obstacles towards the establishment of solar heating have been pointed out, all by applying a socio-technical approach, where the hindrances are traced to the interaction between technology and actors. The importance of well-functioning planning tools for dimensioning solar thermal systems integrated in a model for energy use in buildings is stressed. Furthermore, easy-to-install systems for solar collectors combined with an auxiliary heat source are crucial to attract both the potential user and the installer.

The divergence in hot water use between different households is significant. There may even be a greater potential in energy savings and profitability of a solar heating system in *how* it is used, than in technological improvements of system components such as the collector or the tank. Solar heating is in the middle of its breakthrough. By widen the perspectives from the pure technical it is possible to attend the existing lack of knowledge, and put the effort in the direction necessary to attract the costumer, since interested and satisfied users are essential for solar heating to reach success.

CLIMATIC DESIGN STRATEGIES FOR SYDNEY, ADELAIDE AND PERTH: A STUDY OF BUILDING CODE OF AUSTRALIA'S CLIMATE ZONE 5

Anir UPADHYAY

Architectural Researcher, Kogarah, NSW, Australia, anirupadhyay@yahoo.com

Keywords: Climate, climate classification, climate analysis, building design, design strategies

Summary

Building Code of Australia (BCA) has been developed and maintained by the Australian Building Codes Board (ABCB) on behalf of the Commonwealth, States and Territory Governments. BCA has identified eight different climate zones within Australia. This paper discusses climate conditions of the state capital cities of Sydney, Adelaide and Perth that belong to the same climate zone 5 of the BCA. This comparative study aims to identify the similarities and the differences in climate conditions in these cities, as a result of microclimatic features. Temperature, humidity, sky conditions and, wind intensity and directions are different in Sydney, Adelaide and Perth. Perth experiences higher summer maximum temperature than Sydney and Adelaide. Sydney is warm and humid in summer while Adelaide and Perth are hot and arid. Winter sky condition is clear in Sydney while it is overcast in Perth and Adelaide. Wind intensity and directions are varied during the day and seasons in all the three cities.

This paper outlines a few design strategies; some are same for all the cities while others are different. Street and building orientation, outdoor space planning are specific to the locations while winter heating requirement and necessity of thermal mass are prerequisite to all the cities.

1. Introduction

Global climate classifications basically use prominent climate data to form climate zones of similarity especially useful in agricultural study. Climate zone classifications to describe appropriate building design should be different from those invented for agriculture (Cook 1996). In the context of building regulations, climate zones are regions which are of sufficient similar climate such that, a common solution for energy efficiency measures is possible and justifiable (AGO, 2000).

Climate across Australia is very diverse. Diversity is huge such that even in a metropolitan scale, one can experience differences in the climate (Upadhyay 2008). However, there still is a need to generalise climate to define climate zones using variety of criteria depending on the purpose. Various organisations have classified the whole of Australia into number of climatic zones. The Bureau of Meteorology has six zones while Building Code of Australia (BCA) has eight zones and NatHERS (Nationwide House Energy Rating Scheme) has 69 climate zones for the Australian continent (NatHERS 2008). The six climatic zones developed by Bureau of Meteorology are based on dry-bulb temperature and humidity. Other climate determining elements such as, the wind and solar radiation are not considered because of the complexity arising with the inclusion of those parameters. However, the effect of wind, sky condition and rainfall pattern can not be ignored when considering climate for building design purposes.

This study has considered three state capital cities of Sydney, Adelaide and Perth which belong to the same climate zone 5 of BCA. Sydney Metropolitan has diverse climate conditions. This study has considered only the eastern part of Sydney and has used climate data from the Sydney airport. Climate zone 5 resembles the temperate climate zone of Bureau of Meteorology (BOM 2008). This study has summarised climate information from the three locations; and detailed climate analysis is carried out to understand the prevailing climate characteristics in these cities. Climate analysis is then used to come up with practical design recommendations for the three state capitals Sydney, Adelaide and Perth.

2. Methodology

This paper is a part of a larger study, which aims to develop design guidelines for planners, designers/ builders to help them in selecting the planning/ design options and building elements that are climatically suitable, as well as, energy efficient. The study will cover the major population locations within Australia, such that, it covers all the states and major cities, which are distinctly different in climate conditions. The study is carried out in two steps: climate analysis, and formulating recommendations for planning and building design. In climate analysis, climate data from the Bureau of Meteorology, Australia for each of the locations is summarised in a graphical format. Comfort condition for each location is investigated using Building Bioclimatic charts; and wind roses are prepared to understand the wind flow at different times across different seasons. Final design guidelines are based on preliminary recommendations from Mahoney tables, which formulate design strategies using temperature, humidity and rainfall; and detailed climatic analysis. This paper undertakes the same process of climate analysis and will provide location specific recommendations.

3. Climate study

3.1. Sydney

Climate data over a period of 78 years (1929 – 2007) from **Sydney airport** has been used for this study.

Sydney experiences a hot and humid summers and mild winters. Autumn and spring months are transitional periods between the two main seasons. Mean monthly air temperature ranges from 26°C in February to 18°C in July. The average minimum temperature ranges from 7°C in July to 17°C in December. Humidity in Sydney is high for two months in summer; otherwise it remains within a comfortable range. Requirements of heating or cooling are best described by heating/ cooling degree hours. Cooling threshold temperature is determined by the neutral temperature (Szokolay, 1982) for each month. Heating threshold temperature has been taken as 18°C for the year round (Hart and de Dear, 2004). In Sydney, summer requires cooling, but from mid autumn to spring, heating is required. In total, 3% of the time has cooling demand and 97% of time has heating requirements. Summer and autumn months get substantial rain; the sky is overcast in summer and autumn. In winter, the sky is clearer. The annual mean rainfall of 90 mm, which is approximately 95 days of rainfall, is distributed fairly across all the seasons. It rains more frequently during autumn while least during spring months. Wind changes its direction in each season. Generally, the morning wind comes from the north-west. The afternoon wind blows from the east to the south and the evening wind from the north and south. In summer and spring, wind comes from the north-east to the south directions. Autumn and winter morning wind comes from the west and north-west and afternoon wind comes from the south.

3.2. Adelaide

Climate data from **Kent town, Adelaide** over a period of 30 years (1977 – 2007) has been accessed for this study.

Adelaide experiences hot, dry summers and mild, wet winters. Mean monthly air temperature ranges from 29°C in February to 17°C in August. The highest temperature ever recorded is 44.3°C in February 2004. The average minimum temperature ranges from just 7°C in July to 17°C in January. The lowest temperature ever recorded is –0.4°C in June. The morning and afternoon humidity levels in Perth are within the comfort zone. Summer months are hot and winter months are cold but humidity levels are always in the acceptable range across seasons. Of the annual mean rainfall of 550 mm, which is approximately 84 days of rainfall, about 60% usually fall between May and September. It rains more frequently during winter with 75 mm rainfall in an average of 12 rainy days in a month. In contrast, the total summer rainfall is just 61 mm with an average of 3 rainy days in a month. As winter months get substantial rain, the sky in winter is overcast for about 15 days in a month. Summer months require cooling; but from autumn to spring, heating demand is very high in Adelaide. In total, 93% of the time has heating demand and 7% of cooling demand. The wind is mainly from the south west and west in the afternoon. Prevailing wind in summer is from the south. In winter, morning wind is primarily from the north.

3.3. Perth

Climate data from **Perth Airport** is accessed which is averaged for a period of 63 years (1944 – 2007).

Perth experiences a Mediterranean climate, characterized by hot, dry summers and mild, wet winters. Mean monthly air temperature ranges from 32°C in February to 18°C in July. The highest temperature ever recorded is 46.7°C in February 1991; however, the temperature exceeds 40°C only three days per year on an average. The average minimum temperature ranges from just 8°C in July and August to 17°C in January and February. The lowest temperature ever recorded is –1.3°C in June. The morning and afternoon humidity levels in Perth are found within the comfort zone. Summer months are hot and winter months are cold but humidity levels are always in the acceptable range across seasons. Of the annual mean rainfall of 767 mm, which is approximately 87 days of rainfall, about 70% usually fall between May and September. It rains more frequently during winter with 150 mm rainfall in an average of 14 rainy days in a month. In contrast, the total summer rainfall is just 35 mm with an average of 2 rainy days in a month. Hence, it is not unusual in Perth to have extended dry periods during summer. Perth is one of the sunniest Australian cities and enjoys an annual average of 8.8 hours of sunshine per day. In predominantly clear days of summer, the average daily sunshine duration exceeds 11 hours. As winter months get substantial rain, the sky in winter is cloudy for about 12 days in a month. Summer and early autumn months require cooling; from mid autumn to spring, heating demand is very high in Perth. In total, 85% of the time has heating demand and 15% of time has cooling requirements. The wind is mainly easterly in the morning due to the effect of land mass; and south westerly in the afternoon due to afternoon sea breezes. Winter morning wind comes from the north and changes its course towards the west and south-west in the afternoon. The westerlies are associated with the bulk of the annual rainfall in Perth. The average wind speed in winter is considerably lower than in summer.

Table1: Climate comparison between the three locations

Climatic parameters	Sydney	Adelaide	Perth
Air Temperature			
Extreme maximum	45.2^{0}C	44.3^{0}C	46.7^{0}C
Mean daily maximum			
summer	26.4^{0}C	29.3^{0}C	31.8^{0}C
winter	18.2^{0}C	16.7^{0}C	18.9^{0}C
Mean daily minimum			
summer	17.4^{0}C	15.5^{0}C	14.8^{0}C
winter	7.0^{0}C	7.4^{0}C	8.0^{0}C
Extremely minimum	-0.1^{0}C	-0.4^{0}C	-1.3^{0}C
Mean diurnal range	7.3 – 10.2 degC	7.9 – 12.2 degC	9.7 – 14.7 degC
Heating degree hours *(base 18^{0}C)*	97%	93%	85%
Cooling degree hours *(base neutral temperature)*	3%	7%	15%
Humidity	Humid for two months (Jan and Feb)	Always within comfort range of 4-12g/kg	
Sky Condition	Winter months have clearer days while rest of the seasons are prevalently cloudy	Summer months have more clear days while rest of the year is prevalently cloudy	Summer months have clear sky while winter months have the cloudy conditions.
Rainfall	Summer and autumn months receive substantial rainfall and winter receives the lowest rainfall	Winter and spring months receive substantial rainfall and summer receive the lowest	Winter months receive the highest rainfall and summer months receive the lowest
Wind	In summer, southerly wind is prevalent while in winter, wind comes from the west except wind from the south in the afternoon.	Wind is mainly from the south west and west in the afternoon. Summer wind is predominantly from the south while winter morning wind is primarily from the north.	Perth experiences three distinct wind patterns. Morning wind comes from the east, afternoon wind comes from the south-west and evening wind comes from the south.

4. Climate comparison

The table above illustrates the differences in climate of these three locations, although, they are in the same climate zone in BCA. The differences of the parameters are discussed in detail below.

4.1. Temperature

Temperature profile of Sydney, Adelaide and Perth looks similar at first. Temperature usually surpasses the comfort zone in summer while it drops below the comfort zone in winter. These locations experience very similar extreme maximum temperature, within the range of 2.5 degC. The striking difference however is observed in mean daily maximum temperature in summer, which increases from the east coast to the west. The difference between Sydney to Adelaide is around 3 degC and from Adelaide to Perth, is around 2.5 degC. Winter maximum temperature in Adelaide is the lowest. Perth has got the lowest mean daily minimum temperature among the three. As a result, mean diurnal temperature in Perth is the largest which is in the range of 9.7 to 14.7 degC while it is the lowest of 10 degC for Sydney. The daily temperature fluctuation also increases moving from the east coast to the west. The requirement for heating is the highest in Sydney while Perth needs more cooling than rest of the locations.

4.2. Humidity

Sydney experiences humid condition for two months during summer, while Adelaide and Perth do not experience humid conditions. In general, humidity is not a problem for all the three locations.

4.3. Sky conditions and rainfall

Sydney enjoys winter sunshine while Adelaide and Perth have overcast sky in winter months. Consequently, winter months receive the lowest rainfall in Sydney but other two locations receive the highest in winter months.

4.4. Wind

Wind pattern is completely different from one location to the other. Sydney experiences wind coming from the south and north-east. Adelaide and Perth have three distinct wind directions for the morning, afternoon and the evening. Adelaide and Perth both have afternoon wind from south-west and the evening wind from south while the morning wind in Adelaide is from north and in Perth, it is from the east.

5. Climate analysis

Climate Analysis has been done using Building Bioclimatic Chart and Mahoney tables.

5.1. Building Bioclimatic chart

The Building Bioclimatic chart derived by Givoni (1976) provides suggestions for building design considering the local climatic conditions. Various control strategies, which ultimately lead to a climate-sensitive design, are suggested. Szokolay (1986) defined control- potential zone to describe the range of outdoor atmospheric conditions within which indoor comfort could be achieved by the various passive control techniques. In the Psychrometric chart, different zones are plotted to indicate different strategies depending upon the monthly temperature–humidity relationships. To identify the comfort conditions, the climatic data of all the months are plotted in Building Bioclimatic chart, as shown in Figures 1-3. Two points of each line represent mean minimum temperature with the 9 AM relative humidity and the mean maximum temperature with the 3 PM relative humidity.

Temperature – humidity relationships for Sydney suggest having thermal mass and ventilation arrangement to counteract the summer hot conditions. Adelaide and Perth experience hot but arid conditions, so thermal mass is required to moderate the climate in summer. For the majority of the time, temperature drops below the comfort range for all the locations, making recommendations for passive solar heating strategies.

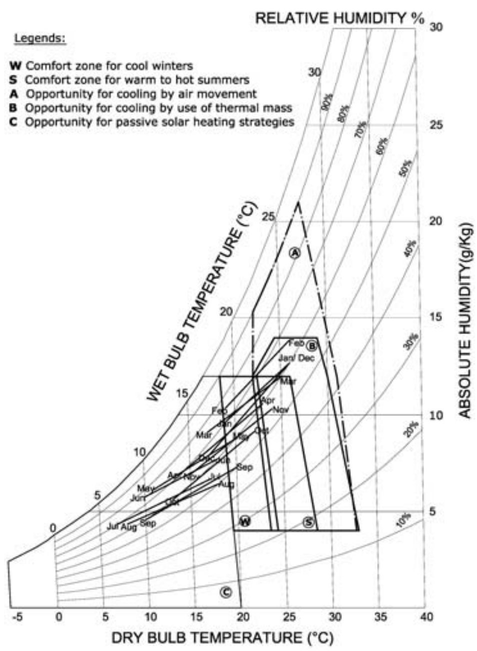

Figure 1. Building Bioclimatic chart (Sydney)

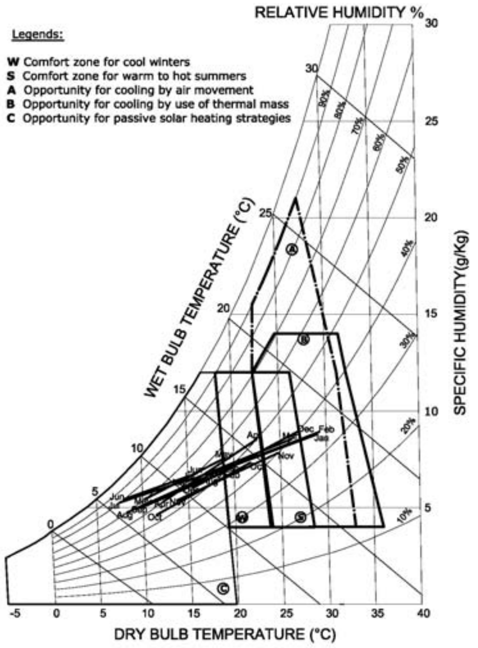

Figure 2. Building Bioclimatic chart (Adelaide)

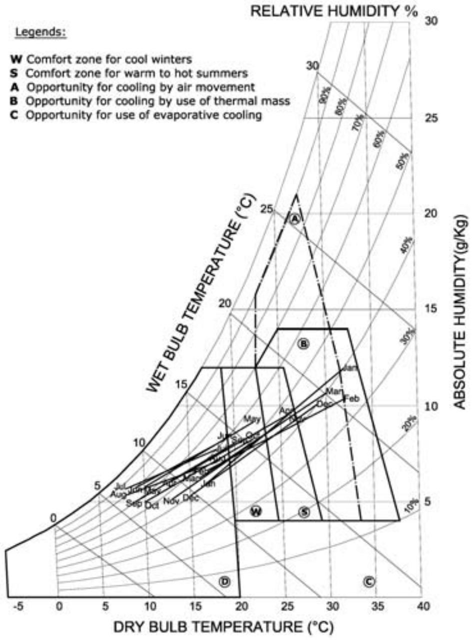

Figure 3. Building Bioclimatic chart (Perth)

5.2. Mahoney tables

The Mahoney tables (Koenigsberger, et al., 1973) provide results of thermal comfort analysis using primarily the temperature and humidity data, and make recommendations for pre-design guidelines.

These pre-design conditions are classified under certain climatic groups or indicators. The Mahoney tables have six indicators (i.e. three ‘humidity indicators’, H1- H3, and three ‘arid indicators’, A1 –A3). The Mahoney tables indicate remedial action involving air movements for humid conditions in H1 and H2. Excess downpours may affect the building structure, so adequate rain protection is advised in H3. Similarly, for hot and arid conditions, thermal capacity (A1) is one of the options for making the indoor space comfortable. When the temperature range is more than 10 degC with relative humidity up to 70%, thermal mass is recommended. Climatic zones with night time temperature above the comfort limit and relative humidity less than 50%, are advised to make provisions for outdoor sleeping (A2). A building with the temperature below comfortable range needs protection from cold wind (A3). Indicators and recommendations from Mahoney tables for Sydney, Adelaide and Perth are presented in table 2.

Table2: Indicators and recommendations from Mahoney tables

	Sydney	**Adelaide**	**Perth**
Indicators	A1, 2 months and A3, 5 months	A1, 7 months and A3, 5 months	A1, 10 months; A2, 2 months and A3, 4 months
Recommendations on			
1. Layout	North and south (long axis east – west)		
2. Spacing	Compact layout of estates		
3. Air movement	No air movement requirement		
4. Openings	Medium openings 20-40 %	Small openings 15-25 %	
5. Protection of openings	Exclude direct sunlight		
6. Walls and floors	Light walls, short time lag	Heavy external and internal walls	
7. Roof	Light, insulated roof	Heavy roofs, over 8 h time lag	
8. Outdoor sleeping	N/A		Space for outdoor sleeping required

Building layout with long axis towards east and west is best suitable for all the three locations and favours compact layout of estates without mandatory air movement across buildings. Recommendation for Sydney is larger opening area than Adelaide and Perth. Openings need to be protected from the direct sunlight. Mahoney tables suggest having heavy walls, floors and roof for Adelaide and Perth while light structures for Sydney. The arid indicator (A1) recommends use of thermal mass. Building in Perth should have outdoor sleeping space for summer

Mahoney tables do not consider night time wind movement to cool the thermal mass, which has been already proved effective in different climate conditions (Givoni, 1994). Even if compact layouts of estates are recommended due to arid characteristics of the places, the need of breeze penetration across buildings are still necessary to cool off the thermal mass in the evenings and at nights. Provision of securing afternoon wind movement can not be overruled as the daytime cooling can be met with the afternoon breezes.

6. Formulating the design strategies

These climatic differences do have implications in building design and planning. The large diurnal temperature range with higher summer mean temperature in Perth needs special care, in comparison to Sydney. Requirement of thermal mass is significant when the diurnal temperature range is more than 10 degC. Sydney needs design response to address humid conditions in summer months, while Perth and Adelaide need different strategies for the arid conditions. Free flow of air through interior is important in Sydney while water bodies in and around the building is advantageous to balance humidity level in Adelaide and Perth. There is an opportunity for passive solar heating strategies for all the three locations. Winter clear sky in Sydney is the most favourable for the use of passive solar heating techniques while it is not the same for Adelaide and Perth due to prolonged overcast conditions in winter. In the local level, wind needs to be attended to, and it has a great influence in street layout, building orientation and the window placement in the buildings. In Perth, rooms that can be extended in covered semi open space are advantageous, as the outdoor sleeping condition is favourable for some months. Some of the design strategies are elaborated to make a clear understanding of the differences.

The design strategies are formulated based on the climate analysis. Design strategies are meant to be comprehensive and schematic to be helpful in the design process so that no major opportunities are missed. At the same time, they have to be few such that they can be easily memorized to be used effectively.

6.1. Building orientation and Street layout

Building orientation and layout of streets have significant effect on accessing sun and wind in the buildings. To maximize solar access and air movement in streets, primary avenues in Sydney, Adelaide and Perth should be oriented some angles west of south. To be more precise, this angle is 20 degree for Sydney, 25 degree for Perth and 30 degree for Adelaide. It helps to secure both prevailing afternoon wind and night breezes in summer; and winter solar exposure on the north facade. Major street orientation within the angle of approximately 20-30 degree on either direction of the prevailing breezes is highly recommended (Brown and DeKay, 2001). The figures below show the preferred wind direction along with the street layout at different locations.

Table3: Building orientation and Street layout considering sun and wind movement

<table>
<tr><th>Sydney</th><th>Adelaide</th><th>Perth</th></tr>
<tr>
<td></td>
<td></td>
<td></td>
</tr>
</table>

6.2. Securing neighbourhood sunshine

Buildings in Sydney, Adelaide and Perth require solar radiation in the winter months. An ideal organization of streets, open spaces, and building for solar utilization is to elongate buildings in the east – west direction and spacing in the north – south direction. This placement allows buildings facing north to collect sun, and at the same time they are far enough apart not to shade each other. However, because of the topography or pre-existing conditions, many streets do not have an east west orientation so the figures 4-6 show several possible options of buildings and open space layout, along with opportunities for solar access. The previous strategy already recommended non –cardinal street arrangement for all the three locations considering the summer wind movement along with winter solar access.

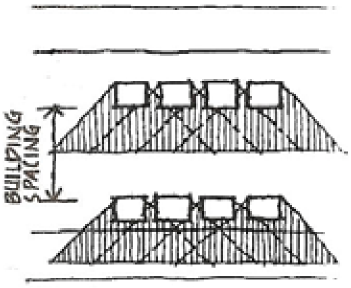

Figure 4. East –west lot arrangements

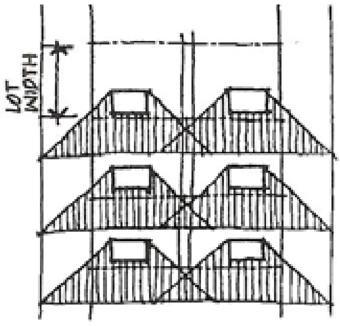

Figure 5. North –south lot arrangements

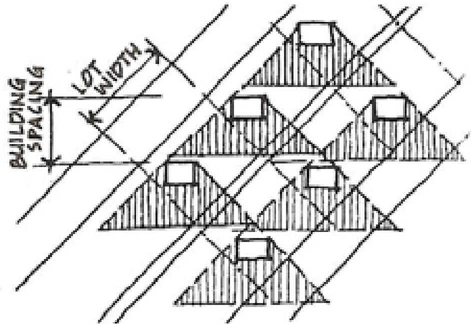

Figure 6. Non cardinal streets, lot arrangements

(Source: Brown and Dekay, 2001, modified)

6.3. Outdoor spaces

In summer months, outdoor spaces towards south are very useful as prevailing evening breeze comes from the south west in Perth. Outdoor sleeping is recommended in Perth for two months in summer. Winter months require sun tempering, as daytime temperature remains below the comfort range. Outdoor space towards the eastern part of a building, securing solar access from north and protecting it with westerly breezes is very useful.

Table4: Probable location of outdoor space for summer and winter in Sydney, Adelaide and Perth

	Plan ↓ **Summer outdoor space arrangements** Section ↓	Plan ↓ **Winter outdoor space arrangements** Section ↓
Sydney	 Summer wind comes from south	 Winter wind comes from west and south
Adelaide	 Summer wind comes from south-west and west	 Winter wind comes from west
Perth	 Summer wind comes from south	 Winter wind comes from west

6.4. Building structure

Sydney, Adelaide and Perth require cooling in summer months and heating in winter months. The large range of thermal conditions requires utilization of both radiation and wind effects, as well as, protection from them. Hence, dual role is required of the structure. Thermal mass helps to store daytime heat during the day and releases it at night to balance room temperature in winter months. Thermal mass can be used to absorb heat from a room during the day and to cool off the radiated heat at night with ventilation in summer months. For this, there must be enough mass in the building to absorb the heat gain, and the mass must be distributed over enough surface area so that it can absorb the heat quickly and keep the interior air temperature comfortably low. The opening must be large enough to allow cool outside air to flow past the mass to remove the heat accumulated during the day and carry it outside the building.

The diurnal temperature range, and summer mean maximum temperature, is higher in Perth than other two locations indicating the requirement of greater area of thermal mass for Perth. Similarly, evening wind movement to cool the thermal mass is also equally important for Perth.

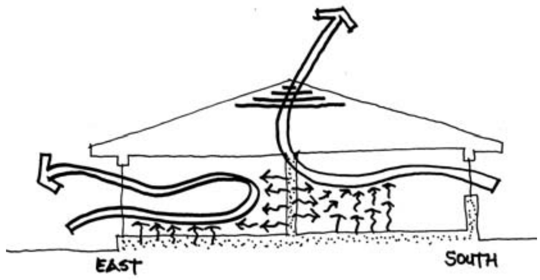

Figure 7. Effective ventilation helps to cool off thermal mass in summer

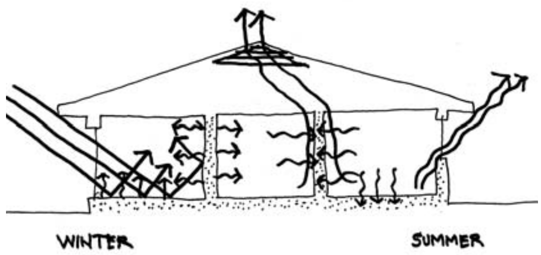

Figure 8. Use of thermal mass in winter and summer months

7. Conclusion

The climate of a place is influenced by various micro-climatic features. The climate classification of Bureau of Meteorology Australia has Sydney, Adelaide and Perth in the same temperate climate zone. Similarly, Building Code of Australia has them together in zone 5. However, the rigorous climate analysis of these locations revealed differences in climate conditions among these locations. This study identified differences in temperature, humidity, sky condition and wind intensity and its directions. All these features are major, considering the climate as an integral parameter in urban planning and building design.

Winter heating and summer cooling requirements together with available solar radiation and wind suggest for different orientations of building and streets in all the three locations. High heating degree hours for all the locations suggest securing sunshine in site and lot planning. Wind directions in different seasons and time are crucial to plan the outdoor open space for summer and winter months. Thus, the variation in summer and winter open space is observed in all the cities. The higher summer mean temperature along with higher diurnal temperature range in Perth require special attention in comparison to Sydney and Adelaide. Sydney has got warm and humid summer while it is hot and dry in Perth and Adelaide. Larger area of thermal mass in building is required in Perth and Adelaide along with evening or night ventilation which can ensure comfortable condition indoors. The winter clear sky condition in Sydney encourages the use of passive solar heating techniques while it is not so in Adelaide and Perth due to overcast conditions.

Keywords: specular reflection, glare, radiance

Summary

With the advent of high-rise building and clustering of the building, range of influence by the new establishment of large-scale building to the surrounding environment is being reinterpreted. Namely, range of estimation is expanding from previous direct or physical elements such as traffic, noise, vibration or structural aspect to sunlight, view, glare influence, energy load and personal psychological elements as well. In case of high-rise building in downtown, most of buildings are finishing the exterior envelopes of the building with glass, the specular material, for the landmark image and securing the view of residents as of now. However, in case the front of building finished with specular reflection material is designed as broad plane, specular reflection of direct sunlight may occur due to exterior envelopes of the building at certain time period and it may bring about danger inducing the discomfort glare or disability glare to drivers and pedestrians on adjacent road. the purpose of this study is analyzing and estimating the influence of direct sunlight reflection of building exterior materials on glare on the road as newly established building Y is constructed near the interchange where big roads are close to one another.

1. Introduction

With the advent of high-rise building and clustering of the building, range of influence by the new establishment of large-scale building to the surrounding environment is being reinterpreted. Namely, range of estimation is expanding from previous direct or physical elements such as traffic, noise, vibration or structural aspect to sunlight, view, glare influence, energy load and personal psychological elements as well. In case of high-rise building in downtown, most of buildings are finishing the exterior envelopes of the building with glass, the specular material, for the landmark image and securing the view of residents as of now. However, in case the front of building finished with specular reflection material is designed as broad plane, specular reflection of direct sunlight may occur due to exterior envelopes of the building at certain time period and it may bring about danger inducing the discomfort glare or disability glare to drivers and pedestrians on adjacent road.

Accordingly, when constructing building, especially high-rise building, in downtown, design considering not only the visual environment of residents in adjacent area but also the specular reflection to prevent the damage on road shall be devised and it is necessary to establish standard and method to determine the likelihood of damage by glare in designing process.

Therefore, the purpose of this study is analyzing and estimating the influence of direct sunlight reflection of building exterior materials on glare on the road as newly established building Y is constructed near the interchange where big roads are close to one another.

1.1 Method and Range

This study was carried out in following orders.

1) To estimate the glare influence on adjacent road, trait of reflection angle based on incident angle of newly established building's exterior materials was measured using self-manufactured Gonioreflectometer (BRDF meter).

2) Spatial relationship was accurately implemented by analyzing the horizontal and vertical location of the building using the drawings first and then drawing up 3-D AutoCAD drawing.

3) Considering the placement of sun's location and the building, etc, estimated location for glare occurrence was set after drawing a reflection map from sunrise to sunset on 21st of Jan. ~ Dec., the representing days of year.

4) Basic data was collected for the computer simulation of glare influence using Radiance program.

5) Analysis and evaluation of image was carried after the simulation using Radiance program.

2. Preparation of Manuscripts

2.1 Discomfort Glare and Disability Glare

Although discomfort glare inflicts pain and discomfort in vision, it does not dramatically decrease the visual capacity and it is influenced by the light condition in overall field of vision. Disability glare decreases the perceptual capacity for visual information and it is influenced by the light of the object - direct light shed on desk from above or headlight of car from the opposite direction at night, etc.

Since average luminance of sun reaches about 2 x 109 cd/m2, be cautious in that disability glare may be induced at angle where specular reflection occurs with reflection of sun on object with lucid surface.

2.2 Bi-directional Reflection Distribution Function (BRDF)

BRDF presents the reflection rate for each wavelength of surface material as function in two directions, namely the direction of incident light and reflection light as illustrated in Fig. 1 and it is the ratio of reflection light intensity to incident light intensity. On the premise that most of construction surface material is either Lambertian surface or specular surface, reflection rate of surface is expressed as a single constant. However, in most cases, construction material is not Lambertian surface thus intensity and direction of reflection light differs according to the incident direction of incident light.

Formula 1 (Karner) expresses the reflection rate for each wavelength on surface of material as function of normal angle θ_r and azimuth angle ϕ_r of reflection light and normal angle θ_i and azimuth angle ϕ_i of incident light. When Item λ is removed from the Formula 1, it is becomes BRDF ignorant of reflection properties for each wavelength and it can be simplified as Formula 2.

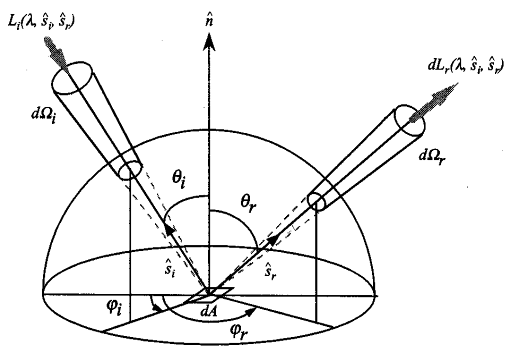

Figure 1 Concept Map of BRDF

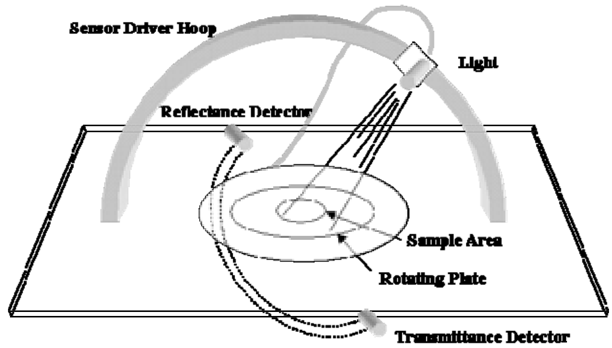

Figure 2 BRDF Meter by Murray-Coleman

$$\rho(\lambda;\theta_r,\phi_r;\vartheta_i,\phi_i) = \frac{L_{\lambda r}(\lambda;\theta_r,\phi_r;\vartheta_i,\phi_i)}{L_{\lambda i}(\lambda;\theta_i,\phi_i)\cos\vartheta_i dw_i} \quad (1)$$

$$\rho(\theta_r,\phi_r;\vartheta_i,\phi_i) = \frac{L_r(\theta_r,\phi_r;\vartheta_i,\phi_i)}{L_i(\theta_i,\phi_i)\cos\vartheta_i dw_i} \quad (2)$$

In here,

$L_{\lambda r}$: Intensity for each Wavelength of Reflection Light [W/sr/㎡]

$L_{\lambda i}$: Intensity for each Wavelength of Incident Light [W/sr/㎡]

(θ_r, ϕ_r) : Angle of Reflection Light[°]

(θ_i, ϕ_i) : Angle of Incident Light[°]

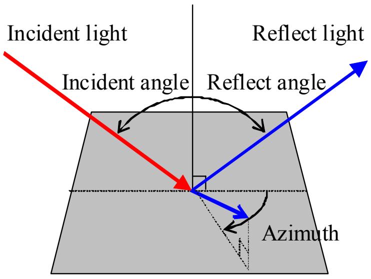
dw_i : Steradian of Incident Light[sr]

As a method to acquire BRDF of material, there are mathematical modeling or experiment (Foo, 1997). Method to acquire BRDF of material through mathematical modeling is to theoretically interpret and apply physical behavior of light on surface of material. Although it is accurate, it is difficult to calculate. Method to acquire BRDF of material through experiment is simple since it actually measures the behavior of light on surface of material and error in measurement can be narrowed down with several measurements with application of Monte Carlo method.

3. Measurement of the Reflection Rate of Exterior Materials

3.1 Outline of Experiment

Definition of incident angle of incident light and vertical (reflection angle) & horizontal (azimuth angle) angle of reflection angle in measurement of BRDF for exterior material sample is as Fig. 3. Define the angle between normal line on sample area of exterior material and incident direction of light as incident angle. In case, incident light is projected vertically on sample area of exterior material, condition is met where incident angle is 0°. Also, define the angle between direction of incident light reflecting on and out of the sample area and normal line of sample area as reflection angle. Direction of incident light going out with specular reflection was set as horizontal angle 0° and direction till 360° was defined as azimuth angle.



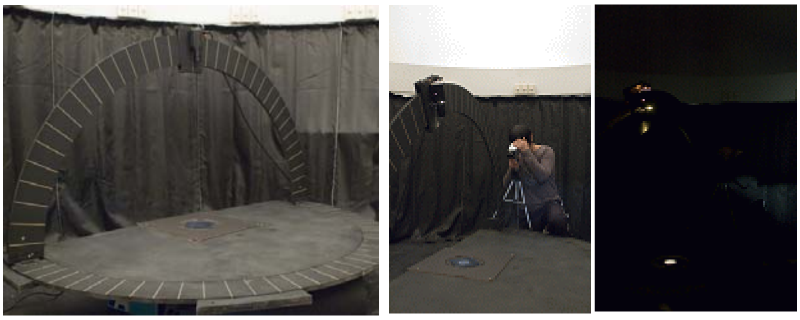


Figure 3 Definition for Location of Incident light and Reflection Light(L)

Figure 4 Form and Actual Measurement of Gonioreflectometer(R)

3.2 Experiment Material

As illustrated in Table 1, measurement of BRDF was carried out with exterior material sample of the building.

Table 1. Specification of Sample for Measurement of BRDF

Section	Sample
Image	Trait	Transparent
Color	Dark Blue

3.3 Experiment Method

Gonioreflectometer (BRDF meter) as illustrated in Fig. 4 was used in the study to measure the BRDF pattern of the sample scheduled to be used as exterior material of the building. The experiment was carried out in artificial sky laboratory that does not receive external influence and equipment used in experiment was painted in flat black to exclude the reflection rate. BRDF meter used in the experiment was self-manufactured to measure the sensitivity for each direction. MR-16 halogen light bulb (50W) was used as standard light source and device that can control the illumination angle of light to make horizontal light as direct sunlight was installed to the bottom of flood lighting. BRDF meter can project light on target from any angle between vertical angle of 0~180° and horizontal angle of 0~360°. Measurement of luminance at certain location is available when placing exterior material for BRDF measurement on the center and changing the vertical and horizontal angle of flood lighting by using BRDF meter.

BRDF measuring reflection rate of reflection angle(0°, 15°, 30°, 45°, 60°, 75°) and azimuth angle(0°~360°, in unit of 30° of reflection light based on change in incident angle (0°, 15°, 30°, 45°, 60°, 75°) of incident light regarding the sample was measured.

3.4 Result of Experiment

As a result of analysis, maximum reflection rate of 88.86% was presented when incident angle of incident light is 75° and reflection angle and azimuth angle of reflection light is 75° and 0° respectively. Also, it was analyzed that trait of propagation and expansion was presented in general. Table 2 illustrates the reflection rate(%) for each reflection angle of sample in case incident angle is 75°.

Table 2. Reflection Rate(%) of Sample when Azimuth Angle is 75°

Azimuth angle / Reflect angle	0°	30°	60°	90°	120°	150°	180°	210°	240°	270°	300°	330°
75°	88.86	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00
60°	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00
45°	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00
30°	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00
15°	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00
0°	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00

3.5 Discussion on Result

Fig. 4 illustrates the reflection rate for each reflection angle in case Azimuth angle of reflection light is 0° when incident angle of incident light of the sample changes. As illustrated in 3.4, the reflection rate was presented to be biggest in most of samples when incident angle of incident light changes and incident angle is same as reflection angle when azimuth angle of reflection light is 0°

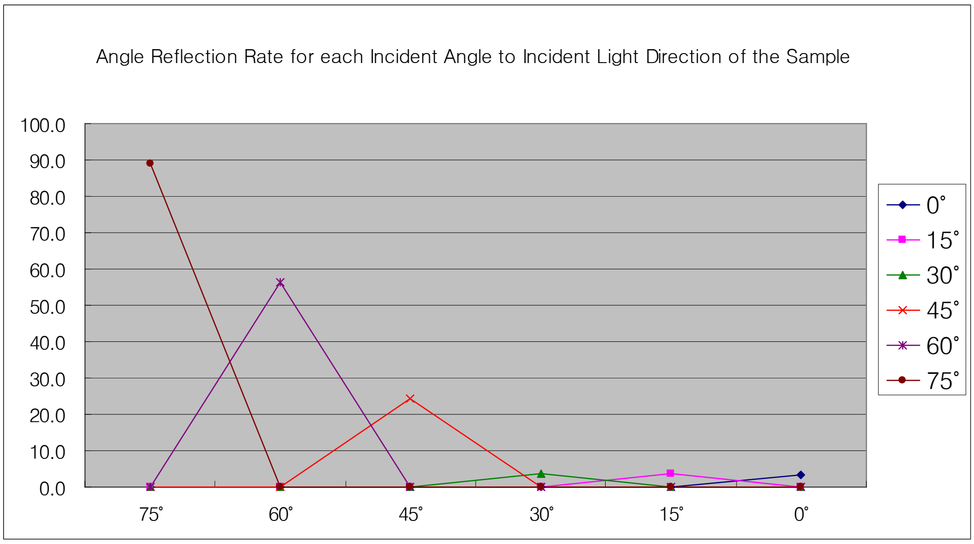

Figure 4 Reflection rate for each reflection angle based on incident angle when azimuth angle is 0°

4. Reflection Area Simulation using Radiance Program

4.1 Location of the Area

Fig. 5 illustrates the horizontal location of the building and the vertical location. Azimuth was set based on true north.

Table 3. Outline of Newly Established Building Y

Classification	Azimuth	No. of Floors	Height of Building	
			34th Floor	Max. Height
Office Building	Southeast 47°	34 Above-Ground Floors	147.2m	160.6m

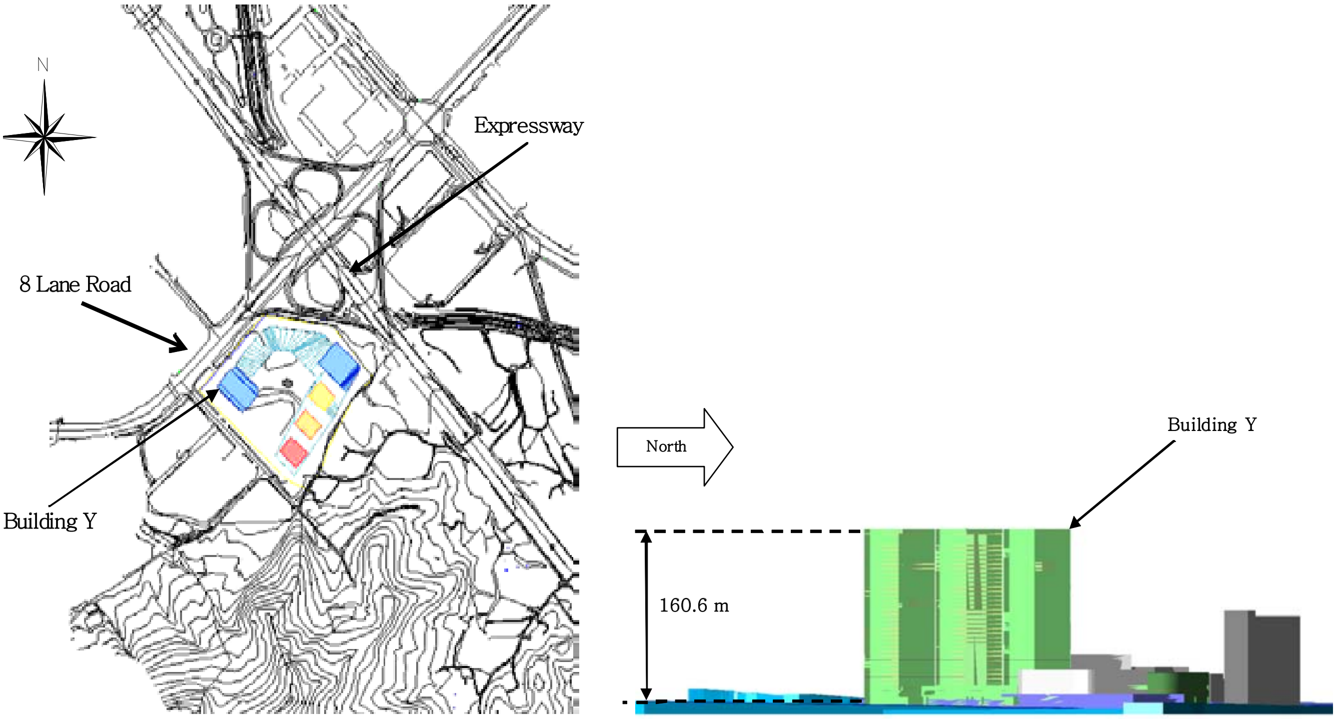

Figure 5 Horizontal Location and Azimuth of the Area (L) and Vertical Location of the Area(R)

4.2 Analysis on Reflection Area for each Month & Glare Visualization Image

Reflection area on representing day (21st) from Jan. to Dec. was drawn up considering the altitude and azimuth angle of sun and glare occurrence observation point was set limiting the range as on road considering the surroundings of the building. 70 estimated glare occurrence points by the reflection light of sun reflected on exterior materials of newly established building for each hour from sunrise to sunset in representing day (21st) of each month from Jan. to Dec were set. These observation points were set within range including the expressway, main road and interchange for access and entrance. A location where the reflection area are within field of vision from the observation point based on the reflection area map was designated as a observation point. To compare the difference in use of exterior materials for the building and high-reflection glass (reflection rate 28%), rendering image of two materials were created through RADIANCE. 4.3 illustrates the reflection area map of Mar. 21st (vernal equinox), Jun. 21st (summer solstice) and Dec. 21st (winter solstice) from Jan. to Dec. Images of estimated glare occurrence points representing each month from 70 points and total 74 instances was inserted. No. of each observation point was set based on order of specular reflection occurrence from Jan.

Table 4. Altitude of Sun & Azimuth Angle on Mar. 21st

Day.	Solar Time	Altitude(α)	Azimuth Angle ϕ)
Mar. 21st	07:00	11.85°	80.74°
	08:00	23.37°	70.64°
	09:00	34.12°	58.67°
	10:00	43.40°	43.48°
	11:00	50.02°	23.76°
	12:00	52.50°	0.00°
	13:00	50.02°	-23.76°
	14:00	43.40°	-43.48°
	15:00	34.12°	-58.67°
	16:00	23.37°	-70.64°
	17:00	11.85°	-80.74°

4.2.1 Vernal Equinox (on Mar. 21st)

It is revealed that the reflection at 10:00~14:00 from the reflection area map of vernal equinox (Mar. 21st) does not have influence on road similar to other season except winter.

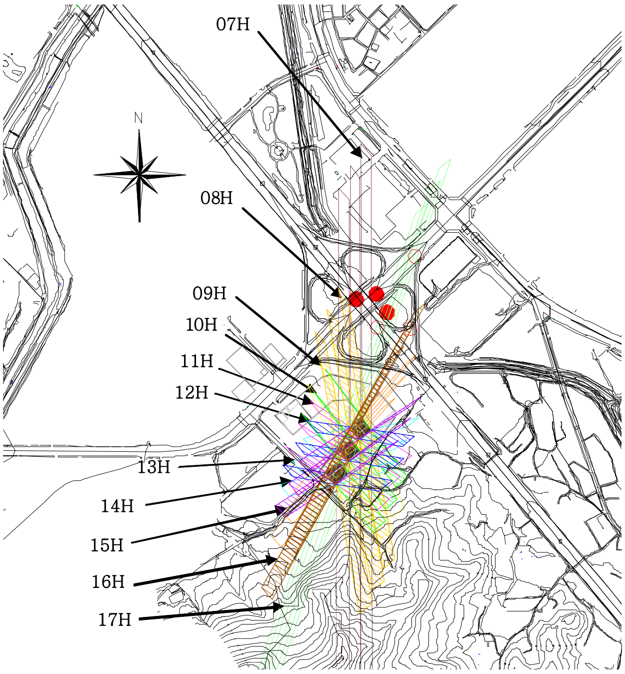

Figure 6 Reflection Area & Observation Point at each Hour on Mar. 21st

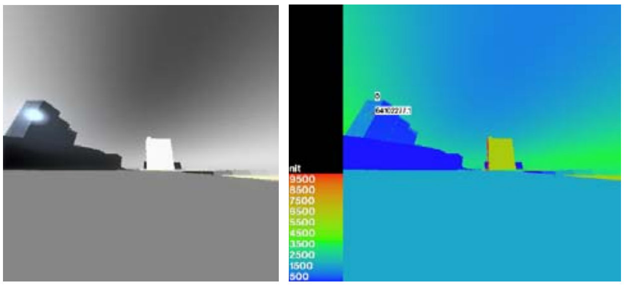
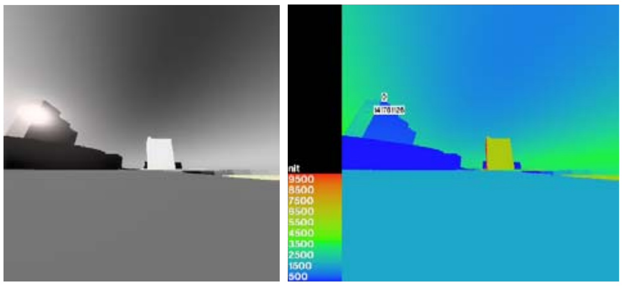


(a) Reflection Rate of 6%



(b) Reflection Rate of 28%

Figure 7 Visualization (L) and Luminance (R) Image at Observation Point 1 (Mar. 21st 07:00)

4.2.2 Summer Solstice (on Jun. 21st)

Glare occurrence point was estimated second most as length of sunrise to sunset is increasing, width of overall reflection area is narrowing down and length of overall reflection area is increasing for the reflection area map of summer solstice (Jun. 21st).

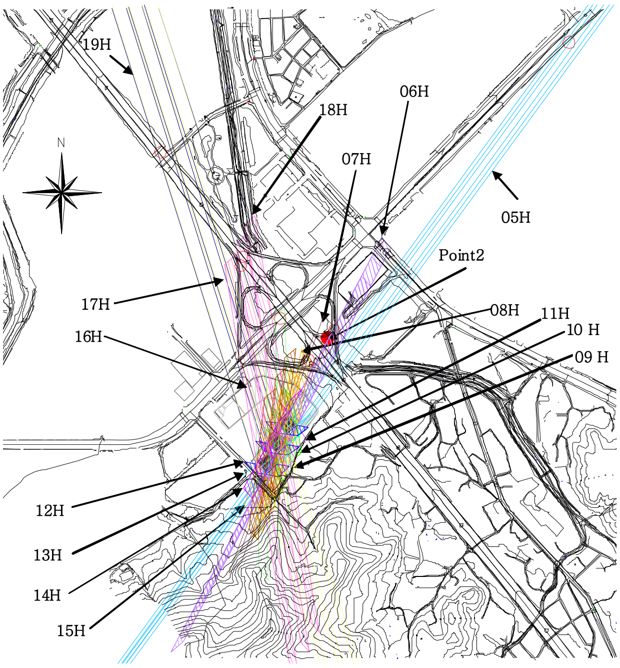


Figure 8 Reflection Area & Observation Point at each Hour on Jun. 21st

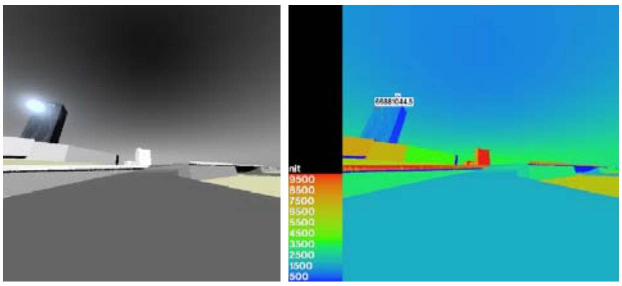
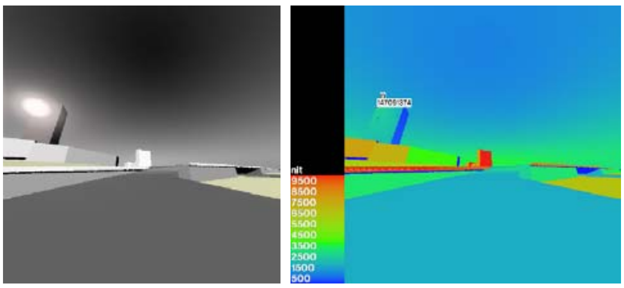


(a) Reflection Rate of 6%



(b) Reflection Rate of 28%

Figure 9 Visualization (L) and Luminance (R) Image at Observation Point 2 (Jun. 21st 07:00)

4.2.3 Winter Solstice (on Dec. 21st)

Direct sunlight reflection of winter solstice (Dec. 21st) was estimated to have influence on expressway and main road at 12:00~15:00. However, it is estimated not to have great influence on driving vehicle since reflected light is projected almost vertical with driving direction except the Observation Point 3 at 13:00.

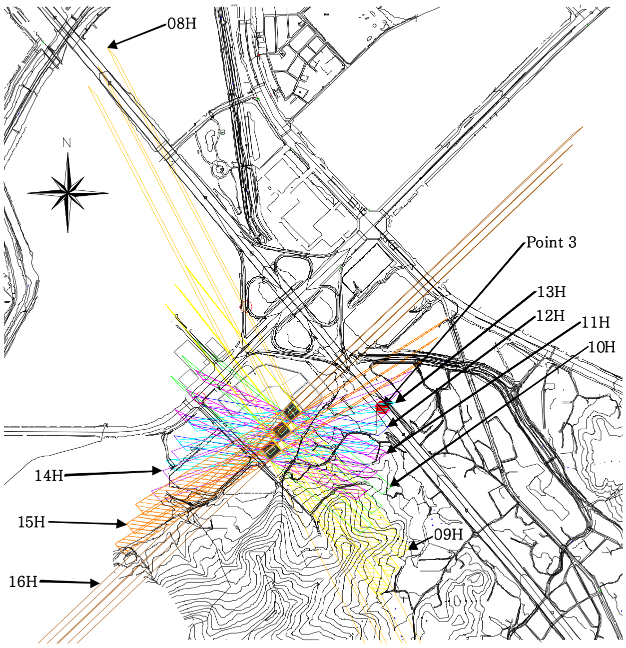


Figure 10 Reflection Area & Observation Point at each Hour on Dec. 21st

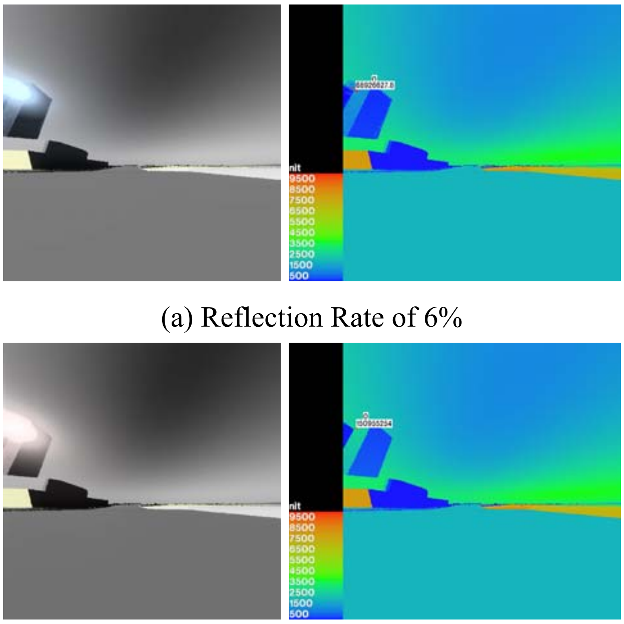

(a) Reflection Rate of 6%

(b) Reflection Rate of 28%

Figure 11 Visualization (L) and Luminance (R) Image at Observation Point 3 (Dec. 21st 13:00)

4.3 Result

As a result of analyzing the glare occurrence by reflection light of sun reflected on exterior materials of the newly established building for each time from sunrise to sunset on representing day (21st) of each month from Jan. to Dec., influence by direct sunlight reflection was estimated for total 70 points and 74 instances. Actual glare occurrence by direct sunlight reflection on exterior materials of newly established building presented to be total 26 points and 26 instances. Since cases where reflection light of sun is directly exposed to field of vision among remaining 44 points and 48 instances is the glare occurred with direct exposure to direct sunlight rather than reflection of direct sunlight on exterior materials of newly established building, it was excluded from the influence of direct sunlight reflection of exterior materials of the newly established building. Also, parts where reflection light is screened by the surrounding buildings and low floors of the newly established building are excluded. As a result of analyzing the month, hour, reflection area, driving direction, etc of glare occurrence with observation point of glare occurrence, it was revealed that glare by the direct sunlight reflection of exterior materials of newly established building mainly occur at 5~6PM in summer on expressway (southeast) and main road (southwest) by the northeastern area of the newly established building.

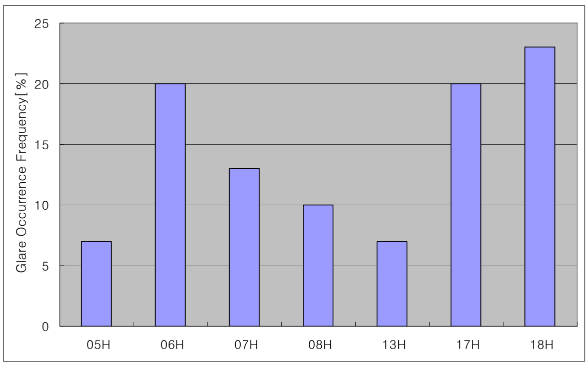

Figure 12 Comparison on Glare Occurrence Frequency for each Hour(%)

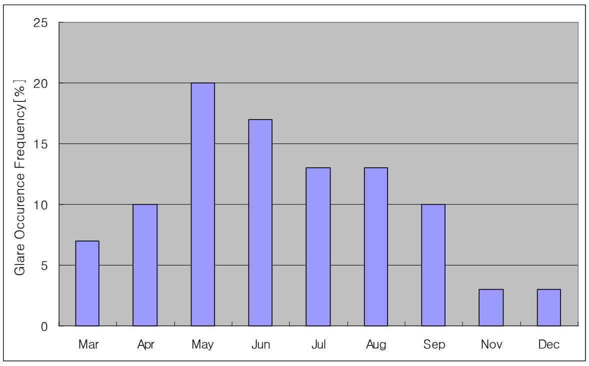

Figure 13 Comparison on Glare Occurrence Frequency for each Month(%)

5. Conclusion

BRDF pattern of sample scheduled to be used as exterior materials of newly established building were measured and analyzed to estimate the visual environment elements that may have influence on surrounding area and adjacent main road as the building is constructed. Total 70 observation points were set with reflection area map and simulation was carried out using RADIANCE to analyze the occurrence of glare by exterior materials of the building in surrounding areas. For the cases where glare is occurred by the direct sunlight reflection of exterior materials of the newly established building, degree of glare influence by low reflection exterior materials (reflection rate 6%) and high reflection exterior materials (reflection rate 28%) was compared and analyzed through simulation.

1) As a result of BRDF measurement of exterior material scheduled to be used in the building, reflection rate was presented high in direction of specular reflection regarding the incident light. Also, reflection rate increased with the increase in incident angle just like general traits of glass. Reflection toward the normal direction of material that presents the reflection rate of glass was 3.32%.

2) Comparing the simulation result of exterior materials scheduled to be used in the building and high reflection (reflection rate 28%) glass, no dramatic difference was presented on image. However, in case of max. luminance value observed at same location, there was huge difference up to 85,958,492cd/m2 on Nov. 21st 13:00 based on the exterior materials of the building.

3) Glare occurrence of estimated glare occurrence observation points projected using reflection area map was determined through simulation using RADIANCE. Simulation analysis/evaluation using RADIANCE based on the analysis on reflection area map is necessary since cases where sun is directly exposed to the field of vision at observation point, glare is blocked by the low floors due to distance between the buildings, etc occur.

4) With the result of RADIANCE simulation based on grasping the reflection traits of the material and reflection area map, it was possible to carry out analysis and estimation on influence of building's exterior materials on surrounding areas. It is expected that in-advance consideration on influence of glare to surrounding areas may be carried out in designing the buildings through above analysis/estimation process.

Summary

Recently domestic construction industry, the needs of construction standardization, construction engineering globalization, and construction informatization are desired for advancing performance system, improving productivity, shortening construction period and reducing cost. Therefore, the development of 3D CAD information's building services design automation system through 3D visualization and informatization of building services design processes is essential in the building services field.

This study is an initial stage for development of BIM based building facility design automation system. The objectives of this study are to understand existing facility design processes, check the feasibility of applying 3D onto major parts, and suggest the direction of system development while considering the analysis of 3D program and BIM.

1. Introduction

1.1 Research Background and Necessity

In recent domestic construction industry, the needs of construction standardization, construction engineering globalization, and construction informatization are desired for advancing performance system, improving productivity, shortening construction period and reducing cost. Therefore, introduction of 3D CAD in building services and computerizations are actively in progress. For building services design, more accurate engineering calculations and simulations are highly requested. Moreover, by computer databasing the collected data during the lifecycle including design, construction, maintenance, and remodeling, its desire to use consistently by steps has increased as well. Due to continuous development of computer technology, calculation capacity has improved greatly while the data processing time has reduced which made it easier for visualizing 3D of the building design plan. Also, development of the Internet allowed no restriction on space limitation which also made real-time cooperation possible. It's because of the realization of practical development due to the improvement of computer processing speed and expression ability with reliability of 3D CAD software and application of building project's lifecycle from the stage where CAD system was just used for existing drawing figures.

As object oriented CAD systems are being introduced, it became applicable to the stages after the building facility design's initial design development such as basic design, detail design, and shop drawing. Also, in order to detect of design problems at the early stage and to reduce the facility design's construction period through virtual simulation, the needs are increasing as an importance of various CAE based simulation. Therefore, the development of 3D CAD information's building services design automation system through 3D visualization and informatization of building services design processes is essential in the building services field.

In advanced countries, researches on the development of new conceptual computer aided design (CAD) tools have been very active based on the above architectural necessities and the development of computer technology. Similar concept applied new generation CAD tools are already being introduced.

This study is an initial stage for development of BIM based building facility design automation system. The objectives of this study are to understand existing facility design processes, check the feasibility of applying 3D onto major parts, and suggest the direction of system development while considering the analysis of 3D program and BIM.

1.2 Research Scope and Methodology

In order to develop BIM based building facility design automation system, reviews on concept of the BIM based building facility automation system and currently used programs are needed. Development of the BIM based building facility design automation system should provide productivity improvement, construction period shortening, and cost reduction through simple building facility design processes of existing mechanical (heat source, air ventilation, sanitary, and fire fighting, etc) and electrical (illumination, electric heat, power, and telecommunication, etc) systems. Therefore, the purposes of this study are to find out the requirements on the development of 3D building facility design automation system and to suggest the direction of research development through analysis of existing building facility design processes and application programs.

Below are the steps for this study.

(1) Study of BIM based building facility design automation system's necessities through theoretical research

(2) Review of BIM based building facility design automation system's concepts through theoretical research

(3) Analysis and study of current BIM based 3D building facility design programs

(4) Review of BIM based building facility design automation system's applicability through analysis of 3D building facility design programs

(5) Derive problems and improved plans during above steps and to suggest direction of the future research developments

2. Theoretical Study

2.1 Necessities of BIM Based Building Facility Design Automation System

The basic concept of BIM based 3D CAD building facility design automation system is to draw 3D drawings by using 3D program based on line and face, 2D drawings, by using 2D programs. These 3D drawings contain object information of machines, materials and, equipments used for building facility. Also through the virtual construction simulation, it allows to check errors and interferences during the facility construction for revision through preview which supports to estimate the facility design processes. The saved object information makes it possible to estimate the cost automatically by calculating the amount of materials through information sharing of each process.

BIM based building facility design automation system reduces the design changes from planning to construction stages and increase its work efficiency by checking the work progress of each process steps. Moreover, increase in work efficiency reduces construction period, increases productivity, and reduce cost as well as increase the quality. However, there are some problems for constructing BIM based building facility design automation system at the moment. In order to solve these problems, review of BIM based building facility design process model's applicability through analysis of 2D building facility design processes. Also, construction of 3D based building facility library, construction of DB by equipment capacity based on equipment capacity estimation and role analysis for building's load calculation automation, review of applicability on automation system for estimated construction cost calculation and improvement of real-time cooperation environment between different parts through network are desired.

By solving these problems through the development of building facility automation system, it can improve the construction project's lifecycle efficiency including facility processes. Therefore, it's highly required for development and competitiveness of domestic building and construction industry.

2.2 BIM and 3D Based Building Facility Design Automation System

Existing 2D programs expressed objects simply as graphical components. These drawings required a lot of time for generating drawings due to change of building designs. Also, there were lots of problems to solve errors due to change in object information. In order to overcome these problems, BIM(Building Information Modeling) solution uses parametric method which reflects all the amendments occurred during work processes which also prevents from omissions and errors from amendments in advance.

By using BIM, the building objects (wall, sleeve, window, door, roof, stairs, etc) contain each property (function, structure, use, material characteristics, etc), recognize its relationship, and reflect building's changes. Based on these, IBM emphasizes that it can construct high quality and low cost buildings with prompt processes including design, construction and maintenance and there are cases regarding to it.

Not just graphical components but also providing information management environment is the major advantages of BIM that includes building facility.

BIM automatically generates and provides various information such as material quantity, cost, schedule, and material list as well as the analyzed data of structure and environment. Through these, it enablers accurate and prompt decision making. Moreover, management environment through BIM provides effective sharing of all the information of building's lifecycle while supporting to solve problems such as data loss, data re-entry, and data redundancy which makes it efficient to manage all the information.

Figure 1 shows some functions of Bentley's BIM solution. During designing stage, all the data of architectural, mechanical, structural, electrical parts can be shared through Internet on the ProjectWise server. Also, during this stage, it can visualize 3D design plan through Navigator as well as check the interference of the parts. For generating duct drawing of mechanical parts, Trane's or Bentley's duct calculating program can be used and enable shop fabrication of duct using CAM(Computer Aided Manufacturing). After the design plan is completed, 3D visualization simulation of construction processes based on the schedule can be executed. BIM data firstly constructed in design stage and added or amended in construction stage can be used at the maintenance stage through facilities server.

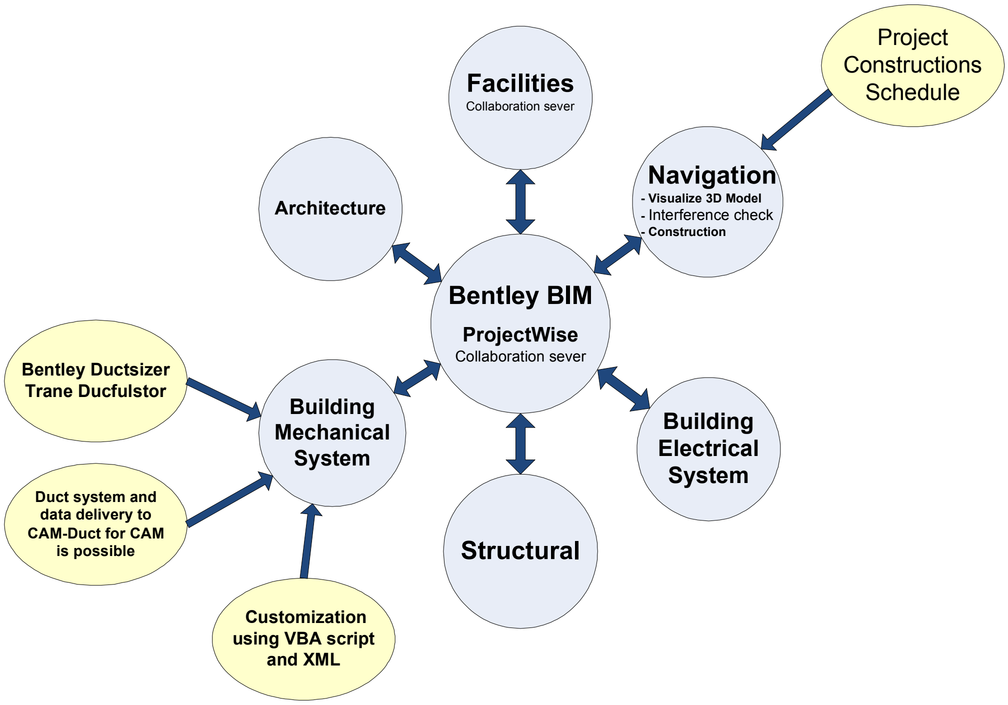

Figure 1 Example of Bentley BIM's Functions

Figure 2 explains the BIM's various application fields and shows that the entered data in BIM can be used consistently and constantly through the building's entire lifecycle from building project's planning stages to regulation review, planning, simulation, specification and statement generation, material purchase, construction management, facility management after construction completion, and building demolition.

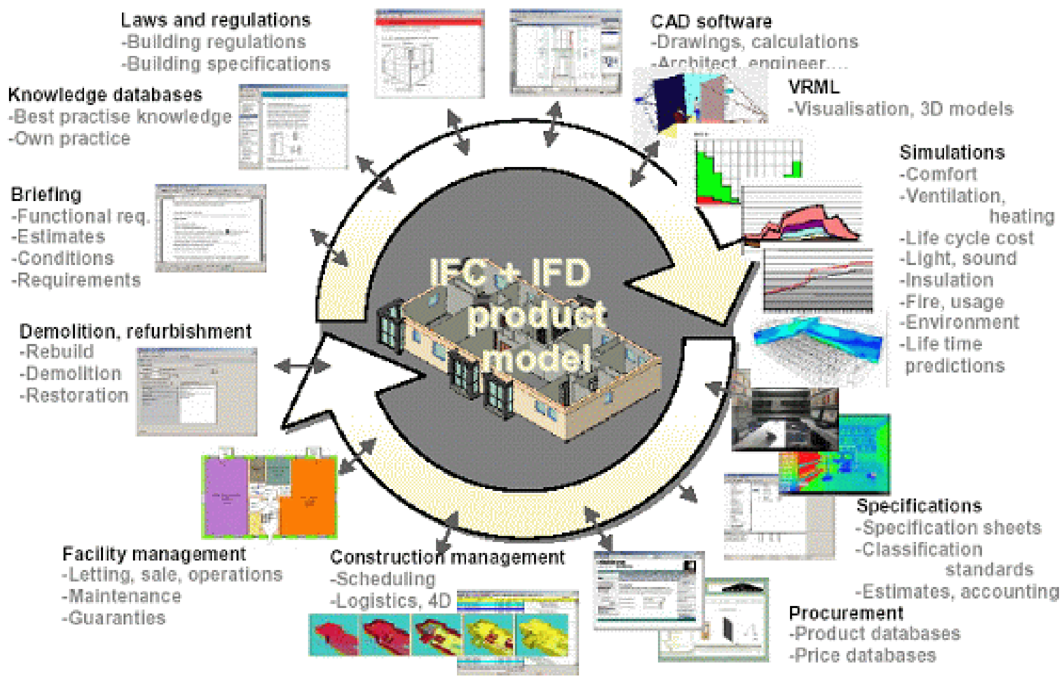

Figure 2 BIM's Application Fields

2.3 Analysis and Study of Currently Used BIM Based 3D Building Facility Design System

This is a CAD tool with BIM concept. Programs that are introduced and on sale in domestic market are ArchiCAD, Revit, and Microstation and for building facilities, there are DDS-CAD, RevitMEP, and Bentley Building Mechanical/Electrical System.

Table 1 shows the summary of program major features and functions indicated in PR brochure. While considering that the required functions in the building facilities field are more standardized than other design fields, it seems that there are similar functions in three different programs even though they are not indicated here. Moreover, as the BIM's standard is not positioned yet and all of the three programs contain too many functions to be used for building facilities in domestic market, it's difficult to discuss and make discrimination between the programs.

Figure 3 and 4 shows the building facility work processes in 3D using GFAPHSOFT's 'ArchiCAD'.

Figure 3 is the drawing of redevelopment complex new building site in Mapo area. Left drawing is the 2D(AutoCAD) drawing of 77py, B type electric/telecommunication PVC which is difficult to check the interference to distribution panel board between electrical pipe. The right drawing, on the other hand, through the virtual construction of 3D modeling, it is easy to check the interferences of piping and easy to select the location of PVC Box location based on the piping interferences.

Figure 4 is the case which mechanical/electrical parts are virtually constructed in 3D and checked and amended the electrical tray interferences in advance. Samsung Corporation's Seocho project, Space in Sajik-dong, and Korea Chamber of Commerce & Industry are the cases using ABS(Autodesk Building System) and mostly applied in design review, interference check, virtual construction simulation of mechanical room, basement floor, and AHU. Likewise, through virtual construction of building facility related duct piping, spring cooler, telecommunication tools arrangement, mechanical/electrical room equipment arrangement, it can not only increase the construction efficiency but also check design error and interference between processes in advance which prevents from reconstruction and minimizes the delay time as well as save cost and shorten the construction period. However, while using the 3D programs on the site, some problems were found.

First of all, there was a lack of 3D based building facility related tools and material's library. Also, there was a compatibility problem on parametric information between 3D programs. In order to solve this kind of problems, design guideline and standard on model construction through study of 3D based library modeling and tools and models on materials are suggested and for most of libraries in future, it can be manufactured in-house and distributed by tool and material producing companies. Moreover, there's a need for research on detail parametric information of IFC(Industry Foundation Classes) based facility materials and tools.

Table 1 Integrated 3D CAD Program Review Table Considering BIM

Classification	Program	Features
Revit	Revit MEP	- Auto 3D model generation - Parametric modeling selection - Engineering calculation of mechanic and electric facilities - Revit building and Revit structure
ArchiCAD	DDS-CAD	- Auto 3D model generation - Mostly used in Europe - Engineering calculation of mechanic and electric facilities - Database construction on Europen maker's machine and equipment
Microstation	Bentley Building Mechanical /Electrical Systems	- Auto 3D model generation - Existence of other part programs (Architecture, Structural, Facilities) and compatible with each other and includes design, construction, maintenance, etc - Customization using VBA script and XML - Construction simulation using project management tool such as Microsoft Project - For mechanical part, sizing and analysis on pipe and duct system and data delivery to CAM-Duct for CAM is possible

Figure 4. Interference Check of Mechanical/Electrical Room's Major Parts

Building facility design related 3D based program's application field and functions are as below.

(1) 3D Modeling
- Building facility visualization: Pipe and duct, machine and equipment
- Advance checking of drawing error and interference of processes

(2) BOM Computation

(3) Engineering Calculation using Object Property Information and Location Information
- Pipe sizing & analysis
- Duct sizing & analysis
- Air-conditioning load calculation

(4) CAM
- Duct manufacturing

(5) Construction Simulation
- Connection with construction schedule

(6) Just In Time Delivery
- Machine and equipment

(7) Facility Management

3. Applicability Review of BIM Based Building Facility Design Automation System

At the moment, design office has the most interest in CAD and by setting up the BIM based 3D CAD program review items based on design works, it can be classified into 3D visualization using BIM data, engineering analysis/simulation, statement automatic generation and code check functions.

Evaluation of BIM based building facility design program functions is as Table 2. In table 2, the mid generation, AutoCAD MEP was also included and compared. It was to relatively reduce its unfamiliarity of existing AutoCAD users changing to other CAD tools. For program's applicability review, there were three classifications including classification on 2D and 3D modeling, analysis through engineering calculation, and construction cost estimation. Also, realization of requirements on required data was review using 'AutoCAD MEP', 'ArchiCAD', and 'Revit MEP' program.

(1) 3D Visualization

3D visualization using computer existed even in the past but it was just for visualization instead of building objects (e.g. wall, window, boiler, AHU). On the other hand, the difference of visualization using BIM based 3D CAD program is that building object itself can be visualized instantly. For building facility field's case, piping, duct, machines and tools can be visualized which allow to check the interference and it's easier to make the manager understand the design plan by showing the complicated drawings in to 3D.

(2) Engineering Analysis and Simulation

By using object property information and geometrical information entered in BIM data, energy analysis, equipment capacity calculation, indoor air simulation, air environment simulation, fire safety evaluation simulation through equipment's (air conditioning load calculation, piping system analysis, duct system analysis, freezer inside the building, cooling tower, boiler, AHU) organic relationship analysis is possible. Some parts of these analysis functions would be directly made by the CAD tool developing companies but it's assumed that most of the parts are created by related professional companies. It's because BIM data can be easily extracted with professional company's program by IFC.

(3) Details Automatic Generation

Details automatic generation function existed in past but due to BIM's existence, it can be generated easier and more accurate.

(4) Regulation Review

It's not applied in domestic system yet and it's very difficult to use as developed in foreign countries. However, if this function can be used properly in the domestic system, it's assumed that the building related various permission works can be simplified and transparent.

Table 2 Program Review for 3D Based Building Facility Design Automation

Requirement		Required Data	Support of Existing Program			Improvement Required Part for Domestic Application
Classification	Sub-classification		AutoCAD MEP	DDS-CAD (ArchiCAD)	Revit MEP	
2D Drawing and 3D Modeling	Tool/Equipment 2D drawing/view	Tool, equipment 2D library	○	○	○	○
	Tool/Equipment 3D modeling	Tool, equipment 3D library	△	△	△	◎
	Pipe 2D drawing/view	Pipe, valve 2D library	○	○	○

4. Suggestion on Development Direction of BIM Based Building Facility Design Process Automation System

For system development, understanding of current 3D based facility design system, development trend analysis, existing facility design process analysis, and analysis of required functions for system development are required. Moreover, in order to construct BIM based 3D object library on 3D based facility machines and materials that fits into domestic situation, guide on construction plan with suggestion on standard model should be along with the IFC model standard.

Through library construction on building facility design process automation system's modeling and pilot test, application of system based on the development and its evaluation should be accomplished. Also, system R&D that allows prediction and analysis on building facility environment should be accomplished.

In order to suggest system development direction, the research directions on the 3D building facility design automation system modeling through analysis of existing building facility design process are established as below.

Firstly, select the 3D program that allows programming and user setup function that can add required function between facility design processes for using BIM which enables information sharing of construction project's entire lifecycle. Moreover, construction method for functions on building facility related tools and materials' detail parametric information data saving and information data on 3D based object properties (density, heat conductivity, emissivity, etc) of wall, roof, glass are suggested. Furthermore, by using these object property detail information, automation on equipment capacity selection through building's air conditioning load calculation, programming development after review the relationship with equipment roles and equipment capacity DB construction plan that fits into domestic situation are also suggested.

Secondly, consideration on the applicability of automation system for construction cost estimation and compatibility with estimation related automation system should be developed. Applicability of the automatic cost estimation generating program on details should be reviewed through various data analysis and derive of estimated construction cost's major influencing factors. Currently, construction cost standard is being preparing by analyzing the construction cost detail data based on direct construction cost standard data. Also, linkage to quantity calculation and estimation related automation system is in review.

Thirdly, in order to use BIM based program in mechanical and electrical field, real-time work through information sharing of each processes is required and therefore, the need for real-time cooperation using the network is required. For smooth information sharing of processes with other fields, compatibility of data became the problem. This can be done through construction of IFC based 3D object library. Currently, development on compatibility between IFC related various programs are actively in progress domestically and internationally. It's assumed that the development of IFC module which is compatible with 3D object's property information can solve this problem.

5. Conclusion

This study is a basic research for the development of BIM based building facility design automation system and was accomplished for the purpose of suggesting the development direction. Therefore in this study, concept and necessity of development through theoretical study for BIM based building facility design automation system development was studied. Based on the analysis and study on the BIM based building facility design program, BIM based building facility design automation system's development directions based on derived problems of applicability review were suggested. Summary on the developments are as below.

(1) Analysis of building facility design related BIM based program application field and required functions

(2) Review and selection of integrated 3D CAD program considering BIM

(3) Select additional functions of applicable filed considering selected 3D program

(4) Development review of engineering analysis/simulation using BIM data

(5) Development and review of details automatic generation and regulation review function

(6) Analysis and construction of library that fits into domestic system

At the same time, development of building facility design module system through analysis of building energy consumption using building facility environment's (heat environment, voice environment, air environment, light environment) computer simulation should be reviewed. Moreover, in order to survive in domestic and international construction industry in future, development of the essential technology should be also progressed.

Keywords: condominiums, operation and management, Taiwan

Summary

For existing houses in Taiwan, condominiums are a very important building type and the number is increasing. To ensure the living environment quality and value of existing building stock, sound operation and management is the basic requirement to be met. Therefore, this study adopts comparative study to compare the operation and management of condominiums in Taiwan and Japan in order to clarify the issues of operation and management of condominiums in Taiwan as reference of ensuing solutions of improvement. The issues discussed in this study include: keeping management organization, community empowerment, general administrative affairs, financial management, and built environment management. The basic data of condominiums in the part of Taiwan is acquired from an empirical survey conducted by this study, and the part of Japan is acquired from references. The findings show that, overall, the condominium operation and management in Taiwan is poorer than that in Japan. Particularly in capital improvement program, collecting funds and recordkeeping of operation and management documents, one can see a significant lag. Moreover, the researcher also finds that residents in the condominiums in two countries have encountered similar problems in condominium living.

1. Introduction

In accordance with Taiwan Agenda 21: Vision and Strategies for National Sustainable Development (Council for Economic Planning and Development, 2004), sustainable development is a major policy that Taiwanese government is progressively promoting. From Housing Condition Survey 2006 (Construction and Planning Agency [CPA]), 2006, number of the total houses in Taiwan is 6.38 million in which condominiums account for 32.1%, the only type of houses is continuing growth. Condominiums are, as a result, a major type of houses in Taiwan. In light of condominiums operation and management, this study believes that, to have sustainable development of living environment quality and value of existing building stock, the main strategies are "to conducting appropriate daily operation and management provides deserved service quality of condominiums. At major refurbishment and replacement, sustainable building concept is introduced to make decisions in order to enhance the sustainability and use value of condominiums". Based on the preceding concepts, this study considers appropriate operation and management of condominiums is the basis of sustainable development of condominiums and also greatly affects the sustainability of overall living environment in Taiwan.

On the basis of preceding viewpoints, this study conducts an empirical survey of current status of condominium operation and management in Taipei and Kaohsiung, two major urban areas of Taiwan. The findings are then compared with those in Japan to clarify the issues of operation and management of condominiums in Taiwan. The findings of this study will serve as reference for the government competent authority in making the decisions of proposed improvement and as the fundamental data of sustainable refurbishment and replacement of condominiums in Taiwan.

In regards of work fields of operation and management of condominiums, based on the articles of Condominium Act (2006), this study divides them into two major fields—keeping management organization and community empowerment related to operation of condominiums with general administrative affairs, financial management, and built environment management (including building maintenance, security management and cleanliness management) related to management of condominiums. These five are the major works of survey and statements in this study.

2. Investigating the current status of condominium operation and management in Taiwan

This study conducted a questionnaire survey to investigate the current status of condominium operation and management in Taiwan. From the statistics of Construction and Planning Agency in June 2004, the total number of registered condominiums in Taiwan is 12,819 with 7,972, or 62%, in Taipei and Kaohsiung urban areas. The samples of this study were taken from condominiums with registered management organization in these two areas. Due to without distinctive different in the modes of operation and management of condominiums in Taiwan and limited study resources, effective size of samples in this study is no less than 30 condominiums in each area for random survey. Each condominium chosen for the survey received one questionnaire for the management committees and three questionnaires for the occupants.

Questionnaires for management organizations include current status of condominium operation and management, satisfaction level with the operation and management of condominiums and satisfaction level with and expectations of the assistance from the government. Those for occupants include satisfaction level with the operation and management of condominiums, troubles encountered in condominium living, satisfaction level with and expectations of the government's assistance, and long-term desire to live in the condominiums.

The questionnaire survey was administered between January and May 2006. A total of 92 effective samples for management organizations (51 from Taipei and 41 from Kaohsiung) and 176 effective samples for occupants (98 from Taipei and 78 from Kaohsiung) were collected.

Regarding the characteristics of condominiums, the condominiums were constructed between 2 to 30 years ago, the average being 12 years. Most of the condominiums were between 9 and 14 years old. Further, most of the condominiums are above 15 stories (48%), followed by 6–14 stories (40%).

Regarding operation and management modes, 16% are owner management mode; 70% are partial company management mode and 14% are complete company management mode. In partial company management mode, the most contracted works is building maintenance account at 80%, followed by security services at 55%, cleaning services at 50%, general administrative affairs at 16% and financial affairs at 15%. Moreover, 71% of the management committees have tenure of one year per term. In addition, 63% of the management committees have a limited number of renewable terms; of these, 77% are renewable for one term.

Regarding the characteristics of the 176 effective occupant samples, the effective occupant samples are primarily nuclear families (86%) and comprise 3.62 members on average. The average dwelling area of a unit is 41.0 m^2/ person.

3. Comparisons of current status of condominium operation and management in Taiwan and Japan

Taiwan is close to Japan geographically, and frequent exchanges of information take place between these two countries. Development of legal frameworks of condominiums operation and management in Japan is much earlier than that in Taiwan.

However, the legal frameworks of condominiums in Taiwan and Japan are both in continental European legal systems and are very similar. Comparisons of current status of condominium operation and management in the two countries will help identifying issues of condominium operation and management in Taiwan. From the analysis construct in this study, differences between the two countries can concluded in Table 1. The sources for facts in Taiwan are the findings of this study and that in Japan are references from the government of Japan.

A. Operation of condominiums

Close to 90% of condominiums in Japan are in complete company management mode, proving high professional development of operation and management of condominiums in Japan. Holding meetings of the owners in two countries are quite the same, although management committee meetings are more frequently held in Taiwan. The reason is that less than 14% of condominiums in Taiwan are in complete company management mode, forcing management committees spend more time to the condominium operations. Also, promotion of condominium bylaws in Japan is better than that in Taiwan. Most of condominiums in Japan have already established their own condominium bylaws.

In community empowerment, Japan has less community activities. However, occupants have stronger long-term intension to live in the condominiums. Condominiums in Japan also coordinated activities related to the prevention of disasters more frequently than did those in Taiwan.

B. Management of condominiums

Overall, condominiums in Japan perform better in general administrative affairs, financial management and built environment management than those in Taiwan do. The most distinctive different between the two countries is capital improvement programs in Japan far exceeds those in Taiwan in the program establishment and financial preparation, which can be proven from over 80% of condominiums in Japan had established capital improvement programs and ratio of sufficient collecting funds close to 70%. Moreover, keeping of drawings and specifications of buildings in Japan is much better than that in Taiwan.

C. Others

Japan had a higher number of occupants satisfied with the overall operation and management of condominiums than do Taiwan. This corresponds to the results of comparisons of current status of condominium operation and management between the two countries. Moreover, the three major things bother the occupants in the two countries include residents owning pets, parking against regulations and neighborhood noises. However, the rankings in two countries are different. The serious one in Taiwan is residents owning pets and that in Japan is parking against regulations.

Based on the survey of this study, only around 15% of the occupants are satisfied with the assistance from the government in operation and management of condominiums. They think the government should adopt measures to improve its assistance toward the condominiums to promote the development of condominium operation and management. The highest priority is offering related information on the current status of operation and management of other condominiums and then subsidizing. What the government has been paying most attention to, improvements in legislation, ranks the bottom.

Even though Japan has better current status of condominium operation and management, to ensure living quality and value of existing building stock, Japan still has made reforms in recent years. In the improvement of legislation, Japan has reviewed and amended relevant legislation on the issues of operation and management of condominiums under social development such as keeping building maintenance records, community empowerment, and occupants failing to pay common expenses as well as troubles encountered in condominium living. In addition, on information policy tools improvement, the government of Japan also offers required information, consultation service and education training through government institutes and NGOs. In economic policy instruments, the government of Japan offers fund subsidizing through banking institutions and programs to major refurbishment and replacement of condominiums. Based on the preceding, Taiwan performs more poorly in preparation of information and economic policy instruments than does Japan, which can be proved from the fact the occupants of condominiums request the government to enhance works of promoting the development of operation and management of condominiums.

Table 1 Comparisons of Current Status of Condominium Operation and Management between Taiwan and Japan

Issues of condominium operation and management		**Taiwan**	**Japan**
Operation of condominiums			
Keeping management organizations	Complete company management mode	14%	89%[*1]
	Holding meetings of the owners in one year	98%	99%[*1]
	Holding more than one management committee meetings in one month	86%	41%[*1]
	Establishment of Condominium Bylaws	86%	≒100[*2]
Community empowerment	Held community activities in one year	84%	55%[*1]
	Fire drills held in one year	36%	38%[*1]
	Intention of moving by occupants	48%	27%[*2]
Management of condominiums			
General administrative affairs	No keeping of drawings and specifications of building	22%	3%[*2]
Financial management	Condominiums have more than 5% of the total occupants paying common expenses behind the due date	8%	6%[*2]
	Collecting funds meeting future demand	Almost none	78%[*2]
Built environment management	Establishment of capital improvement programs	Almost none	83%[*2]
Others			
Satisfaction of operation and management	Satisfaction of occupants of current operation and management	48%	61%[*2]
Troubles encountered in condominium living	Residents owning pets	43%	49%[*2]
	Parking against regulations	31%	56%[*2]
	Neighborhood noises	27%	52%[*2]

4. Conclusions

In the issues of condominium operation and management in Taiwan, composition of management organizations basically conforms to the legislation of Taiwan. However, the promotion of condominium bylaws is not thorough. In community empowerment, occupants do not have long-term intention to live in the condominiums and they have weaker community awareness. As for general administrative affairs, poor recordkeeping of condominium operation and management documents will fail to support condominiums to do maintenance, refurbishment and replacement. In built environment management, maintenance of buildings is not duly made and almost all condominiums lack of capital improvement programs. In financial management, balance of common expenses is basically acceptable. In light of long-term operation and management of condominiums, insufficiency of collecting funds will not sustain the future refurbishment and replacement in the future. On the other hand, only less than 15% of occupants are satisfied with the assistance from the government in condominium operation and management. They desperately hope to obtain the information of operation and management of other condominiums for their reference and subsidy of funds.

Based on the results of this study, we propose following improvements for operation and management of condominiums. First, for management organizations of condominiums, they must duly establish and execute the operation programs and enhance promotion of community activities in order to strengthen the community awareness. Secondly, they must have proper daily maintenance of condominiums to ensure the sound service quality and public security. Thirdly, they are required to establish long-term improvement program and have sufficient collecting funds to meet the needs of refurbishment and replacement of condominiums, and then enhance use value and sustainability of condominiums. Finally, the government, in addition to enhancing preparation of information and economic policy instruments of condominium operation and management, must aggressively help condominiums without management organizations to expedite establishing management organizations, and subsequently, promotion of the overall development of condominiums to achieve sustainable development of the living environment.

THE RATIONAL FOR TENANT CENTRIC BUILDING MANAGEMENT TOOLS

Jalkotzy, Christoph[1]

[1] Sustainable Development Specialist, Planning By People, Ottawa, Ontario, cjalk@rogers.com

Keywords: behavior, commissioning, guide, building, green,

Summary

Cultural change is a key component of the development of a sustainable society. The social environment, physical surroundings and innate behavior affect people's behavior. The combination of these aspects plays an important role in the evolution of the human species to a sustainable behavior. Social marketing, behavior of influential members of society, the cultural upbringing and advertising form much our social environment. The design of buildings, urban communities and cities affects the individual in their ability to act sustainably. The genetic character of our brain affects our wants and needs based on the evolution of the brain that made us into a successful species.

This paper explores the influence of these three components on our behavior and the rational for a Tenant Centric Building Management Tools. Surveys have shown that employees are not inclined to participate in sustainable activities if their bosses don't visibly participate. Studies of children have shown that they are influenced more by their peers than parents. Advertising is researching the neurological character of the brain and tests ads out using MRI scans to determine whether an ad is effective or not. We already know that the participation of tenants in the design of green building changes the design as well as behavior. The brain has a high level of plasticity. In addition, much of our most complex problem solving happens in our subconscious. Both the physical and social environment can have a dramatic effect on our subconscious thought processes.

1. Introduction

The foundation of human behavior is the subject of great debate. The role of nature vs nurture vs god in forming the way we act will always be controversial. None the less, it is our species behavior that has created a great civilization and is also the key to eliminating our species over exploitation of Earth. In "Occupant Participation in Green Building, 2005" I provided a brief outline as to why and how tenants could be integrated into the design and management of a building. At SB07 Toronto, Anthony Hillard, Chris Caners and I participated in a plenary session discussing "Developing a Sustainability Culture". In "Rewire: Changing Habits, Changing Minds" (Caners) looks at the University of Toronto's "Rewire" program aimed at changing the behavior of U of T students through Social Marketing. In "Can Human Factor Methods Help Design Sustainable Buildings? (Hillard) looks at how the physical design of space affects human behavior. The presentation "Neuroscience and Sustainability" (Jalkotzy) investigates the role of the evolution of our brain on our behavior. "The Blank Slate" (Pinker) also suggests that our behavior is a function of the social environment of our upbringing, the social and physical environment we are currently immersed in and the physiology of our brain.

Commercial buildings are designed so that people can accomplish a task efficiently and effectively. Most manuals that provide advice for Building Managers are centered on the optimal management of the building from the owners and/or managers perspective. However, it is the tenants at we want to satisfy, so it would be logical to manage the building from the tenants' perspective. This report outlines the basic requirements for a tenant centric building operational manual. It includes the broad management principles and techniques that that will enable a building manager to operate a "green" building in a "green" way. This includes recommendations on how to develop green stewardship in the building; conduct assessments of the building's sustainability and design renovations. All of the recommendations are based on the authors understanding of human behavior and incorporates all three human behavior drivers; the physical environment, the social environment and the physiology of the brain.

This outline of a "tenant centric building management manual" is divided into four parts. Part one provides a description of the people in the building and their general roles. Part two outlines the physical environment of the building. Part three describes the general social environment. Part four provides recommendations on how to manage the building from a tenant centric perspective. The operation of the facility is reviewed during the two basic stages of a building; conception and operation. It takes the perspective of the tenant.

2. People in the Building

2.1 Groupings

A commercial building is built to house people to produce a good and/or service. A building goes through three basic stages in its life. Stage one is the design and construction of the building (conception stage). Stage two is the productive life of the building (operating stage). Stage three is the eventual its eventual death (demolition stage). The demolition stage of the building will not be discussed. There are three groups of people involved and /or resident in a commercial building. In each stage, the three basic groups of people remain the same, their composition changes somewhat. These three groups can broadly be characterized as the following: a) the people for whom the building is designed built and is being operated; b) the people that assist the first group in organizing themselves as a functional unit and c) the people that design, maintain and operate the building. The tenants are usually thought of as group a) and b). The building owners, operators and designers are group c). The tenants are divided into a) and b) because their role in the building is quite different.

Group a) directly produce the good and service that the building was designed to produce. In the case of a car factory they are the individuals that make the cars or in the case of a bank building they people who manage and administer bank accounts.

Group b), even though they are also tenants, are the people that ensure that group a) can operate efficiently and effectively from a governance perspective. They are the managers, human resources personnel, planners, strategic thinkers and policy makers that ensure that group a) can achieve the organization's production goals, whether these are reports or cars.

Group c) are the people who create the building, ensure that the building protects the occupants from the weather, possible feed at nourish the occupants and plan the continual operation and maintenance of the building.

For simplicity group a) is referred to as the "tenants", group b) is referred to as "managers" and group c) as "operators".

2.2 Current Roles

During the two stages in the life of the building there are different roles for each group. Only the "tenants" are made up of the same people during all stages. The "operators" and "managers" groups have slightly different people involved at the three stages. Current roles are divided into two approaches. The first description is when a building is built for a specific organization which would include "tenants" and "managers". The second description is when a building is built "on spec" or the organization that intends to lease the building comes on board during the construction.

2.2.1 Building for a Specific Organization

2.2.1.1 Conception Stage: The "managers" are made up of senior directors in the organization and the people specifically responsible for accommodation. Depending on the size of the organization an individual or group may be responsible. The "operators" are made up of the designers such as architects and engineers, constructors and people financing the building where an organization will lease the building. Where the building will be owned by the organization there are no financers

The "managers" of the organization work directly with the "operators" to design and construct the building. The "tenants" work with the "managers" to develop the functional program.

2.2.1.2 Operation Stage: The "managers" are made up of the of senior directors, human resources department, the organization's planners and strategic thinkers, trainers and any other personnel involved in ensuring that the "tenants" are able to produce the good and service the building is intended to for. The "operators" include the building's maintenance personnel, services within the building such as food preparation, the owners of the building where the organization is leasing the building and any personnel directly related to ensuring the building functions for its intended purpose.

The "operators" operate the building in such a fashion that the "tenants" are able to function to produce the goods and services intended. The "managers" ensure that the corporate governance (social environment) for the organization is such that the "tenants" function.

2.2.2 Building on Speculation (in this case there is no specific tenant only prospective tenants):

2.2.2.1 Conception Stage: The "managers" are made up of the "operators" sales and senior personnel. The "managers" may also be an independent real-estate sales organization. The "operators" are made up of the designers such as architects and engineers, constructors and people financing the building where an organization will lease the building. Where the building will be owned by the organization there are no financers

The "managers" of the organization work directly with the "operators" to design and construct the building for a specific market segment.

2.2.2.2 Operation Stage: The operation stage is the same as 2.2.1.2 once there are organizations that lease the building.

3. The Physical Building Environment

3.1 The Parts

A commercial building has several major components. The main and first part of the building is where the "tenants" conduct their activities for which the building was built. This also includes the space that the "managers" use. This is the space that is primarily used to produce the good and service that the building intended for. This will be referred to as the "usable space". The second part of the building consists of the mechanical, electrical and plumbing systems as well as stairs, elevators and other means of egress. This will be referred to as the "systems" of the building. The third part of the building is the parts that protect the building from the outside elements such as windows, walls and doors. This part also includes the structure of the building. This will be referred to as the "envelope" of the building. The fourth part of the building is the site and outside environment in which the building is located. This will be referred to as the "outside".

3.2 The Role of the Parts

The design of each part of the building has specific effects on how the "tenants", "managers" and "operators" will behave. The physical design of a part will lend itself to specific "affordances" (Hillard). The height of a ledge, the character of a handle and the location of a stair will suggest a specific use and may also suggest untended uses (Hillard). In each part of the building there are opportunities to affect behavior either by channelizing unsustainable behavior into sustainable behavior or by taking advantage of innate behavior to foster sustainable activities (Jalkotzy). In addition, the governance structure of an organization may suggest some specific design elements that will make it easier for an organization to operate and produce goods and services sustainably. Most sustainable design assist and assessment tools such as LEED ™ already suggest solutions such as individual control of the environmental conditions, access to natural light, noise control, the use of non hazardous material, access to recycling, bicycle racks, showers, access to transit, natural landscaping, etc. This will not be repeated. There are more things that could be done with a better understanding of how humans behave. Some of the aspects that make common sense are listed here. In addition, the way some parts are designed will provide clear messages to "tenants" on what an organization and "managers" value most. As well, the involvement of the "tenants" in the design and management of the building and its' parts will have a direct affect on "tenants" behavior relative to the sustainability features, the sustainability elements to be included, their design and the future operation of the building.

3.2.1 Usable Space: Real-time displays of resource use accessible to all "tenants" and "managers"; location of light switches in a logical location and order; used resource center; location of "managers" offices relative "tenants" cubicles;

3.2.2 Systems: Location of stairs, windows in stairs, music and art in stairs, location of bicycle racks and car pooling relative to car parking

3.2.3 Envelope: Operable windows; ease of use of blinds;

3.2.4 Outside: Right of way for pedestrian and bicyclists over cars, location of senior "managers" parking;

4. The Social Environment

4.1 Background

As noted previously our behavior is affected by the way our brain evolved, the social environment we are a part of and the physical environment we have created. We like sugar and fat a lot, not because we need them now, but because we needed them when we were a hunter-gatherer society. If you didn't like sugar and fat you did not survive to a child rearing age and you had no offspring. Only the people that liked these high value foods had children and their genes were passed on. The "Blank Slate" (Pinker) outlines in detail where much of our behavior likely comes from. "The Blind Watchmaker" (Dawkins) also describes how complex organisms may have evolved. The evolution of language and social structures such as religion came about because they increased the survival rate of the human species. In the same way walking is hardwired evolutionarily into the brain of a new born calf our brain is hardwired for language and some social behaviors. These are behaviors that are very difficult to change. We may be able to channelize such destructive behavior, but we likely cannot change it (Jalkotzy).

The social environment can support sustainable behavior. We already realize that many of our economic models and governance structures do not encourage sustainable behavior. We simply reward ourselves for doing the wrong things. The way that the "tenants", "managers" and "operators" organize the operation of a building will have an affect on how sustainably the building is managed.

4.2 Elements of the Social Environment

There are three social environments within a building. The organization made up of the "tenants" and the "managers" constitute the first social environment. This will be referred to as the "company". The relationship between the "tenants" and the "operators" is also forms a social environment. This will be referred to as the "team". The organization made up of the "operators" is also a social environment. This will be referred to as the "maintainers". Generally these social environments work independently, however one social environment does have an effect on the individuals within another social environment. For example, if the social environment within the "company" is not conducive to recycling, then there will be an effect on the ability of the "maintainers" social environment to encourage recycling. Current and potential social environment characteristics are described.

4.2.1. Current Social Environment Characteristics: These are generalized social environment characteristics of organizations that exhibit unsustainable behavior.

4.2.1.1 Company: Typically this is a hieratical structure with vertical reporting structures. Usually there are more than four levels going from the employee to the senior executive. The departments of the organization are organized around specific activities such as finance, human resources, production, etc. There is little interaction between departments except at the senior executive level.

4.2.1.2 Team: This social environment has no structure in most buildings. This environment is the informal relationship between "tenants"/"managers" and building "operators". Generally the operators maintain a "tenants" complaints system. The only formal interaction is through a health and safety committee that is mandated in some jurisdictions (countries, states). There may be some accounting of how complaints are handled back to the "managers" of the organization. There usually is similar accounting back to the "tenants".

4.2.1.3 Maintainers: This social environment is usually structured around contracts between the building owners and the individuals maintaining the facility. In some cases the individuals maintaining the facility are employees of the owner. There is generally little interaction between the cleaners, mechanical system operators, physical building maintainers and any services within the building such as food preparation, dry-cleaning and other services.

4.2.2. Suggested Social Environment Characteristics: These are generalized social environment characteristics of organizations that exhibit sustainable behavior.

4.2.2.1 Company: Typically this is a non-hieratical structure without vertical reporting structures. Usually there are fewer than four levels going from the employee to the senior executive. Work groups are developed made up of individuals from many departments or directorates. Instead of each employee continuing to report to their immediate supervisor, they would report to one manager. The "managers" group is seen as a team. The departments of the organization are organized around specific production tasks. There is interaction between departments at all levels.

There is an important culture change within organizations that is fundamentally necessary to have a successful sustainable behavior change occur. For the most part the executive class of the "managers" group believe that the "tenants" (employees) are there to serve "them". This is clearly not the case. In an enlightened and progressive organization there is a fundamental understanding and belief that the executive class of the "managers" serves the "tenants" (employees). The executives would not exist if it is not for the work that the "tenants" do.

4.2.2.2 Team: There is a building management team made up of "tenants", "managers" and "operators". This would function similar to a health and safety committee. They play a formal role in the building and asset management plan for the building. They review and analyze the complaints data for the building. They provide advice to the "operators". This is where a Green Stewardship Committee could be formed.

4.2.2.3 Maintainers: Similar to the "company" this governance model would encourage interaction between the various "operators". From a governance perspective they could be a sub committee of the building management team.

5. The Tenant Centric Building Management Guide

5.1 Background

A tenant centric building management manual would incorporate a governance model that takes the concept of an integrated design process in the design of new building or major renovations into the formal management of a building and then takes it a step further. Unfortunately, the integrated design process currently pays only lip service to the role that "tenants" could play in the design of a building. There still is a fear that "tenants" will complicate the work of the "operators". Architects and engineers are always concerned about "scoping" the "tenants" involvement for fears that their involvement will unnecessarily raise expectations. Where "tenants" have been involved in the design process the reverse is generally the case. "Tenants" actually enhance the creative process. They bring new perspectives and solutions to the design process. It also develops a sense ownership in the building and its operation. For "green" buildings this is particularly important. "Tenants" can and do negate some of the "green" features designed into buildings. This model is proposed for the management of a building. However, "operators" in designing new buildings or conducting major renovations can use it.

As the title indicates, management of the physical environment and social environment of the building is taken from the point of view of the "tenant". There are several steps that set a foundation for managing a building from this perspective. There are many buildings that use some of the following principles. Most do not use all of these principles. Buildings that are owned and occupied by the same organization, particularly if it is an environmental "organization sometimes combine all these principles. However there is almost always a gap between the "operators" and the "tenants"/"managers".

5.2 Steps and Principles

The steps suggested are divided into two parts. Part one requires a governance model for the building that produces the social environment outlined in 4.2.2. An outline of such a model and the interrelationships is provided. Part two follows a typical pattern of finding out where you are, "base-lining"; developing goals, objectives, an action plan and setting targets, "planning"; implementing the action plan, "implementation"; measuring results against the targets and base-line, "measuring"; then back to "base-line". This list of principles can be applied to the management of a building. It can also be applied to the design of a new building or major renovation.

5.2.1 Part One, Governance Model: The principles to good governance model are as follows:

5.2.1.1 Rational for Building Management Team: There is a direct relationship been "tenants" involvement in the management of a building and the level of complaints about a building. In addition, by involving the "tenants" in the asset management plan, the "tenants" buy-in to the solutions proposed for the building. If this is combined with providing real-time feedback on performance measurements of the building significant reductions in resource use have been observed. In addition, complaints about the building decrease. After the cost of operating a building, answering complaint calls is the next highest cost center in operating a building.

5.2.1.2 Development of a Building Management Team:

- Inclusive,
- Must have a charter,
- Must have a formal role in the building and asset management plan,
- Should incorporate a green stewardship committee,
- Needs to be funded,

5.2.1.3 Roles of a Building Management Team:

- Review building "tenants" satisfaction data for the building and asset management planning process
- Manage "tenants" events in the building such as environment week
- Develop sustainability targets for the building

5.2.2 Part Two, Process

5.2.2.1 Base-lining:

Indicators:

- Must be measurable,
- Must be understandable by the "tenants",
- Must reflect what the "tenants" values,
- Must be useful for making decisions and
- Indicators need not be directly measurable if there are other measurable values that vary in direct relationship with the proposed indicator,

The building management team develops a narrative describing the sustainability performance of the building using the base-line indicators of the building and the "tenants" satisfaction data for the building.

5.2.2.2 Planning: When developing plans for new roads, subdivisions and other municipal infrastructure planners use as system that is useful for planning the operation of a building. Planners rely on two groups of people. Technical Advisory Committees (TAC) are made up of engineers, architects and planners. TACs advise the process from a technical perspective. Planners also form Public Advisor Committees (PAC). PACs are made up of people from community associations and other public advisory groups such as cycling associations. PACs advise the process from a community perspective. Planning the management of a building can be approached in the same way. The Building Management Committee would be similar to the PAC. Their role will assist the "operators" in understanding building issues from a "tenants" perspective.

5.2.2.3 Implementation: As outlined in the roles of the Building Management Committee, the "tenants" can play the most substantial role in ensuring that the targets set in the "planning' step are met. As previously stated they can also ensure that targets are not met. There are many ways that "tenants" can interact with the "operators" to successfully meet sustainability targets. The following is a list of methods that can be organized and used by the "tenants":

- Press and media communications
- Television documentary
- Website
- Signage and posters
- Lunch and learn
- Kiosks
- Add on buttons on programs on personal workstations
- Move in package developed by "tenants"
- Green Stewardship Teams
- Green Building Champion
- Training and orientation sessions
- Challenges and recognition

5.2.2.4 Measuring: The key to "tenants" ability to assist "operators" in meeting a building's sustainability targets is real-time indicator measurement. Human behavior is such that "only what gets measured done" and as individuals if we are able to access real-time information on utility resource consumption we reduce our consumption by 10 to 15%. Self reported sustainability behavior has been shown to be reasonably accurate. Where this can be cross referenced with actual data it is highly reliable.

- Sustainability footprint calculators,
- Metering of building utilities accessible to "tenants" at desktop computers

6. Proposed Public Works and Government Services of Canada Tenant Involvement Program

How can building occupants participate in operating green facilities

There are four activities that occupants could take part in to increase the effectiveness of green building features.

Participate in Building Survey (National Tenant Satisfaction Survey)[1].Appendix 1 provides a link to resources relating to the use of surveys in the development of sustainable buildings.

Focus groups made up of building occupants then could review optional Lists of Projects developed assessing each to see how they addressed issues identified in the National Tenant Satisfaction Survey. This review would be conducted during of the Asset Management Plan (AMP) cycle and form part of the deliberation leading to a preferred List of Projects for the AMP.

Some of the kinds of areas where employees can help increase the effectiveness of energy reduction strategies and green features are listed below. It is important that these areas be assessed in detail for how occupants' involvement can improve the sustainability of the asset cost effectively[2]:

<u>Base Building</u>

- Control strategies for:
- Lighting; switches and levels
- Heating and Cooling; switches, temperature levels and ventilation rates
- Monitoring strategies for electrical, water, paper, waste and fuel consumption[3]
- Location of bicycle, transit and car pool parking allocations, decreasing use of single occupant cars
- The character of stairwells and their attractiveness for use, decreasing use of elevators
- Fit-up
- Design of business centres; reuse storage and new material storage cabinets,
- Location of recycling facilities
- Kitchenette facilities that reduce the use of non-refillable or reusable products

Building occupants could review building operations procedures manual and modify it to incorporate green features. The manual will be downloadable on Buildings Online Site and distributed to staff in paper or electronic form

Building occupants could develop their sustainability objectives using PWGSC's SDS targets as a baseline, particularly energy reduction targets for the five year AMP cycle through a "consensus building" process.

<u>Methodology</u>

The proposed process for each asset would have to go through a three-step approval at the Service Integration Team (SIT) and asset levels. Approval will be required from:

- Director General or Director of the SIT
- Building management team, Asset and/or Building Manager
- Client Management, Assistant Deputy Minister, Director General and Director levels

The final check of the occupants' willingness to participate will come from the number of volunteers that indicate their interest in the program. The invitation to participate will come from their respective Assistant Deputy Minister and/or Director General.

The draft outline of the process follows the four areas previously outlined. Each area will have a detailed process and goals.

Participate in Building Survey (National Tenant Satisfaction Survey)[4]

---

[1] The National Tenant Satisfaction Survey # provides an excellent mechanism for communication between the tenants and the building management; documents the perceived quality of PWGSC services; allows PWGSC to ensure tenants receive the best service possible

[2] This is a draft list of ideas based on current sustainability design assist and assessment tools such as Green Globe and LEED. It may be possible to do some things at low cost during regular fitups and maintenance of the asset, others may only be cost effectively done during a major refit of the building.

[3] If employees do end up setting some GHG emission reduction or waste reduction targets, then there needs to be ways of reporting on achieving the targets. This is a critical motivational strategy.

[4] This survey could be reviewed using the work done by Adrian Leaman and Bill Bordass in Britain in the Probe Study of existing building.

Focus groups made up of building occupants could review optional List of Projects during the Asset Management Plan (AMP) cycle relative to issues identified in the National Tenant Satisfaction Survey. (see previous list of areas where occupants could assist)

We propose to hold a 1/2-day brainstorming session with 15 to 20 people (for example if the building population is 1000, 4 to 5 focus groups would be optimal, this would provide a demographical representative sample as well as provide the seed individuals necessary to continue the program). These employees would be invited to participate on a first come basis by the Director Generals and Directors of the respective client departments.

Building occupants could review building operations procedures manual and modify it to incorporate green features. The manual will be downloadable on Buildings Online Site and distributed to staff in paper or electronic form

(We would seek the assistance of Environmental Citizenship Initiative Support Centre.)

Building occupants could develop their sustainability objectives using PWGSC's SDS targets as a baseline, particularly energy reduction targets for the five year AMP cycle through a "consensus building" process.

We would develop option energy reduction targets and scenario's using the Existing Building Sustainability Assessment and the Environmental Citizenship Initiative Support Centre work on developing baseline occupant energy and products use. The occupants would then modify and adopt a five-year target with year-to-year goals

SURFACE TREATMENT IN BUILDINGS: A SUSTAINABLE PRODUCT SERVICE SYSTEM

Myung-Joo KANG
Robert WIMMER Dr.

GrAT (Center for Appropriate Technology), Vienna University of Technology, Vienna, Austria, kang@grat.at, rw@grat.at

Keywords: product service systems (PSS), sustainable, surface, treatment, building, maintenance

Summary

Product service systems (PSS) can be an innovative solution in the material intensive building industry. PSS are packaged system solutions of products and services that fulfill specific consumer needs. If immaterial services are efficiently combined with material products, overall resource and energy consumption of the system can be significantly reduced.

In this paper, a PSS strategy is described for the surface treatment segment in the building industry. Throughout a series of system analyses and idea generation processes, the idea of ‘contract-based service for surface management’ is suggested. The basic concept is that the company and/or its partners provide(s) a complete result of treated surfaces, instead of selling treatment agents. A professional painter or carpenter treats certain surfaces, and visits the customer on a regular basis, or on request, to maintain the surface quality. The PSS concept has several advantages. Through the high quality product application and tailorised professional services, the amount of material consumption can be reduced. Furthermore, it can create new opportunities of employment. This service model is adaptive for private households, public buildings, and even restoration and maintenance of historic buildings. As a result of the feasibility investigation and user group surveys, a number of practical requirements for the successful implementation of the idea are defined.

1. Introduction to Product Service Systems

Product Service Systems (PSS) are commonly defined as the result of ‘an innovation strategy, shifting the business focus from designing and selling physical products only, to selling a system of products and services which are jointly capable of fulfilling specific client demands’ (Manzini and Vezzoli, 2002). The main goal of PSS is to satisfy users not only by means of material artifacts, but more by immaterial services. In order to deliver the expected values, and even beyond the expectation, suitable products and services need to be assembled in the most efficient way. In doing so, both functional (e.g. food, mobility) and non-functional (e.g. satisfaction, social status) aspects of customer demands need to be considered.

Primarily, the concept of PSS was introduced in the market as one of product marketing approaches. Companies began to provide additional services in order to attract customers to their products and increase their satisfaction. Therefore, PSS are often perceived as ordinary ‘business proposition’ or ‘product promotion’. Since the concept began to be discussed in the sustainable development field, however, the role of services has been highlighted, the role of which is no longer increase of sales volume, but the direct fulfillment of customer demands.

Our society is always changing, and accordingly, our market is changing. To be outstanding among numerous business entities, it is necessary for enterprises to capture and fulfill the changing demands of customers and market trends in a new and different way. Many researchers and business developers inspired by the concept try to further understand the intrinsic nature of PSS and to implement the idea in the market.

1.1 Product Service Systems Corresponding Socio-Economic Changes

PSS are in concert with emerging socio-economic transitions in the society. There are economic, environmental, and social trends underpinning the adoption of PSS strategies in business units. Not surprisingly, PSS have been already implemented in many industries. In the building sector, however, PSS are fairly new and rarely existing (Ness, et al. 2005). One of the reasons is that the building industry has been classified as a *manufacturing* sector for a long time, concerning its inherent material-intensive aspects. However, when we consider the actual values we get from buildings, such as safety, comfort, coziness, and relaxing moments, will it be impossible to reorient the industry as a *service* sector, by providing those needs behind the needs?

1.1.1 Economic trends

It is obvious that the economic paradigm has shifted from the traditional mass material market to the post-industrial market. One of the indicators is the remarkable growth of service industries among all industrial activities in the last half century (Statistik Austria, 2006; Statistics Bureau, 2005; U.S. Census Bureau, 2008). Business activities increasingly rely upon immaterial values in tertiary industries (e.g. consulting, information technology) instead of relying only on the material values in primary and secondary industries (e.g. mining, manufacturing goods). It is partly because margins from product sales are getting smaller in the severe competition among global producers. Many of European and North American countries have witnessed that a great part of production facilities were moved to those countries with growing production capability, due to the relatively low costs for natural resources and labour. In terms of technical functions and prices, the difference between brands is no longer clearly distinguishable. Therefore, as one of marketing means, companies provide services such as delivery, guarantee, repair and take-back. The scope of services can be further expanded.

1.1.2 Environmental trend

From an environmental point of view, PSS solutions contribute to decoupling amount of natural resource consumption and value creation. It is primarily because services can create values out of immaterial sources such as knowledge, information, ideas, labour, and time. Service-based solutions show, in general, higher resource productivity compared to pure product solutions, as well as increased efficiency in product use (Kang and Wimmer, 2008). For example, repair and maintenance services prolong the useful life time of products, and take-back and recycling services impose a new useful life to certain materials and products. Also, the success of information and communication technology has dramatically increased the possibility of immaterialized answers to many customer needs for knowledge and information.

1.1.3 Social trend

The beliefs of citizens are changing. In most of early industrialized countries, issues related to the quality of life, such as well-being, work-life balance, and emotional satisfaction arise. The old perception that ‘the more, the better’ is being replaced by new common sense, ‘the less, the better’ or ‘the better, the better’. These quality-oriented criteria are already recognised in the food production industry and consumption behaviour (Kang and Wimmer, 2007). Such convergence of values can be valid in other production and consumption areas as well. Additionally, the shift in social attitudes toward moral responsibility has made the ethics of personal decision become a major professional concern. There lies a great potential of creating new services or improving current services in order to address these high-level needs/demands, which are hardly able to be fulfilled by mere products.

1.2 PSS in the Building Industry

Innovative PSS are created from questioning ‘what are the real needs?’ With this new way of looking at our everyday needs and material artifacts, more radical solutions can be found in many sub-segments in the building and building-related industries. If this transformation is combined with the sustainable deliberation, a new perception on our living and working places can be established.

The potential of the innovative change can be seen in a number of PSS examples in the building sector: the remanufacturing service for unit houses by Sekisui Chemical (Iwahara and Suzuki, 2005), co-housing systems in Europe and America which facilitate space sharing, the ‘office space rental service’ by Regus (2008), the carpet leasing and take-back service by Interface (Ness, et al. 2005), and so on. Those PSS examples currently running on the market can help enterprises understand PSS in a more practical way. We can also learn how to design, implement and operate the systems successfully.

One of the common characteristics of the PSS models above is that the companies regard a building not as a last destined object of their business, but as an intermediate medium to deliver customers’ various needs. Here, the customer needs about buildings are not only physical and spatial places to live or work in, but also sources of refreshment, intimacy, self-esteem, and convenience. Therefore, their design approaches lie on a system level beyond a product or material level.

2. New PSS Development for Building Surfaces

A new PSS model for the building surface treatment sector has been developed. Surfaces include most of building elements such as façade, floor, window, walls, etc. and other consumer products (e.g. furniture). This branch involves chemical-based materials including paint, polish, lacquer, etc. and services for the application of those materials. In such a material dominant conventional market, the relationship between the provider and the customer simply ends up at the point of product sales.

From an environmental perspective, the product segment – as an overlapping field of building and chemistry -shows high natural resource consumption, while creating relatively low economic values compared with other industrial branches (Fig.1). A new approach has been taken in order to reduce the material consumption amount and to increase economic and other values, in surface treatment for buildings.

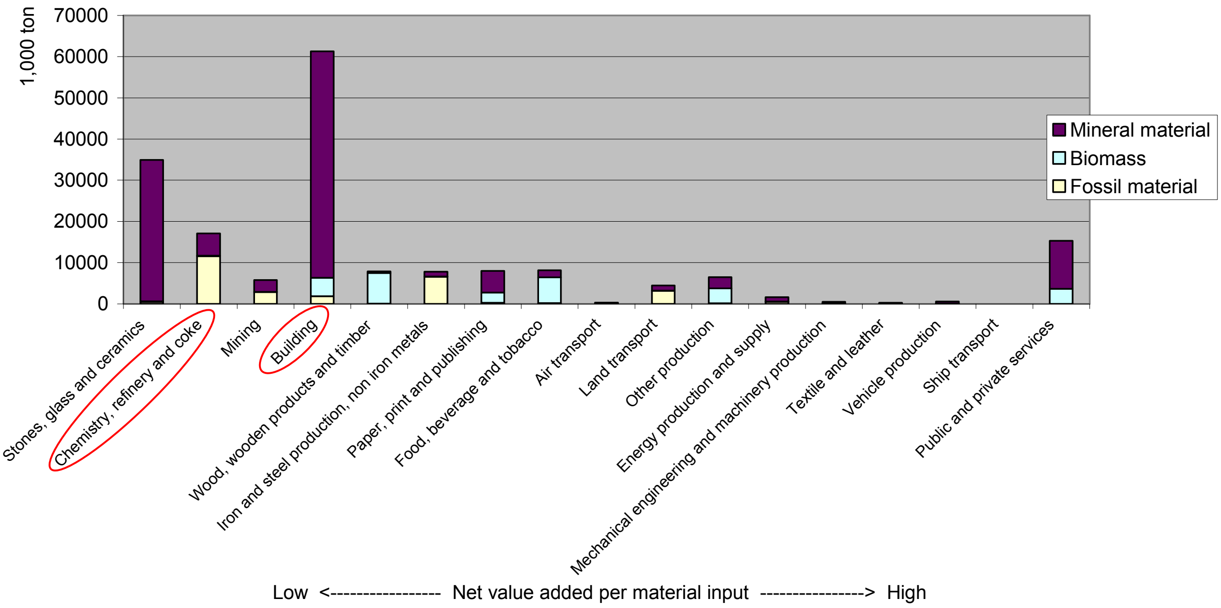

Figure 1 Material consumption and net value added in different business sectors (Wimmer, et al. 2007 based on Statistik Austria, 2003)

The project was carried out in collaboration with the natural paint producer, AURO Austria. The company is specialised in producing natural paint, oil, and other surface treatment products. As a part of mid-term strategies, they plan to engage service elements into their business to be more competitive in the saturated market. In advance to actual tryout, beneficial and risky potentials need to be clearly grasped. With the help of systematical methodologies and tools, a new PSS model has been built up.

2.1 Processes and Tools Used for the Development

2.1.1. Simplified PSS development handbook for small- and medium-sized enterprises (SMEs)

The 'simplified PSS development handbook for SMEs (Wimmer et al, 2007)' was employed. The handbook consists of a series of analytic and strategic tools selected and/or refined from the tools in 'Methodology for Product Service Systems Innovation (MEPSS) (Van Halen, et al. 2005)'. The 5 phase-step-process structure of MEPSS has been trimmed down into 3 phases, to respond to the demands of SMEs for easy use. The basic flow of system development and the sequence of tools used in the each phase are shown in Figure 2.

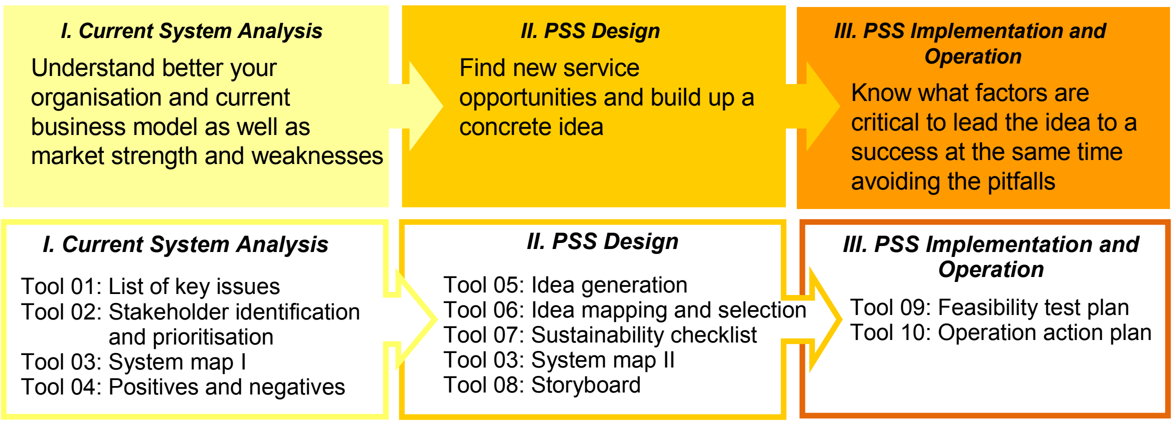

Figure 2 Three phase model of PSS development and tools used in each phase (Wimmer et al, 2007)

2.1.2. Key processes and results

Among the tools applied, a few key tools and the respective results are summarised.

1) Current system analysis - stakeholder identification and prioritisation

Instead of the linear relationships between stakeholders along the supply chain (e.g. material provider–producer–retailer–customer), PSS require a network of vertical and horizontal relationships among them. The following tools enable to identify all relevant actors who already have stakes in the business, or who could have a relationship with the company in the future. They are categorized according to their interest in and influence on the system. Each stakeholder category is defined as follows:

-Primary stakeholders are those who have a direct stake in the organisation and its success
-Secondary stakeholders may be influential, but their stake is more representational
-Social stakeholders can be directly communicated with
-Non-social stakeholder cannot be directly communicated with

Table 1 Stakeholder identification

	Direct stakeholder	Indirect stakeholder
Primary stakeholder	• Mother company • Employees and managers • Customers • Regional dealers • Construction managers • Regional painters • Shareholders and investors	• Competitors • Environmental pressure groups
Secondary stakeholder	• Raw material providers • Governmental institutions • Social interest groups (e.g. labour union) • Media	• Natural environment • Future generation • Non-human species

The stakeholders are mapped along the value chain (Fig.3). The map is sectioned into internal-/external-entities and former-/next-value chains. The dotted line in the middle shows the boundary of possible PSS partnership. The boundary and the location of individual stakeholders can be updated as the strategy of the company changes as well as system solutions develop.

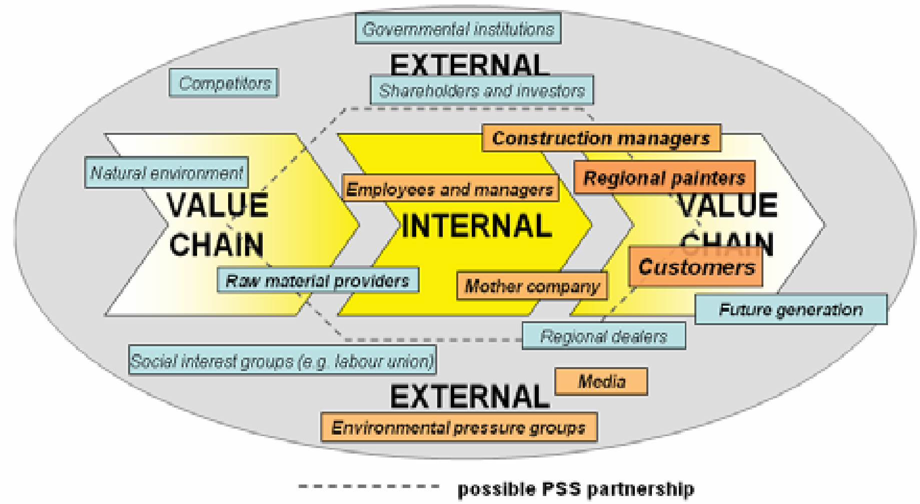

Figure 3 Stakeholders along the value chain and possible PSS partnership

The involvement of stakeholders in the early design phase is one of the requirements for successful development and implementation of PSS. Therefore, the prioritized stakeholders were invited to a workshop for the system analysis and idea generation.

2) Current system analysis - system map

The 'system map' is a codified and progressive representation tool. Its main purpose is to facilitate conversations among partners. This drawing helps viewers to understand the overall system structure and major stakeholders in the system (Jégou, et al. 2004). A system map consists of graphic elements symbolising the stakeholders and the three flows between them: material-, information-, and financial-flows. The following system map (Fig.4) visualises the primary system of AURO, which focuses on selling natural paint to private or business clients through regional dealers or painters.

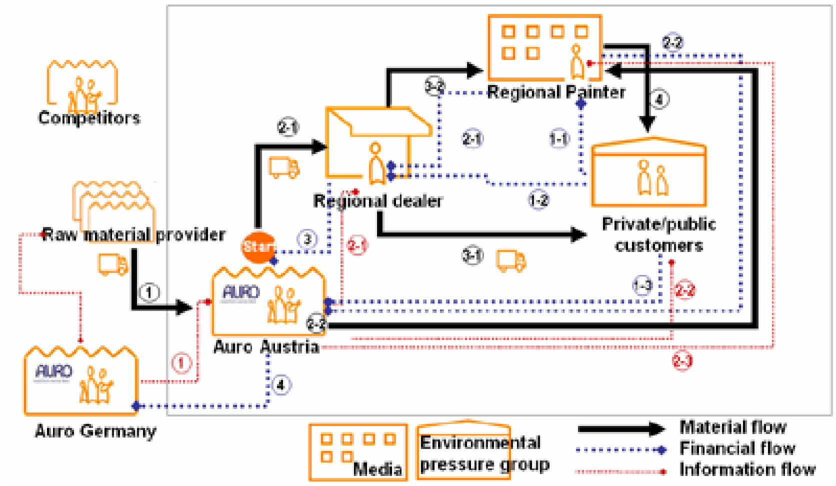

Figure 4 System map of current business

3) Current system analysis - positives and negatives (SWOT analysis for the product and the system)

Based on the factual understanding of the current system, positive and negative aspects are discussed. The widely used SWOT analysis was used with regard to the target product (Tab. 2), and key strategies were derived from the analysis results (Tab.3).

Table 2 Product and market SWOT analysis

Strength	Weakness
• No negative impacts on health • Durability of the treated surface • Easy maintenance • Comfortable smell and atmosphere • The raw material does not have to be extensively modified → Possibility of individual formation/variation	• Perceived to be expensive ('kg' measure) • Long drying time • Know-how required for correct application • Improvement of environmental performance of synthetic materials • Lack of access by large number of customers (available only via special retailers) • Environmental performance as a weak unique sales proposition
Opportunity	**Threat**
• Interest from customers with environmental consciousness • Regulations for occupational health care have been tightened for professional users • Disposal regulations have been intensified • Simple compositions/ simple production • Volatile Organic Compounds (VOC) regulations come into force • Professional maintenance is getting more and more popular • Growth of 'do it yourself' market • Wellness trend (modern, well-being)	• Improvement of synthetic products (competitors) • Easy availability of synthetic products through conventional trade (e.g. home merchandise retailer) • New competitors appear in the market • Conventional paint producers discover the opportunities of the ecological market trend

Table 3 Strategies derived from combinations of SWOT analysis

	Strength	Weakness
Opportunity	• Emphasis on the compliance with health-related regulations • Patents with the VOC control	• PSS offers can compensate the price difference • Emphasis on the cost saving over surface lifetime • Educational programmes for the proper application of this product
Threat	• Visible differentiation from conventional products • Emphasising accompanying benefits (e.g. texture, smell)	• Exploring new marketing channels • Emphasising the lower life cycle costs especially in comparison to conventional products

A characteristic of this process is that a 'system' SWOT analysis was added to the conventional SWOT analysis. The analytic method often focuses on a target product/service and its market situation only. The system SWOT analysis is newly suggested to enhance the subject of consideration up to a system level. In stakeholder workshops the system map (Fig.4) is used to scan all the flows as well as to aid the communication among stakeholders. The advantages and disadvantages in the flows and the relationships among stakeholders have been figured out. The results are utilised in the next processes in order to construct promising strategies that smartly strengthen the advantages, and compensate the disadvantages.

4) Idea generation and mapping

From the previous analyses and liberated brain storming sessions, a pool of PSS ideas was generated. The ideas were, then, mapped according to a set of criteria. The following figures show the actual ideas and its simplified mapping.

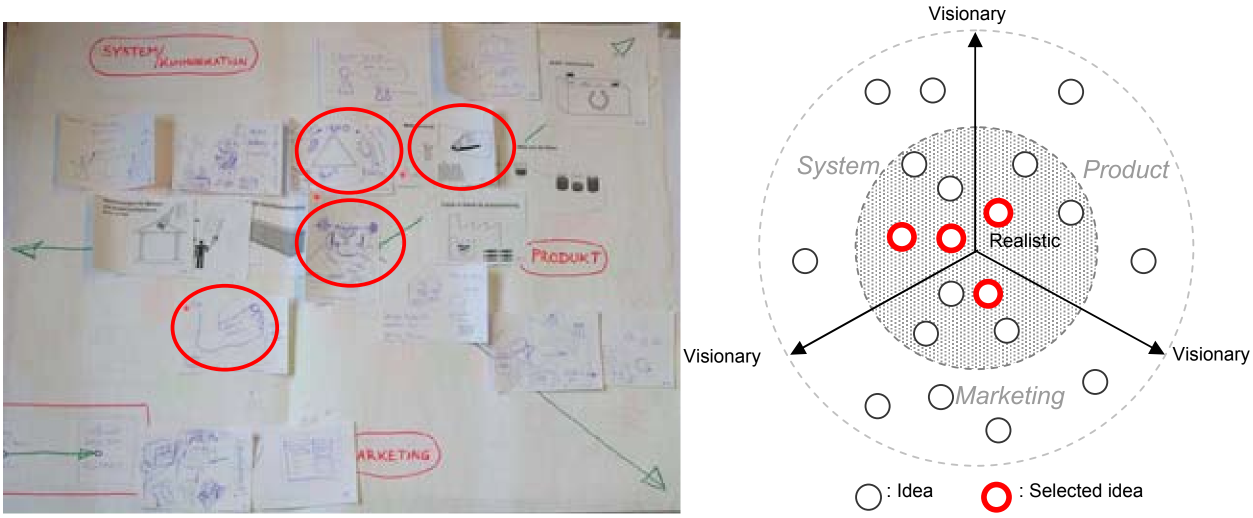

Figure 5 Actual ideas (left) and simplified mapping (right)

The ideas for surface treatment are divided into three groups: products, marketing strategies, and system (organisational) communication. The other mapping dimension is the feasibility of ideas. According to the technical, administrative, and financial feasibility assessment, individual ideas were placed along the axis: visionary and realistic. Four alternatives were chosen for further analysis and development.

1) Professional surface treatment service
2) Painting course for DIY customers
3) PR activities in wellness-related branches
4) Emphases on healthy and comfort aspects of AURO products

With regard to the selected four ideas, their sustainability performances were assessed by using a qualitative sustainability checklist. Among the ideas, the 'professional surface treatment service' was evaluated to hold the largest potential for environmental, economic and social benefits. On the other hand, this idea is most challenging, because it requires a customers' different perception on the traditional product purchase model. The remaining three ideas can be taken as supportive means of launching the selected idea.

3. Contract Based Surface Treatment Service

3.1. Description

The basic concept is that the company and/or its partner provide(s) a complete result of treated surfaces, instead of products only. A professional painter or carpenter treats surfaces, and visits the customer on a regular basis or on request to maintain the surface quality. The quality level of the treatment and service performance are ensured by a contract which is agreed upon at the beginning of the offer and renewed periodically. The basic structure of this service contract is elaborated through benchmarking the general standards of Service Level Agreements (SLAs) and the 'energy contracting service' model (Oegut, 2008). The contents can be further supplemented by discussions and interviews with representative stakeholder groups, as well as through investigation of legal contract components. The contract draft includes an escalation management plan* and a fixed rate of payment, thus, the customer can foresee the cost in advance.

* Escalation management plan arranges alternative solutions in case that the primary specialist cannot deliver defined service performance within the indicated time periods.

3.2. Benefits

The benefits of this PSS model are manifold. First, resource consumption can be reduced owing to the expanded lifetime of the surface and efficient material application. Second, professional painting and maintenance services can keep the quality of results at best status, and thereby, satisfy customers. Other benefits are also anticipated from the interview with a professional surface treatment technician who is specialized in restoration of historic buildings in Austria, such as Schönbrunn Castle and Belvedere Museum. According to the expert, normally surfaces need to be maintained partially, rather than in whole. To sustain the precious floors and fragile surfaces of historic buildings, he carefully examines the current status of the surface, and treats only some parts that call for maintenance (e.g. worn-out visitors' paths). This partial renovation can not only save materials, but also preserve the original surface in a better condition. Further, he mostly uses natural materials that are similar to the original application materials. Through the contract based PSS model, this type of high-quality professional services with valuable knowledge and experiences can be provided to other customers.

In this model, the profit arises from certain dimensions (m²) of treated surface, rather than weight of products (kg). Consequently, the service takes preventive care of the surfaces to avoid a major application, and consumes materials as efficiently as possible. In this concept, the fact that this natural paint can apply a larger surface, compared to a synthetic paint, has been taken as an advantage.

Users no longer buy and own tines of paint material, but simply pay for well-treated surfaces. They do not need to be concerned about organisation of treatment service themselves, maintenance of the surface over a long period, storage of leftover materials, and disposal.

For successful PSS implementation, intelligent networking among companies in different industrial branches is important. Emerging socio-economic trends of today do not necessarily require competitions against each other. Instead, competences of each of the partners can be taken to constitute new and advanced industrial solutions. The company can decide whether they will expand their business scope by integrating the service factors (i.e. in-house provision of professional painters and customer services), or they can outsource the service. Alternatively, an umbrella organisation could be founded as a supervisory management institution and an information centre for customers. Such a control and consultation unit can recruit a number of technicians and train them with technical knowledge and know-how's. In either scenario, there is a possibility of new job creation.

4. Consumer Attitude

For refinement of the idea, its market acceptance was investigated by means of questionnaires and interviews. The primary target groups were divided into three groups: regular users (who purchase materials and hire technicians for private buildings), Do It Yourself (DIY) users (who purchase and apply materials themselves for private buildings), and public bodies (who purchase materials and hire technicians for public buildings).

In general, the regular users are interested in the service offer for some building elements, for example, façade, windows and wood preservation. They suppose the proper duration of a service contract between 5 and 10 years. In terms of the price, they seem willing to pay about 20% more than the material cost, over a defined period. The most appreciated advantage of the offer is the competence of professional technicians for high quality treatment.

The survey of DIY users shows that they highly appreciate the environmental benefits of the natural paint and reduction of transportation energy, etc. Nevertheless, it is not only technical functions that influence customers' decision, but also non-technical values. In this case, the DIY users voluntarily go through the self-application procedures and enjoy own labour. Therefore, they seem to be not keen on giving this 'experience' to other professionals.

Generally speaking, business-to–business (b2b) PSS offers are more successful than business-to-consumer (b2c) offers in the market. One of the reasons is that companies make a decision based upon rational evaluation of options, while household customers are often emotionally biased (Wimmer, et al. 2006). The effect of demonstrations in a b2b field is often far stronger than that in a b2c market, due to the capability to win public credit. If a new business model works successfully in a public organisation, the idea can be more widely talked than when it was adopted at a private household.

Considering all conditions above, public organisations were selected as the first trial target group, and the municipal school building administration of Vienna was interviewed as a prospective customer. Through verbal explanations and visualized scenarios, the PSS offer was able to be clearly understood, and the new method of public building management was perceived to be captivating. In advance to real application, however, some institutional and financial hurdles were recognized, such as extensive administrative decision making process and more concrete financial benefits over a long term.

As an alternative target within the public building sector, kindergartens, hotels, hospitals, and sports complexes are suggested. These branches are supposed to be more concerned about the issues such as health and air quality as well as brand images. With regard to the maintenance aspect, the PSS offer suits the treatment of historically valuable buildings and restoration work. Churches, museums and other heritages that are under protection regulation can be implementation subjects.

5. Conclusion

Along the systematic approaches, a PSS strategy for surface treatment has been elaborated. The result is an advanced solution for quality improvement, new profit generation, reduction of material consumption and opportunities for job creation. This practice may show the potential of market transformation in the building industry. In many industrial places, we see the product-dominant age is ending. Larger and powerful values are originated from immaterial services, knowledge, information, and experiences. While some industries have quickly adapted themselves to fit this new stream, some segments have adhered to the conventional material-oriented business models. As one of the latter, the building industry has been ranked as the most material intensive industrial branch. However, not exceptionally, creative and clever PSS strategies can be created in this sector as well.

The value position in our economy is changing, from production of material goods to service offers. This transposition requires that firms should develop corresponding business strategies. By caring about the true needs behind material needs, building enterprises and institutions can discover more diverse options of value propositions, and consequently achieve the system level innovation. The answer to ‘what is the real need?’ and ‘how can we address this need?’ would not always require enormous amounts of resources and energy. Customers’ comfort, welfare and happiness can be directly served.

Consumer mindset is diverted gradually. In the innovation process, therefore, companies may face several challenges such as a change of the organisational mindset and new financial schemes. To accelerate the market change into more sustainable solutions, more success stories in the same industrial sector are needed. One of the substantial tasks in promoting PSS in marketplace is to disseminate their benefits and to improve the information flows between providers and possible target groups. At the same time, methodological, financial, and institutional support of governments is required to facilitate the implementation of public organisations and enterprises.

Keywords: office, thermal environment, Japan, cool biz

Summary

Recently, the Japanese Government recommends 28 °C as the room temperature of the office for cooling and 20 °C for heating. But, it is a well-known fact to get behind in the work in the hot office. Therefore, the authors investigated indoor thermal environment of the actual office rooms of 41 buildings simultaneously. This investigation was carried out by mailing a super-miniature temperature and humidity logger to 41 people working in the different office. The authors asked to set a logger on the edge of each person's desk and send it back by mail to the authors again after one week. This measurement was repeated from summer until winter, and the authors could collect indoor environment data of the actual offices for the long term. Furthermore, it was proved that the indoor thermal environment of the offices which equipped the central air conditioning system was different from that of unitary air conditioning system. This knowledge is very precious information to predict the amount of energy consumption and carbon dioxide discharge of air conditioning system.

1. Background

Japan previously laid down regulations concerning the indoor thermal environment of offices and other buildings with total floor areas of 3,000 m2 or more. The law allows for a great range of thermal conditions, with dry bulb temperature permitted within the range of 17 °C to 28 °C and relative humidity between 40% and 70%. The law is intended for the prevention of health hazards, rather than for securing comfort. Meanwhile, in the actual design of air-conditioning systems, a long-standing common practice is to try to keep the dry bulb temperature in offices at 26 °C and the relative humidity at 50% while cooling, and at 22 °C and 50% humidity while warming. These temperatures are considered to strike a balance between comfort and economy, two factors that usually conflict with each other, and this balance has been learned through experience.

Recently, with the aim of reducing the effects of greenhouse gas emissions originating from air-conditioning systems, the Japanese government announced a program to set air-conditioning temperatures at 28 °C for cooling and 20 °C for warming. This suggests that the government added a new criterion of eco-friendliness to the two existing evaluation criteria for air-conditioning systems; namely, comfort and economy. Since 2005 the government has been carrying out a large-scale campaign titled “Team Minus 6%” in order to encourage people to follow specific action plans. To help people adjust more easily to this relatively high government-recommended temperature for cooling systems, the government introduced a dress code called “Cool Biz,” and has been promoting its widespread use.

Although “Cool Biz” did not meet with any serious resistance from the people, the recommended temperature of 28 °C for cooling systems in summer encountered harsh opposition from many office workers. The authors hear that many offices are still refusing to introduce this government-recommended temperature setting.

2. Objectives of the study

Against the background described above, the authors of this paper measured the indoor thermal environment of many offices to conduct a survey of actual temperature and humidity in offices and confirm how closely the Japanese government’s recommended temperature settings are being followed. Although a great number of survey reports on the indoor thermal environment of offices have already been published, most of these cover only a single building, and they vary considerably in terms of dates of survey, measurement methods, etc.. Consequently, comparing the results of the survey reports has been difficult. To solve these problems, in this survey, the authors simultaneously measured the indoor temperature and humidity in many offices over a long, continuous period of time, using consistent measuring methods. This helped us understand the general trends among many offices. In addition, the authors conducted a questionnaire survey of people working in those offices to find out about their clothing styles at work and their perceptions of their thermal environment.

3. Methodology

The authors chose 41 offices, all in Japan and listed in Table 1, and sent miniature data logger that could measure temperature and humidity and questionnaires on thermal environment directly to people working in those offices.

The miniature temperature and humidity data logger measures 17 mm in diameter, 6 mm in thickness, and 3.3 g in weight. It has built-in sensors, a battery, and a memory. Its resolution is 0.1 K for temperature and 0.1% for humidity (Fig. 1). The measuring interval was set to 10 minutes. The authors asked each cooperating office worker to attach the data logger onto the front edge of his/her desk, at least 50 cm away from his/her body (Fig. 2). Each recipient was asked to fill out the questionnaire at their convenience, and send it back to the authors one week later, together with the data logger. Table 2 lists the survey items of the questionnaire. The authors collected the information recorded in the data loggers, sent them back to the respective offices, and repeated this procedure several times.

Location	Sensitive to heat	Radiated heat	Region where the respondent spent his/her childhood
Weather	Sensitive to cold	Predicted room temperature	Distance to the entrance
Date and Time	Work	Ideal room temperature	Air-conditioning system
Sex	Clothing	Predicted humidity	Current subjective warmth/coldness
Age	Physical fitness	Ideal humidity	Work efficiency under the current thermal environment
Kind of work	Air current as sensed by the respondent	Distance to the window	Remarks

4. Survey results

4.1 Business hour temperature and humidity at all of the offices surveyed

Figure 3 shows the daily mean indoor dry bulb temperatures measured in all of the offices during the business hours. From summer throughout winter, the authors see that temperature varies considerably from one office to another. The mean temperature distribution is roughly around 24 °C to 28 °C during summer, and 21 °C to 26 °C during winter. Mean room temperature gradually declines as the season changes from summer to winter.

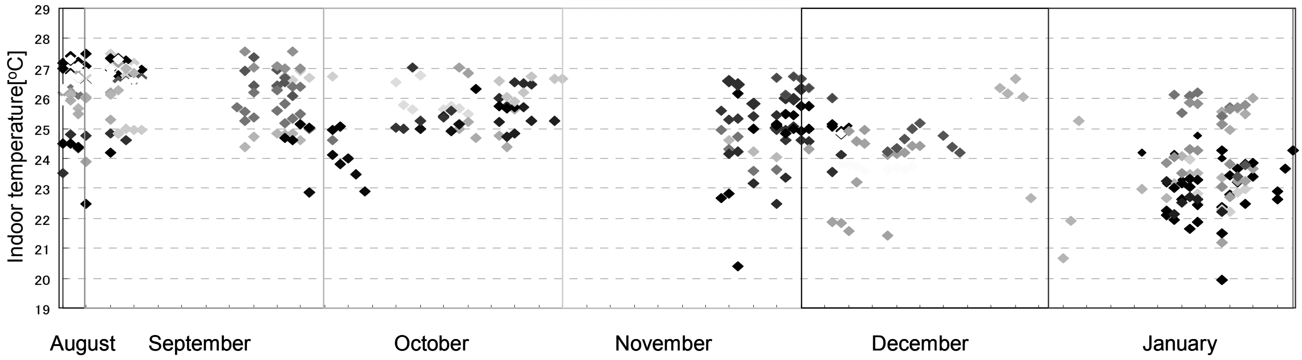

Figure 3 Daily mean indoor dry bulb temperatures during business hours

Figure 4 shows the daily mean indoor relative humidity during business hours in all of the offices measured. As with the dry bulb temperatures, the authors also see a great diversity here. The distribution is around 40% to 65% during summer, and 20% to 55% during winter.

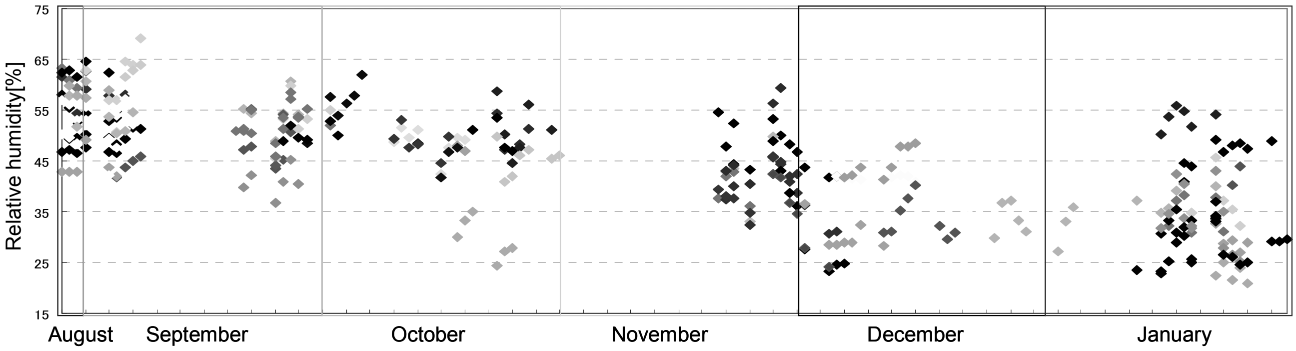

Figure 4 Daily mean indoor relative humidity during business hours

Many of the offices covered by this survey performed clerical or design work. Still, as the results show, the thermal environment differed greatly from one office to another.

Figure 5 shows the frequencies in different temperatures that were measured each month. Here the authors see a wide range in the lower temperature in each month surveyed. Figure 6 displays chronological changes in mean room temperature across all the offices on a weekday, in different months. During summer, the room temperature dropped when the air-conditioning began to work in the morning. During winter, temperature rose in the morning. Typically, the cooling system was in operation from summer to November, and the heating system from November.

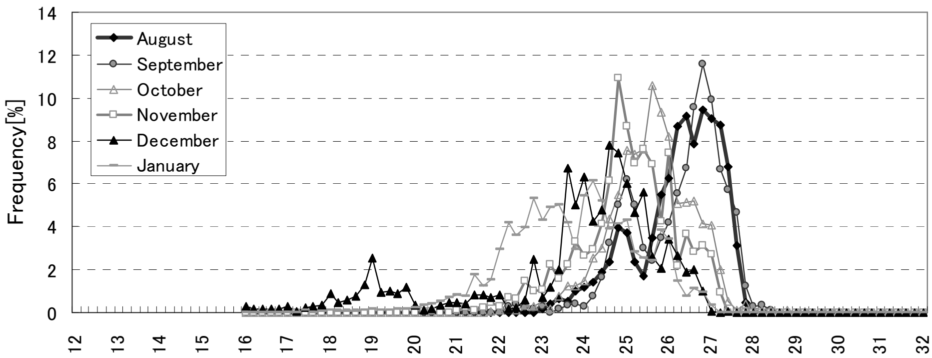

Figure 5 Frequencies in different temperatures measured during business hours

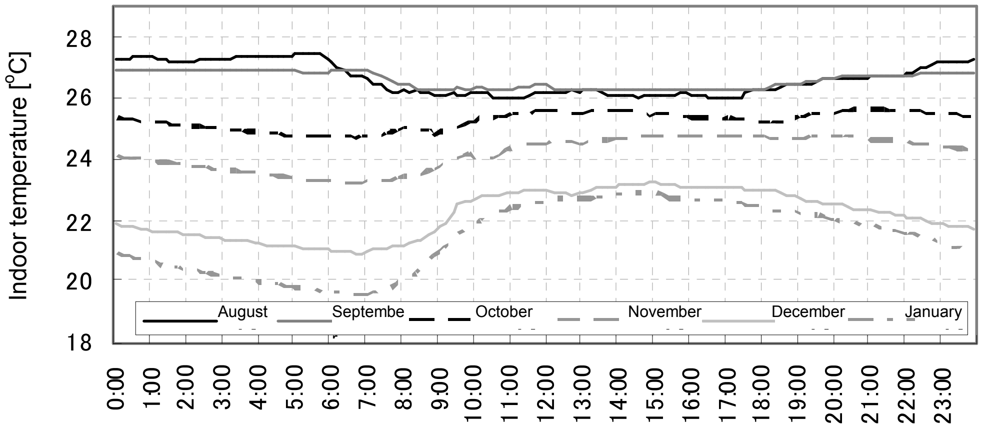

Figure 6 Chronological changes in mean room temperature in different months

4.2 Room temperature outside business hours

The typical business hours in Japan are, roughly, 9 a.m. to 5 p.m. In reality, however, many people also work overtime on weekdays and on weekends and holidays. The office air-conditioning system works intermittently, usually only during business hours. During overtime and on weekends and holidays, air-conditioning is usually provided in response to workers' requests.

Figure 7 shows the frequencies in different room temperatures that were measured outside regular business hours. As compared with Figure 5, the distributions cover an even broader range. Especially in winter, the distributions spread very broadly in the lower temperature range. Still, a typical air-conditioning system in Japan is capable of warming/cooling specified zones or floors only. Thus, when an office worker finds his/her thermal environment unbearable during overtime or on a weekend, he/she requests air-conditioning of the zone where he/she works alone.

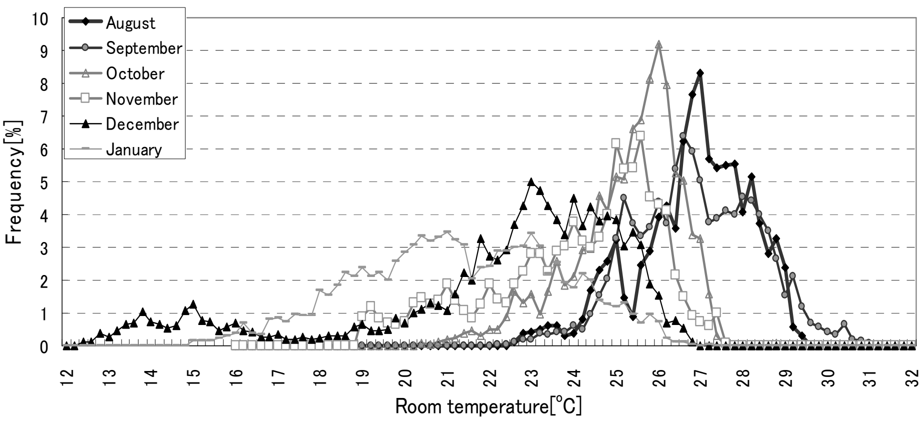

Figure 7 Frequencies in different room temperatures measured outside regular business hours

4.3 Differences between different methods of air-conditioning

Currently, two major methods of air-conditioning are in common use in Japan. One of the two, a central system, combines a central heat source unit and many air-conditioners. The other, a unitary system, consists of package air-conditioners as represented by the VRV system. Although the former is capable of providing relatively good quality of air-conditioning, it does not leave many choices to users. The

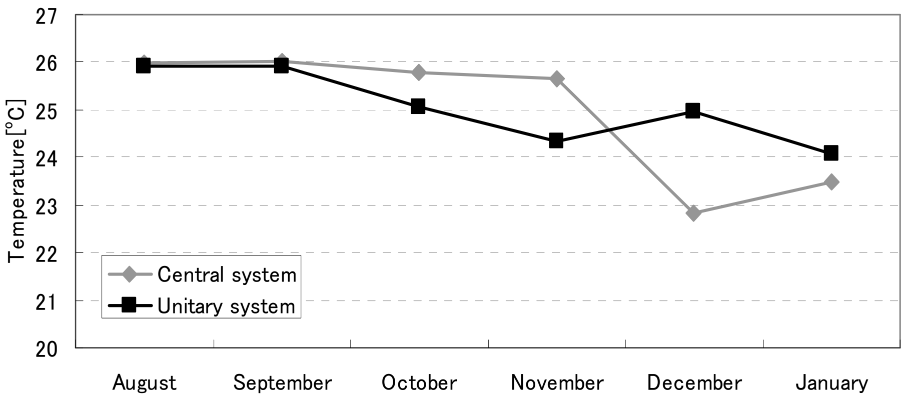

Figure 8 Mean room temperature during regular business hours for the different methods of air-conditioning

latter, on the contrary, allows users to choose from many choices of operation. Users can turn the respective air-conditioners ON/OFF and change their pre-set temperatures by remote control. Of the 41 offices covered by this survey, 24 employed a central system and the remaining 17 a unitary system.

Figure 8 shows mean room temperature during regular business hours of each month, for the two different air-conditioning systems. Although during summer the two didn't show much difference, the difference grew larger in fall and winter. With central systems, mean room temperature remained almost constant until November and then suddenly plunged in December. In contrast, with unitary systems the transition was much smoother, with no sudden ups or downs

4.4 Amount of clothing worn by workers

This survey covered 38 male and 3 female workers. Figure 9 shows month-by-month changes in the amounts of clothing the workers wore in their offices. Although many respondents replied with 0.6 clo as the amount they wore in summer, the amounts changed greatly from October to December.

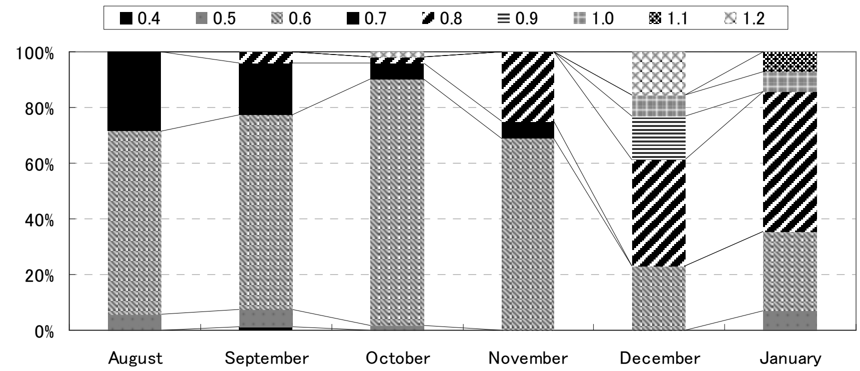

Figure 9 Amounts of clothing worn in offices

Figure 10 displays the correlation between temperature within the offices and the amount of clothing worn. Although a negative correlation is evident between the two, the authors see some workers who are heavily clothed in the range of lower office temperature.

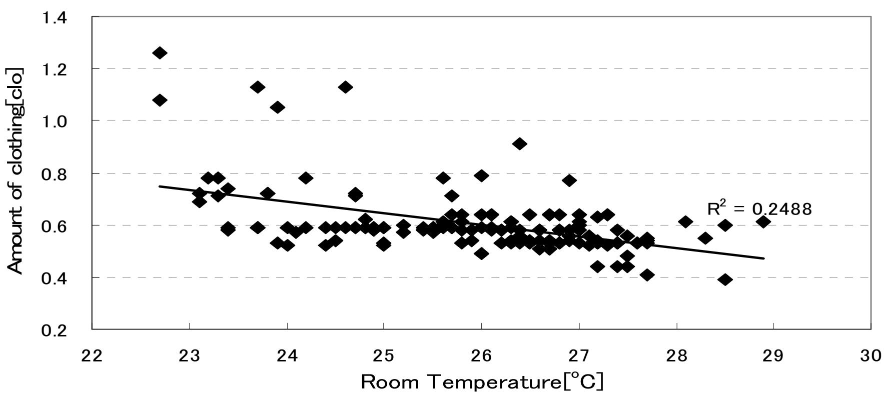

Figure 10 Office air temperature and amounts of clothing worn by workers

4.5 Thermal sensation felt by the workers

Figure 11 shows how many of the workers surveyed felt cold or hot in their offices. Synchronous with the major changes in amounts of clothing they wore from October to December shown in Figure 9, the authors see changes in the subjective warmth / coldness they felt during the same period.

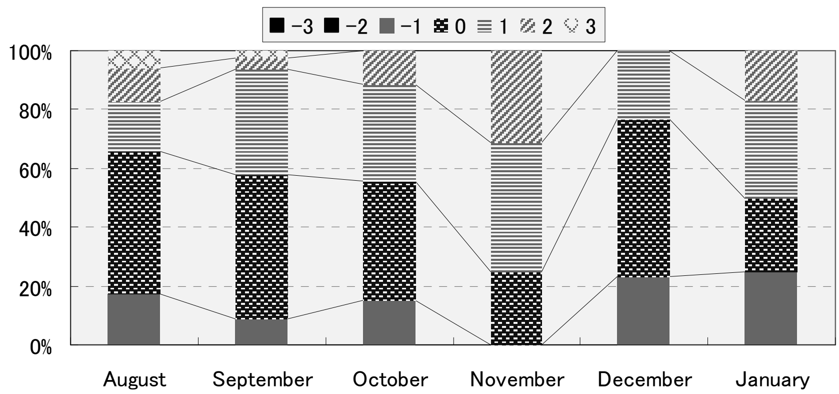

Figure 11 Coldness / warmth felt by workers in their offices

4.6 Effects of office thermal environment on work

The questionnaire asked the workers how their offices' thermal environment affected their work. Please note that this question asked for the workers' subjective impressions and was not intended to quantify their productivity. Figure 12 shows the replies. This same question was asked of the same person multiple times, and the vertical axis indicates a total of replies.

While "Seldom affects" and "Somewhat affects" are roughly equal in number, a considerable number of workers replied with "Does not affect at all." None of them said "Seriously affects."

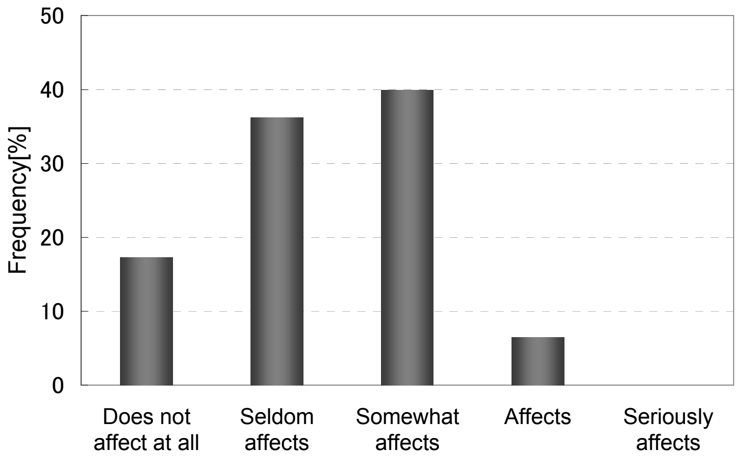

Figure 12 Effects of office thermal environment on work

5. Discussion

The survey results show that, even in offices performing similar work, indoor thermal environment can differ considerably from one office to another. Now, how do workers working in offices perceive their indoor thermal environments?

Figure 13 displays the relationship between room temperatures predicted by the workers surveyed and those recorded by the data loggers, for the same points in time. Although some positive correlation does exist between the two, the authors can hardly claim that the office workers correctly know the temperatures in their offices. The predicted temperatures carry prediction errors, on both the positive and negative sides, off the actual temperatures.

Judging from those survey results, the authors can infer that workers may illogically ascribe any change in subjective coldness/warmth to room temperature, disregarding disturbances to their senses brought about by changes in their own metabolism, amounts of clothing they wear, etc. Furthermore, the survey results also give us a concern that the temperature for cooling recommended by the Japanese government, 28 °C, might actually be seen as a very vague standard, in that people have different perceptions of what this temperature feels like.

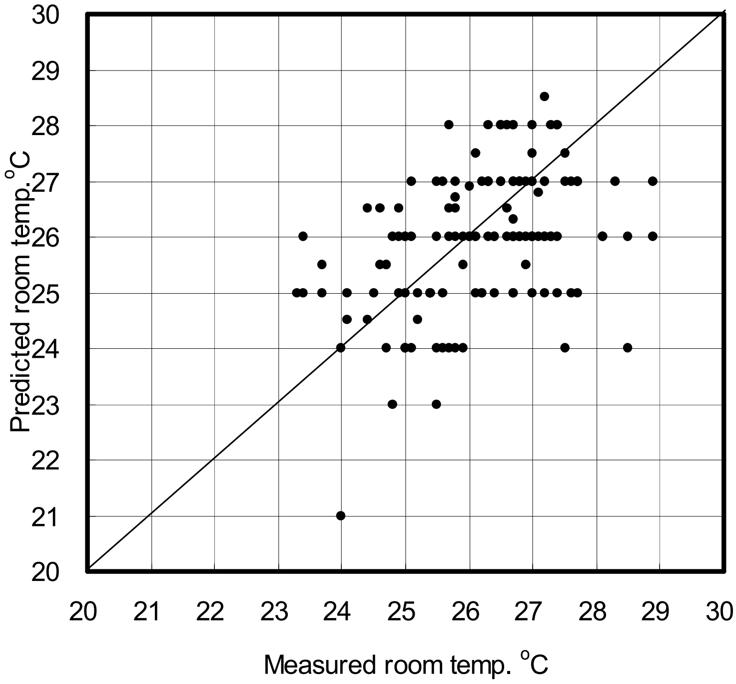

Figure 13 Room temperature measured and predicted by workers

6. Conclusion

The authors conducted a survey of indoor thermal environment in 41 offices in Japan. The results show considerably broad distributions of room temperature and relative humidity during regular business hours with each office as well as during each season. The authors also found that the Japanese government's recommended room temperature for cooling of 28 °C was not followed by a lot of offices surveyed but some of them kept their room temperatures rather higher. The government's call for fewer emissions was met with acceptance by some offices. Still, there is a concern that the physical quantity of "room temperature" might not be correctly recognized by some workers. To persuade more offices to follow its call for a temperature setting of 28 °C, therefore, the authors believe that the government needs to consider and take further measures in the years to come.

Acknowledgments

The authors hereby express our gratitude to all the people who kindly collaborated with us in conducting the office environment measurement and completing the questionnaire.

Keywords: education, natural environment, construction, sustainability, building, technology, trades

Summary

The British Columbia Institute of Technology (BCIT) is an innovative polytechnic specializing in advanced technology training in Western Canada. The largest of six schools at BCIT, the School of Construction and the Environment (SoCE) is concerned with the built environment, the natural environment and the relationship between them. The School integrates sustainability concepts, processes and technologies over the entire spectrum of programming and applied research. The belief is that in order to be effective, sustainability education needs to be embedded within each conventional trade, technology, and engineering sector and not be a stand alone endeavour. A Sustainability Framework has been established to guide research, curricula adaptation, and operations. Six themes spanning ecological, social and economic interests give focus to reflecting sustainability in action. The Framework underpins three foundational notions: i) ecological carrying capacity, ii) global equity, and iii) full-cost accounting. The School has also formalized a working partnership with BCIT's Administrative Services Department to reduce the Institute's ecological footprint and transform BCIT campuses into living laboratories of sustainability. The partnership approach has proven instrumental in accelerating sustainability as a focus for action across the institute.

1. Combining Construction and Environment Programs in One School

The BCIT School of Construction and the Environment (SOCE) represents a unique approach to interdisciplinary education. Whereas many schools adopt a "Built Environment" focus, concerned predominantly with buildings and their interactions with ecosystems, the approach at SOCE has been to pursue the integration of a full spectrum of natural resources programs within a School that simultaneously offers a suite of building design and construction-related programs. The intent in offering multiple disciplines housed within a single school is to encourage opportunities for interdisciplinary learning and research across the widest possible interface of natural and built environment systems.

This combination of programs offers a platform for the parity of value of both construction and environmental education. The School of Construction and the Environment espouses to be: "concerned with the natural environment, the built environment and the relationship between them." The direction of the School's evolution towards sustainability in all aspects of its curricula, operations and research activities, and its multi-disciplinary format, boasts a rich diversity of educational opportunities. Programs in natural resource management range from Mining to Fish, Wildlife and Recreation. Technology programs include: Civil Engineering, Environmental Engineering, Architectural Building Sciences, and Interior Design. Trade programs encompass: Steel Fabrication, Piping, Saw trades, Joinery, Carpentry and Electrical.

1.1 Targeting Curricula and Aligning Administrative Practices to Reach New Horizons

In 2006, observing the links between changes in global ecosystems due to anthropogenic activities and the implication that the building sector accounts for two-thirds of global energy and materials consumption (Worldwatch 1995), the School's management team embarked on a "sustainability agenda" that targeted four strategic areas:

i) creating new and emerging disciplines;
ii) morphing of existing disciplines;
iii) embedding the practices of sustainability into existing disciplines;
iv) integrating operations with academic programs.

The objective of the SOCE is to accelerate a transformation in the state of practice of natural and built environment sectors towards the embodiment of sustainable development and environmental stewardship.

To institutionalize this strategy, the SOCE embarked on a three year initiative that commenced with the creation of a full time director position in the School. This significant role is dedicated to incorporating progressive environmental management and rapidly emerging sustainability themes into the education programs and applied research activities of the School. Since mid 2006, the Director, Sustainable Development and Environmental Stewardship has been working with the School's Associate Deans and Program Heads to transform academic programs and to proactively embed environmental and sustainability concepts, technologies and processes within the mandate of the SOCE. The state of practice for commercialization of new and emerging technologies, their applications and industry standards are explicitly considered through lenses of sustainability: social and environmental impacts, efficiencies, conservation opportunities, and restoration of potential natural resources. The Director is a resource to the SOCE and builds research capabilities in sustainability while addressing the general needs for transformation of academic portfolios. However, in order to gain rapid traction, the Director's priority has focused on the immediate needs of the Natural Resources Portfolio of programs. This area of the School is already engaged in formative thinking about sustainability issues. Several programs within this portfolio are in the process of being adapted and/or introduced. The intent is to focus preliminary efforts in this area of the School as a strategy to lodge the initiative and build a base of confidence for implementation approaches.

The formal transformation towards a pervasive sustainability culture within SOCE began by development of a Sustainability Framework (http://www.bcit.ca/construction/sustainability) to guide thinking and practice within the School. The Framework was developed by the School's management team in consultation with the Department Program Heads. An incremental approach was developed whereby the Dean stipulated that all departments would have to clearly and specifically demonstrate how their portfolio was moving towards sustainability in curricula, operations or research activities. BCIT's status as a Polytechnic facilitated this level of leadership since faculty are predominantly in educational roles that are not tenured, and research activities are linked to programs. Ultimately, program funding could be tied to the performance of departments to respond to the sustainability agenda.

The School's annual operations planning process was amended to include a focus on "Sustainable Development and Environmental Stewardship" whereby each department is asked to reflect their program changes accordingly. As an annual planning tool that is used for both performance assessment and budgeting purposes, the incorporation of sustainability as a focal point in the Operations Plan enables the School to both monitor its progress towards sustainability goals as well as align its administrative decisions and resource allocations accordingly.

1.2 Developing an Interdisciplinary Research Agenda

As a polytechnic institute, BCIT has a mandate to pursue technological development in applied research. For the School of Construction and the Environment, a research agenda that pursues interdisciplinary innovation in technology is a "natural" fit. Within the School, several research portfolios were initiated to reflect both a need and desire to use applied research to both: a) apply technology that integrates the natural and built environment towards more sustainable outcomes, and b) inform the evolution of educational programming toward sustainability goals. Examples of "Centres" developed by the School to meet these dual objectives include: the Centre for the Advancement of Green Roof Technology, the Building Science Centre, the Canadian Housing and Construction Centre, the Centre for Infrastructure Management and the Centre for Energy Systems Applications (www.bcit.ca/construction/research/areas.shtml).

2. Incorporating Sustainability Concepts, Processes and Technologies

2.1 Adopting a Sustainability Framework

To begin the process of transforming SOCE towards an organizational culture of sustainability, the management team consulted with the School's Program Heads to develop a Sustainability Framework with six guiding themes. The Sustainability Framework is based on a systems perspective that links the natural and built environment through a global cycle of resource flows, see Figure 1. It recognizes that production starts with ecosystems from which natural resources are derived, as a function of economic activity aimed at meeting societal aspirations for improved quality of life. Natural resources are then turned into the commodities used to construct and operate built environments with the help of engineered systems. The wastes from these activities are, ultimately, absorbed by ecosystems to re-produce natural resources, and so on (www.bcit.ca/construction/sustainability). The integration of environment, society and economy can be conceived as a circular flow where economic activity bridges the relationship between the environment and society – it is the vehicle for extraction of resources and deposition of wastes through the process of manufacturing and consumption. The implication is that an imbalance in the rate of resource harvesting or pollution production that exceeds an ecosystem's reproductive or assimilative capacities creates an unsustainable condition. A nested hierarchy of systems is also implied whereby ecosystems are viewed as the foundation for societal activities that are implemented through economic activities. The economy exists because of and is dependent on society, which exists because of and is dependent on the environment. However, the economy, despite its ultimate dependency on people and the planet, exercises an "organizing" capability – it can control the rate of extraction, distribution and consumption of resources. Through globalization, the economy brokers relationships between society and the environment: directing both the flow of resources and the location of labour. It has the power to both serve as well as dis-serve society. Similarly, society can serve as well as dis-serve the environment – to its peril.

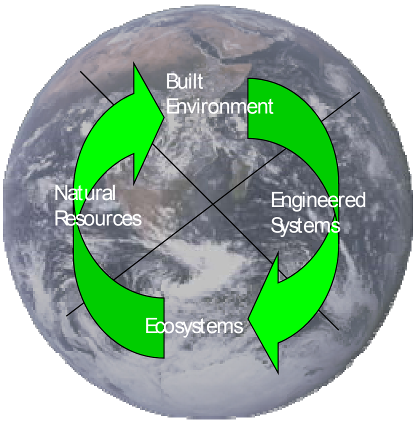

Figure 1 Sustainability Framework: systems perspective of resource flow.

The Sustainability Framework underpins three foundational notions:

i) ecological carrying capacity,

ii) global equity, and

iii) full-cost accounting.

To give meaning to these foundational notions within the Sustainability Framework, six themes spanning ecological, social and economic interests were developed to give focus to departmental programs and the work of individual faculty and staff. The intent is that the themes be used to guide thinking and inform adaptations to curricula, education delivery, applied research, and School operations.

The six sustainability themes are:

- Strengthen and protect assets
- Balance use with renewal of resources
- Account for all costs and benefits
- Reduce waste and eliminate toxics
- Ensure safety and access to services
- Support opportunities for improvement and enjoyment

2.2 Pedagogy and Practice: Incorporating Sustainability Across the Curricula

Sustainability within the context of urban development is becoming an industry standard in British Columbia. All industry sectors are undergoing rapid transformation. Global issues such as livability, climate change and shifting economics are seen to need new approaches by practitioners. Entry level and mature students have an expectation that programs address these issues. There is also a general trend towards integrated consideration of health, sustainability, ecological principles, and community-based solutions as the basis for “sustainable” industrial and social development. SOCE strives to drive this industry agenda into its program delivery as quickly and as seamlessly as possible to meet the mandate for job-ready graduates. Alignment of existing and emerging programs and applied research focused on core sustainability themes is intended to ensure that all existing and future engineering, trades and technology programs in SOCE produce graduates that are at the cutting edge of sustainability practice within their fields.

A broad, progressive, innovative and consistent strategy has been designed to manage the incorporation of sustainability across the curriculum of the School. Given that programs range from trades to Master’s level, the unique approach at SOCE consists of encouraging integrated systems thinking and trans-disciplinary solutions.

2.2.1 Creating new and emerging disciplines

To immediately implement the sustainability agenda, the School has developed the new Bachelor of Technology in Ecological Restoration program. It aims to provide students with a strong foundation in the methods available to restore a broad range of ecosystems impacted by human influence. Graduates will obtain skills to assist in the recovery of degraded ecosystems. They will also be encouraged to develop leadership and innovation skills to enable cross-disciplinary work with other professions in a pre-emptive approach to avoid or mitigate impacts to ecosystems from human activities (BCIT, 2008, 2).

SOCE is also pursuing a new Sustainable Urban Development Bachelor of Technology. The goal of this degree is to prepare graduates with the technical, valuation, managerial, and capacity-building skills relevant to all industry sectors that are transitioning to a sustainability-focused economy. Through community-based experiential learning, students will be exposed to dimensions of sustainability and "integrated practices." Although originating in the SOCE, this program will be open to diploma graduates from all Schools within BCIT and will extend opportunities for students to pursue integrated, or trans-disciplinary studies, and to study sustainability in-depth in order to fill the needs of industry for human resources at the operational levels, and entry management levels (BCIT, 2007a).

2.2.2 Morphing of existing disciplines

Existing disciplines are continually changing. Therefore, striving to keep the curriculum as current as possible is an imperative. SOCE, for example, is meeting this need through its Civil Engineer distributed learning courses that provide a variety of training to the municipal utilities' sector. Municipalities in Canada are facing fiscal and human resource constraints. Meanwhile civil infrastructure is aging and new technologies are usually expensive. This predicament prompted the SOCE to create the Centre for Infrastructure Management (CIM) (http://commons.bcit.ca/infrastructure). The CIM promotes improved infrastructure management, develops and supports best practices through workshops and distributed learning and is formulating programs to provide professional development and training opportunities in an integrated and sustainability focused fashion. This is an example where new programs are created to enable multi-disciplinary and flexible education to existing students and to industry practitioners who need to update their knowledge. The opportunity for morphing of existing disciplines is, therefore, not squandered on traditional education silos. Instead, modern, integrated and sustainability-focused concepts (for example promotion of trench-less technologies) are included at the onset of program formulation. As such, sustainability is not an add-on, but rather an integral consideration to the morphing of traditional sectors such as public works management.

The CIM also intends to target its programs to suit a matrix of learning requirements at the functional, working, and detailed knowledge levels. For example, an elected official may only need a functional understanding of infrastructure management topics, whereas a public works manager will need a combination of functional understanding, working knowledge, and detailed knowledge depending on the topic. The scope of the education program is being given extensive breadth even at the entry level of delivery. This approach is much more robust in terms of keeping student's and practitioner's options as open as possible, while allowing for staged consolidation of certificates, diplomas and Bachelor programs.

Adapting existing curricula is being addressed through a School-wide approach. Recognizing that the work load for educational faculty impedes opportunities for reflection and research that might commonly accompany a research/teaching appointment, the School has launched "The Pacific Spirit Project." This initiative is modeled on the Ponderosa Project (http://www2.nau.edu/~ponder-p/) that was pioneered at Northern Arizona State University and subsequently adapted as the Piedmont Project (http://www.scienceandsociety.emory.edu/piedmont/) by Emory University in Atlanta, Georgia, USA. Both initiatives focus predominantly on the environmental aspects of sustainability and place an emphasis on inter-disciplinary faculty engagement and empowerment.

The Pacific Spirit Project represents a unique adaptation to a polytechnic context. Like its predecessors, the project enables faculty who are interested in incorporating sustainability concepts and practices into their curriculum. The project commences with a two day workshop followed by a commitment over the following six weeks to reflect on how to use what was learned to adapt curriculum so that it includes sustainability content. The project reconvenes with a one day meeting at the end of the six week period where faculty share their plan for next steps as well as reflect on experiences and lessons learned through the process. Usually, the workshop is held in May and the reconvening meeting occurs in late August. However, because the Pacific Spirit Project aims to meet the needs of faculty in both technology and trades programs, there is an additional layer of complexity that must be addressed regarding the timing of the project. This is because trades instructors seldom enjoy the "break" in teaching responsibilities that traditionally occurs over the summer months. This poses a challenge to the structure of the project that assumes the built-in reflective period.

To address some of these challenges, the Pacific Spirit Project is being undertaken in cooperation with the BCIT Learning and Teaching Centre (LTC). Faculty who wish to pursue significant changes to their curriculum will be offered advice and guidance by the LTC on how best to proceed, and what incentives or other resources are available to assist. These incentives, in the form of paid leave from teaching duties for example, are critical to enabling faculty with full and continuous teaching loads to succeed in securing the time needed to revise curricula. Additional resources are also being provided by the SOCE for discretionary use by the Steering Committee that have been appointed to oversee the initiative. These funds will be provided on an as-needed basis to faculty that are engaged in the Pacific Spirit Project and who are embarking on or are in a process of adapting their curriculum.

2.3 Administrative Change: Sustainability in Education Delivery and Departmental Operations

Technology enabled learning is an institute-wide priority at BCIT. Within SOCE this is reflected and modified to technology enabled learning that also achieves sustainability objectives. An example is distributed learning. An emphasis on e-learning and other forms of distributed learning is a strategic focus within the School. This is partly in response to the fact that a significant portion of SOCE students are commuting long distances to attend classes. A large percentage of the student body also comprises part-time studies enrollment, meaning that students who are commuting usually do so to attend only one class per day.

Different educational programs lend themselves to different approaches. While e-learning can work as a delivery vehicle for portions of or indeed whole courses in some program areas, skills training such as those prevalent in trades programs require hands-on, supervised instruction. Administratively, the educational content requirement for trades programs is far more prescribed by industry and government certification bodies than are the technology programs. This means that adapting the delivery or substantive content in trades training becomes extremely difficult. This remains an ongoing challenge.

2.3.1 Embedding the practices of sustainability into existing disciplines

Recall the four strategic areas adopted by SOCE's management team that were introduced in section 1.1 above. The third strategic area: embedding the practices of sustainability into existing disciplines is perhaps the entry point for many trades training programs to respond to the challenge of incorporating sustainability.

Embedding the practices of sustainability into existing disciplines is a way to demonstrate the values of full-cost accounting, social equity and environmental stewardship without necessarily having to revise the substantive content of curricula. An example of this approach is demonstrated in the School's Joinery program. A criteria-based point system to evaluate the department's operations is being developed. The point system aims to reflect the themes of the Sustainability Framework and will be used to evaluate product purchases for the program. A range of materials will be assessed for use in the production of office furniture ranging from Forest Stewardship Council certified wood to alternative fibers such as bamboo and straw. Continuous application of the point system will be used to:

- Review commonly used materials and identify those considered to be toxic,
- Assess opportunities to substitute non-toxic materials,
- Reduce waste and identify options that divert wood fiber from the waste stream,
- Upgrade furniture production to meet LEED^{TM} minimum requirements.

2.4 Transforming the Campuses to become "Living Laboratories" of Sustainability

BCIT has five campuses scattered across the Vancouver Metropolitan area, one of which is shared with several other universities and institutes. Each campus is unique and several cater specifically to the needs of individual technology areas. Examples include the Aerospace Campus, or the Marine Campus. However, what all campuses share is a commitment to embodying the best in state of the art technology. More recently, this vision is being complemented by an aspiration to become "Living Laboratories" of sustainability.

2.4.1 Integrating operations with academic programs

The fourth and final strategic area of the SOCE's management team approach is: Integrating Operations with Academic Programs. This requires a collaborative effort with BCIT's Administrative Services Department that oversees institutional responsibilities for campus planning, facilities management, purchasing, safety and security, among others. In March of 2007, the Dean of the SOCE signed a Memorandum of Understanding (MOU) with the Executive Director of the Department of Administrative Services pertaining to: Environmental Stewardship and Sustainability Practices. The signing took place during BCIT's biannual "Eco-Fair" event and was witnessed by the VP Education and Student Services who then gave a public address in support of sustainability as both a value in education and opportunity for campus-wide engagement. The MOU enables students, faculty and staff to work collaboratively towards environmental stewardship and sustainability practices on BCIT campuses. Ten activities are articulated that include the annunciation of the commitment to "developing and promoting the concept of the campuses as living laboratories to further the evolution of environmental stewardship and sustainable development practices" (BCIT, 2007b). Other activities include:

- Involving faculty and students in creating examples of new technologies, methods, and approaches and demonstrating and documenting those as part of the educational and research interests of the Institute.
- Providing input to master planning of the Burnaby campus and to specific development activities related to the plan's implementation.
- Promoting BCIT's activities in environmental stewardship and sustainability practices within the Institute and to external audiences.
- Developing a "green" plan for the campuses belonging to the Institute and those managed in partnership with other institutions.
- Disseminating information throughout BCIT campuses to inform, educate, promote and encourage best practices in sustainability and environmental stewardship by staff, faculty and students.
- Assessing the ecological footprint of the Institute and developing the means and methods to minimize and/or repair that impact while achieving economies and adding value to the Institute and industry clients.

2.4.2 Reducing the ecological footprint of campus

A Greening Campuses Strategic Plan is being drafted by the Director Sustainable Development and Environmental Stewardship and the Director of Campus Planning. The document is intended to complement the Institute's Campus Master Plan (http://www.bcit.ca/planning/masterplan), which cites sustainability as a planning principle. The strategic plan utilizes the Sustainability Framework that was developed by the SOCE and introduces an overarching, aspiration to reduce the Institute's ecological footprint sufficiently to "model sustainability by achieving a four-fold decrease in the amount of energy and materials throughput on campus" (Moore and Wong, 2007, 6). In effect, this is similar to the concept of a "Factor Four Economy"

(Weizsacher et al., 1998) or the 80 per cent reduction in the level of greenhouse gas emissions that scientists claim would be required to stabilize global climate (UCSUSA). Seven sub-goals are articulated to guide the initiative in support of the proposed objective:

i) Greenhouse gas neutral
ii) Net energy producer
iii) Zero Waste
iv) Water Balanced
v) Ecologically Restored
vi) Equitable and Socially Responsible
vii) Accessible to All Students and Faculty

Given the ambitious nature of this effort, the goals and overarching objective will be applied and tested at the BCIT main campus in Burnaby. A faculty researcher has been retained on a part-time basis to investigate the Burnaby Campus ecological footprint using a comprehensive material flow analysis approach. The findings will be used as a baseline. The method will be documented for purposes of informing new curriculum development for SOCE's Environmental Engineering Program and the proposed Sustainable Urban Development Program, mentioned above. The initiative is building momentum slowly as service units within various departments recognize the opportunity to meet multiple objectives through the initiative. For example, the Institute's waste management and energy management programs are benefitting from the increased communication and awareness that is building around the campus "Ecological Footprint" initiative. People want to be involved in solutions and there is a keen interest to learn about how to reduce one's own footprint. When that overlaps with energy conserving activities on campus, for example, there is a dual benefit: to the Institute and the individual.

2.4.3 Engaging other schools and departments

The Living Laboratories concept was initiated at BCIT through the School of Health and the related research that was being undertaken within BCIT's Technology Centre. The concept has tremendous appeal as an overarching banner for the relationship that the administrative and services arms of the institute can have in collaboration with the academic and applied research areas. The engagement of SOCE with the Administrative Services Department forms one of potentially many similar initiatives that aim towards further integration of operations with academic programs. It may also serve as a spring-board for increasing inter-disciplinary activity across the schools of the Institute. For example, in forming the steering committee to oversee effective implementation of the MOU referenced above, the Administrative Services Department and SOCE invited the Institute's Information Technology Services unit to participate permanently in steering committee meetings. The rationale was based on a shared interest in sustainability and interest in learning about what embracing sustainability would mean for each of the operations and academic units. The steering committee also agreed to adopt a working-group model whereby different groups of individuals could work on specific projects related to the overall implementation of the MOU, regardless of their home department affiliation. The longer-term, shared objective is to find initiatives and opportunities to engage a broader cross section of the Institute's operational and academic business units within the activities of the steering committee and under the banner of creating Living Laboratories of sustainability on BCIT campuses.

3. Reflections on Lessons Learned and Challenges to Overcome

SOCE's transformation to a culture of sustainability is a broad and multi-faceted endeavor. It is, therefore, essential to hire dedicated staff whose responsibility it is to nurture, inspire and constantly attend to the various initiatives and opportunities that such a process engenders. It cannot be done on the side of one's desk. By the same token, one person alone cannot bring about a complete organizational transformation. Building relationships and opportunities to demonstrate leadership across the organization is also important.

It is noteworthy that the interest in sustainability is now so prevalent amongst students, faculty and staff, that the initial intended focus on the Natural Resources program portfolio has very rapidly spread to many other parts of SOCE and indeed the BCIT Institute simultaneously. This has happened in a much more accelerated manner than was originally envisaged. By the same token, while this is an exciting evolution, managing expectations is important. Success in many regards, like the road to partnership, is a journey of many steps. Some feel like giant leaps and some feel like steps backwards. Nevertheless, being clear about roles and responsibilities, what can be reasonably accomplished within a given time period and with available resources are all important management skills that equally come to bear here. An important insight for gaining momentum is to identify clear goals that meet the interests of multiple parties and to begin working on their implementation right away. For example, BCIT holds a biannual event called "Open House." This is the Institute's most significant student recruitment activity. In 2008, the organizers of Open House developed a theme that aimed to demonstrate how being a part of BCIT enables opportunities to make a positive contribution to society. Environmental stewardship was chosen as a concept to help illustrate the theme. Simultaneously, the Director of Sustainable Development and Environmental Stewardship and a handful of BCIT employees were organizing an employee volunteer committee called the Green Team. Some members of the Green Team were also part of the Open House organizing committee. Once the theme was announced, the synergy created between the Institute-wide focus on Open House and its concomitant themes and the actions of the Green Team created a tremendous momentum that seemed to feed itself through a year-long "buzz of activity" culminating in a very successful Open House that featured a tent display dedicated to the Green Team's activities as well as local media coverage. This type of excitement could probably not have been achieved by either initiative acting alone.

WASTE PREVENTION POLICIES, ITS REDUCTION POTENTIAL AND ECONOMIC IMPACTS

Ana Paula BORTOLETO M.Eng.[1]
Keisuke HANAKI Dr.Eng.[2]

Keywords: Integrated Solid Waste Management, Waste Prevention, Life Cycle Assessment and Life Cycle Cost Assessment.

Summary

The quantities of municipal solid waste in the world are increasing each year, fast growth as GDP. This presents a challenge for metropolitan cities in developed and developing countries. Waste prevention encompasses activities of waste avoidance, reduction and reuse. These activities are considered to be preventative as they contribute to decrease the amount of household waste entering the collected waste stream. Previous researches identified many approaches across a wide range of waste prevention policies to be implemented in metropolitan cities. To gain a better understanding of which effort should be focused on this study, an analysis of current activities of all stakeholders at the study field was conducted. For each program, it was identified the component of household waste that the approach was likely to impact upon. Based on that, reduction potentials were calculated as well as its economic impacts using life cycle cost assessment. The results demonstrated that costs decreased as a result of waste prevention policies implementation combined with recycling and composting. In setting the context for this study, it was possible to notice that this type of solid waste requires action at all levels in the production chain. Understanding the social and institutional performance of environmental policies is an area of significant and growing concern. Thus, the assessment of activities that influence consumption patterns is highly relevant. While waste prevention is certainly not easy, the rewards are potentially very significant in terms of cost savings, social inclusion and the local and global environment. In the long term, these activities should continue to decrease solid waste in absolute quantities and hopefully also the underlying growth rates.

1. Introduction

In early times, the disposal of human and other wastes did not pose a significant problem because the population was small and the amount of land available for the assimilation of solid waste was large. However problems with disposal of wastes can be traced from the 14th century, littering of food and other solid wastes in medieval towns led to the breeding of rats and the outbreak of the plague epidemic killed half of the Europeans and caused many subsequent epidemics and high death tolls.

Nowadays, limited space for new landfill sites and social acceptance of solid waste management policies are the majors concerns related to solid waste issue. All policies in this area must be environmentally friendly, economically sound and socially acceptable to guarantee their success, since social movements and conflicts between residents and authorities sometimes lead to closure of an existing facility or to fail an applied policy. Therefore, in dealing with solid waste, there are two fundamental requirements: reduce the amount of solid waste generated and then an effective system to manage the waste still produced.

Solid waste management must be sustainable. In other words, it must consider the whole life cycle of waste from the cradle to the grave. An integrated solid waste management – ISWM system combines solid waste streams, collection, treatment, and disposal methods, within a life cycle approach [White, 2002]. Using a range of management options in an integrated system gives the flexibility to channel waste via different treatments as economic, environmental and social conditions change.

Nevertheless, for an ISWM system to reduce solid waste effectively waste prevention is necessary. In other words, waste prevention is an alternative to avoid solid waste generation. Waste prevention, “waste reduction” or “source reduction” refers to any change in the design, manufacture, purchase, or use of materials or products (including packaging) to reduce their amount, toxicity and fugitive emissions before they enter into solid waste stream.

Recently, new studies have been developed in order to understand how waste prevention helps to reduce solid waste generation. Most of them are based on the conventional solid waste management, which do not include all the activities in urban cleansing. Although, all these studies have presented trusty data, no absolute results have been achieved. Economic and environmental aspects must be included simultaneously to improve the decision-making tool.

Hence, this study will address the lack of comprehension about waste prevention inside ISWM system subject, based on the evaluation of environmental and economic impacts. And, to achieve this it will introduce the unique system adopted in Porto Alegre, presenting how this system works in the local context and also as a potential model for adaptation elsewhere.

2. Study Case

According to the National Survey of Basic Sanitation [IBGE, 2000], about 69% of the solid waste produced in Brazil is disposed in adequate landfills but the remaining part has being still disposed in waste dumps. The 13 biggest cities are responsible for 32% of the waste collected in urban centers and almost 100% of them has adequate final disposal.

In addiction, 236 out of the 5507 Brazilian municipalities have a selective collection implemented as an alternative to resolve the environmental, economic and social problems consequents of informal solid waste collection in wastes dumps [CEMPRE, 2004].

The research was delimited to Porto Alegre considering the previous elements and the fact that its ISWM system is internationally recognized as a good example of the municipal urban cleansing management in developing countries.

2.1 Porto Alegre City

Porto Alegre City is located in the southern part of Brazil and has a population of approximately 1.5million [Fig.1]. Since 1996, Porto Alegre has consistently had the highest standard of living of all Brazilian metropolitan areas, with a human development index of 0.865 and a gross domestic product per capita of US$4697 per year, according to IBGE (2000a, b). Its progress is primarily linked to the way in which the city has been managed since 1989, with the adoption of the participatory budget, in which citizens and local government divide the responsibility to designate the municipal budget.

Figure 1 Porto Alegre's location in Brazil's Map, (CIA, 2005).

As a direct consequence of the high level of citizen involvement in allocating the municipal budget, the proportion of investment serving public environmental management policies, as well as solid waste management, and the regeneration of public spaces has increased in recent years [Carrion, 2005].

These results represent an important advance in prioritizing social issues and an improved political relationship between government and society. However, an emergency situation that Porto Alegre faced in 1989 also contributed to the increase of these investments. At that time, the dumpsite had already reached its capacity; its soil was contaminated and pollution levels were increasing in environmentally protected areas. In addition, a large number of people were making a living by searching for and collecting recyclable waste from inside the dumpsite and consequently spreading the diseases associated with waste among the population.

In 1990, the Municipal Department of Urban Cleansing, with objectives that not only included sustainable development but also a strategy to fight poverty with income generation, implemented an ISWM system. This system was based on four interrelated components: (a) citizen participation, (b) public environmental management programs, (c) comprehensive knowledge of Porto Alegre's natural and built environment and, (d) environmental education [Menegat R., 2002].

As shown at Figure 2, the ISWM in Porto Alegre uses a combination of four methods:

a. Source separation into domestic, industrial, commercial and hospital solid wastes;
b. Selective Collection;
c. Different treatment, re-use, disposal for each type of solid waste, and;
d. Promotion of environmental education.

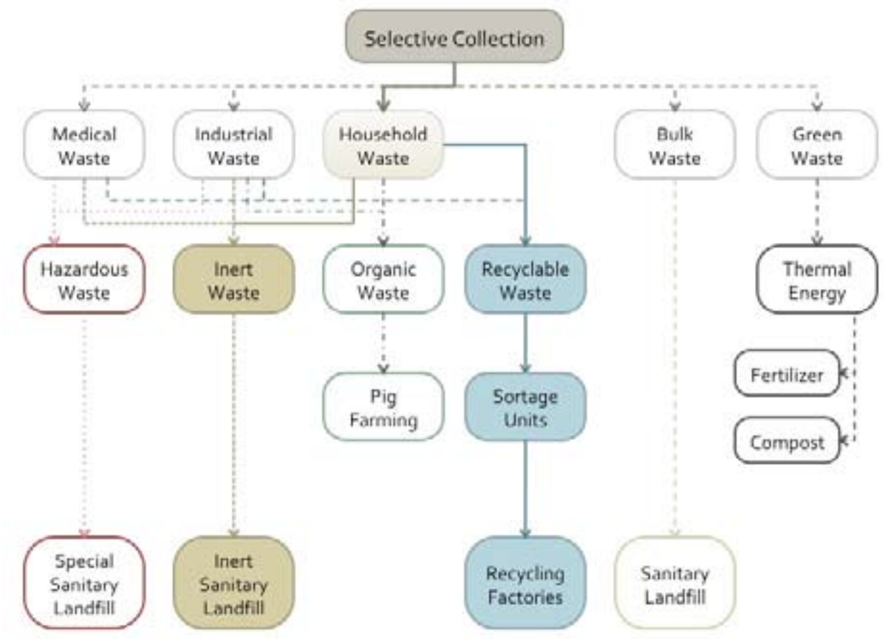

Figure 2 Porto Alegre's integrated solid waste management system flowchart.
**Highlighted processes in grey correspond to the boundary system adopted in this study.*

Consequently, to promote the inclusion of poor communities, the first action was to create an organization for those who were living by collecting recyclable wastes (the Former Scavengers Association), and after that a partnership to intro-duce selective collection in the city. Based on a mutual agreement, it was established that the local government would be responsible for collection and delivery of recyclable waste to the so-called unidades de triagem (sorting units), where former scavengers would separate, store and sell them to recycling factories. Through this partnership, the former scavengers man- aged to obtain higher prices for their recyclable materials and a larger quantity of such material has been sold directly to the formal recycling industries, thus avoiding the middlemen.

Construction and demolition debris, considered as inert waste, are recycled and disposed in a different site. Waste concrete and brick is usually crushed, screened and used as road-base and paving pieces, this process is accomplished by the local government but paid by the waste generators. Vegetation removed during clearing of the site is also collected by the local government and used in the composting of organic waste. In case of steel, glass and plastic wastes, they are usually sold to recycling factories in the region. The entire process consists in: (a) on-site source separation; (b) concrete and brick recycling; (c) green waste composting and, (d) disposal at the inert sanitary landfill.

Environmental education is also one of the important elements inside Porto Alegre's ISWM system. In 1998, the environmental atlas of Porto Alegre was published, providing the basic knowledge that citizens need in order to participate in an informed way. Hence, public participation as a part of the ISWM system was established in Porto Alegre through a participatory budget, the former scavengers associations and an environmental education programme.

At the present day, the selective collection has 80 employees, 29 trucks and collects around 40t/day of solid waste. According to DMLU, the cost of the selective collection is US$42 per ton, being one of lowest cost in Brazil. It is estimated that independent collectors (not members of the scavengers association) collect 150 tons of solid waste out of which 70% is potentially recyclable [Tab.1].

3. Waste Prevention

Realizing the limits of downstream, end-of-pipe approaches, during the early of 1990's many environment administrations fully embraced "source reduction" and "pollution prevention" as general, overarching goals.

This meant, among other things, that as little solid waste as possible was to be finally disposed of, and this objective was to be achieved with priorities focus on preventive efforts, generally followed by recycling.

In most of previous studies, both waste prevention and waste minimization usually have the same meaning. However, according to terminological definition at OECD report [OECD, 2000], waste minimization is a broader term than prevention in that it includes recycling and incineration with energy recovery. As discrete activities, both recycling and incineration are distinct from waste prevention.

Table 1 – Porto Alegre's ISWM System Data [DMLU, 2005].

Population	1,448,322 inhabit
Total solid waste collected	296,140.33 t/year
Local population attended	100%
Household solid waste production	0.62 Kg/ inhabit.day
System's cost	US$ 3,575,320/year
System's self-sufficiency	51.3 %
Recycling efficiency	20 %

Therefore, waste prevention is fundamentally different from the waste minimization. Recycling and disposal options all come into play after goods have been used. In contrast, prevention takes place before materials have been identified as solid waste. To implement waste prevention, managers need to promote practices that reduce solid waste before it is generated.

The consensus understanding of waste prevention achieved by OECD in 1998 can be broken into three types of action:

a. Strict Avoidance, involving the complete prevention of solid waste generation by reducing material or energy intensity in production, consumption and distribution;
b. Reduction at Source, with minimization of materials or energy consumption;
c. Product Re-use, considering the multiple use of a product in its original form or purpose for an alternative with or without reconditioning.

It is important to highlight that the potential contribution of prevention to overall waste minimization has not been realized. While waste prevention will never make recycling obsolete, the application of both will generally have a greater influence on overall solid waste reduction than the singular application of one or the other. For example, there are numerous applications of source-reduced packaging, made with recycled materials, which can also be recycled.

At the municipal level, waste prevention avoids unnecessary solid waste collection, processing, storage and final disposal. It also offers significant potential for diverting materials from landfill, as well as contributes to greenhouse gas mitigation. Secondary materials market development can also be avoided and, consequently, it saves money and conserves natural resources. However, experience at the municipal level is still limited as well as the difficult to access its contribution to solid waste diversion relative to recycling.

Waste prevention also includes a sustainable design of products, including buildings. It consists in using all resources efficiently while creating healthier buildings with cost savings through improved human productivity, lower cost building operations and resource efficiency. In other words, is a structure that is designed, built, renovated, operated or reused preventing unnecessary waste from construction until its demolition. It is also designed to improve employee productivity, using energy, water and other resources more efficiently and reducing the overall impact to the environment.

4. Methodology

A large number of methods, approaches and modeling tools that can be used for supporting solid waste management decisions at different levels in society have been developed in the past years. Life-cycle thinking and life cycle assessment – LCA have become important methods for solid waste management and policy, and have been successfully applied to ISWM systems in a number of case studies.

Based on the methodology of life cycle assessment, as introduced by White et.al (2002), the ISWM system of Porto Alegre was investigated, focused on solid waste materials from households and small shops, only. Environmental loadings were analyzed through life cycle assessment and economic costs were estimated through life cycle cost assessment – LCCA. The activities of ISWM inside each process, collection, transport, treatment, recycling, landfilling were determine as well as the corresponding costs and savings.

Quantitative analysis was performed through LCA and LCCA to determine environmental and economic aspects, respectively. In both methods, two different scenarios of the system were applied, namely the current (scenario 1) and the improved (scenario 2) situations, for comparison.

Scenario 1 consisted of ordinary solid waste collection and selective collection with source separation. After selective collection, recyclable waste materials were delivered to sorting units separated into four categories (paper, glass, plastic, metal) and then sold to recycling factories. Solid waste that was collected through ordinary collection was delivered directly to a landfill site.

Based on the status quo (Scenario 1), the following scenario 2 for improving ISWM practice in Porto Alegre was analyzed: (a) full coverage of ordinary, selective and organic waste collection; (b) composting of collected organic waste; (c) increasing of existing recycling rates; (d) implementation of waste prevention programs; and, (e) upgrading of existing disposal practice to sanitary landfill with energy recovery.

At this study, five waste prevention programs were adopted at the scenario 2. Home composting and clothing reuse as residential waste prevention programs, while office paper prevention (duplex copping initiative and reducing waste) and paper towel reduction as commercial programs.

5. Discussion

The purpose of this study was to investigate on a general and approximate level, how waste prevention influences solid waste generation and its integrated management in Porto Alegre. First, waste prevention programs were determined and applied. Next, a future scenario with the improvement of current collection, recycling, landfilling, treatment and source separation was analyzed in view of their impacts on environment and on network costs. This study's findings provided a quantitative understanding of waste prevention inside solid waste management and revealed consistent approaches to improve its environmental and economic performances.

Life cycle thinking are becoming the principal decision support tool of solid waste management systems and, in this study, it illustrated the benefits of different waste management methods and waste prevention programs applied in the improved scenario, mainly with the reduction of solid waste disposed at the landfill and with the production of new raw materials that could replace production from virgin materials.

Here, waste prevention has been showed to have considerable environmental impacts, particularly decreasing greenhouse gas emissions and, water and soil contamination. However, no single solid waste management process or technology produced the overall lowest environmental impacts. Tradeoffs among management options were needed in both scenarios, indicating that society will have to make choices regarding the type of environmental impact that is least desirable in a certain place.

Applying waste prevention as a part of integrated solid waste management system in Porto Alegre has led to a reduction in the quantity of solid waste at the landfill and has also decreased unnecessary collection, processing, storage and final disposal.

Another important fact identified by this study concerned the relationship between industry and the former scavengers' association in Porto Alegre. Nowadays, the association's employees only earn enough to maintain their own survival but not to improve their living conditions; usually middlemen and industry receives most profit. A well-organized market for the recyclable waste trade is needed to structure this relationship in a fair manner for all parties. Increasing prices do not mean decreases in industry savings; in fact it might increase the availability of recyclable waste in the market.

The main objectives of solid waste management are to protect human health and the environment, and to conserve resources. In Porto Alegre, this study presented that direct impacts of solid wastes on human and the environment may be eliminated by introducing extended recycling strategies and waste prevention policies such as reuse.

Summary

The Comprehensive Assessment System for Building Environmental Efficiency (CASBEE) is an environmental assessment tool for buildings built in Japan. New CASBEE tools have already been developed for new buildings, old buildings, buildings in urban districts, etc. In Japan, approximately 500,000 detached houses are constructed every year. In order to improve the quality of houses, “CASBEE for Home” was introduced in 2007.

In this paper, we present the main features of the CASBEE for Home. Since the CASBEE for Home is expected to be used by various stakeholders in the housing construction industry, such as clients, designers, contractors, and builders, it is designed to be easy to use. The structure of the CASBEE for Home is similar to that of other CASBEE tools, and it can be used to evaluate both quality and environmental loads. The evaluation criteria are divided into 6 categories— Q1: comfortable, healthy, and safe indoor environment; Q2: sustainability to service life; Q3: regional contribution for view and ecology; LR1: energy and water conservation; LR2: resource conservation and reduction in construction waste generation; and LR3: contribution to improvement in regional and global environment. The assessment also includes 54 evaluation criteria that are based on the standards established in Japan. The comprehensive assessment considers not only the features of houses but the environment outside the houses, home appliances, information provided to the occupants by the house owners, and the techniques used in the building material production and the house construction.

1. Introduction

We have developed the “Comprehensive Assessment System for Building Environmental Efficiency (CASBEE) for Home (Detached House)” (hereafter called as the CASBEE for Home below.) to improve the quality of detached houses in Japan. Approximately 500,000 houses are built in Japan every year. The CASBEE is an environmental assessment method for buildings built in Japan. CASBEE tools for new buildings, old buildings, buildings in urban districts, etc. have already been developed. The CASBEE for Home was introduced in 2007. In this report, we mainly present the outline of the evaluation system used in the CASBEE for Home. Since the CASBEE for Home is expected to be used by various stakeholders in the housing construction industry, such as clients, designers, contractors, and builders, it is designed to be easy for use.

2. Structure of Evaluation

The CASBEE for Home evaluates general environmental condition on the basis of two indices Q and L. Index Q indicates the environmental quality of a detached house, and index L indicates the environmental load of the detached house. BEE is evaluated as shown in Figure 1.

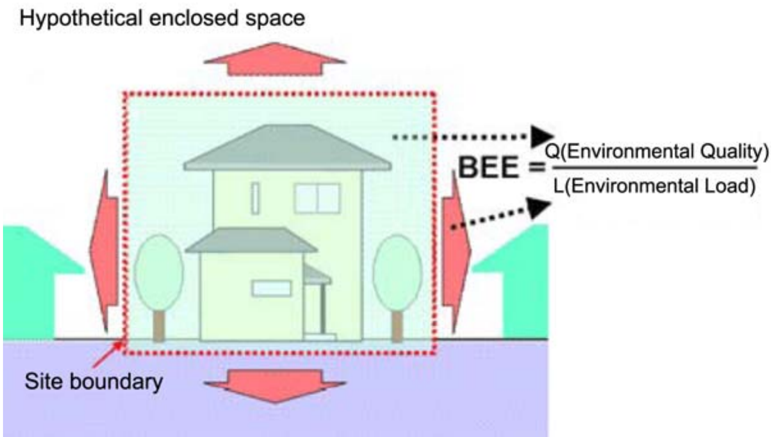

Figure 1 Hypothetical Enclosure for Estimation in CASBEE for Home

The structure of the CASBEE for Home is similar to that of other CASBEE tools, and it can be used to evaluate both quality and environmental loads. The environmental load is evaluated by the load reduction (LR) parameter. The evaluation criteria are divided into 6 categories—Q1: comfortable, healthy, and safe indoor environment; Q2: sustainability to service life; Q3: regional contribution for view and ecology; LR1: energy and water conservation; LR2: resource conservation and reduction in construction waste generation; and LR3: contribution to improvement of regional and global environment. The assessment also includes 54 evaluation criteria that are based on the standards established in Japan.

Because the CASBEE for Home evaluates the overall environmental quality of detached houses, the 54 evaluation criteria include not only the features of the houses but also the features of their surroundings, home appliances used by the occupants, information provided to the occupants by the house owners, and the techniques used in the building material production and house construction. There are some evaluation criteria that builders cannot fulfill; however, we have decided to evaluate basically everything that affects the environment considerably.

The evaluation of Q and LR in the CASBEE for Home is based on the CASBEE for new buildings, although the criteria for the former have been slightly modified.

In the CASBEE for new buildings, the evaluation of water resources is included in the LR2 category. However, in CASBEE for Home, we have shifted the evaluation of water resources to the LR1 category. This is appropriate for the $LCCO_2$ estimation since resource conservation is considered in the LR1 category.

The 54 evaluation criteria are listed in Tables 1 and 2.

Table 1 Criteria for Evaluation in CASBEE for Home (Quality)

Q1 Comfortable, Healthy, and Safe Indoor Environment		
Additional Criteria	Minor Criteria	Merits
1. Hotness and Coldness	1.1 Basic Performance	1.1.1 Efficient Thermal Insulation and Airtightness Performance
		1.1.2 Sunlight Control Settings
	1.2 Control of Temperature in Summer	1.2.1 Natural Ventilation
		1.2.2 Proper Cooling
	1.3 Control of Temperature in Winter	1.3.1 Proper Heating
2. Health, Security, and Safety	2.1 Countermeasures against Chemical Contamination	
	2.2 Proper Ventilation	
	2.3 Prevention of House break-ins	
3. Brightness	3.1 Use of Sunlight	
4. Peaceful Atmosphere		
Q2 Sustainability to Service Life		
Additional Criteria	Minor Criteria	Merits
1. Basic Life Performance	1.1 Building Frame	
	1.2 Exterior Wall Material	
	1.3 Roof Material	
	1.4 Resistance against Natural Disaster	
	1.5 Fire Detection System	1.5.1 Fire-proof Structure (Excluding Windows)
		1.5.2 Fire Detection System
2. Maintenance	2.1 Ease of maintenance	
	2.2 Maintenance System	
3. Functionality	3.1 Floor Area and Room Layout	
	3.2 Barrier-free Housing Design	
Q3 Regional Contribution for View and Ecology		
Additional Criteria	Minor Criteria	Merits
1. Consideration of Townscape and Scenery		
2. Creation of Biological Environment	2.1 Tree Plantation	
	2.2 Creation of Biological Environment	
3. Safety and Security in Region		
4. Use of Regional Resources and Assimilation of Regional Culture		

Table 2 Criteria for Evaluation in CASBEE for Home (Load Reduction)

LR1 Energy and Water Conservation		
Additional Criteria	Minor Criteria	Merits
1. Energy-saving Design of Building	1.1 Thermal Load Restriction for Buildings	
	1.2 Natural Energy Use	
2. Energy Saving with Equipment Performance	2.1 Air-conditioning System	2.1.1 Heating System
		2.1.2 Cooling System
	2.2 Hot-water System	2.2.1 Hot-water Supply Equipment
		2.2.2 Heat Insulation of Bathtub
		2.2.3 Hot-water Plumbing
	2.3 Lighting/Electric Home Appliance	
	2.4 Ventilation System	
	2.5 Energy-efficient Equipment	2.5.1 Household Cogeneration System
		2.5.2 Photovoltaic Power Generation System
3. Water Saving	3.1 Water-saving System	
	3.2 Rainwater harvesting	
4. Devices of Maintenance and Management	4.1 Presentation of Lifestyle	
	4.2 Energy Conservation	
LR2 Resource Conservation and Reduction in Construction Waste Generation		
Additional Criteria	Minor Criteria	Merits
1. Use of Materials that are Useful for Resource Conservation and Reduction in Waste Generation	1.1 Building Frames	1.1.1 Wooden Structure
		1.1.2 Steel-framed Structure
		1.1.3 Concrete Structure
	1.2 Reinforcement Materials for Construction of Foundation Ground and Foundation	
	1.3 Armoring Materials	
	1.4 Interior Finishing Materials	
	1.5 Materials for Outdoor Facilities	
2. Reduction in Waste Generation in Production and Construction Stages	2.1 Production Stage (Parts of Building Frames)	
	2.2 Production Stage (Excluding Building Frames)	
	2.3 Construction Stage	
3. Promotion of Recycling	3.1 Dissemination of Information on Material Usage	
LR3 Contribution for Improvement of Regional and Global Environment		
Additional Criteria	Minor Criteria	Merits
1. Consideration of Global Warming		
2. Consideration of Regional Environment	2.1 Control Load on Local Infrastructure	
	2.2 Preservation of Existing Natural Environment	
3. Consideration of Surrounding Environment	3.1 Reduction in Noise, Vibration, Exhaust, and Exhaust Heat	
	3.2 Improvement in Warm Environment of Surroundings	

3. Method of Evaluation

The houses are given grades 1 to 5 according to the abovementioned criteria. The criteria are adjusted by the weighting factor on the basis of their importance. The score is calculated at every stage, additional criteria, and main criteria for Q and L. Finally, the BEE of houses can be determined.

The criteria are set such that normal houses built these days can get grade 3. However, we have given grade 3 to the relatively good efforts which especially need to be promoted in the future.

The CASBEE for Home is not meant for a specific purpose. We are developing it so that it can be used by various people who are involved with house construction. Our aim is to make the assessment as simple as possible. In fact, the evaluation method does not involve investigation, measurement, and complicated numerical analysis and basically involves simple calculations; the number of steps involved in the evaluation depends on the environment.

We have already presented proposals for "Housing Performance Indication System in Japan," "Authorization and Supporting System of Environmentally Symbiotic Housing in Japan," and an environment-friendly design titled "Design Guideline for Low-Energy Housing with Validated Effectiveness." We have developed the CASBEE for Home on the basis of systems and methods that are widely used and are well known to reduce the time taken for evaluations. We have used the proposed housing performance indication system without making any changes to it and have taken care to prevent contradictions or double standards in the evaluation.

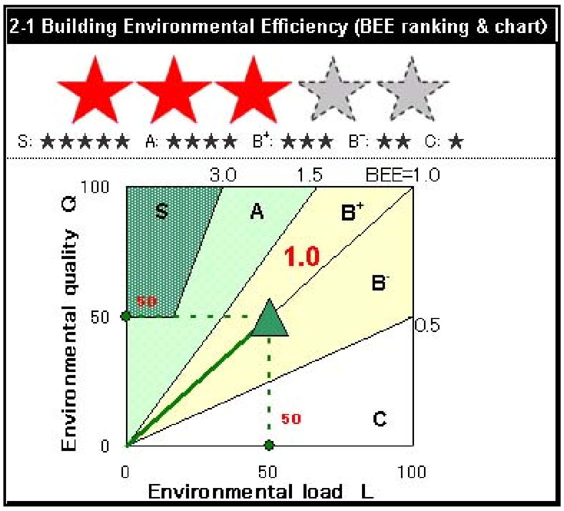
4. Presentation of Results

Special software transforms BEE from the final result and Q and L for each process into graphical form. BEE is shown in the form of a BEE chart in Figure 2.

Houses are ranked by BEE and given grades 1–5, indicated by the number of stars. The BEE values are represented in a graph by plotting L versus Q on the x- and y-axes, respectively. The BEE value is expressed as the gradient of the straight line passing through the origin (0, 0). The higher the Q value and the lower the L value, the steeper is the gradient and more sustainable is the house. Using this approach, the results of BEE can be presented graphically. Figure 2 shows a BEE chart for buildings ranked on the basis of class C (poor), class B^-, class B^+, class A, and class S (excellent), in ascending order the BEE value. The result of BEE is presented in such a manner with ★ to be easily understood.

Figures 2–4 show three charts of the evaluation of the CASBEE for Home.

The radar chart shows the equilibrium between the 6 major criteria, Q1–Q3 and LR1–LR3 (Figure 3).



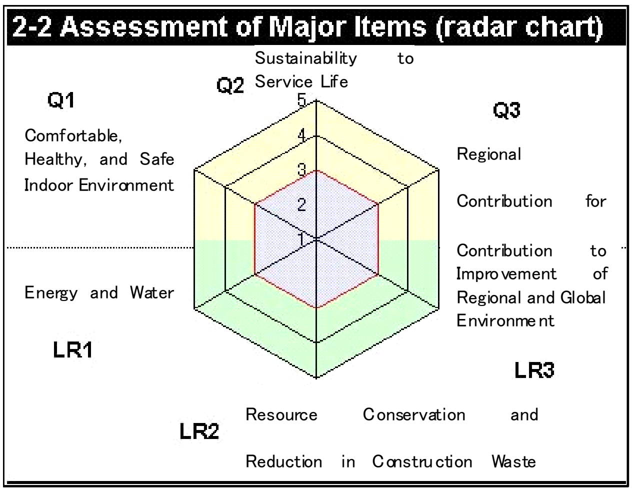


Figure 2 BEE Chart of CASBEE for Home

Figure 3 Radar chart of CASBEE for Home

The warming effect chart presents the $LCCO_2$ of a simple detached house and shows the reduction rate comparing to referenced general houses (Figure 4). Using these tools, detached houses can be evaluated precisely.

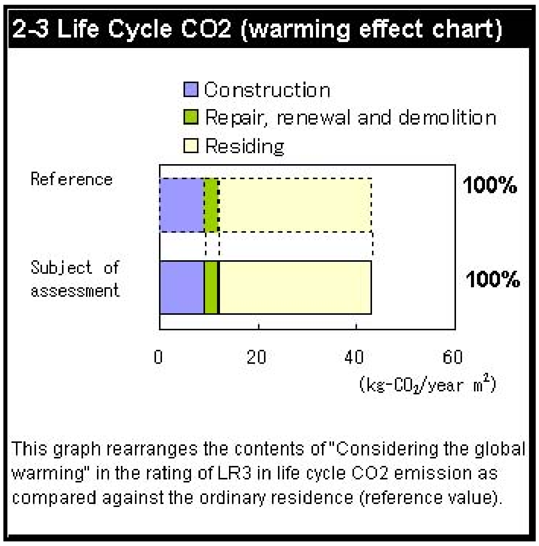

Figure 4 Warming Effect Chart of CASBEE for Home

It is assumed that the CASBEE for Home is used at an advertising stage and a tool of communication between a client and an architect at planning and designing stages. At these stages, the requirements for the evaluation are not usually determined yet, so you could only get an interim result. Special software classifies the results obtained from the evaluation on the basis of location, structure, area, number of houses, specifications, electrical appliances used, surrounding, etc. and shows if the parameters have been determined, partially determined, or assumed.

5. Conclusions

We have developed the CASBEE for Home, which includes 54 evaluation criteria and gives output in the form of charts showing grades assigned to houses. The CASBEE for Home can be used to evaluate detached houses. It is expected to develop assessment tools for existing houses and renovation. We plan to disseminate the information on this system to clients, designers, and constructors, which will contribute to the improvement in the quality of detached houses in Japan.

TIMBER LCI CASE STUDY: THE PRACTICALITIES OF REPRESENTING AUSTRALIAN VENEER, PLYWOOD & LVL PRODUCTS

Pene MITCHELL Ph.D[1]
Stephen McFALLAN[2]

[1] Sustainable Ecosystems, CSIRO, Glenview, Queensland, penemitchell@aapt.net.au [2] Sustainable Ecosystems, CSIRO, Brisbane, Queensland, Stephen.mcfallan@csiro.au

Keywords: LCI, forest and wood products, veneer, plywood, LVL, LCA

Summary

A Life Cycle Inventory (LCI) of veneer, plywood and laminated veneer lumber (LVL) was undertaken as part of an initiative to assess the environmental impacts of Australian wood products for a comprehensive Timber LCI. CSIRO conducted the investigation for the FWPA to create a rigorous LCI of representative Australian forest and wood products and processes. The LCI included in separate unit processes all cradleto-gate inputs and outputs for a product's creation including raw material extraction, transport to mill, and manufacturing.

The focus of this paper is the production of the LCI for veneer, plywood and LVL products. 80% of Australian plywood and LVL mills were included in the project making it the most comprehensive analysis of these products undertaken. The paper addresses the requirements of assessing these wood product industries and the issues arising.

The differences from international LCI research and the differences between varying wood products are investigated. The practicalities and realities of mill sampling, data collection, quality assurance and other methodological considerations are focused on. Problems encountered and lessons learned are also detailed. The paper is set out as guidance to future LCI data collectors who intend using results in a national LCI database.

1. Background

A life cycle inventory (LCI) of timber, LCI Timber, has been undertaken by CSIRO for the Forest and Wood Products Association (FWPA) to create a rigorous Australian LCI of representative forest and wood products and processes. The assessment includes all energy and materials associated with manufacturing wood products in separate unit processes. Main raw material extraction and transport, secondary input materials' production and transport, energy inputs, all outputs, emissions and wastes have been analysed. The in-use and end-of-life phases are not however included in this project.

The key output is a forest and wood product LCI database covering categories including Forestry, Sawn Timber, Veneer, Plywood, Laminated Veneer Lumber (LVL), Particleboard, Medium Density Fibreboard (MDF), Glulam and Engineered I-beams. The significance of this study is that all environmental impacts from gate-to-gate and the transportation of materials to manufacture are detailed providing an objective overview of timber products in terms of their environmental profiles. This study adheres to the ISO 14040 guidelines (ISO 2006a, 2006b, 2002) and LCI Timber's stringent Quality Assurance (QA) requirements. (Tharamarajah, 2007)

The specific interests of this paper are the practicalities, realities and the issues arising in collecting and assessing the required data for the LCI of veneer, plywood and LVL within the Timber LCI project (see Figure 1) and reported in Mitchell and McFallan, 2008. The primary data incorporates site-specific data collected from eight Australian mills using methods such as survey, mill inspections and discussion with mill personnel. The data was collected using records spanning from 2004 – 2007. Secondary data sourced from LCI Timber's SimaPro database includes the manufacture of energy, fuels, CO_2, emissions, production of resins and preservatives. The main log inputs are detailed in Module B: Forestry (Tucker, 2008).

1.1 System Boundary

In LCI Timber the system boundaries provide a gate-to-gate assessment of timber products used in the building industry. The project does not include transportation after manufacture, use, or end-of-life scenarios. The raw materials are the materials obtained directly from the environment. The inputs between the Life Cycle Inventory boundary and the module boundary are common or pre-defined processes which can be called upon by any module model. The common processes include logs from forests, glues, imported products and materials, energy, transport modes and equipment. The output products include the main product, co-products, and wastes.

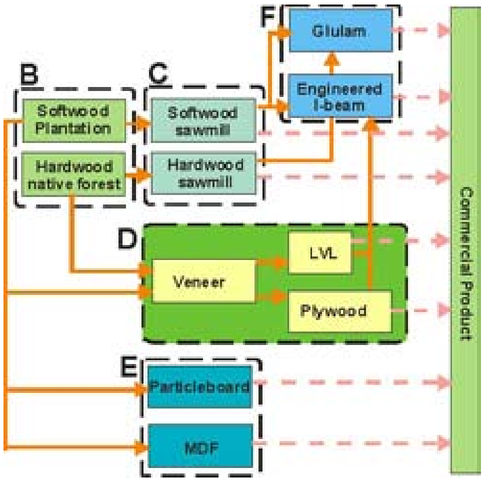

Figure 1 Veneer, plywood and LVL within the forestry and wood products LCI project.

1.2 Unit Processes

The unit processes for veneer, plywood and LVL form the complete 'gate-to-gate' processes. Each unit process consists of one or more sub-system and is determined to have identifiable inputs, outputs or separable processes. Aggregating the subsystems into unit processes creates identifiable data collection points and reduces the complexity of the system. If a co-product is produced and used within the unit process it is considered within the internal recycling loop and thus not included in the inventory, as the co-product does not cross the unit process boundaries. The veneer process has four unit processes within the system boundary (Preparation, Conditioning, Green Veneer, Dry and Finish). The plywood and LVL processes both have three unit processes (Manufacture, Finish, and Packaging). There is also a separate boiler process and a glue-mixing unit process which have been detailed as separate unit processes, but secondary data created for LCI Timber is currently used.

2. Review of existing studies and Australian industry

Initial reviews of existing veneer plywood and LVL studies, and in depth analysis of the Australian industry, provided a background which informed the project methodology.

2.1 International and Australian studies

International LCI studies and reports of veneer, plywood and LVL were reviewed to determine ways forward with the Australian LCI Timber. Pinpointing major impacts, for example, allowed reduction of scope and data collection focus. In Australia there is a lack of published LCI information relating to the engineered wood products however the project had access to some confidential in-mill studies. Examination of the ISO 14040 LCA series was also necessary to be accepted in the International LCI field (ISO, 2006a, 2006b, 2002).

The Consortium for Research on Renewable Industrial Materials (CORRIM) was of particular interest, as they had recently (Wilson, 2005) undertaken a similar timber LCI study in the US. CORRIM underwent an external critical review ensuring compliance with ISO14040 protocols. Their support of LCI Timber was beneficial to the methodology development and allowed the project to learn from experiences, processes, models and methods.

2.1.1 Methodological issues

CORRIM undertook a gate-to-gate analysis considering all inputs, outputs and impacts associated with plywood and LVL manufacture (Wilson & Sakimoto, 2004, Wilson & Dancer, 2004). CORRIM used different analysis methods dividing plywood manufacture into six unit processes but using a black-box approach for LVL. Due to similarities between plywood and LVL, veneer was taken directly from plywood system LCI data for LVL.

CORRIM's experience was read in context as the US produces 80 times more plywood and 20 times more LVL than Australia. CORRIM's data sampling size was selected based mainly on production capacity, surveying the least number of mills to cover the largest product volume. Five plywood manufacturing plants in the Pacific North West (PNW) accounted for 26% production and five in the South East (SE) accounted for 14%. CORRIM based their assessment on single plywood and LVL types: one thousand square metres (MSM) 9mm thick basis for plywood; and, 1 ¾ inch thick, 4ft wide and 60ft length basis for LVL.

Survey of manufacturers was used to collect primary data and existing sources were utilised to obtain secondary data such as energy, CO2 and press emissions, and resin production. The growth and harvesting of trees was undertaken as a separate study in the project, and the boiler was considered as a separate operation within the system boundary. The data collected was averaged and weighted and modelled using SimaPro (Pre Consultants, 2007).

2.1.2 Inputs and assumptions

CORRIM did not include inputs that contributed to less than 2% of total input. Energy was considered particularly significant and CORRIM used state profiles to specify percentage shares of fuel source. Hydro for example attracts no impact in SimaPro. Published data sources as opposed to survey data were used to determine distribution of energy amongst unit processes. Hogged fuel was given a green weight average (as per industry practice) and assumed to be at 50% moisture content.

CORRIM's assumptions relating to transport, wood densities, data issues, weighting and averaging, assigning burdens, unaccounted wood mass, etc. were analysed. Sensitivities were undertaken to examine effects of using different fuel sources for heat generation. Carbon balances and cost analyses were used for checks. The LCI results were generated in SimaPro5.0.9 version 5 using the survey results and the secondary data.

2.2 Australian Plywood and LVL Industry

In 2007 there were eight plywood production facilities and two LVL manufacturing plants. Many small operators had exited the market and two organisations controlled over 60% of the plywood market. Despite this domination, the majority of plywood mills are small to medium sized. With the newer and larger mills has come a change in technology and investment in plant and equipment modernization. The small and medium mills have also invested in computerized technology to make production more efficient.

Manufacture of plywood and LVL consists of turning high quality logs into thin veneers which are then transformed into plywood using adhesives. Softwood and hardwood veneers are used to produce plywood and LVL and softwood accounts for 70%. There are many variations of interior, exterior, flooring, formwork and structural plywoods. LVL is also available in a range of sizes making it difficult to specify a single product for assessment.

2.3 Lessons learned

The decisions made by CORRIM and issues detailed in LCI studies have been useful to examine in relation to the industry as guidance for determining a methodology for the Australian context. An energy coefficient study (Hall and Janssen, 1997) shows that international data can be considerably different to Australian data. Thus most of the information obtained was used strategically to analyse potential issues of importance to Australian industry; consolidate research to efficiently utilise time; and check data and results. The review of the industry provided information on existing mill structures, existing in-house systems for information collection, processes, supply chain, mill operations, environmental management strategies, current understanding of LCI/ LCA in mills. These contextual issues, alongside the review of international studies, informed the LCI Timber methodology.

3 Methodology for LCI Timber veneer, plywood and LVL

The initial methodological processes, which were determined using the reviews as well as the Timber LCI Guidelines (Tharumarajah et al, 2007), included:

- Mill Sampling – determining mill types to concentrate on; (Planning)

- Engaging Mills – to participate in project; (Planning)
- Data requirements – determining what data to be collected; (Data Needs)
- Product Sampling – establishing relevant products for analysis; (Data Needs)
- Data Collection strategy – collecting and mapping data methods; (Data Collection)
- Data Quality/ Evaluation – data analysis (Validation, Documentation, Communication)
- Assumptions – identification and treatment of data gaps (Identification)

The basic methodological processes were not followed in a lineal order rather they became iterative processes, whereby information ascertained from one step would inform another step which could be further modified to better reflect the project and mill requirements.

3.1 Mill Sampling and engaging mills

In contrast to the CORRIM experience, where sampling size was statistically representative, Australia has only a small number of mills. If the two largest plywood mills and one LVL mill are included, the sample is statistically representative at over 50% market share. CORRIM noted however that their samples had to be adjusted when, for example, kiln drying was found to be a significant contributor to the results. Thus the sample group for LCI Timber needed to be relevant in terms of representation of factors which may vary the results. It was decided that, as there were only ten mills, to undertake an initial analysis of them all to determine the differences and similarities which might make a difference to the inventory results. This was not onerous given the small range of mills, but set the project up to have a strategic focus based on factors which might be of significance in the results, as follows:

- Production capability: mills surveyed had to produce a representative amount of plywood i.e. it is no use surveying six mills, if the other two produce 60% of total.
- Product range: representative products with significant market share to be included. Small mills often have greater product range or niche market products and large mills produce commodity products, such as structural or formwork plywood.
- Mill location: geographical cross-representation of mills analysed to consider the variety of regional issues and test whether issues make a difference to LCI results.
- Proximity to forests: considered as log inputs are significant to plywood production and transportation is therefore an important impact issue.
- Technology types: technology differences need investigation as processes may be similar, but efficiencies, recoveries, waste reduction etc. may be improved with modern technology. The labour intensive processes utilised with older technology may make little difference. (Note: Labour is not considered an input in this project)
- Energy Sources: CORRIM report that energy has the potential to make significant impact on LCI. It is necessary to investigate different energy types and cross-representation of energy use. Wood waste is the most predominant fuel for drying furnaces and hot pressing but gas and co-generation are also used.
- Log Types: many log types are used in production and significance of these differences (whether relating to issues of region, transportation, waste etc.) need addressing. Hardwood versus softwood also requires further investigation.

In addition, willingness to participate in the project and availability were of vital importance as any mill surveyed would be critical to data quality given the small range of mills. The mills had to commit to both collecting and providing data which is an onerous task, particularly in smaller mills where day-to-day operation is the focus (Mitchell, 2004). Other potential issues, such as water supply, co-products, preservative treatments and wastes and emissions, were also noted at this point, but they were issues that would need further investigation using mill data, so were not part of the initial sampling investigation.

It was decided to collect data from all but two mills initially as these two duplicated two other mills in details such as size, locality, output, etc. It was deemed necessary to have at least one mill that could be used to test results or check methodology validity. The mills selected for inclusion contributed to more than 90% of plywood production and 100% of LVL production. It was considered important to have the variety mills involved as differences could be investigated and the implications of the differences, in terms of LCI results, analysed.

The sample mills selected were members of the Engineered Wood Products Association of Australasia (EWPAA). The EWPAA's support and involvement allowed entry to discussion with mill executives and helped disseminate the significance of the project to the industry. Letters seeking involvement in the project were sent to mills and on participation agreement the executives of each mill were contacted to discuss involvement requirements, as follows:

- Collection and delivery of required data;
- Allowing mill inspections and discussions with executives and employees, which was quite different to CORRIMs survey only approach;
- Confirmation of process map and data;
- Allowing data to be used in the Timber LCI database, in an industry averaged form.

Once the level of involvement was ascertained to be appropriate for the project requirements, the mills were engaged to collect data.

3.2 Data requirements and product sampling

Data collection is usually based on the purpose for use of data, but since LCI Timber will be a publicly available database, the objectives for use are not known. Data collection is a time consuming process, as documented in many LCI reports, and all data cannot be collected. It was therefore pertinent to be quite specific about data requirements based on data transparency, quality, and completeness, for example, and on specific industry processes.

Given the necessary understanding of industry processes, determining data required was an iterative process. The knowledge obtained during initial data collection processes, such as mill visits led to the refinement of data requirements. CORRIM's and other data surveys, as well as data considered relevant for our own knowledge of the industry, informed the initial survey, which included information on: inputs and outputs; energy and water; waste and emissions; transport; plant and equipment; and personnel

Part of this analysis consisted of determining product types manufactured by each mill. CORRIM based their report on a single plywood and LVL product. The LCI Timber project required a more comprehensive analysis of products based on market share. Product sampling however proved difficult despite the common range of products (see *Table 1*). Within this range there are many descriptors used to determine specific plywood products (including, grades, thicknesses, bond types, panel sizes, treatments, timber species, F-rating and finish) and LVL products, which are generally produced to customer specification (including thickness, bond, length, treatment, timber species and F-rating). Each range is made to many different specifications and even after data collection it was difficult to determine specific products with the greatest market share. One small plywood mill provided a detailed product breakdown for a year which consisted of over 400 distinct products.

A product list was therefore determined based on discussions with mill executives and other module leader's who required inputs of plywood or LVL as opposed to market share. The main purpose for analysing different products was to determine differences in LCI impact of different product types. It was therefore considered reasonable to generate a table of diverse, actual plywood types as shown in *Table 1*.

Table 1 Veneer, plywood and LVL product list for LCI Timber

Product	Details (Note: all panel sizes taken as 2400 x 1200)
Veneer	1mm & 3mm
Interior plywood	9mm & 12.5mm
Exterior plywood	6.5mm, 9mm & 19mm
Formply	17mm & 19mm
Structural plywood	12.5mm, 18mm & 19mm
T&G Flooring	12mm, 15mm & 17mm
LVL	90 x 36mm, 200 x 45mm & 240 x 63mm

3.3 Data collection strategy and data quality

A number of data collection strategies were analysed as CORRIM and Mitchell (Mitchell, 2004) both reported low level response to surveys by industry. Personal one-on-one discussions, information dissemination, and mill inspections, in conjunction with a survey, was deemed most appropriate. This more time intensive strategy could be implemented given the relatively small number of mills engaged.

An initial comprehensive survey was drafted and reviewed at a work-shop with EWPAA personnel. The survey was modified to better reflect Australian industry operations and be better understood by industry personnel. The survey was tested with one mill in a workshop to ensure understanding, determine the relevance of the questions, determine whether the information could be collected, and to establish any commercial in confidence requirements.

This initial survey was intensive requiring much time to complete to a satisfactory level. The test mill worked through this survey, but the survey was reduced into 'survey sets' which could be completed in short time slots. The 'survey sets' were based on impact which was determined using a basic model and running sensitivities. With each new piece of data received, the survey sets could be further refined and data collection streamlined. CORRIMS 2% rule was not utilised, and inputs contributing to less than 2% were still analysed to determine impact capabilities.

With the reduction of time required for each 'survey set', the completed form was often e-mailed back the same day as it was sent. The test mill with the full survey, and an LVL mill who received the full survey due to late inclusion, both struggled to return data. The survey sets were considered very successful allowing a set to be sent to the mills every week or fortnight depending on the mill. If the survey sets were not returned within two weeks a follow up e-mail was sent. Usually this prompt would see a return of the information, at which stage the next set would be sent out immediately. During this process other questions arose and questions were asked directly of mill personnel via telephone or e-mail.

Mill visits were simultaneously undertaken and in the first mill visited it was established how much of the required information could be collected on a site-visit (machinery details, waste points, etc) and processes were documented and process mapping was initiated. The mill walk-throughs were an excellent method of obtaining a reasonable understanding of mill operations allowing a lot of basic information to be documented including mill and process differences, and provided opportunity for mill personnel to ask project questions. The mill visits also assisted in the identification of unit processes and identification of inputs, outputs and separable processes (including energy, wastes, and emissions). It also allowed the process models to be refined, as the initial process maps detailed all actions within a mill. After several mill visits the process was reduced to key unit processes at a level which was manageable and took into consideration actions which would make a difference to the LCI.

The data provided by the mills was based on measurements, calculations, bills, records, mill statistics, as well as estimation and calculations where no other information was available. All data collected from the mills was time specific, and related to information from a period from 2005 – 2007. The iterative process of data collection, survey refining, mill inspections, etc. allowed for ongoing validation of data. Quality Assurance (QA) documentation of a high quality have been produced as part of the LCI Timber project to provide transparency to data uncertainty, distributions, subjective estimates, sources of variance, etc.

3.4 Data Evaluation and Assumptions

Evaluation of data was important to the process and several processes were undertaken to ensure data was of the highest quality. The data was verified with other data sources including international data and any available Australian data. Sensitivity analyses were undertaken to identify the areas of potential high impact. In particular where the data was not of a high quality, sensitivities were utilised to see whether variations would make a high degree of difference. The things which showed to be of significance to the overall impact included electricity, log input/ volume and resins. The data was varied based on minimum and maximum values to determine what difference the variation would make to results.

Data quality was continuously tested, and whenever variations appeared the original source was revisited and questioned. Where data precision was considered questionable or the sample size was restricted (i.e. in some cases all mills did not provide data for all issues, such as glue mixes) a triangular distribution was used. In the cases of all mills providing data which was considered high quality and reflective a normal distribution was used. Although not all mills provided data for all issues, the data used is considered representative as the similarities and differences between the mills were noted and data analysed accordingly. In the case of glue mixes, the mills were very hesitant to provide data due to the commercially sensitive nature of mixes. Only one mill provided decent data and although this was considered very high quality, could not be used in these results, and the common glue mix process had to be reverted to, despite the plywood glue mix being more specific.

There were limitation with not obtaining full data sets from all mills, and one LVL mill provided limited data, and the mill visit was used mainly to compare the two existing mills, to determine whether the results from one mill would be representative. The comparison of the plywood and LVL processes proved that the unit processes in most cases were interchangeable, so that LVL mill results could be adequately masked by combining plywood and LVL data for specific processes.

4. Results

The results were generated by a single server version of the SimaPro software using the FWPA data libraries updated on August 7th 2008. The results show average Australian veneer, plywood and LVL, although specific plywood and LVL products have also been detailed in the report (Mitchell and McFallan, 2008). Average Australian structural plywood is discussed here with veneer included in relation to plywood production.

The main inputs to manufacture 1m^3 structural plywood include: 58.8kg A-bond glue (which includes resins, flours, fillers, catalyst, etc.); 0.33m^3 hardwood veneer; 0.59m^3 softwood veneer; and 0.0034kg AACQ preservative. There are other inputs but in non-registering quantities. It takes 2.1m^3 of logs to produce 1m of veneer. The average preliminary results show that the yield of veneer from logs is approximately 47% compared to 50% estimated by CORRIM but varied between mills, with small labour intensive mills reporting higher recovery rates. The main source of energy is the boiler (7.7gJ) which is mainly used in the veneer drying process. The electricity input is 135.1kwm^{-3}; LPG is 3.1ltrs; and natural gas 0.734gJ. These energy sources are mainly used in the veneer drying process (40%). A large amount of water (344ltrs) is also consumed.

Preliminary results show that production of 1m structural plywood contributes 742kg CO2 emissions. Veneer drying accounts for about 10% of the CO2 emissions while glue production accounts for just over 25%. Forklift operation (predominately electrical) is responsible for a further 10%. Overall 66% of the CO2 emissions were attributable to electrical inputs and a further 20% to log production.

The initial results show that:

- Manufacture of adhesives are particularly intensive and emissions from adhesives is most significant during the manufacture and pressing processes;
- Energy for the production of veneer, plywood and LVL comes from several sources, including electricity, natural gas, LPG, diesel and hogged fuel, and is significant in LCI results.
- The use of high voltage electricity (within the pressing process in particular) is considered one of the significant impact factors
- Energy impact is higher than CORRIM as hydro electricity has no impact in SimaPro
- Main energy use is biomas as was the case with CORRIM
- Wood fuel is used for drying timber in all mills. The burning of wood is considered (along with use of high voltage electricity) to be one of the major impact areas.
- Water use in Australia particularly significant and the conditioning process accounts for a significant proportion of the 344ltrs used to produce 1m^3 plywood

5. Value to Australian LCI database

The LCI Timber project will be a very valuable resource for the Australian LCI project (AusLCI). The SimaPro models are highly detailed and complete. Data has been input in the system based on unit processes making the models highly flexible which will enable easy future modifications and updates. The associated Quality Assurance (QA) documents provide a comprehensive picture of the data quality and details data precision, completeness, collection and treatment methods, and representativeness. A pedigree matrix with a series of indicators which provides a scoring system to communicate the quality of each piece of data was utilised. Data evaluation was intensive and several validation and verification methods were utilised including comparisons with other sources, data checks and volume balances. Sensitivity analyses were also undertaken to identify the areas of potential high impact. In particular where the data was not of a high quality, sensitivities were utilised to see whether variations would make a high degree of difference.

The methodology for data collection, evaluation and quality has been thoroughly developed which resulted in excellent quality data being collected. This methodology will be beneficial for future LCI inputs and development. The methodology also led to excellent industry collaboration and cooperation which aided the data collection process, the dissemination of information and the support for Australian LCI developments. The data will be beneficial to future data collectors as areas of importance have been highlighted and future work can concentrate on the significant impact areas. The project has created a significant new benchmark for veneer, plywood and LVL products in Australia.

DEVELOPMENT OF LCA-BASED BUILDING COMPONENT ASSESSMENT TOOLS

Daniel Kellenberger ME[1]

[1] Sustainable Design, Scion, Wellington/Rotorua, New Zealand, Daniel.Kellenberger@scionresearch.com

Keywords: building, LCA, calculator, wall, thermal, energy, GWP

Summary

Background: Although much is known about the building of houses in an environmentally-friendly way, very few tools have been developed to support the design of components/buildings. People involved in the building process (e.g. owners, builders, architects, civil engineers, product suppliers) find it very difficult to assess the effects of specific components and to compare alternatives. Several modules are currently being developed to calculate the environmental impact of components and technologies in a house. One of these modules is a calculator of the environmental impact of lightweight wall systems.

Benefits: These calculators allow comparisons to be made at the level of the smallest elements of the overall building system. These are based on properties common to all elements (e.g. structure, thermal resistance). It is, for example, possible to compare different designs of a wood-framed wall system, providing that the thermal resistance is the same.

Approach: The system calculators are based on analyses of designs that are currently used in New Zealand. The parameters of specific components (e.g. thickness, type of insulation, cladding etc.) are entered as inputs into the calculator. The calculation provides the thermal resistance (R-value) and lists the required materials. The material list is then linked to a list of Life Cycle Impact Indicators (e.g. Cumulative Energy Demand, Global Warming Potential). As the methodology is the same for all different calculators, only the lightweight wall calculator is presented here, as an illustration of the calculators. Furthermore, a case study comparing two different wall designs with the same R-value is presented and discussed.

Outlook: The overall aim of the project is the development of an LCA-based building assessment tool. This requires several additional system calculators (e.g. interior walls, windows, heating, etc.) as well as a connection of all tools with an overall building heat loss calculation tool. The results can then be allocated to the different components.

1. Introduction

A building assessment tool allowing comparisons on the basis of components with a specific function (functional unit) requires a virtual partition of the building into different systems or components/technologies (Kellenberger 2008). A possible structure is presented in Table 1.

Table 1 Systems/technologies/components related to the envelope of a building

System / Components	Example of Designs or Technologies	Possible Functional Unit
Exterior lightweight Wall	Heat insulated timber frame with fibre cement cladding	x m^2 of lightweight wall with specific R-value and specific load/wind etc. resistance
Exterior heavyweight Wall	Heat insulated concrete wall	x m^2 of heavyweight wall with specific R-value and specific load/wind etc. resistance
Groundfloor/Foundation	Concrete slab	x m^2 of floor with specific R-value and specific load resistance
Roof	Timber-framed roof with corrugated steel sheets	x m^2 of roof area with specific load/wind etc. resistance
External Door	Massive timber door	x m^2 of massive door with specific thermal and fire resistance
Window Glazing	Double glazing	x m^2 glazing with specific R-value
Window Framing	Insulated aluminium frame	x m framing with specific R-value
Heating/Cooling/Ventilation	Pellet heater	x MJ heat

The structure in Table 1 is based on an LCA study of the "Exemplar House" (Szalay, Z. et al. 2006). It compares different residential timber framed building designs made from different materials, located at different sites within New Zealand, with different heating systems and different heating schedules. Szalay's study showed a high contribution (up to approx. 50 %) from the materials to the overall environmental impact over 50 years including the operational energy for heating.. With a general improvement of the insulation level in future the impact from operation will be even more reduced and in relation the significance of "embodied" impact rises. This supports the idea of taking a closer look on the materials/components used in a building and to relate them to their heat, sound or other resistance (e.g. load, wind, etc,).

2. Structure of the Wall Calculator

Based on the "Exemplar House" study (Szalay, Z. et al. 2006) an exterior wall calculation tool has been developed which enables the user to calculate the thermal resistance and the environmental impact from different NZ wall designs in function of several parameters such as geometry of the wall and the openings, the location within the house (single storey, top of two storey), the type of wall (load bearing or not), the roof weight, the expected wind exposure etc. The calculator is structured as shown in Figure 1.

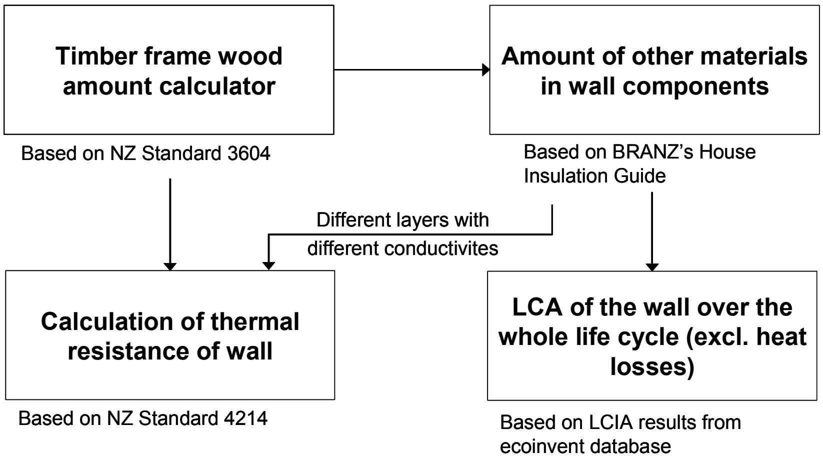

Figure 1 Structure of the LCA-based wall calculator

Most new housing in New Zealand (>90%) is constructed using a timber framed wall assembly. The timber frame wood amount calculator is based on the NZ Standard NZS 3604 (1990) for timber structures. This calculates the total area of wooden framing (m^2) on the main wall face and the corresponding volume (m^3). The wooden frame is a thermal bridge within the overall construction. As thermal bridges are taken into account when calculating the overall thermal resistance, it is essential to know the exact wood framing area. Together with other relevant sources of heat loss, the LCA calculator calculates the thermal resistance based on the NZ Standard NZS 4214 2006.

For all the different wall constructions listed in BRANZ House Insulation Guide (BRANZ 2005), a list of the included materials has been assembled. The tool enables the user to choose between different commonly used NZ insulation materials within the available wall cavity and define other parameters specific to the wall. After defining the overall wall a definitive list of materials is compiled and the corresponding thermal resistance is recalculated. The resistance is only needed when comparing different wall constructions.

As a result of the wall calculator, all the used materials required to produce a wall with a given thermal 'R' value are linked to corresponding LCIA (Life Cycle Impact Assessment) datasets (ecoinvent 2006). Together with the life-span of the products, and with a default disposal scenario at the end of life, the overall environmental impact is calculated and presented as a table and as a graph. The overall environmental impact does not include the impact from the heat generated and lost through the wall because the 'R' value is consistent between all wall designs being compared.

3 Goal and Scope

3.1 Goal

The main goal of the project is to provide independent tools which allow for comparisons of different designs of a specific component based on a specific functional unit. Furthermore, the tools should be implementable into an overall LCA-based building assessment tool that includes heat loss.

Sub-goals for the wall calculator are:

- To provide a comprehensive calculation of the overall wall thermal resistance (R-value) including a detailed material list
- To provide information on the influence of geometry and design (e.g. amount of wood) on the overall environmental impact

3.2 System and System Boundary

The system boundary used for the calculation of the different wall LCA's is illustrated in Figure 2.

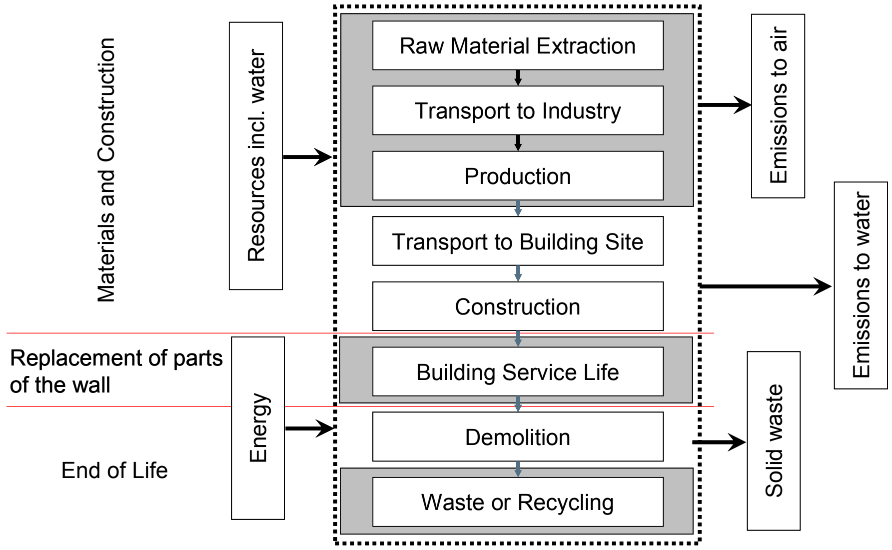

Fig. 2 System Boundary for the LCA-based wall calculator

Figure 2 shows the life cycle phases of a wall which are usually taken into account when doing an LCA. The grey boxes show the phases which have been taken into account within the wall calculator. The remaining boxes, transportation of the materials to the building site and the construction and demolition process, have not been taken into account as it is assumed that they are similar for all the wall systems. The building service life only includes materials that have to be replaced over the whole life cycle (e.g. Paint every 8 years). In addition to the used material amount, 10% cutting waste has been added.

3.3 Functional unit

The functional unit is a fully defined lightweight wall area (e.g. geometry, roof weight, wind exposure, etc.) with a certain thermal resistance (R-value in m^2°C/W) over an overall life span of 50 years.

3.4 Impact assessment categories

Based on the fact that the tool should be simple and comprehensible the chosen impact assessment categories are:

- Cumulative Energy Demand (CED) fossil, nuclear [MJ]
- CED water [MJ]
- CED biomass, wind, solar & geothermal [MJ]
- EcoIndicator 99 (H/A) [Points]
- Global Warming Potential (GWP) [CO_2-Equivalent]

Currently the LCIA data are taken from the European (and international) LCI database (ecoinvent 2006), as sufficient data for New Zealand and Australia is currently not available. The ecoinvent LCI database provides a transparent and consistent dataset for all relevant materials in this project. However, the calculators are designed in a way that allows the incorporation of country specific LCI data once it becomes available, e.g from the AUS LCI project or for the updated New Zealand data (update of Alcorn 2006).

4. Wood Amount Calculator

4.1 Introduction

Most of the lightweight wall constructions in the BRANZ' Insulation Guide (BRANZ 2005) are wooden frame based constructions. These wall designs are the most common constructions for residential houses in New Zealand. The calculation of the overall thermal resistance of insulated lightweight wall constructions takes into account the wooden frame as a thermal bridge. The BRANZ Insulation Guide (BRANZ 2005) calculates the thermal resistance based on the NZ Standard 4214 (NZS 4214 2006). The share of the area of wooden frame versus insulation area in the NZ Standard is based on an area between two studs (centre to centre) and assumes a wall height of 2.4m, including the dwangs and a top and bottom plate. In contrast, the calculator takes into account a real wall geometry which is planned to be built. The aim is to calculate the ratio between wooden frame and insulation in more detail. The wood amount calculator helps the user by providing a minimum of an input parameter to calculate these areas. Furthermore the calculator provides the total volume of wood needed for the specific wall system. This amount is also used for the calculation of the environmental impact from treated wood.

The calculator follows the main steps listed in the NZ Standard 3604 (NZS 3604 1990), 'Code of Practice for light timer frame buildings not requiring specific design'. Section 6 of this Standard goes through the wall design and supports decision making regarding the required timber parts. Bracing has not been taken into account as the influence on the required amount of wood and the visible frame area are minor. The input parameters in the next chapter concentrate therefore on the parameters which affect the wooden part of the framing most.

4.2 Input Parameters

The wall is defined as a rectangle with a specific length and height (between 2 and 5m). For other geometrical forms the tool should be used with care as it has not yet been tested for other forms. Furthermore, the geometry of up to three windows (rectangle) needs to be inputted. It is envisaged that the tool will be able to deal with more than three windows in the final version.

Besides the geometry, the function (load bearing or not) of the wall, the weight of the roof (heavy, light) and the location of the wall within the house are important parameters and are included in the calculator. The wall can either form the top storey of a multi storey house (same situation as in a single storey house), the lower of two storey house (same situation as the subfloor beneath one storey) or the subfloor beneath a two storey house. Another parameter is the wind exposure which is selected from the choices "very high wind exposure", "high wind exposure", "medium wind exposure" and "low wind exposure". The stud size is allocated to eight height categories depending on the wall height. The maximum span of member supported also plays an important role and is therefore a user input. For the stud spacing the user can choose between the most common ones; 400mm, 480mm, 600mm from centre to centre (ctr). For the dwang spacing the tool offers two default values: 600mm if the stud spacing is 400mm or 480mm and 800mm if the spacing is 600mm. The user can also manually input a value rather than using the default values. In future it is planned to connect the calculator to one of two existing main timber framing software systems currently used at prenailing factories in New Zealand (i.e. Pryda New Zealand and MiTec).

The following lightweight wall parts are calculated based on pre defined parameters:

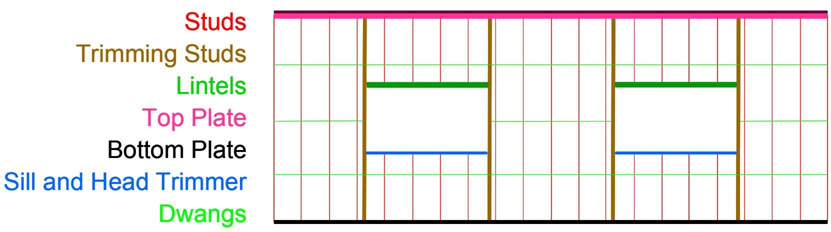

Fig. 3 Main elements of the timber frame taken into account in the calculator

The information from the timber calculation is the basis for the overall R-value calculation as well as for the calculation of the impact from different timber types (e.g. treated, untreated, etc.)

4.3 Output Parameters

The output parameters from the wood amount calculator are the view area in m^2 and the total volume in m^3 of wood needed for a specific framing. This area is then used to calculate the overall wall R-value and the volume is used to include the impact from timber production into the overall impact assessment.

5. Lightweight Wall Components

5.1 Introduction

The lightweight wall components which have been taken into account are mainly taken from the BRANZ Insulation Guide (BRANZ 2005), as they represent the common New Zealand building situation. The publication includes a raw sketch of the design and lists the most important material layers, including the type of framing, the thickness of the plasterboard, and whether or not it is directly fixed. The calculator includes this information, where possible, and adds missing information either from NZS 4214 2006 or in some cases from other sources, for example the ecoinvent LCI database documentation (e.g. Kellenberger, D. et al. 2004).

5.2 List of components

The tool will allow the uptake of other components based on existing or new materials. The calculator offers different options for the materials used (i.e different insulation and cladding materials).

The following list shows a choice of some of the included 16 wall components:

- Bevel-back Weatherboard, Timber frame – direct-fixed
- Bevel-back Weatherboard, Timber frame – cavity
- Fibre cement cladding, Timber frame – direct fixed
- EIFS (Exterior Insulation and Finish Systems), Timber frame – cavity

5.3 Parameters within Components

The LCA-based lightweight wall calculator allows a choice of different options within a certain design. For example, the tool offers the choice of different Insulation materials in different thicknesses and different R-values which are available in New Zealand (based on www.consumer.org.nz). These are, for example, polystyrene, glass wool, natural sheep wool and UF foam, from different producers with different thicknesses, different densities and therefore different thermal performances.

Furthermore the tool allows choosing between different plywood, fibre cement and brick cladding thicknesses, and many other options. When choosing a material all the connected information (density, conductivity, etc.) is adapted and the calculation of the overall R-value is updated.

An overall life span of the house of 50 years has been assumed, based on the New Zealand Building Code requirement. The life span of the materials is attached by default based on Szalay, Z. et al. (2006). To calculate the replacement rate it has been assumed that no replacement will be made in the last 5 years. The calculation routine therefore takes the number of replacements before the age of 45 into account and adds the first investment.

The calculation of the thermal resistance of the wall components are based on NZS 4214 (2006). The wall components are split into different layers (e.g. exterior sheet, interior surface). For each of these layers the corresponding R-value is calculated. For single materials the R-value [m^2K/W] is defined as the division of the thickness [m] by its conductivity (W/mK]. For insulated frame spaces it's important to calculate the ratio between the wooden (thermal bridge) and the insulation area.

5.4 Used LCIA data

The following table gives an example of the LCIA datasets used in the wall calculator. Due to a lack of transparent and consistent data in New Zealand, the lightweight wall calculator is currently connected to publicly available Swiss datasets. The design of the tool allows a replacement of these datasets as soon as new and consistent New Zealand datasets are available at end of this year.

Table 2 Choice of LCIA building material datasets (disposal not included in the values)

Name in ecoinvent v1.3	Default Disposal			cumulative energy demand, fossil & nuclear	cumulative energy demand, water	cumulative energy demand, biomass, wind, solar & geothermal	eco-indicator 99, (H,A), total	IPCC 2001, GWP 100a
		Unit	Density [kg/m3]	MJ-Eq	MJ-Eq	MJ-Eq	points	kg CO2-Eq
Brick, at plant, Europe	Disposal, building, brick, to final disposal, Switzerland	kg	1000	2.58E+00	4.03E-02	2.28E-01	1.11E-02	2.36E-01
Concrete block, at plant, Germany	Disposal, building, concrete, not reinforced, to final disposal, Switzerland	kg	2380	7.49E-01	4.86E-02	4.17E-02	3.84E-03	1.20E-01
Fibre cement facing tile, at plant, Switzerland	Disposal, building, cement-fibre slab, to final disposal, Switzerland	kg	1800	9.91E+00	9.96E-01	1.04E+00	3.83E-02	8.11E-01
Gypsum plaster board, at plant, Switzerland	Disposal, building, plaster-cardboard sandwich, to final disposal, Switzerland	kg	800	5.90E+00	1.53E-01	2.24E-01	2.79E-02	3.63E-01

The materials listed in the first column are an example of the materials used in the calculator. The second column indicates the datasets from a Swiss list called ecological building material list (version 1.0.2) (in

German: http://www.bbl.admin.ch/kbob/00493/00495/index.html?lang=de) which is based on the ecoinvent 2006 database. Each of the datasets is connected to a default disposal option. The impacts displayed in the last five columns do not include disposal. These datasets are additional datasets included in the calculator, but are not shown in the above example.

At the moment the default disposal scenarios are based on the Swiss/European situation. The mineral building materials are mainly disposed or recycled, the metals are mainly recycled and all the flammable products are incinerated as this is a law in Germany/Switzerland.

The LCIA datasets from the ecological building material list unfortunately only offer the following impact categories: Three types of cumulative energy demands (CED “fossil and nuclear”, “water” and “biomass, wind, solar & geothermal”), EcoIndicator 99 (H,A) (Goedkoop, M. et al. 1999) and GWP (global warming potential). The choice of impact categories??? is based on the publicly available datasets used.

The calculator is set up in way that Australian and New Zealand LCIA datasets can be easily added as soon as they are available.

6. Case Study (Comparison of two lightweight Wall Components)

6.1 Introduction

In order to show *how the tool can be used* and *how the results can be interpreted*, this publication concentrates on a comparison between two different lightweight wall systems. The results are *indicative* as they lack robust scientific information (e.g. life span) and are not based on New Zealand datasets.

Based on a pre-defined overall R-value of 1.56 m^2°C/W, the results for a timber frame construction with direct fixed bevel-backed weatherboard and polystyrene insulation has been compared with a timber frame construction with direct fixed fibre-cement weatherboard with mineral wool insulation (Pink Batts). The latest version of the tool does not offer the opportunity for the user to enter a specific R-value or to select from all possible options. At the moment the user has to choose different insulation materials (includes thicknesses) to come up with a specific overall R-value.

In general, the category CED fossil and nuclear is dominated by the fossil part. This is because the nuclear part mainly stems from electricity usage in Europe, which has a very small contribution to the production of the products used in the two wall components. However, a high amount of aluminum in the wall components would increase the nuclear energy component of the CED fossil & nuclear, mainly due to the large share of electricity produced from nuclear power in Europe.

6.2 Cumulative Energy Demand

Figure 4 shows the results for CED (Cumulative Energy Demand) (MJ) for the different sub categories and overall..

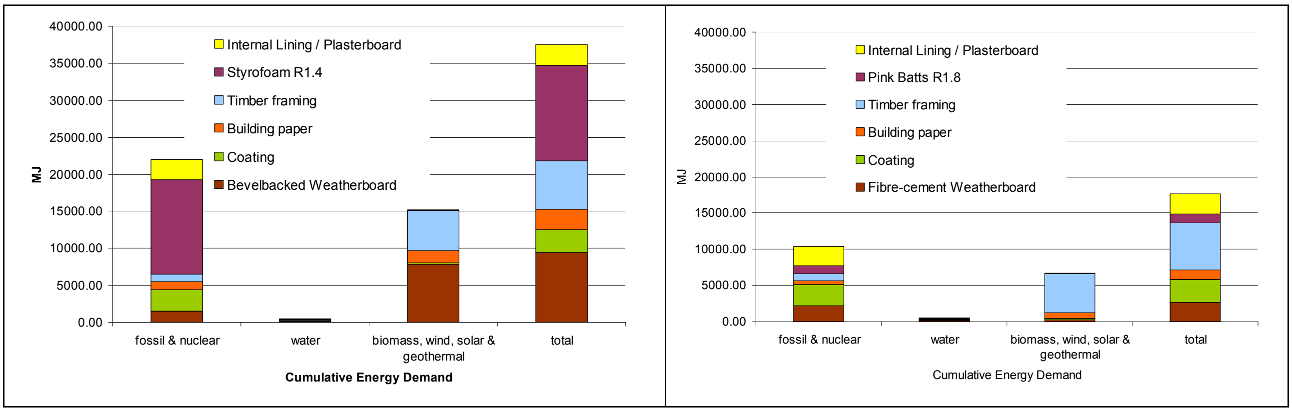

Fig. 4 Cumulative Energy Demand for timber frame wall system with bevel-backed weatherboard and Styrofoam insulation (left) and fibre cement weatherboard and mineral wool insulation (right)

The total CED for the timber frame construction insulated with mineral wool (right graph) is about half of the construction insulated with polystyrene. Analysing the CED from biomass, wind, solar and geothermal in the construction with bevel-backed weatherboard, the cladding and the frame have a high contribution (left graph). This is due to the energy stored in the wood which stays in the wood as long as there is no end-of-life treatment with energy recovery. The fibre-cement weatherboard has a much smaller contribution to the CED than the bevel-backed weatherboard due to the longer lifespan of the cladding. The insulation materials also have different CED results for each wall system. One reason is the different lifespan of the cladding systems which results in the replacement of the weatherboard once in 50 years whereas fibre-cement cladding is not replaced. The second reason is the higher energy demand in the production of polystyrene than in the production of mineral wool.

6.3 EcoIndicator 99 (H/A)

Figure 5 shows the results for the EcoIndicator 99 (H/A) impact assessment methodology.

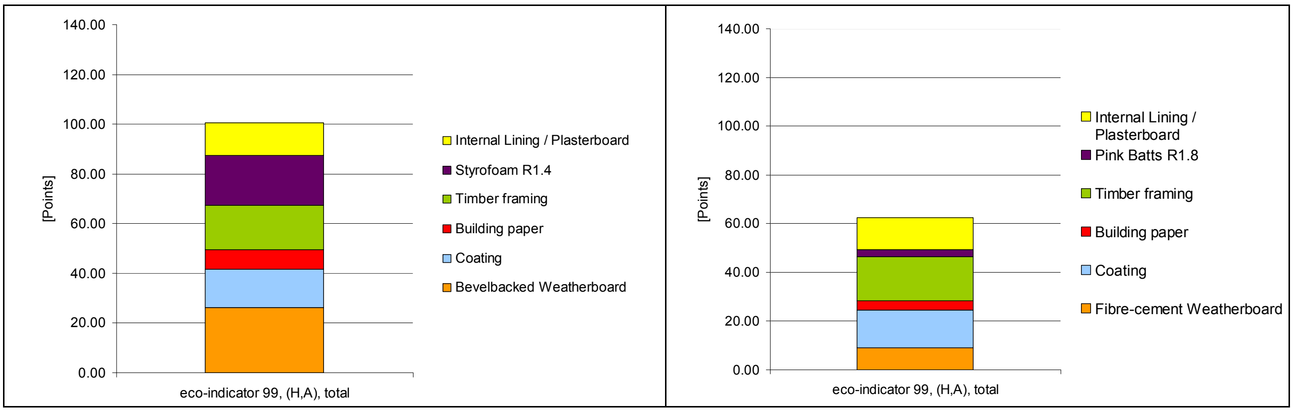

Fig. 5 Results for Eco-indicator 99 (H/A) for timber frame wall system with bevel-backed weatherboard and Styrofoam insulation (left) and fibre cement weatherboard and mineral wool insulation (right)

The results for the total EcoIndicator 99 (H/A) is similar to the results for Global Warming Potential. The impact from internal lining, timber framing and coating are the same comparing the two lightweight wall designs. The replacement of the bevel-backed weatherboard within 50 years lifespan is accompanied with a replacement of the building paper as well as the insulation. The high impact of bevel-backed weatherboard is on one hand due to this replacement and on the other hand due to the higher land-use of forestry products which is taken into account in Eco-indicator 99 (H/A).

6.4 Global Warming Potential

Figure 6 shows the results for the Global Warming Potential.

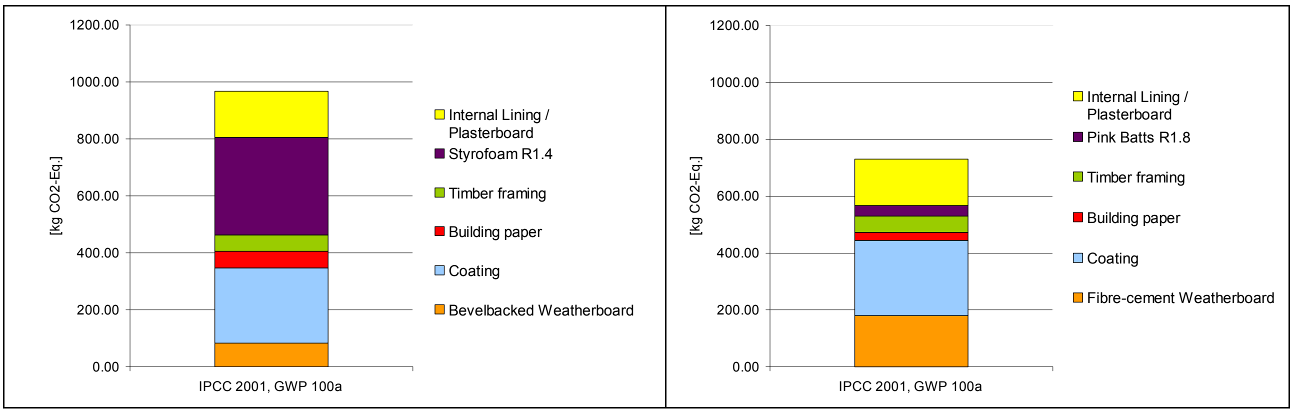

Fig. 6 Results for Global Warming Potential for timber frame wall system with bevel-backed weatherboard and Styrofoam insulation (left) and fibre cement weatherboard and mineral wool insulation (right)

The wooden parts in the wall are CO_2-neutral, i.e. the same amount of CO_2 which is taken up during the growing process is released when disposed (in this model it is burned). This is reflected in the low GWP for the timber products. However, this advantage is reduced by the high GWP from producing polystyrene insulation and its replacement during 50 years. It is also assumed that both type of claddings are repainted five times over its life-span which shows up in the high impact of coating in both wall designs.

From the Proceedings of the World Conference SB08 - ISBN 978-0-646-50372-1 www.sb08.org

7. Conclusion

7.1 Lightweight Wall comparison

Although the used datasets are based on European data, the results clearly show the sensitivity of the lifespan of the materials on the results. The replacement of the bevel-backed weatherboard including insulation and wall paper, together with the bigger environmental impact of the polystyrene production, results in a much higher impact for all the studied indicators.

The assumption that the cladding is repainted 5 times over its lifespan results in a relative high contribution of the paint to the overall results, making the results highly sensitive to the quantity of paint in a system.

7.2 Lightweight Wall calculator

The key aspect of the lightweight wall calculator is that it is based on an actual wall design, including geometry (including window and door openings), and taking into account other design aspects. This offers the possibility to easily calculate the overall wood amount, and to study changes in the amount and the environmental impacts in relation to certain parameters (wind exposition, wall function, stud spacing, etc.).

If the user desires a comparison of different wall designs with the same thermal resistance, the tool currently does not offer a backward calculation starting with the definition of the R-value and giving a choice of possible comparable designs. This is an important requirement when bringing the calculator to a next stage.

The potential of the tool was demonstrated by conducting a case study. It has demonstrated the convenience of analysing results through changing parameters. To present the full strength and potential of the calculator more case studies are needed.

8. Next Steps

The lightweight wall calculator has now been converted from an existing MS Excel-based tool by using a more appropriate programming tool 'Microsoft Visual Studio 2008' and the programming language C# to design a user friendly interface and to be able to connect the results from and to other software. This will allow an update of some of the background information (e.g. densities of the insulation materials, adding new LCIA datasets from existing studies, an inclusion of cost as an "impact" indicator, etc.). In parallel a window calculator has been developed and will be transferred into the new software. The background information for further system/component/technology calculators will be developed (e.g. heating, floor, roof etc.) and the information converted into the chosen software. The overall product will be a connection of all the modules (calculators) to an existing heat loss calculation tool. This will allow a model of the full house, and, by choosing the functional unit "one inhabitant", even allows the inclusion of behavior related parameters (e.g. water consumption).

Summary

Existing assessment tools for the built environment have been designed for use in a reactive evaluation process rather than in a proactive decision process. Whereas current assessment tools generally catalog past decisions, the proposed decision-assistance [DA] tools focus on (1) guiding decisions when they are made and (2) directing relevant and timely information to specific decision makers. These proposed tools may be more able to support the implementation of environmental strategies in the building industry.

The authors advocate:

A. The identification of topics within existing assessment tools for use in applicable decision categories.
B. The development of new DA tools tailored to specific decision makers.
C. An overarching framework to coordinate DA tools, track past decisions, and collect public contributions.

1. Current Use of Assessment Tools

Existing assessment tools for the built environment have been designed for use in a reactive evaluation process rather than in a proactive decision process. Although professionals in the building industry have accepted the use of building rating systems during project development, the existing assessment tools are not well designed to function as design aids. The proposed DA tools would guide decisions as they are made rather than documenting the decisions after they are made. The current assessment tools do not fit this intended purpose for the following reasons:

1.1 Current assessment tools present achievements categorized by physical components or environmental aspects, missing the opportunity to highlight a process of decision-making over time. Commonly, tools relate to a particular building typology and then group individual assessment topics by project components or environmental resources or impacts. By presenting the individual assessment topics all at once, the current assessment tools deemphasize decisions made at various stages of a project in terms of its timeline.

1.2 Current assessment tools stress the integrated approach of sustainable initiatives, inviting several disciplines to provide input in a holistic process. The emphasis on integration denies the assessment tools the opportunity to present clear directives for each decision maker. Because they include information that is applicable to so many participating entities, the assessment tools become diluted overall, failing as specific and thorough guides.

1.3 Current assessment tools tend to be ignored in the earliest stages of project development and do not address changes in the building throughout its lifetime. Often the owner commences the assessment services during the design phase; thus the assessment tools are applied to a project only after the site has been selected and the building program established, decisions that may have been guided, if at all, by only a vague understanding of the assessment criteria. Also, many of the earliest decisions will have been made by entities other than the owner, such as local, state, and federal governments, or international commissions. Current assessment tools are closely linked to the design and construction phases of a project, and building operations and renovations are addressed in subsequent, non-integrated rating systems, if at all. As a result, the produced ratings tend to become quickly outdated since they fail to reflect building modifications or fluctuations in life-cycle operations and maintenance.

1.4 Current assessment tools do not provide for clear interaction between project team members. Preferences by one team member may not be apparent to another unless expressed outside of the system.

1.5 Current assessment tools, in general, focus on one project at a time and cannot demonstrate associations between several buildings in a complex or portfolio. Thus they do not educate users about the cumulative effect of several buildings that rate well in the certification process. Nor can the current assessment tools aid the design team in developing a sense of greater environmental responsibility, such as for a region or the planet, outside of their desire to reach a higher rating level when their perceivable scope and effect is limited to singular projects.

1.6 Current assessment tools also do not provide accumulated data from one project to another, or between rating systems. Because they fail to track and update information from the decision makers, assessment tools consider each project in isolation, and cannot be used to guide decisions in subsequent developments.

1.7 Current assessment tools can only indirectly affect the building industry. Through the advertising potential of positive ratings, they claim to affect the market at large by economically incentivizing environmentally responsible decision-making in the building industry. However, this market-driven approach appears somewhat circuitous and less effective than a direct method to affect change. Some of the current assessment tools do act as incentive programs, promising an award for a positive rating. A certification or plaque thus represents an opportunity to achieve broad market exposure, but requires very long feedback cycles to begin affecting the building industry's production methods. Furthermore, relying on entities like building product manufacturers, outside of the direct reach of building rating systems, to affect the market significantly weakens the argument that assessment tools assert pressure towards market-wide sustainability.

2. Proposed Objectives for Decision-Assistance (DA) Tools

Based on the above shortfalls in the current assessment tools, the authors propose the following objectives for DA tools:

2.1 Allow for a decision-making process over time

2.2 Provide clear guidance to each decision maker

2.3 Support the entire life-cycle of a building

2.4 Show input from project team members

2.5 Demonstrate the impact of decisions beyond a singular building

2.6 Track decisions in a public database

2.7 Affect direct change on the market

The proposed tools would each be directed at a particular decision maker, whether a developer, international commission, mechanical engineer or building operations vendor, and would be tailored to that entity's relationship to the project from inception throughout its lifetime. These tools would help guide the decision makers through their range of choices in the built environment, and would be called decision-assistance (DA) tools.

3. Proposed Framework for DA Tools

In order to establish DA tools with thorough access to relevant and timely information, an open-source framework based on wiki technology is hereby proposed. Such a framework will ensure that the DA tools are available for use as design guides and that they contain publicly shared knowledge on topics relevant to each decision maker. In detail, the DA tool framework will:

3.1 Allow for a decision-making process over time: The framework will be made up of a number of DA tools. Each of the DA tools will focus on how to positively affect decisions when they are made rather than after they are already in place, allowing decision makers to actively take environmental impact into account. Rather than a single assessment tool that catalogs decisions made by different entities at various points in the lifetime of a project, one can imagine a set of several DA tools that each focus on a single responsible team member. The DA tools may be linked to form a greater system, a framework, or they may stand as individual options to be used as needed.

3.2 Provide clear guidance to each decision maker: Because each DA tool will focus on a single decision maker, the information provided will be tailored to that entity's specialized knowledge-base. Introducing sustainable options directly to the relevant decision maker will allow issues to be addressed very early in a development's progress, facilitating integration of sustainable policies from a project's initial stages.

3.3 Support the entire life-cycle of a building: The DA tools, each directed at one decision maker, will give guidance to the decision maker throughout their relationship with the project. From international commissions to architects to facility managers and demolition contractors, the combined DA tools will reach out to everyone throughout the entire life-cycle of a project. A framework of DA tools will therefore resemble an overlapping group of timelines, each timeline representative of a particular entity's involvement in a development, in contrast to the approach of current assessment tools in which all the decision makers are required to participate in the assessment during one brief period in the project development.

3.4 Show input from project team members: Although each DA tool will emphasize the needs of a particular decision maker, it will also allow the other decision makers or project team members in supplementary roles to offer advice or information regarding their preferences. For example, within an owner's DA tool, the architect may stress the aesthetic desirability and environmental benefit of underground parking, although the owner will ultimately make the choice.

3.5 Demonstrate the impact of decisions beyond a singular building: Each of the DA tools will identify and describe the greater impacts of any potentially applied development strategy, on a region or the planet for example, based on past facts and future projections - including differing opinions and the surrounding debates between politicians, scientists, special interest groups and others. The open-source capability of the DA tools will keep information current and abundant as it facilitates a democratic dissemination of knowledge to the decision makers from all sides of the debates; and the participation of the public will keep the maintenance of DA tools manageable.

3.6 Track decisions in a public database: Each DA tool will inherently include more data capture and tracking than is common with current assessment tools. A historical record of environmental choices could become a powerful political instrument and prove useful to public interest groups or consumer advocates who value transparency in government. Such a database will also provide researchers the ability to track common disincentives towards certain environmentally responsible decisions and may lead to the development of economic incentives.

3.7 Affect direct change on the market: By being specific to decision makers, DA tools will have an immediate and fast opportunity to affect market change. Within the knowledge base associated with each tool, readily accessible information on incentives, such as financial benefits or marketing exposure, may directly influence decisions.

4. Content of DA Tools, as derived from Current Assessment Tools

The authors suggest thirteen DA tools, based on proposed major decision categories as shown in Table 1, where each category relates to decisions in the entire project development that can be assigned to a single type of decision maker. Current assessment tools were reviewed in order to determine what existing individual assessment criteria, "credits," may easily transfer into the proposed DA tools.

Table 1 Decision Categories

1. International Policies
2. National Policies
3. National Land Planning
4. Community Plan
5. Community Operations
6. Investment (ownership, location)
7. Building Property Design
8. Building Structure Design
9. Building Interior Design
10. Building Product Manufacturing & Distribution
11. Construction
12. Portfolio or Building Operations
13. Building Operations Vending

In order to identify which individual credits could become part of a DA tool based on an intended decision maker, the current assessment tools that were reviewed are: LEED-NC 2.2, Green Star NZ - Office Design v1.2, CASBEE-NC, 2006 NABERS Office, SBTool version SBT07, and BREAAM: Offices 2006.

Because these reviewed assessment tools sort their individual credits into groupings based on the building systems affected or resources used, commonly including groups for water use, air quality and recycled materials, no entire grouping from these assessment tools may be easily transferred into a single DA tool. For example, the current assessment tools typically include credits for general location and context; however, these credits may be mixed in with sustainable site design items and landscape design issues, requiring several decision makers to participate in the "Site" grouping of an assessment tool.

The focus of the research was on the most commonly used assessment tools; those not reviewed include rating systems specifically designed for building operations and community design. For example, the U.S. Green Building Council's Leadership in Energy and Environmental Design program includes a rating system called LEED for Existing Buildings: Operations & Maintenance, whose assessment topics could be extracted for use in decision categories like "Portfolio or Building Operations" or "Building Operations Vending." LEED for Neighborhood Development could also be useful for the DA tool, "Community Plan."

The following analysis of each proposed DA tool describes the intended decision maker involved and gives examples of relevant topics from some of the reviewed assessment tools.

4.1 International Policies

International Policies related to buildings are addressed by ongoing international forums, potentially leading to the ratification of internationally accepted protocols. Environmental issues like climate change affect the entire planet; thus the evolution of international policies in regard to the building industry is critically important. Decisions regarding these policies are implicitly addressed in several building rating tools, such as:

The use of alternate refrigerants that are less depleting to the ozone layer and that create lower amounts of greenhouse gases, as addressed in LEED-NC 2.2 EA Credit 3, Enhanced Refrigerant Management.

The practice of sustainable forestry, protecting against the destruction of forests including rainforests and old-growth forests, and the encouragement of reforestation for carbon sequestering, as touched on by LEED-NC 2.2 MR Credit 7, Certified Wood.

The Green Star Credit Ene-2: CO_2 Emissions encourages the reduction of carbon dioxide, a contributor to climate change, by requesting descriptions and comparisons of a building's energy sources in terms of predicted carbon dioxide emissions.

Recognizing the critical importance of reductions in harmful emissions from building energy use, BREEAM Credit P11 advocates the completion of a feasibility study in the use of local renewable energy. The credit further encourages the implementation of energy plans that incorporate a high percentage of the researched strategies.

4.2 National Policies

National policies related to the development of buildings are typically directed by national technical departments under the authority of a country's political leaders. These technical departments look into curbing pollution; the discharge of waste into water, land and air; limiting energy use per capita; and developing principles for the protection of ecosystems and wildlife throughout the country. Strategies researched by these teams may translate into laws and regulations, or they may provide the basis for environmental tax incentives. Examples for how these policies are addressed in building rating systems include:

The prevention of soil erosion and stream pollution, addressed in LEED-NC 2.2 SS Prerequisite 1, Erosion & Sedimentation Control, for temporary measures during construction, and in SS Credit 6.1, Stormwater Design: Quantity Control and SS Credit 6.2, Stormwater Design: Quality Control, for permanent measures during building operations.

Air pollution and energy use are affected by transportation to and from buildings by its occupants. LEED-NC 2.2 SS Credit 4.3, Alternative Transportation: Low-Emitting & Fuel Efficient Vehicles incentivizes the use of hybrid and alternative-fuel vehicles.

Green Star Credit Tra-2: Small Parking Spaces recognizes the tendency for smaller cars to be more energy efficient, and rewards the incorporation of parking spaces for very compact vehicles in the general parking plan.

4.3 Land Planning

Land planning on a national level is also conducted by national departments subordinate to political leadership. This large-scale planning frequently deals with land to be set aside for highway and train transportation or for the protection of natural or historic treasures; but it may also safeguard bodies of water or agricultural land. Government property may be allocated through these programs for military purposes and regional public transportation systems. Current assessment tools may likely address some of these planning criteria:

Sites should be selected to avoid prime land that may better serve other purposes and should be avoided as building sites. Previously developed land or brownfields may be more suitable for building sites. For example, LEED-NC 2.2 addresses some of these issues in SS Credit 1, Site Selection and SS Credit 2, Brownfield Redevelopment.

BREEAM Credit P11 requires that a project team hire an ecology professional to oversee the development and implementation of an ecological management plan, as well as to educate the relevant workforce on how to protect local biodiversity during the project works.

The net improvement of a building site's local ecology over its previous condition is addressed in Green Star Credit Eco-4.

Recognizing the often negative environmental impact of removing soil or adding fill to development sites, Green Star Credit Eco-5 encourages the balancing of cut and fill onsite requirements.

4.4 Community Operations

On a local level, community departments, sometimes in close relationship with private vendors, address operational services to the general public on a daily basis. These services include the routing and maintenance of public transportation and the management of landfill and/or recycling waste. Examples of how these operational policies are addressed by current assessment tools include:

LEED-NC 2.2 SS Credit 4.3, Alternative Transportation: Public Transportation Access encourages development within ½ mile from a commuter train station or within 1/4 mile of two stops for more than one roundtrip bus line.

BREEAM Credit T08 encourages the investigation of transportation issues at an early stage in the project. This credit addresses the development of a travel plan tailored to the specific needs of the building occupants and incorporating public transportation options where possible.

4.5 Community Planning

Community planning departments, frequently with public input, devise ordinances for the physical layout of both new and existing developments. The resulting zoning ordinances regulate lot coverage, building height, historic preservation, solar access, the protection and planting of trees, and the avoidance of exterior light trespass, for example. Individual credits that could become part of a Community Plan decision-assistance tool include:

Dense developments and mixed-use communities maximize opportunities for pedestrian circulation. For example, LEED-NC 2.2, SS Credit 2, Development Density & Community Connectivity provides some criteria for higher density and mixed-use areas.

An exterior light ordinance may regulate that no exterior light can fall on a neighbor's property. Such a requirement is addressed in LEED-NC 2.2 SS Credit 8, Light Pollution Reduction.

Achieving local continuity in desirable neighborhood character is addressed in Green Star Credit Mat-2: Re-use of Facades, in which building facades are preserved and reused.

4.6 Investment

A building venture is typically undertaken by a building owner or developer. The owner may be any combination of private (for profit or non-profit) and/or public entities, and may include a group of investors not directly linked to the design and building decisions. Thus, a bank or real estate investment trust, or several private investors may be linked to a project. Many decisions at the time of investment chart the course for the project, such as identifying the type of building, its intended use, its targeted tenants, tentative building area, and a general target location. Decisions at this level lock the project development into some crucial design parameters.

Decisions reflecting site selection are for example addressed in the earlier discussed LEED-NC 2.2 credits SSC1 Site Selection, SS C2 Development Density & Community Connectivity, SS C3 Brownfield

LEED-NC 2.2 MR Credit 1, Building Reuse addresses the choice between renovation and tearing down an existing structure.

4.7 Building Property

Site plans are designed by the architect and/or civil engineer with direction from the owner or developer, who often aim to maximize the building area on the site. Within the permissible ranges of zoning requirements and other regulations, the site plans address how much of the property is covered by structures and what areas are designated as open space. Environmental goals at the property level include the minimization of the building footprint and any hardscape, the use of light-colored/ shaded surfaces, the reduction and treatment of stormwater runoff, and the preservation, restoration or establishment of vegetated, wetland, and wildlife areas. Existing individual credits relating to these issues are addressed in several tools.

LEED-NC 2.2 SS Credit 5.1, Site Development: Protect or Restore Habitat and SS Credit 5.2, Site Development: Maximize Open Space reward the incorporation of designated open space on a development's site and the restoration of that open space to native vegetation.

Recognizing the participation of low-albedo materials on local temperature increases, LEED-NC 2.2 SS Credit 7.1, Heat Island Effect: Non-Roof describes alternative hardscape colors and materials to lessen the development's impact on local microclimates.

4.8 Building Structure

The design of the building structure is often the first phase in which an architect and a green building assessment consultant are involved. Many of the design issues at the structural stage are driven by the owner, who may draw on the recommendations of the architect and green building assessment consultant. A structural engineer also has an important role in the selection of materials and dimensions of the structural building elements. The design issues considered by all the players at this stage include: anticipated length of use and desired durability of the structure, available structural materials, building orientation, shape, configuration and height, floor-to-floor height, major vertical circulation elements, desirable views and solar access, floor plate size and depth, building envelope materials for the roof and walls, glazing, insulation, and air tightness. In this phase, decisions as to the building area and volume per occupant are solidified and the energy use per occupant will largely be determined.

LEED-NC 2.2, SS Credit 7.2, Heat Island Effect: Roof considers the incorporation of vegetated roofs or high-albedo coatings to reduce local heat gain and reduce building cooling loads.

LEED-NC 2.2 EA Credit 1, Optimize Energy Performance incorporates the building's shape, materiality, orientation, and operational systems to determine the building's net energy savings over a baseline building.

Natural daylighting strategies contribute to energy efficiency as well as to the well-being of occupants, as addressed in LEED-NC 2.2 EQ Credit 8.1, Daylight & Views: Daylight 75% of Spaces, and EQ Credit 8.2, Daylight & Views: Views 90% of Spaces. These individual credits use the building envelope configuration and materials to reward the inclusion of access to daylight and views for a high percentage of occupants.

BREEAM Credit HW02 encourages shallow floor plates in order to locate desks in an office setting within a reasonable distance from exterior windows.

SBT07 Credit A2.9 encourages the building orientation to suit local climates and aid in energy efficiency through the potential for passive solar systems.

4.9 Building Interior

Following or concurrently with the structural decisions, the architect and/or interior designer prepares documents for the building's interior environment, including the mechanical, electrical, and plumbing systems designed by engineers. Design issues related to the building's interior systems and materials contribute to energy efficiency, water conservation, indoor air quality, and controllability of the systems. Decisions could be more guided if specific disciplines were addressed; they could me more integrated if considered by a small team and alongside the building structure. Interior layouts and material selections may address the life-cycle of the building elements, and contribute to the healthfulness of the interiors, a major environmental consideration for this decision phase.

Controllability of system is addressed in LEED NC 2.2 EQ Credit 6.1 for Lighting and in EQ Credit 6.2 for Thermal Comfort.

Healthfulness of materials is addressed in LEED NC 2.2 EQ Credit 4: Low-Emitting Materials, which caps the VOC content of paints, composite wood products, and adhesives.

Interior noise pollution can contribute to negative impacts on the well-being of occupants and its avoidance is recognized in both BREEAM Credit HW17 and Green Star Credit IEQ-12: Internal Noise Levels.

4.10 Building Product Manufacturing & Distribution

Independently from the building development and design process, the building industry with its manufacturers, distributors, transportation providers, show rooms, sales representatives, and sales centers make many decisions contributing to the ratings reflected in green building assessment systems.

The decisions address recycled content, recyclability, and the sourcing of products (renewable sources, regional availability/manufacturing, harvesting, ecosystems endangerment through harvesting/extraction, and earthcrust exploitation may be considered, but may also be previously be addressed by governmental policies and regulations). For example, sustainable forest practices are addressed in LEED-NC 2.2 MR c7, Certified Wood.

4.11 Construction

The contractor or construction manager in charge of constructing a building project makes many building purchasing decisions and construction site management decisions, within the parameters defined by the owner and the designer team's documents and in cooperation with the subcontractors. Issues include the indoor air quality management of the building under construction, the management of construction waste, and the sourcing and delivery of purchased products. In the contractor's DA tool, the owner and designers could make their preferences visible regarding construction management.

Regionally manufactured and regionally extracted materials may be given preference, for example. In LEED-NC 2.2, this is addressed in MR C5 Regional Materials.

Construction site management issues as to waste and indoor air quality are addressed in several rating systems, for example in LEED-NC 2.2 MR C2 Construction Waste Management, or EQ C3, Construction IAQ Management.

4.12 Portfolio & Building Operations

Once the building is constructed, the facility managers will make many decisions for the building operations throughout its lifetime. Decisions are made for the single building or for a portfolio of several buildings, and may include the use of vendors for cleaning, landscape maintenance, pest management, consumer waste removal / minimum waste generation, and building consumables purchases. Building operations may address the maintenance of systems affecting indoor air quality, energy efficiency, and water use, and the measurement and verification of utility costs through submetering. This monitoring of energy uses and costs may inform the facility managers of what improvements make sense for the continued energy efficiency of the project, providing data regarding energy load per occupant or per unit area of the building.

These decisions are somewhat addressed in assessment tools for new design and construction, but usually in more detail in tools specifically geared toward the operations of existing buildings.

LEED-NC 2.2 EA Credit 5, Measurement & Verification establishes parameters for periodic measurement and verification programs.

Recognizing the varying limits of human comfort, LEED EQ Credit 7.2, Thermal Comfort: Verification addresses input from the building occupants regarding their satisfaction with the building's thermal characteristics.

4.13 Building Operations Vending

Each vendor for building operations makes decisions that affect the environment. If the DA tools for these entities described the preferred operations and maintenance methods of the facility managers, vendors could tailor their services accordingly. The maintenance vendors may offer more environmentally sound cleaning, landscape management, pest control, consumer waste removal, and building consumables purchasing. Providers of utility services like electricity, gas, water, or communications, could also use the DA tools to track decisions related to the building operations and may suggest how different decisions could positively affect energy efficiency and what incentives may be available.

Many of these issues are addressed in assessment systems more geared toward the operations of buildings, such as LEED for Existing Buildings: Operation & Maintenance.

NABERS, a building rating system developed in Australia, deals primarily with post-occupancy environmental performance. This assessment tool addresses the relationship between a property owner and the utility companies that serve the project.

5. Summary and Recommendations

No easy correlation between current assessment systems and the proposed DA Tools was found. Existing assessment systems do not provide clear decision making paths toward more environmentally conscious built environments. If the need for new decision tools should become recognized and widely acknowledged, a large undertaking would be necessary to rework the existing assessment tools into DA tools. While the individual credits from current assessment tools used in the examples above may be suitable for some DA tools, they would require extensive modification to become user-friendly in such a new application. Also, the existing credits do not have the capability to project the greater environmental impacts of applied building strategies in an interactive format, or to track decisions. For now, existing assessment tools are primarily framed to document the results for singular projects, results of decisions that have already been made. The authors recommend:

5.1 To those developing current assessment tools: Relate assessment topics to decision categories. Existing credits may be suitable for integration in future DA tools, specific to particular decision makers, and although they would need further development to be user-friendly in such an application, identifying their decision categories now will ease a future transition. More specialized assessment systems, such as those for neighborhood planning or those for building operations, appear to be a better basis for DA tools; thus entire systems or parts of systems could be converted to decision categories.

5.2 To those developing DA tools: Consider specific uses and tailor the tools to a specific type of decision maker identified by a major decision category. Tools should be available to decision makers over the length of their relationships with a project, and should be capable of maintaining user accounts for a long time period.

5.3 To those developing all tools: Add a framework that coordinates assessment methods and supports both data tracking and a searchable public-knowledge database. Current assessment tools rate project characteristics with differing methods, and there appears to be little dialogue between systems. Coordination would more easily allow for the development of DA tools by providing quick access to the topics in existing assessment tools. Synchronize decision topics related to a global scale across systems, and add data, opinions, and other public information that support decision making. Consider adding the capability to track decisions and maintain a database of such recorded information.

THE SUSTAINABLE REFURBISHMENT OF EXISTING BUILDINGS: THE GREAT CHALLENGE FOR THE PROPERTY INDUSTRY

Jeffrey ROBINSON BCS (Eng)[1]
Mark QUINN AIQS[2]

[1]Connell Wagner, Consulting Engineers, Melbourne, Australia, robinsonjh@conwag.com
[2]Rider Levett Bucknall, Cost Consultants, Melbourne, Australia, mark.quinn@au.rlb.com

Keywords: sustainable, refurbishment, environmental rating

Summary

The Australian Commercial Property Sector has fully embraced environmentally sustainable design for new commercial buildings. The challenge now is what can be done to improve the environmental performance of the existing stock without resorting to the environmentally damaging option of demolition and redevelopment of new buildings. Through a series of interviews with commercial building owners, the authors discussed some of the technical and management strategies that are being employed in Australia to improve the environmental performance of existing commercial buildings. The interviews discussed the financial aspects of these refurbishments and how major commercial property owners decide whether to refurbish their existing stock and to improve their environmental performance in an effort to retain their tenants, or to sell or demolish and redevelop their properties. Government can encourage the sustainable redevelopment of existing properties through legislation and incentives.

1. An Evolution for new buildings

The Australian Property Industry has fully embraced Environmentally Sustainable Design for new commercial buildings. This can be evidenced by the vast majority of developers seeking to have their new commercial buildings rated as four, five or six star buildings under the Greenstar Office Design rating scheme.

As of April 2008 there were 51 Green Star certified properties in Australia and many more have applied for certification. In recognition of this, the Property Council of Australia (PCA) acknowledged the green rating schemes in their May 2006 matrix which specified that new Premium and A Grade buildings are encouraged to be designed to achieve a 4 Star Greenstar rating and a 4.5 Star rating under the Australian Building Greenhouse Rating Scheme (ABGR).

It is fair to say that these minimum standards are generally being exceeded in most capital cities with most new PCA A Grade buildings seeking a 5 Green Star rating and Premium Buildings targeting a 6 Green star rating, in design. The next challenge for the developers of commercial offices will be to convert their "Design" Green Star ratings into "As Built" ratings. Educated tenants are now asking that the design promises are delivered as "As Built" GreenStar and ABGR ratings.

Developers and property owners are reluctant to agree to sign an ABGR Commitment Agreement which requires them to deliver a 4.5 Star ABGR rating to 18 months after occupation. Many are concerned that if the building does not achieve the ABGR rating specified that the tenants may be entitled to an unequitable rent abetment or require the lessor to pay for Green Power to deliver the contracted ABGR rating. It is with some justification as several recent commercial buildings which were built in recent years have yet to achieve the ABGR ratings which were promised when the building was designed. The NABERS web site pays testament to this in that in April 2008 there are no Melbourne commercial buildings listed as having achieved a 4.5 ABGR star rating.

Tenants commonly want the buildings which they occupy to achieve a 5 Star Green star tenancy rating and a 4.5 Star Tenancy ABGR rating whilst being unwilling to sign a requirement in their lease that they achieve any back to back tenancy rating. We believe that the industry has yet to evolve to accept that this is normal practice, where as the development cycle caters for majority of demand leaving sustainability behind as a point for negotiation. It is apparent that if the property industry is to achieve meaningful reductions in the Greenhouse emissions resulting from the occupation of its buildings, a partnership approach or back to back contractual arrangements will have to become commonplace with landlords and tenants working co-operatively together to assist each other in reducing their Greenhouse emissions.

2. The existing building dilemma

Approximately 2% to 4% of the available commercial office buildings are developed each year and new buildings retain their "new" status for approximately 5 years leaving about 90% of the existing stock which is largely not achieving high levels of Greenhouse and Environmental performance.

If the Australian Federal and State Governments wish to achieve reductions in Greenhouse emissions resulting from buildings, then much needs to be done in the next few years to improve the Greenhouse and Environmental performance of the existing commercial building stock albeit to an average below that of the energy ratings expected from new buildings.

Should the property industry wish to assist the Government to achieve reductions in Greenhouse gas emissions, is it willing to make the considerable investments in both capital improvement, education and better facilities management in order to improve the environmental rating of their existing buildings over and above the opportunities that are presented by developing new buildings?

3. The interviews

Through a series of interviews with commercial building owners, we discussed some of the technical and management strategies that are being employed in Australia to improve the environmental performance of existing commercial buildings. The interviews discussed the financial aspects of these refurbishments and how major commercial property owners decide whether to refurbish their existing stock and to improve their environmental performance in an effort to retain their tenants, or to sell or demolish and redevelop their properties.

The structured questions as summarised below were used to discuss the motivation of existing owners to improve the environmental performance of the existing buildings.

1. What are the important factors in commercial property investment decisions
2. What factors require cultural change to promote investment in sustainability through property
3. What are the key drives for retaining existing or old stock
4. What are the significant issues faced in retaining tenants
5. What incentives would assist in retaining tenants in existing buildings
6. What physical elements are paramount for the redevelopment of a financially successful building
7. Is upgrading existing buildings an appropriate way to develop a sustainable built environment
8. Is a focus on the quality and experience of building management necessary in delivering sustainable outcomes

4. The Findings

- *What are the important factors in commercial property investment decisions?*

The two most important factors were considered to be the investment horizon and "fit" within an existing or new portfolio and the capital costs of acquiring and /or refurbishing the property, but an underlying attribute that was sought was the inherent refurbishment potential.

Other factors discussed included compliance with industry standards, regulations and risk in development although these were also seen to be combined with the overall refurbishment appraisal where poorly performing buildings could be seen to be offering the greatest potential for capital improvement.

Green branding or specific tenant's requirements, at this point was not considered an overriding issue.

- *What factors require cultural change to promote investment in sustainability through property*

Interestingly there was no real move to change the cultural of their businesses, but there was an absolute need to have sustainable outcomes achieve investment parameters. (this leads to a greater motivation to invest in energy saving measures which generally have a greater return on investment that water saving measures).

- *What are the key drives for retaining existing or old stock*

The overriding factor to retaining existing assets is that the financial performance must be achieved within the investment criteria. Most felt that their asset management delivery systems needed to respond to this requirement once an asset was acquired.

- *What are the significant issues faced in retaining tenants*

Although over 50% of respondents felt that the green performance of the building played an important factor in attracting new or retaining existing tenants, it was also noted that perception and education were also important. Interestingly perception is not just green but relates also to perceived quality, function and design appeal.

- *What would assist in retaining tenants in existing buildings*

Improving the sustainability performance of the existing buildings was seen as an effective way of changing existing tenant's negative perceptions about the age of the buildings they occupy.

- *What physical elements are paramount for the redevelopment of a financially successful building*

The design of the entrance and Foyer has a great impact on tenants first impressions, equally building services that provide an enhance functionality and comfort (eg Lifts and air-conditioning).

Interestingly although aesthetics were important quality of finishes was not high on the list.

Facades and passive design features were desirable although generally felt to be cost prohibitive unless absolutely necessary.

- *Is upgrading existing buildings an appropriate way to develop a sustainable built environment*

All of the respondents agreed that the upgrading excising buildings was desirable

- *Is a focus on the quality and experience of building management necessary in delivering sustainable outcomes*

Again all of the respondents agreed that a focus on the quality and experience of building management was an absolute necessary in delivering sustainable outcomes and many were concerned about the apparent shortage of suitably skilled and experience building managers

5. What can Government do?

It was identified that the Government can provide an important role in directing coordinating and assisting with the delivery of sustainability through regulation, incentive and participation in the industry as a tenant, however the motivation for intervention was often queried. We note below some opportunities for government that were discussed.

- Tax incentives are often referred to an easily implemented incentive and one that is simply a deferred method of public investment; however the implementation needs to be carefully considered to ensure that the concessions granted are easily claimed, provide a reduction in emissions and water usage and drive innovation.
- Tax incentives should also be implemented allowing for the revaluation of existing buildings for tax concessions where a significant increase in environmental performance can be demonstrated.
- An innovative solution that was suggested by one of the interviewees was for the State Government or local authorities to refurbish a large commercial building which could be used by commercial building owners to relocate tenants while their buildings were being refurbished to improve their environmental performance. This would help overcome the problem that many landlords have when trying to schedule a major refurbishment, that of leases finishing at different times within the building.
- Government whether local, state or federal can encourage existing building owners to refurbish their properties by proactively leasing properties which have been upgraded to improve their

environmental performance. In this manner existing building owners can compete on an equal playing field with the developers of new buildings with high environmental ratings.

- One problem for investors wishing to buy an existing building or for tenants wishing to secure a lease is the lack of information on the amount of Green House Gases (GHG) generated by the buildings operations and their water usage. The introduction of mandatory reporting of the yearly GHG and water usage for commercial buildings may encourage existing building owners to improve their GHG and water performance. A league table of NABERS and energy and water ratings with positions this year and last year could be published to encourage building owners and tenants to maintain or improve their environmental performance.
- Government can play a more proactive role in the development and delivery of more efficient infrastructure such as for the water and power utilities that will in turn encourage innovative use and reuse of our scarce resources.

6. Conclusion

It is apparent from our research that age old investment criteria still stands for all property assets, in fact the investment models being implemented today scrutinise to a much grater detail than in the past, therefore any environmental initiative must deliver appropriate returns that suit the investment criteria of the developer or owner. However, this does not mean that every aspect of an environmental solution must achieve above market returns but it must contribute to the overall investment criteria. The term “future proofing” was often referred to in the interviews.

With over 90% of commercial building stock being over 5 years old, Existing Buildings are not discounted as being below investment grade any less than for new buildings, but rather provide an opportunity for repositioning and enhancing existing portfolios where their attributes suite an organisations investment criteria.

It was also apparent from various aspects of our interviews that it was believed that well educated and sound asset management practices from investment decisions through to the day to day management of buildings will pick up on sustainable opportunities. However it was also apparent that education was lacking in many areas of asset management.

It was identified that as tenants create demand their desire to occupy in a sustainable fashion must be backed up with not only their financial support but also their behaviour.

It was identified that the Government can provide an important role in directing coordinating and assisting with the delivery of sustainability through regulation, incentive and participation in the industry as a tenant.

There was a strong feeling that experience and quality of Building Management provides an important link in the delivery of sustainable outcomes and that the shortage of experienced building managers and engineers is a concern. It was also suggested that some tenants were equally concerned with the building management as they were with other aspects of buildings they seek to occupy.

PRO-ENVIRONMENTAL URBAN GRASSROOTS MOVEMENTS: COMMUNICATION THROUGH CULTURAL LANDSCAPES OF ENVIRONMENTALLY RESPONSIBLE CITIZENSHIP

Lusi MORHAYIM, M.Sc., Ph.D. Student[1]

[1] Department of Architecture, University of California, Berkeley, USA, lusi_morhayim@berkeley.edu

Keywords: Environmentally-responsible citizenship, grassroots movements, urban interventions, cultural landscapes, sustainable cities.

Summary

This paper focuses on pro-environmental urban grassroots movements that are pursuing their goals by transforming physical spaces in urban areas. Case studies, such as the creek mark on Center Street, Critical Mass, Park(ing), Save the Oaks, and "Stop (driving)," demonstrate the ways in which pro-environmental grassroots groups use and alter public and private spaces to communicate their desire for physical environments that will accommodate sustainable ecosystems and provide opportunities for healthier and environmentally-responsible lifestyles for their residents (e.g., bicycling instead of driving.) Through their interventions, they challenge the existing norms about cities and communicate messages about alternative urban forms to the rest of society.

Insurgent aspects of their movements portray the grassroots actors as active citizens who are also challenging conceptions of environmental rights and responsibilities. Their practices indicate that they consider living in a healthy and environmentally-friendly physical environment their fundamental right. They argue for and are committed to protecting the "environmental rights" of all members of the ecosystem (humans and non-human beings). Recognizing and understanding the needs and contributions of these grassroots actors is essential for environmental designers, planners, and governments in creating sustainable built environments, since it is a social challenge as much as a technical one.

1. Introduction

This paper focuses on pro-environmental urban grassroots movements that are pursuing their goals by transforming physical spaces in urban areas. The city of Berkeley, California is known as the home-town of liberals and environmentalists, both in historical perspective and in the present-day. In Berkeley, liberal, socially considerate, and pro-environmental groups have historically succeeded in manifesting their goals by reclaiming public spaces for the purposes they wanted and turning their social commitments into currently existing cultural landscapes (e.g. People's Park[1] and Sproul Plaza[2]). While historical examples are icons of civil rights and social justice movements, the movements discussed in this paper are emblematic of social responsibility for environmental problems. These grassroots actors transform the built environment in order to create sustainable urban environments, as well as to increase environmental awareness. Insurgent practices of these grassroots actors indicate that they consider living in a healthy and environmentally-friendly physical environment their fundamental right.

In this paper, "sustainable urban form" is used to mean urban form that encourages environmentally responsible behavior, such as bicycling instead of driving, and places where minimal environmental impact is the foremost principal in their design.

Participant observation, interviews, content analysis of mission statements of the various movements, and archival research are amongst the methods used to analyze the grassroots actors' motives and the messages they are willing to communicate to the audience around them who are not participating actively in the movements. The following case studies demonstrate the ways in which pro-environmental grassroots

[1] People's Park, created on university-owned land, was initially planned to be a site for student housing. Then, a decision was made to turn it into a parking lot. For the three weeks the site was vacant, people from the neighborhood started to build a garden, an action which eventually resulted in armed disputes between park volunteers and the university, which lead to many injuries. Nevertheless, after following negotiations, people in Berkeley succeeded in converting the site into People's Park, a space devoted to use by homeless people. Today it is still used that way. (http://www.afsc.org/about/hist/2002/peoples_park.htm, accessed in 12/10/2007).
[2] Sproul Plaza at the University of California, Berkeley Campus, became a symbol of 'free speech' during students' protests against a university ban on political activities on campus in the early 1960s.

groups use and alter public and private spaces, streets, and sidewalks for environmental campaigns and for communicating pro-environmental and sustainability-oriented messages:

- Creek mark on Center Street, by Friends of Strawberry Creek: a blue mark on the street indicating the portion of Strawberry Creek that is flowing underground;
- Critical Mass, anonymous: large groups (enough people to cut off traffic in a three lane avenue) meeting for bicycle rides on the streets once a month;
- Park(ing), by Rebar: creating temporary green spaces in parking lots or in spaces for car parking;
- Save the Oaks, anonymous: a tree-sit scene lasting for more than a year and sustaining itself with food donations from residents;
- "Stop (driving)" signs, anonymous: "stop" signs are converted to "stop driving" signs through the application of stenciled lettering.

These examples are important for the environmental design professionals, because they show a demand for change in urban environments. The movements, some of which were started in the San Francisco Bay Area, represent not only a local uprising for urban environmental change but a global demand, which is proven by finding supporters replicating the same movements (e.g., Park[ing] and Critical Mass) in cities in other parts of the world. Signs of permanent and temporal physical interventions in urban space demonstrate those communities' values regarding how they want to make use of the urban spaces in which they are living.

Case studies and interviews in particular show that those pro-environmental urban grassroots interventions are also a reaction to corporate capitalism and mass consumption culture, as much as they are about dissatisfaction with current urban forms, planning, and the uses imposed on society. Underneath the motives of these grassroots actors seems to be a desire for change towards more sustainable lifestyles (socially and environmentally) and a struggle of "rights" to sustain a healthy ecosystem, for people and for other living beings that are also part of the earth. The practices of these movements bring up several issues, including alienation from nature, healthy lifestyles, and lack of sense of community and public life. Some of the grassroots arguments stem from ecocentric values over anthropocentric values, i.e. prioritizing the ecosystem as a whole, rather than prioritizing human needs or any one individual organism in the ecosystem.

What is most intriguing about these environmental movements is the importance given to the physical environment itself. They aim for restructuring existing urban forms and current unsustainable lifestyles that are closely related to urban forms. Their actions do not consist solely of adapting urban spaces and enacting their goals about each particular space, but also of choosing space as a tool to communicate their pro-environmental messages to the public. Thus, their activities should not be overlooked as simple "tree-hugger" behavior; they are also agents/citizens structuring cultural landscapes of environmental responsibility.

These grassroots movements are also striking, because they do not limit their political environmental behavior to recycling their own garbage or closing their own tap when brushing their teeth, but instead they are interested in public behaviors and opinions that can be formulated and communicated in public spaces. They are interested in taking action and taking responsibility for public spaces and public behavior as active citizens. Therefore, after presenting the grassroots movements, this paper analyzes the pro-environmental urban grassroots movements from two angles: 1) construction of cultural landscapes of change for a sustainable future and the communication of social and environmental sustainability-oriented messages; and 2) environmentally responsible citizenship, environmental rights and duties, and ecological democracy.

2. Pro-environmental Urban Grassroots Interventions

The grassroots movements presented in this paper are chosen because of the ways in which they use and transform public space (and private space in the case of the Save the Oaks movement) in the city. Each of them demonstrates a claim, in different levels of intensity, about participating in decision-making for urban spaces. They share similar underlying pro-environmental intentions while using the space as an instrument to bring public attention and while enacting their will on the space.

The mission statement of Friends of Strawberry Creek presents their goals as protecting the quality of the creek, exposing it to sunlight wherever possible, and increasing the native vegetation and habitat around the creek. Their consequent goal is educating and involving the public in the pursuit of rehabilitation of the creek. Their way of executing this objective has been through bringing attention to the creek by painting a blue line on Center Street in Berkeley where the creek would be flowing openly if it was not flowing under the ground (Fig. 1). They choose to argue for their case where it exists. Moreover, they leave an actual mark of public will on the exact space they find problematic. Thus, the creek almost talks for itself, representing what would be healthy for the natural environment and pleasant for people.

Critical Mass is an event concerned more with sustainable behavior. It is a community bike-riding movement that takes place on streets designated for motor-vehicle traffic. Even though the city of Berkeley has been responsive to the needs of bicycle commuters by implementing various traffic calming measures, adding bicycle lanes, and creating bicycle-only streets, it seems that there is still a demand for more space for non-vehicle traffic. Critical Mass is a monthly bike-riding event first started in San Francisco in 1992 and now spread worldwide. Several websites about Critical Mass suggest that it is a self-organized social event with no leaders. The "unofficial" website of Berkeley Critical Mass describes the movement as a global non-authoritarian movement of celebration, street reclamation, and demonstration. The same website names the event also as “a rolling free speech stage and playground.” This association with the free speech movement hints at the political face of the movement.

Critical Mass may seem like people simply gathering for bicycling; however, for many participants, it means more. Besides riding bicycles, many participants also imply that they prefer seeing more space designated for pedestrians and bicycles rather than automobiles. Some participants communicate their reaction to oil dependency and automobile-dependent lifestyles and carry “Stop Global Warming, Stop Driving” campaign boards behind their bikes (Fig. 2). As local newspaper Modesto Bee suggests in one article, reasons for people’s participation are multiple: “Some want safe bike paths and more bike racks. Others want to show motorists that there is a healthier, cheaper, pollution-free mode of transportation. Some want to show that bikes are traffic too and should be respected. And some just want to be noticed -- not applauded, but seen, so they aren't hit by heavier modes of transportation (Hightower, 2007).”

Figure 1 *Creek mark on Center Street in Berkeley, CA indicating the portion of Strawberry Creek that is flowing underground (Morhayim, 2007)*

Figure 2 *One of the riders carrying a “stop driving” sign on the back of his bike during Critical Mass in Berkeley, (Morhayim, 2007)*

Having participated in the cycling event in Berkeley in 2007, my observation is that it is a temporary but empowering opportunity to have a voice in how people make use of a certain place in the city, instead of being contained by the existing physical, social, and political configurations of how to use the city. They take over control of the street and change its designated use, based on the motivation of biking freely in the city. They express their needs through simply acquiring what is needed. Furthermore, the riders are not the only celebrants of the bike rides; very often, I have seen drivers passing by and supporting the ride by honking. Hence, Critical Mass shows that both participants and several passersby share similar values regarding automobile dependency and, perhaps, regarding the amount of room it takes up in urban space and in urban life.

Park(ing) is an event that uses on-street car parking spaces as temporary public parks (Fig. 3). Park(ing) activists bring their lawn and furniture and lease a metered parking spot to transform it into a green space. It was initiated in November 2005 by Rebar, a San Francisco-based art collective, and has turned into an annual global event celebrated in 13 cities in 2006 and in over 50 cities in 2007. Their mission is “to rethink the way streets are used, call attention to the need for urban parks, and improve the quality of urban human habitat.” Their website also claims that, “[a] playful idea has become a lively and visible symbol of the desire to reprogram the street and increase public open space in cities all over the planet.” Park(ing) activists around the world manage to voice their needs for more green space by actually creating that space, for their own use and for the public. Even though it is a one-day event, it engages the public in the cause, as they sustain the event by public donations to the parking meter, and the public can use the randomly occurring temporary green spaces in the city.

Figure 3 Passersby enjoying one of the Park(ing) spots in San Francisco, CA (http://www.rebargroup.org/projects/parking/#, accessed in April, 2008)

Figure 4 'Stop Driving' signs on Milvia St. and Oregon St., Berkeley CA (Morhayim, 2007)

A rather radical and illegal activism in urban space is the production of "Stop Driving" signs: regular stop signs on poles stenciled with "driving" to read "Stop Driving." The same is also done for the stop sign markings on the roads at intersections (Fig. 4). This movement, of which the actors are unknown, communicates to many people not to drive and instead to choose walking, biking, and public transportation. This insurgent act, on the one hand, aims to provide an alternative perspective for street use; on the other hand, it transforms the exact element that is viewed as a problem and communicates a message of sustainable behavior and environmental protection.

Save the Oaks is another grassroots movement in the city depicting environmental sensitivity in an insurgent manner. The Memorial Oak Grove (containing a threatened native Coast Live Oak ecosystem) on the east side of the University of California at Berkeley campus, dedicated to Californians who died fighting in WWI and property of the University, has been fenced by UC Berkeley since August 2007. As of March 2008, a group of people have been tree-sitting for more than a year to protect the trees from UC Berkeley's plan to build an athletic facility on the site. They built wooden rope structures to sleep on, ladders to climb into the trees, and bridges to cross between the trees. Banners hanging around say "Home is where the trees live" (Fig. 5). The site has created a long controversial process between the university, environmental groups, students, and the city, given that some of the oak trees are 200 years old (older than the university itself), and that the proposed site is on a fault right next to the seismically challenged and aging UC Berkeley stadium. Tree-sitting has become widely known in the United States; a number of local and national newspapers have covered this issue since November 2006[3]. By February 15, 2007, the site attracted more than 80 people to support the cause; they have taken turns sitting in an oak tree (Bender, 2007). Tree-sitters sustain their movement through public support. They get donations of food and material from their supporters, especially from a group that call themselves "Berkeley Grandmothers."

The tree-sitters' argument is one of ecocentric values over anthropocentric values. The tree-sitters argue that a healthy functioning native oak ecosystem, supporting a whole network of other plants and animals, should not be lost for the sake of further development. Moreover, as it is stated on their website, the group also stresses the educational value of such a vital ecosystem existing in urban space.

Figure 5 Save the Oak Trees, tree-sitting site (NY Times, accessed in October, 2007)

Figure 6 Pro-environmental messages on the sidewalks around the Memorial Oak Grove (Morhayim, October, 2007)

Tree-sitters continue to organize events regularly to keep their case alive and to communicate other messages as well, one of which is creating an alternative community. The sidewalks in front of the site are painted with messages, such as: "A football team does not stop global warming, but trees do!" (Fig. 6). On October 28th, 2008, the tree-sit site was also used as a "free market" "to create a truly alternative economy" for "sharing," as stated in a flyer. Tree-sitters also announced the following in the flyer:

> "As globalized capitalism consumes more of the Earth every day, let's answer with creative resistance. This event is made by and for you/us. Bring anything you have that could be useful to others."

Analysis of these movements shows that all these grassroots groups perceive physical space as the center of environmental and social sustainability. They therefore choose to address their cases through physical interventions in these spaces in the city. Grassroots activists use the spaces as the locus of their action. This way, on one hand, they enact their agendas though transforming the spaces to more pro-environmental ones; on the other hand, they publicize their cases. As active citizens, they act as if it is their right or their responsibility to address the issues they perceive as unsustainable. Some grassroots actors show such a strong commitment that they take the risk of engaging in illegal behavior.

[3] According to a key word search of "Memorial Oak Grove" and Berkeley (in News Bank, www.newsbank.com, accessed, 10.11.2007)

3. Underlying Social and Pro-environmental Messages of the Movements

One of the active participants of these movements, who has given several speeches in the Memorial Grove and who has been reported on in several newspaper articles, describes the underlying messages of their activities as being beyond mere physical interventions. During my informal conversation with him, he refers to the overarching goal of stopping global warming, of which the tree-sit is part of, according to him. In order to reduce the risk of environmental deterioration such as global warming, he recommends a "paradigm of a lifestyle change; i.e., instead of thinking of green energy, [he calls forth for] thinking of reductions, [and] simplifying one's lifestyle." He also adds:

> "…[oil] economy, in basic terms, is a war on Mother Earth. It is use of resources quicker than you can replace them, and we can no longer afford it. By 2003, I find money hard to basically be justified…stop abusive lifestyle of capitalism!"

He extends this idea of "thinking reductions" and "lifestyle change" to physical interventions of private residential spaces, as well. He describes how the layout of residential buildings in a block needs to be transformed for social change:

> "How you could change society is you take inner city block, instead of having fences in the middle put one around the entire block and drop the inner one[s]. Then you would have an entire football field (excuse the term) inside that block, and you could become a community of one block…We don't think of community, we think of personal [in our current lifestyles today]."

> "There are so many resources…how many people have 2 or 3 bicycles in the garage, just sitting? We could, quite literally, and this is revolutionary thought, take all the bicycles we are not using and put them out on the street just leave them unlocked. Just have people whenever they wanted to go take a bike and go."

These rather utopian ideas show that grassroots activists' focus is more than environmental protection, and that they in fact long for social change. Such a configuration of dwelling units and shared private spaces proposes creation of a neighborhood community that will share their goods and their physical space, which suggests a very different social life than the existing one in many parts of the world.

Overall, the issues that came up in the interview are the problems of modern life, the isolation between people, isolation from nature, the fast pace of our lives, and increased consumption, which all are directly and indirectly related to and moderated by the way the physical environments are constructed. This explains why urban space becomes so central to the grassroots' activism to create change towards sustainability. While such attitudes need to be substantiated by a larger number of interviews, still at this point, this data provide important clues about values underlying the interventions of the grassroots actors. Grassroots actors strive to create sustainable urban forms that will encourage sustainable lifestyles and sustainability-oriented society. Through interventions, they communicate messages of an alternative form to the rest of the members of the city, including design professionals.

4. Pro-environmental Interventions as Cultural Landscapes

Urban space is important for these actors in multiple ways. Transformations in the urban space create opportunities for encountering like-minded people in the society and allow pro-environmental grassroots groups to experience the kind of city they want. Also, through their transformations in urban space, the grassroots actors bring attention to unsustainable parts of the city.

Dave Horton (2006), in his article "Demonstrating Environmental Citizenship," emphasizes the importance of "green spaces" and "green times" in constituting and strengthening green identities. He refers to places and times of social networking, like cafés that are renowned as places of green culture, green meetings like festivals, and environmental protest events (2006). One special thing about the "green spaces" in this paper is that the pro-environmental grassroots actors use the same urban spaces that they view problematic as the locus of their activities and for gathering. Choosing public space (or publicly visible private space, as in the case of the tree-sit) as the locus of their action allows grassroots actors to encounter their supporters. As in the case of Save the Oaks, Berkeley grandmothers regularly donate food to tree-sitters and help them to sustain their movements; likewise, drivers in traffic support Critical Mass bikers by honking even when bikers are cutting through traffic.

Lefebvre states that the "space of the city is said to embody a discourse, a language." Space represents the messages and intentions of the producers of the space (LeFebvre, 1961). When these grassroots groups appropriate the space, they also create cultural landscapes of "green identities." Cultural landscapes communicate environmental messages to the rest of society. Critical Mass and Park(ing) are prominent examples. These movements change the physical conditions of the space, and they change the use. They enact sustainable behaviors in public space. First, they create a pro-environmental spectacle, explicitly to create contrast with the modern, consumptive, and late capitalist spectacle. In a way, they act out a public show. Next, this act changes the meaning of the space, not only for that moment, but also for longer periods of time. Such a scene stimulates the viewer to question the taken-for-granted ways about how urban space is used and taken-for-granted public behaviors. Additionally, it reminds the viewer that there is not an adequate amount of space, such as adequate bike paths and other green space, designed for environmentally-friendly behaviors. Actors choose to show their need by using the existing space as they would like to see it being designed and used, even though it is not currently designed for their needs. Consequently, appropriated urban space becomes an instrument to raise awareness for creating sustainable urban spaces and to strengthen green identities.

Douglas Torgerson (1999) states that, "green movement provokes a reconsideration of the entire human/nature relationship." Practices of these grassroots activists challenge the current attitudes that society holds about physical and natural environments, such as how we live, how much we consume, how much we are connected or disconnected from nature, and problems like a loss of sense of community and spaces that will encourage sustainable behavior (e.g., bicycling).

As suggested by Pierre Bourdieu, active agents alter their actions based on their desires and needs, independently from the social structures (Stevens, 1998). Pro-environmental grassroots movements explicitly adopt and transform physical spaces, instead of being constricted by the existing physical, social, and political configurations. In turn, this adaptation becomes the usage of space as a tool of enculturation for environmental awareness, while they create the space they want. Grassroots activists bring attention to taken-for-granted uses of urban space as social problems as much as physical problems, in order to point to the kinds of unsustainable environments architects and planners choose to create and the role that these spaces play in a society trying to live sustainably. They question the ways in which our physical surroundings shape our lifestyles and the societal values and the worldviews people hold about nature. Grassroots activists transform the physical environments in an attempt to re-create the social structures towards a sustainable society. The illegal aspect of the movements, such as tree-sitting on private land and stop (driving) signs, show that constraints of existing structures can be challenged by the agents, to the extent of acting illegally[4].

When those actors alter physical spaces and use them for a different purpose than their conventional use, they exercise control over public space in addition to communicating their opinions. As Lefebvre states, that space produced "…also serves as a tool of thought and of action; that in addition to being a means of production, it is also a means of control, and hence of domination, of power…" Pro-environmental communities, whose needs haven't been addressed adequately through planning, take control and govern their spaces (Etzioni, 1968; Foucault, 1991).

By enacting their goals on the spaces they find unsustainable, grassroots actors address environmental and/or social problems occurring in those spaces. In time, places that pro-environmental movements create might become symbols of change towards environmentally responsible lifestyles. For instance, even if in the future oak trees might be replaced with an athletic facility, the tree-sit site will be remembered as a place of environmental struggle and a base of pro-environmental sub-culture, having been taken over for more than a year. A new image is already attached to the Memorial Oak Grove site, which is communicating messages for an alternative lifestyle and worldview that prioritizes ecological balance. This and other pro-environmental interventions in urban space become an instrument and embody an active role for raising awareness. Grassroots actors turn those spaces into cultural landscapes of pro-environmental change.

5. Environmentally Responsible Citizenship

As analysis of the movements show, some of the grassroots activists are so committed to their causes that they don't mind participating in illegal activities, as if it is their right or their responsibility to address and solve the urban matters that they perceive as unsustainable. This fact suggests that these grassroots actors are active citizens who are also challenging conceptions of environmental rights and responsibilities.

These pro-environmental urban grassroots movements claim the right to live in a healthy ecosystem, for themselves and for other living beings. Non-living elements are essential as well, since they are constituents of the natural environment that allow the existence of the living beings, just as the small creek ecosystem allows the plants and the animals that are its dependents to live.

Their everyday practices allow the grassroots actors to practice direct democracy and create a public sphere for decision making for the places in which they live. Pro-environmental grassroots movements make use of the public space as an "agora" to share their point of view and to create an "ecologically democratic" society. I use this term, ecological democracy, to point to a longstanding disregard of environmental problems and the need for compensation through a prioritization of the sustainability of ecological systems. Given that there is not an immediate platform to participate in decision-making for ecological justice in the city (socially and environmentally), the grassroots actors create their own political platform through physical interventions.

Derek Bell's concept of "liberal environmental citizenship" and Andrew Dobson's concept of "ecological citizenship" highlight different aspects of being an environmentally-considerate citizen (Dobson, 2003; Bell, 2005). Environmental citizenship proposes a rights-based approach: it "extends the liberal list of rights beyond civil, political and economic rights to include environmental rights, that is, rights to environmental goods or to protection from environmental bads" (Bell, 2003). Bell (2005) states that liberal environmental citizenship is based on the understanding of being a "citizen of the environment" and of a local environment. On the other hand, ecological citizenship is concerned more with behavioral duties and responsibilities, in order not to consume more than one's fair share of ecological space, so as to leave enough ecological space to other people (Dobson, 2003). Environmental citizenship is also concerned with others' right to a fair share of ecological space; however, this is mediated through supporting "institutional arrangements that [will] secure everyone's right," rather than securing it through a negative duty of not consuming more (Bell, 2003). In this light, ecological citizenship represents a rather active form of citizenship that is concerned with self-control of behavior, and environmental citizenship operates through liberal rights. Nevertheless, both formulations of environmentally considerate citizenship describe people that are interested in social change for sustainable future.

[4] In a similar way to how People's Park was used.

Each of the movements presented in this paper holds their own particularities in terms of rights and duty claims and in terms of their special interests in urban space. Some are illegal in their approach. Some are less active movements, like Friends of the Strawberry Creek, whose awaited contribution is influencing institutional arrangements as much as increasing public awareness. On the other hand, the tree-sit would be an example of the most rigorous activist citizenship amongst them all. While the Park(ing) movement is concerned with creating greener urban habitats for people, the tree-sitters in Memorial Oak Grove care about the rights of trees to exist and to sustain their ecosystem. The tree-sit shows that citizenship rights can be extended to protect rights of non-human beings (even if it might stem from self-interest), because all elements of the ecosystem are interdependent, and because living beings other than humans don't have means to fight for their existence. Nonetheless, even though all grassroots movements are slightly different from each other, they all claim rights and take responsibility for their environments. This suggests the existence of a political community of active, environmentally-responsible citizens who are aiming to achieve social and physical change in urban space.

Citizenship has always been a struggle for more rights. Given that, these pro-environmental grassroots movements, even the illegal ones, may be seen as part of an emerging form of citizenship. Illegal or not, grassroots movements may still be perceived as being "uncivilized;" however, their contribution to raising awareness and realizing their goals of creating sustainable lifestyles (even if it is for a temporal period) and creating a political platform for debating environmental and social problems of sustainability can not be ignored. As Dobson (2003) states, all of these movements aim to "re-moralize" the existing politics. According to Jamieson (2001), such insurgent attempts constitute a stronghold in democratic progress, and they are, as Carter (2001) states, "a significant political force, in the innovative repertories of protest and in the radical organizational forms and ideologies of ecological new social movements." Grassroots activists, through insurgent practices, negotiate for sustainable urban forms in order to promote sustainable lifestyles and to foster ecological democracy and an environmental community. Finally, they represent new identities of environmentally considerate citizens, whose needs have to be taken into account by designers, architects, planners, and policy makers.

6. Conclusions

Pro-environmental urban grassroots actors are active citizens who are arguing for and committed to protecting "environmental rights" of all members of the ecosystem (humans and non-human beings). Thus, the ecosystem can sustain its healthy balance, and we can all live in healthy environments. Moreover, analysis of the movements shows that these grassroots groups perceive physical urban space and urban social life as central to their goal of sustainability-oriented change, since sustainable places promote and allow sustainable behaviors.

These grassroots actors manifest their concerns about environmentally-unsustainable physical environments through physical interventions in those places. Insurgent practices of pro-environmental actors transform existing places into pro-environmental landscapes, and these places gain a new meaning. Hence, grassroots actors manage to bring attention to those places and promote a rethinking of the sustainability of existing urban forms and their uses.

Even though this paper covers grassroots groups in the San Francisco Bay Area, many similar local pro-environmental groups exist all around the globe. Grassroots actors strive for physical change in urban environments and for change in public behaviors and attitudes towards sustainability. They deliberately show their need for sustainable urban spaces with their practices. Creating better sustainable environments is a challenge ahead of us, not only consisting of inventing better building technologies, but also a challenge of increasing environmental awareness and increasing demand for more sustainable environments. Grassroots movements are important because of the effort and motivation they demonstrate to challenge existing conditions and to publicize the cases. They also show that there is a group of people in society who advocate design for a healthy ecosystem and whose needs ought to be recognized by designers, planners, and policy makers when making decisions for the built environments.

OPTIMAL AIR TEMPERATURE AND AIR SPEED FOR BUILT ENVIRONMENT IN HONG KONG FROM THERMAL COMFORT AND ENERGY SAVING PERSPECTIVES

Kwong Fai FONG Ph.D, Tin Tai CHOW Ph.D[1]
Baruch GIVONI Ph.D[2]

[1] Division of Building Science and Technology, City University of Hong Kong, Hong Kong, bssquare@cityu.edu.hk, bsttchow@cityu.edu.hk
[2] UCLA, Los Angeles, California, United States, bgivoni@ucla.edu

Keywords: thermal comfort, comfort air speed, acclimatization, comfort expectation

Summary

In this study, 140 human subjects wearing typical summer clothing were invited to an environmental chamber to conduct a thermal comfort survey in sedentary position. The studying air temperatures were in the range of 25 to 30°C, air speeds 0.5 to 3 m/s at 50%RH. Their thermal sensations were collected by using the ASHRAE 7-point scale. Multiple regression analysis was carried out to study the effect of both indoor air temperature and air speed to the thermal sensation of Hong Kong people in the age group of 19 to 25. The difference in thermal sensation between male and female subjects was also studied. A comfort zone for different air speeds in the temperature range of 25 to 30°C was developed. The results of the thermal sensation of different combinations of air temperature and air speed were compared with the predicted mean vote (PMV).

1. Introduction

In the subtropical Hong Kong, air-conditioning is a norm for the built environment, it is a standard expectation of the occupants. The provision of air-conditioning is necessary, but the reality is the excessive cooling in many places, no matter due to the wrong settings or control problems. In fact, the primary objective of air-conditioning is to provide a thermally comfortable indoor environment instead of simply cooling. Human thermal comfort may be dependent to a number of physiological, cultural and habitual factors. For the people in the tropical or subtropical Asian cities, the thermal sensation would be different due to the effect of acclimatization (Givoni 1998). The thermal sensation at higher air temperature can be still neutral if appropriate air speed is involved without causing nuisance. Cheng and Ng (2006) conducted a study of comfort temperatures for naturally ventilated buildings for Hong Kong, they found that the comfort temperature could be elevated by increasing the air speed. Huda et al. (2006) had the same idea, and they conducted experiments to study the sensitivity of neck and ankle to higher air speed. In a working environment, it is important to prevent the occurrence of uncomfortable draft and annoying air speed. From both the thermal comfort and energy saving perspectives, it is essential to have an optimal setting of air temperature and air speed to provide a comfortable but not over-cooled built environment. On the other hand, Feriadi and Wong (2004) had a thermal comfort study in Indonesia, showing that there was discrepancy between their obtained results and the prediction by the conventional PMV. de Dear (2006) also argued the appropriateness of the PMV model to reflect the thermal comfort. In Hong Kong, application of PMV and PPD to assess a thermally comfortable indoor environment is common. It is necessary to review whether the thermal sensation derived by the PMV equations, particularly the involvement of air speed, would closely reflect the sensation of the Hong Kong people.

This paper presents the indoor thermal comfort study for the Hong Kong people in the age group of 19 to 25 at 50% RH. By varying the air speed from 0.5 to 3 m/s, the range of 90% comfort temperature was determined. The difference in thermal sensation between male and female subjects would be discussed. The conventional PMV was compared to the experimental results to understand the effectiveness of representation for the thermal sensation of people in Hong Kong.

2. Thermal Comfort Survey for Different Temperatures and Air Speeds

The thermal comfort survey was conducted in the summer (June) in 2007. In this survey, 140 volunteers were recruited and they were not paid. There were 102 males and 38 females in the age group of 19 to 25. All the subjects were requested to wear local typical summer clothing, including the polo shirt, long trousers, underwear, socks and shoes. This would have an expected clo-value of 0.55. Six temperature settings of

25, 26, 27, 28, 29 and 30°C and six air speed settings of 0.5, 1, 1.5, 2, 2.5 and 3 m/s were covered in this study, altogether thirty-six combinations at 50%RH.

2.1 Environmental Chamber and Equipment Arrangement

A thermally insulated environmental chamber (7.9 m × 5.9 m × 2.4 m H) was used for this thermal comfort survey in the City University of Hong Kong. Two existing fan coil units with room thermostats were installed for general air-conditioning purpose. There was a waiting area outside the environmental chamber, where the subjects could settle down themselves before the survey.

In each survey, four human subjects could be involved at the same time. Each subject had a working desk and sat comfortably to carry out light office works, such as reading and writing, during the survey period. There was a tower fan beside each subject, the fan speed could be changed according to the required setting from 0.5 to 3 m/s. The fan had a 500 mm-long slot outlet centred at 0.6 m above floor level, located at 30° from the longitudinal side of the desk and 1 m apart from the subject. The actual location of each fan was commissioned in the preparation stage. Four 2,000 W air heaters with thermostat control were installed evenly inside the environmental chamber, in order to provide the required temperature setting from 25 to 30°C. Eight ultrasonic humidifiers were also installed, in order to maintain the 50%RH at different temperature settings without contributing any space sensible heat gain.

A set of central measurement probes and data logger were used to monitor the air temperature, air speed, air humidity, operative temperature and radiant temperature asymmetry. Before starting the survey, a thermal tracer was used to make sure the surface temperatures at all the inside surfaces of the environmental chamber were close to the required setting of air temperature.

2.2 Questionnaire Design for Thermal Comfort Survey

There were two parts in the questionnaire. The first part covered the background information of the subject, and the second part was used to collect the thermal sensation and the related comments. With the linguistic consideration, the contents were in both English and Chinese to let the subjects understand this questionnaire precisely. In order to make sure the subjects had adapted themselves well in the Hong Kong climate, they should have continuously lived in Hong Kong at least for ten years.

Before implementing the actual thermal comfort survey, a number of trial runs were carried out to test the appropriateness of the survey questionnaire and the length of thermal response time. Comments were collected from the volunteers involved, and the questionnaire and surveying period were continually revised and verified.

2.3 Conduction of Survey

Each session of survey involved two air speed settings at a certain temperature and 50%RH. The whole session would last for about 1 hour and 15 minutes, including briefing and form filling. Initially, the human subjects were briefed about the objectives and procedures of the thermal comfort survey, and they were asked to fill up their general information on the questionnaire. Then the subjects were arranged to sit comfortably inside the environmental chamber so that they would perform a sedentary activity naturally. The survey for each air speed setting was conducted for 30 minutes, in order to achieve the steadiness of thermal sensation. Throughout this 30-minute period, the subjects were asked to give their thermal sensation based on the ASHRAE 7-point scale in a 5-minute interval. In the whole survey process, the air temperature, air velocity, air humidity, operative temperature and radiant temperature asymmetry were logged at 0.6-m level of the representative monitoring location inside the environmental chamber.

3. Results and Discussions

3.1 Comfort Air Speeds at Different Air Temperatures

From the last entries of the thermal sensation of the subjects, the results for each setting of air temperature and air speed were consolidated. Multiple regression analysis was applied to determine the relationships for thermal sensation in terms of air temperature and air speed. These mathematical relationships cover the cases of all the subjects, male subjects only, and female subject only.

3.1.1 Overall results: Through the regression analysis, the thermal sensation as a function of air temperature and air speed between the computed and observed data is expressed in Eq (1). The coefficient of determination was 0.7350, which showed good correlation of the data, as shown in Figure 1.

$$TS_o = 0.1574t - 0.2960v - 3.789 \quad (1)$$

where,

TS_o: overall thermal sensation

t: air temperature (°C)

v: air speed (m/s)

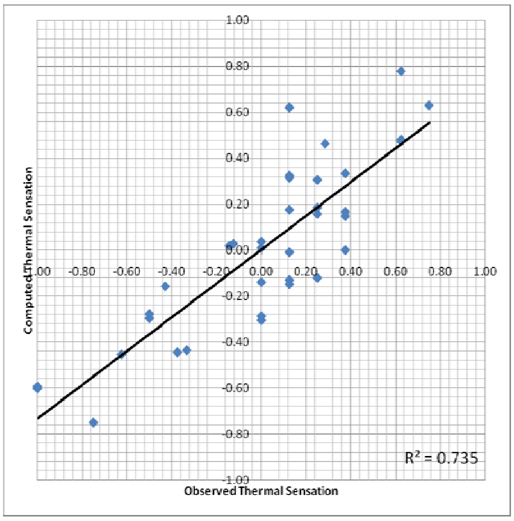

Figure 1 Computed thermal sensation vs. observed thermal sensation from survey.

Based on Eq (1), a band of 90% comfort zone was developed for comfort air speed as a function of air temperature in the range of 24 to 30°C at 50%RH. This band was developed by considering the bounds of thermal sensation between -0.5 to 0.5. From the energy perspective, the negative thermal sensation was not expected due to the tendency of over-cooling and energy-wasting. If looking at the band for thermal sensation between 0 and 0.5, the comfort air speed difference was 1.69 m/s at any temperature. For the neutral thermal sensation, the change of comfort air speed was in the range of 0 to 3.12 m/s for temperature from 24 to 30°C. The air speed was linearly lower with the decrease of indoor air temperature, or vice versa.

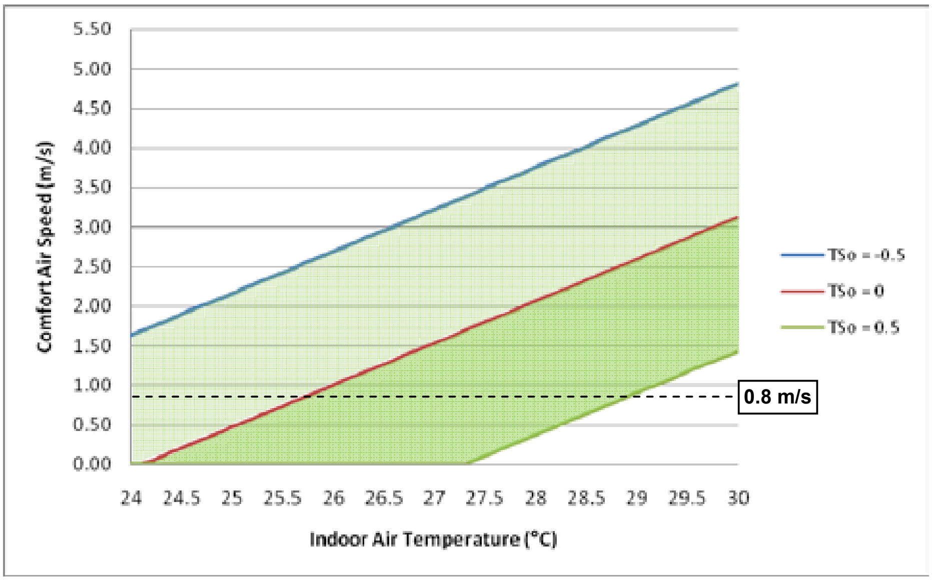

Figure 2 Comfort zone of general occupants based on comfort air speed vs. indoor air temperatures at 50%RH.

If the air speed limit of 0.8 m/s as recommended by ASHRAE was applied, the neutral air temperature could be up to 25.6°C. If the lower bound of this comfort zone was considered, the neutral air temperature would be up to 28.8°C. At the lower bound, the air speed in effect started its role in thermal comfort from 27.2°C, and up to 1.44 m/s at 30°C. Therefore it is possible to elevate the room air temperature by increasing the air speed up to a threshold according to the feature of room activity. Higher and suitable air speed would provide a sense of freshness, that may contribute to the psychological pleasure of thermal comfort.

3.1.2 Results of different genders: The regression analysis of the thermal sensation of male occupants TS_m and that of female occupants TS_f are consolidated in Eqs (2) and (3) as follows.

$$TS_m = 0.1535t - 0.3203v - 3.600 \quad (2)$$

$$TS_f = 0.1702t - 0.2328v - 4.366 \quad (3)$$

Based on these two regression equations, the 90% comfort zone of male occupants and that of female occupants are presented together in Figure 3. It was found that these two comfort zones were largely overlapped, showing that the thermal sensation of male and female occupants was generally the same. However, it was observed that the female occupants could withstand a higher temperature at a lower air speed as shown in the lower right non-overlapping region. On the other hand, the male occupants could withstand higher air speed at a lower temperature as shown in the left non-overlapping region, but this became opposite when the temperature was above 27.5°C.

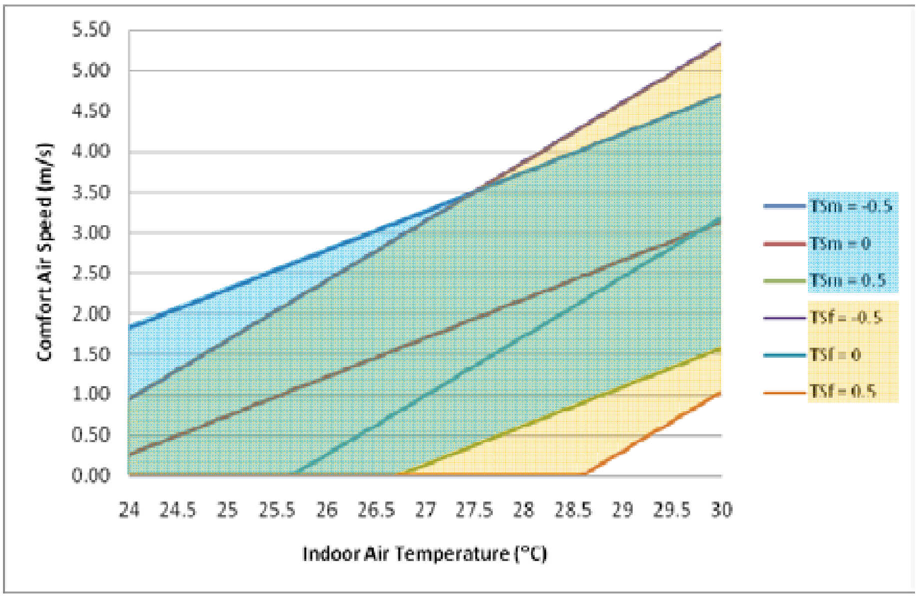

Figure 3 Comfort zones of male and female occupants based on comfort air speed vs. indoor air temperatures at 50%RH.

3.2 Comparison between Thermal Sensation from Survey and Conventional PMV

Based on each setting of air temperature and air speed, the conventional PMV was determined by using the ASHRAE Thermal Comfort Program (ASHRAE 1995). Then a 90% comfort zone of air speed against temperature was developed for the PMV between -0.5 to 0.5. This is plotted in Figure 4, together with the comfort zone based on the thermal sensation as developed in this survey in Section 3.1. It was found that the comfort zone from the PMV was narrower, steeper, and located at a higher temperature side in the range of 24 to 30°C. From the viewpoint of the comfort zone established from the survey, the local occupants had a wider range in thermal sensation. Appropriate air speed was required to achieve comfortable thermal sensation at the lower temperature, but the comfort air speed was not as high as that from PMV at the higher temperature. If the thermal sensation was determined by PMV, the involvement of air speed would be only necessary when the indoor air temperature was above 26.4°C, as indicated at the upper bound of the PMV comfort zone. In addition, a negative PMV would be expected due to air speed for temperature lower than 26.4°C. Therefore, the difference between these two comfort zones showed that the PMV had problem to represent the thermal sensation of the Hong Kong people in the summer time.

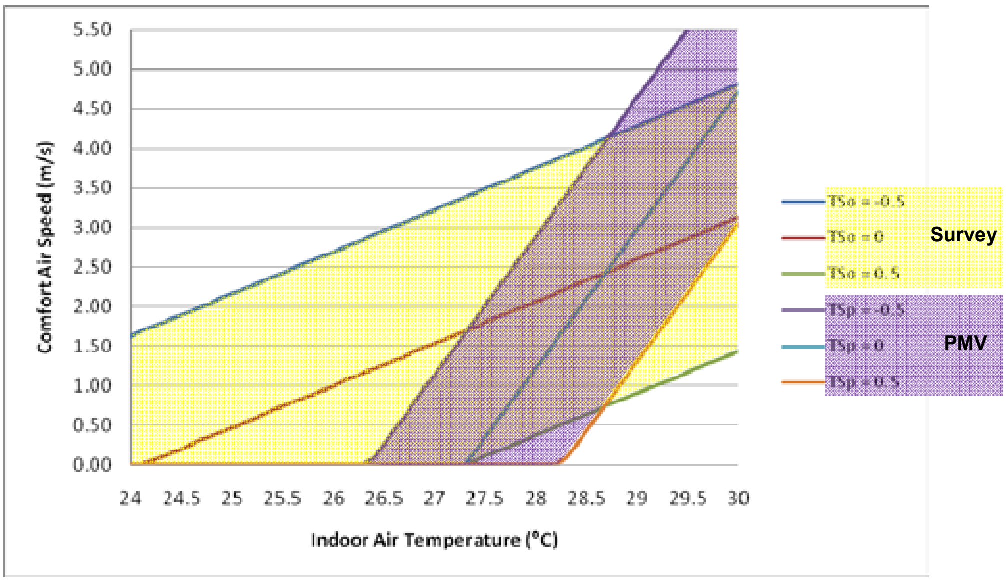

Figure 4 Comfort zones developed from PMV and thermal sensation in this survey.

Figure 5 also presents the difference between the survey results and those from PMV in another viewpoint. The survey results would generate the thermal sensation in the range of -1 to 1 for the air speeds from 0.5 to 3 m/s, while those from PMV would have the thermal sensation in the range of -3 to 1.5. It is obvious that the latter would be more sensitive to the air speed and feel cool or cold in the temperature range of 24 to 27°C. If the thermal sensation based on PMV was used, it would have a discrepancy between the predicted comfort and the actual thermal sensation of the Hong Kong people. This had a potential to underestimate the thermal sensation of occupants wearing typical summer clothing at sedentary position in the summer time. In addition, the PPD (predicted percent dissatisfied) as determined from the PMV would have problem accordingly.

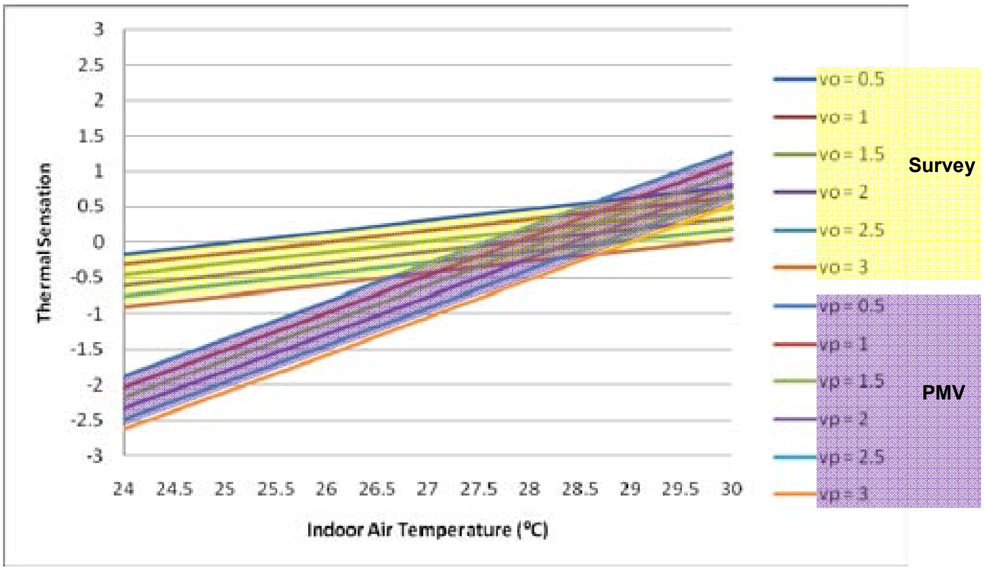

Figure 5 Thermal sensation vs. indoor air temperature for air speeds from 0.5 to 3 m/s at 50%RH.

4. Conclusion

This thermal comfort survey was conducted to study the acceptable comfort level as attained by suitable combination of air temperature and air speed in the summer in Hong Kong. For the people wearing typical summer clothing at sedentary position, a regression equation was developed for the thermal sensation as a function of indoor air temperature and air speed at 50%RH. It was found that the air speed could be up to 3.12 m/s for the indoor air temperature from 24 to 30°C, provided that it would not cause nuisance to the indoor activity. The air speed would be linearly lower with the decrease of indoor air temperature. The elevated indoor air temperature would save energy in refrigeration for air-conditioning, and outweigh the additional energy consumption incurred by the fans. The thermal sensation of male and female occupants was largely the same in the summer time, but the female occupants could withstand higher temperature at a lower air speed. About the representation of PMV for Hong Kong people, it was found that there was discrepancy to the actual thermal sensation in the survey. The PMV and PPD would have a potential to underestimate the thermal sensation of the occupants in the summer time. Another stage of thermal comfort survey will be carried out, and the study of humidity effect to thermal comfort will be included for the subtropical Hong Kong.

TITLE : AN ECOLOGICAL APPROACH TO REGIONAL DEVELOPMENT : SOLUTIONS TO PUBLIC HOUSING COMMUNITY IN HONG KONG

Ken Cheung, Clifford Cheng, Patrick Luk and Susanna Wong
Hong Kong Housing Department, HKSAR Government, HKSAR

Keywords: health, comfort, livability, ecological, green ribbons, biodiversity, long life / loose fit technology, biotechnical research, greening coverage, water recycling, hybrid ventilation, community

Summary

High density cities carry undesirable effect of pollution and congestion which demands immediate attention. With a portfolio of high-rise building accommodating over 650,000 households, the Hong Kong Housing Authority (HA) is exploring new strategies and solutions to create healthy, comfortable and livable environment.

This paper looks at ecological planning focusing on possible solutions for completed and ongoing developments constrained by planning densities. The HA's pioneering attempt to bring transformation to the fabric of Yau Tong / Eastern Harbour Crossing Sites through an Ecological Master Plan featuring the following will be examined -

The compact urban fabric of metropolitan Hong Kong proliferates with its boundary abutting the country park which contains rich resources of greeneries and natural habitat. On the other hand, ecological planning inside the metropolitan area is depicted with a landscape plan of compromised quality. This paper offers a long term vision to realize green ribbons as a planning strategy for regenerating and linking the ecosystems from the country park into the built-up areas under the implementation of public housing redevelopment programme.

To nourish a harmonized urban habitat for the community, we recognize the intrinsic value of biodiversity / natural ecosystems, restore and replenish them to inject a new lifestyle and workstyle in the coexistence of the man made environment and nature.

Technology and innovations are means to empower the development of green living. We, in collaboration with the builder and research institute, innovate for the development of long life, loose fit greening technology and biotechnical research.

The compromised and piecemeal greening measures adopted in the past should be rectified. With the expanded provision of intensive and extensive green coverage in public housing estates, the demand for irrigation water is a growing burden. To capitalize on the operation of central air conditioning system for the regional shopping centre of Yau Tong Estate, collective use of A/C condensate will enable irrigation in a substantial scale. Furthermore, we also exploit the practice of rainwater harvesting with the prevail of rainy weathers in Hong Kong to promote sustainable and cost effective water supply for irrigation and cleansing purposes.

To cultivate a comfortable outdoor lifestyle surrounded with lush greeneries in the estate compound, we further innovate for the opportunity of reshaping tenants' shopping habit by using the hybrid ventilation system in the Yau Tong 4 and EHC 6 shopping centres. Natural ventilation will be resumed when the weather condition (humidity and temperature) is moderate and suitable to switch over from the air conditioning mode without compromising human comfort. Environmental design with the ecological concept of garden shopping will enlighten the shopping experience in lush greeneries and natural ventilation during the transitional seasons. Temporal operation of the system will promote energy saving and a green living habit in the long run.

To prepare for adaptive changes to a new ecological lifestyle, we will keep the local community abreast of the creative objectives in the development processes, from inception, design development to construction and occupation. In the course of community participation, the local community is enlightened and empowered to address their needs in a more effectively. Hence, self-recognition of their neigbourhood identity and further participation to enhance well-being could be fostered.

Not least, active and passive mitigation initiatives that are involved as part of the theories, strategies and solutions are presented holistically for appraisal and benchmarking.

1. Introduction

Extremities in density in the built-up environment brings along undesirable side effects of congestion, pollutions, heat island, and visual discomfort. Dominated by highrise buildings, Hong Kong is one of the cities with the highest density in the world. With a population at about 6.96 million and a total area of 1104 square kilometres, the city supports a density of 6410 people per square kilometre mostly concentrated in the built up area [1]. On a net site basis for some of our private or public residential development, it can be more than 5,000 persons per hectare [2].

At 2007, the Hong Kong Housing Authority has a portfolio of about 650,000 public rental flats housing one-third of the population in Hong Kong. The physical size, height and density of the built urban fabric contributed by public and private development poses strong physical impact on the environment which is irrevocable. The 21th century cities in the world demand a strong agenda to confront the challenges posed by rapid urban growth.

Whilst architects, planners, engineers and environmental specialists in the world are mapping out environmental strategies for virgin developments in various scales, equally important is the need to improve and transform the environmental conditions of completed and ongoing development constrained by planning densities. In the context of public housing development, design for comfort, health and livability [3] is the vision for enhanced functionality and efficiency as we migrate from the recovery of SARS (Severe Acute Respiratory Syndrome) in 2003. Solutions are many, this paper focuses on the goals and strategies to replenish and recreate the ecological balance and symbiotic existence between man and nature [4], human and other living systems, built form and bio-climate at a regional/community scale.

2. The Ecological Master Plan

The Yau Tong (YT) / Eastern Harbour Crossing (EHC) Sites is a major re-development occupying an urban site with overall site area of about 14 hectare housing over 80,000 persons featuring a high density Plot Ratio of 7.5 [5]. Enhanced mobility is provided by the mass transit railway extension line as a mechanism for urban regeneration. The west-bound linear configuration of the development rises above the waterfront along stepping terrain screening off the green mountain side at the back. This is atypical compared to the low density built-environment where rich greeneries from an intermingled landscape network exist. Rather, it is representative of the typical high density topographic development found in other metropolitan counterparts. Planned and built over a series of stages to serve the peak demand of public housing at the turn of the century [6], the existing high density built fabric has posed an antithesis to nature. Many opportunities were lost due to the need for rapid urban growth during which the bulk of redevelopment along the terrain has been constructed.

The Housing Authority is committed to transforming YT / EHC for ecological responsiveness. In the planning and design of subsequent phases of work from north to south, passive mitigation design features that optimize lighting and ventilation, sunshine, pedestrian comfort, pollution dispersion, energy conservation and water conservation have been adopted. Where applicable, active mitigation, including hybrid ventilation, motorized ventilators, water-cool air-conditioning, reclaimed water have also been employed, mostly at the commercial developments [7]. Most importantly, to tie these initiatives together holistically, and to positively address the impact of density; the associated heat island effect and to reconcile the gap between built environment and nature, an Ecological Master plan for the district has been created to achieve the following focus areas [8] -

a) Provide a long term vision to realize green ribbons linking the ecosystems between the development and the surrounding country park

b) Recognize the intrinsic value of biodiversity and natural ecosystems, protect, restore and replenish existing fabric

c) Enable development of long life, loose fit greening technology

d) Enable adaptation and sustainable growth through biotechnical research

e) Expand intensive / extensive green coverage

f) Expand a network for sustainable sources of recycled water

g) Promote ecological concepts in garden shopping/ hybrid ventilation

h) Engage the community, empower people and foster participation to promote awareness and ownership

3. Green Ribbons

Green Ribbons have been instigated as a concept to link isolated systems and to form an ecological community in long term which will depict the central characteristic for consolidated urban development at the edge of city with the countryside. The development at YT / EHC stretches over 1 km in length. It is bordered by Wilson Trial of the country park at the northern rim. This serves as the 'secret garden' of YT / EHC, which apart from the historical reference of derelict quarry and ruin battery, there is also a rich habitat of biodiversity of flora and fauna.

Figure 2 Green Ribbons linking pocket greenery within the development to the country park along the hillside

Through intensive / extensive planting, restoration and replenishment of ground cover at slopes and retaining walls; comprehensive structural podium plaza planting; strategic carpet greening of open space, linkages and jump-boards between green pockets within the development and the mountain green are established.

Along the ribbon, pockets of greenery are strategically planned at about 100m apart to attract the migration of insects within short flying distance from their hillside habitat. The novel landscape strategy is an attempt to foster the biodiversity of nature in the residential setting, thereby bridging the physical and psychological gap between people and the natural habitat as a credit for enhancing mental health. More importantly, the proposed Green Ribbons allow for people exchange and interaction as the base of the urban design framework.

4. Restoration and Replenishment

Restoration and replenishment are key strategies that recognize and protect the intrinsic value of biodiversity and natural ecosystems at the disturbed landform. The major development at YT/EHC involved formation of 6 artificial platforms to accommodate over 50 residential towers of up to 30 to 40 stories. To mitigate the visual and heat island effect associated with man made slopes and retaining walls in between these platforms, every opportunity has been sought to maximize green coverage on the inclined surface. Slope greening using hydro-seeding on soil slope has been adopted comprehensively through out the site. Hard surface such as retaining walls are softened by creepers, colour treatment and introduction of planters. More innovative solutions of bio-engineering planting such as hydro mulching system for instant greening have been adopted to sustain round-the-year plant growth on the dry, rocky surface originally not suitable for plant growth.

5. Long Life Loose Fit Green Technology

Innovative concepts are underpinned by the enabling force of technology. The concept of long life, loose fit vertical green panels in the form of thin claddings is developed jointly with the contractor and applied in EHC Site Phases 4 and 5. Recognizing that truncated pocket greening at the ground level could not be reconciled by roof greening at 30-40stories above ground, the solution to meaningfully increase greening percentage for pedestrian comfort is to extend on-grade greening to the vertical dimension.

The vertical green panels compose of 1000 x 500mm aluminum trays with 40mm thick proprietary product as the growing media. Plant Species commonly used in HA projects, such as Parthenocissus himalayana, Zephyranthes grandiflora, Lantana montevidensis, Nephrolepis exaltata, etc, are selected for trial. Our landscape team has thoroughly searched the country park and a few wild plant species have been identified for further cultivation in the estate environment.

To facilitate ease of operation and water conservation, networks of automatic irrigation pipes have been introduced to form an integral part of the system. Trial panels have been set up to explore various possibilities of optimizing the design. They have been installed at the roof top of the site office to serve as green roof during construction stage. A total of around 240 nos. of the panels will be permanently erected at EHC Phase 4. Some of these green panels will be installed at the vertical walls of lift tower and rock slopes, others will be installed at roof areas with limited loading allowance.

Figure 3 Green Panels have been set up at the roof of the construction site to work out design optimization.

Continuous research is in place to test out the compatibility and maintainability of the proposed vertical landscape. The trial of vertical green panels at YT and EHC is unique for its modular, prefabricated clad-on character purposely designed for long life loose fit and reuse purposes. It is flexible in application, versatile and easily assembled on site and addresses the need for replacement and future maintenance. The thin profile addresses spatial constraints both for new construction and retrofit purpose.

Apart from the clad-on panels, EHC 4 has adopted self-standing vertical green panels to arrive at an integrative green hoarding. Similar to the trial panels installed at the roof of the site office, green hoarding enhances the site environment by providing dust and an element of noise screening. The long life, loose fit concept has been further extended as these large reusable panels are demountable and could be moved to other areas of the site as permanent green walls, or to other construction sites as green hoardings.

Figure 4 Vertical green panels designed to clad onto the external wall and laid flat on roofs of lift tower.

6. Biotechnical Research

To ensure long term performance of the vertical green panels, biotechnical research is being conducted, in collaboration with Hong Kong Chinese University, to -

a) test out the most optimal plant selection criteria in relation to their performance under different seasons and orientations

b) sustain vegetation growth relevant to water saving and the available management resources in housing estates

c) prepare guidelines for the future development and maintenance of the vertical green panel system.

A field site for the technical study has been set up in end July 2007 at the open space of EHC Site Phase1 with four light weight metal structures in north-south orientations to support the green panels. This is a 15-month research project due for completion in early 2009. The research comprises four studies exploring different aspects of the vertical green panel system including plant performance under different watering regimes for individual panels and panel clusters; Species selection; effect of soil thickness on plant growth; fertility persistence of the system and nutrient loss from the panels.

The research facilitates an optimum vertical green design in terms of technicalities and maintainability; evaluate the environmental effectiveness of vertical green panels at congested urban areas; and establish benchmarking performance based on the current design, for further improvement. The initial results have established the need for daily irrigation in an optimum amount to sustain healthy plant growth with the help of moisture sensors. Empirical studies of the daily thermal variance in a summer day also reaffirm the benefits of soft landscape in the mitigation of heat island effect.

Figure 5 Biotechnical research to test out the plant performance, species selection, soil thickness, fertility persistence and nutrient loss

7. Greening Coverage and Roof Greening

Expanding the targets of intensive / extensive green coverage is one of the fundamentals to materialize an ecological community [9]. Completed phases at YT/EHC developed over the last 10 years have a greening coverage at around 10%. Conscious of the need to enhance green coverage, HA has a standard since 2000 of planting a tree for every 15 built flats.

At YT / EHC, major breakthroughs in greening coverage have been made for projects in the pipeline. Podiums of low rise commercial developments and shopping spines have been fully maximized for intensive or extensive roof greening resulting in a greening coverage percentage of over 40% at YT Phase 4 and EHC Site Phase 6. Roof greening are also applied elsewhere on lift tower, ground floor canopy and intermediate floors of domestic blocks. A green tract [10] provides major enhancement to visual comfort. Roof greening could effectively reduce the surface temperature for 20 - 30°C as compared to hard roof surface. It reinforces building insulation and energy efficiency and lowers the overall heat island effect, greatly promotes community interaction and exchange in the pedestrian hubs.

Figure 6 Roof Greening commercial centre with strong improvement to green coverage percentage

Figure 7 Roof Greening at intermediate floors of residential tower brings enhancement to visual comfort

8. Reclaimed Water

Expanding the network for sustainable source of recycled water will support the expansion of vertical green coverage. The commercial centres at YT ph 4 and EHC Site Phase 6 will work as reservoirs of reclaimed water to irrigate both extensive and intensive greening over these sites. Rainwater will be harvested [11] from green roofs, concrete roofs, covered walkways and the main pedestrian plaza. Condensate from the commercial centres' central air-conditioning system will provide huge volume of sustainable water supply. Both sources of reclaimed water will initially pass through a set of break tanks and then stored for re-use. A set of filtration and disinfection treatments maintains the water quality to an international standard. By using the reclaimed water system, an annual reduction in water consumption of 9,263m3 is anticipated, which equates to 65% of the total irrigation amount required per year.

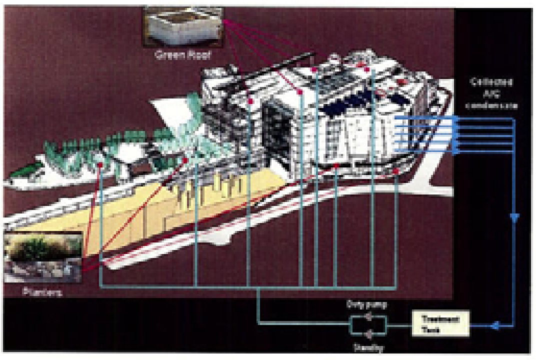

Figure 8 Reclaimed water system at commercial development collects condensate water for irrigation.

Recycling of reclaimed water is also introduced to the domestic development at EHC 5. Apart from collecting rainwater from roof gardens, and taking into consideration the requirement for regular cleansing of roof water cistern, waste water for cleansing of potable water cistern will also be collected for irrigation after filtration and sterilization. Subject to the outcome of the trial in EHC 5, the success of the scheme should contribute significantly to the agenda of water conservation at residential settings.

9. Garden Shopping and Hybrid Ventilation

Promoting garden shopping and hybrid ventilation will extend the ecological concept from external to internal environment. The shopping centre at EHC ph 6 is nestled in a luscious garden environment using greening strategies to reduce the centre's overall CO_2 emissions. Intensive greening is provided inside the commercial centre at various levels accessible to users. The garden shopping environment eventually leads to the roof with extensive greening provided to over 40% of the roofed over area of the centre.

Virtual greening is achieved by using a hybrid ventilation system alternating between natural ventilation, free cooling and full-scale air-conditioning. Temperature, humidity, wind and rain sensors would provide signal to activate intake and exhaust openings when the external environment matches the designed indoor comfort conditions. In YT Phase 4 and EHC Ph 6, with a predicted 10% of operating hours per year using natural ventilation, an annual reduction in air condition electricity consumption is approximately 82MWh, which equates to 35,260kg/yr CO2 emission, or the equivalent of planting 1,618 numbers of trees per year to absorb it.

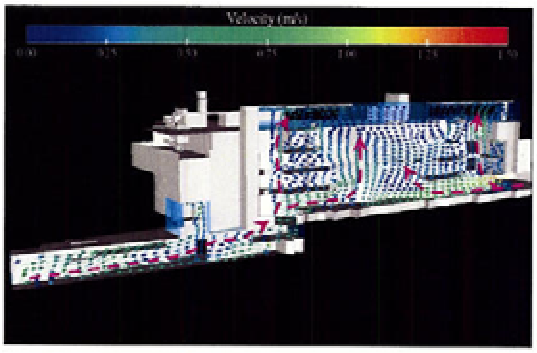

Figure 9 Hybrid Ventilation achieves reduction in CO_2 emission

10. Community Engagement

People of cities are key drivers for transforming cities towards sustainability [7]. We engage the community, empower people and foster participation so as to raise their environmental awareness and instill a culture of environmental protection. In EHC Ph 4, where the trial panels were installed at the roof top of the site office to serve as green roof during construction stage, the vertical green panels together with the growing medium and plants were delivered to the adjoining schools for initial establishment and care in April 2007. They have since been relocated to roof top of the site office in May 2007 after establishment.

As a long term programme, the Green Delight in Estate Programme has been launched with recruitment of public housing tenants as "Green Ambassadors" to spread the green message. Education and promotion programme by Green Groups on subjects such as estate greening; building up green infrastructure and promotion of green practices are continually cascaded to our tenants. The ultimate aim is to establish a volunteer core group which will gradually own the programme and guide other residents in the promotion of a green lifestyle. All the engagement programme is a people powered process to nurture ownership and hence a sustainable community in the long run.

Figure 10 Community engagement involving school student in promoting green culture

11. Conclusion

In embarking on the concepts, strategies and solutions towards an ecological community, we are conscious of the constraints and limits within the confines of a high density fabric that has been half established. This paper demonstrates however that the vision of the ecological master plan together with resolute actions towards restoration, innovation, research, passive and active mitigation, conservation and the active engagement of people are promising notes to nurture and replenish an ecological community. This requires, as illustrated in the paper, conscious review and communication of targets and benchmarks for monitoring and continuous improvements. This paper attempts to increase awareness, generate ideas, provides a framework for action without prescribed solutions. It encourages local and international efforts in creating sustainable high density living environments.

In all, we try harder to rupture the contrast and cultivate the meetings between building development and planting, between architecture and landscape – between culture and nature.

Keywords: sustainable, master planning, ecotourism, design, planning

Summary

With the current population growth in urban areas, developers are seeking permission to create new communities in previously undeveloped areas. Equally, tourism operators are seeking permission to develop "eco resorts" in pristine natural environments. Key stakeholders, such as Local, State and Federal governments and the community, want to ensure that these built areas are sensitively integrated into the natural environment and that they will provide for the needs of the region now and in the future.

This paper discusses the need to integrate sustainability principles into master plan and ecotourism developments and the opportunities for embedding sustainability into each phase of the development including planning, design, construction and operation and maintenance. In order to ensure sustainable outcomes for the development, it is vital that the process of integrating sustainability into the project phases is commenced from the early concept design phase with a framework is set up to deliver it.

1. Defining sustainable master planning and ecotourism

1.1 Sustainable Masterplanning

Sustainable master planning is the process undertaken in order to create a sustainable community. It is the process of embedding sustainability initiatives and mechanisms into each stage of the project lifecycle (i.e. planning, design, construction and management and operation) in order to ensure that sustainable outcomes are achieved and to ensure continual improvement of sustainability performance.

A sustainable community can consist of a collection of buildings and infrastructure, a planned development, suburb, town, city or region. It can also be a vertical community i.e. a single building comprising integrated mixed uses, such as commercial, residential, retail. Sustainable communities are planned with consideration for the future needs of the community and have the capability to adapt to changing modern needs. They have a high degree of self-sufficiency in terms of infrastructure, such as energy generation and water recycling and re-use systems, and a viable local economy supporting them. The culture, demographics and needs of sustainable communities are typically diverse resulting in the requirement for a broad range of land uses, activities and development densities. Well-designed public and green spaces and supporting facilities provide a high degree of amenity for residents, workers and visitors. The community has established transport links within it as well as strong connections to the wider region. There is active participation by stakeholders in planning the future of the community. Sustainable communities aim to minimise the impact of development on the environment through energy, water and resource conservation. A key priority of sustainable communities is the continued health, comfort, social amenity and safety of their residents.

Sustainable master planning initiatives and mechanisms that can be employed during the project lifecycle to ensure sustainable outcomes for the development can include: Development Control Plans that require sustainability features to be integrated into the development at the planning stage; computer modeling of options during design phase to ensure optimal façade design for energy performance; insertion of clauses into builders' contracts with waste recycling and minimisation targets, and the monitoring of utilities during the operational phase of the development.

1.2 Ecotourism

Ecotourism was initially defined by Mexican architect Hector Ceballos Lascurain in a campaign to conserve the Yucutan wetlands as a habitat for the American flamingo. The ecotourism program of the International Union for the Conservation of Nature (ICUN) adopted this in 1996 and defines ecotourism as:

"Environmentally responsible travel and visitation to relatively undisturbed natural areas, to enjoy and appreciate nature (and any accompanying cultural features - both past and present), that promotes

conservation, has low visitor impact, and provides for beneficially active socio-economic involvement of local populations."

Ecotourism developments represent a pinnacle of sustainable masterplanning due to their location, often being: remote, unconnected to mains facilities, and in an environmentally sensitive or culturally significant area. The restrictions of ecotourism development actually represent opportunities to create innovative solutions for the autonomy of a site that can serve as an example for mainstream development of what it is possible to achieve. Best practice requires an ongoing commitment to improvement an approach required in masterplanning if it is to provide for future generations

Ecotourist resorts are those that encourage guests to interact with natural areas adjacent to them. They are designed, constructed and operated using the principles of ecologically sustainable design. Ecotourism resorts are generally mixed use in nature and may comprise a number of distinct facilities and activities in the one precinct, including: hotel accommodation, cabins, retail, health centre, gymnasium, swimming pools, walking trails, day spas, interpretation and educational facilities, and natural features.

2. Defining the "greenness" of master plans and ecotourism developments

There is a plethora of rating tools in Australia. Some tools address a wide range of sustainability aspects and some address only one aspect, such as energy or water. There are tools for specific building types (e.g. commercial, residential, education). There are tools that predict the building's sustainability performance at the design stage and those that assess the building's actual performance in operation. There are very few tools in Australia and internationally that are capable of assessing the sustainability performance of a master plan or ecotourism development, which are typically mixed use by nature. The exception is EnviroDevelopment (Australia), Leadership in Energy and Environmental Design (LEED) for Neighbourhoods (US) and Green Globe 21 (international), which are outlined below.

2.1 EnviroDevelopment

The EnviroDevelopment tool was developed by the Queensland branch of the Urban Development Institute of Australia (UDIA). This rating scheme is the only tool so far in Australia that addresses sustainability at the master planning stage of a development. EnviroDevelopment is a voluntary best practice tool. Projects can be assessed under, and gain certification in, any or all six EnviroDevelopment categories; water, energy, ecosystems, community, materials and waste. Developers must demonstrate that their development satisfies the EnviroDevelopment requirements and standards for the target category. The developer's submission is then evaluated by the EnviroDevelopment Board of Management and certified if it meets compliance. The certified rating must be renewed annually.

The EnviroDevelopment tool is not a true indicator of a development's overall sustainability performance as not all categories need be addressed and a certain level of compliance in all six categories is not required. For example, a developer can certify a development in the EnviroDevelopment water category, but this does not mean that the development is energy or resource efficient. A true sustainability tool would require all aspects of sustainability to be addressed and certain standards achieved in all of these categories, as the very nature of sustainability requires a balance to be attained between social, economic and environmental aspects.

2.2 Leadership in Energy and Environmental Design (LEED) for Neighbourhoods

LEED is a voluntary good/best practice scheme in the United States managed by the US Green Building Council (GBC). LEED addresses a variety of sustainability issues at various stages of the development process, such as design, construction and operation. LEED applies to a range of building types, such as residential dwellings, commercial core and shell, commercial interiors, school, retail, healthcare and neighbourhood development.

LEED for Neighbourhood Development is currently in pilot phase and was developed by the US GBC in partnership with Congress for the New Urbanism (CNU) and the Natural Resources Defense Council (NRDC). The tool is aimed at new mixed use and regeneration projects developed by a single entity which then sells or leases components to numerous consumers. LEED for Neighbourhood Development focuses on communities and their connections to the region and to the landscape. The tool is applied at the design stage and consists of a number of credits under several categories, such as "smart location and linkage", "neighbourhood pattern and design" and "construction and technology". There are pre-requisite standards of sustainability performance for each of these categories that must be achieved in order to attain certification.

2.3 Green Globe 21

Green Globe is an international benchmarking and certification program providing a methodology to define and assess best practice sustainability integrated into travel and tourism operations. It was established by the World Travel and Tourism Council in 1993 specifically to recognise and promote sustainable travel and tourism globally. The program is based on Agenda 21 principles for sustainable development. The CRC for Sustainable Tourism Australia, with input from sixteen universities and over two hundred researchers, developed a benchmarking system (Earthcheck™) which was introduced to the program in May 2002 to inform the standards. Prior to this, the standards were based on process based initiatives. Benchmarking has provided a more powerful tool for comparing the environmental and social performance of ecotourism

operations internationally and establishing overall savings and achievements of the program.
Green Globe consists of a number of standards to inform and assess either, the design and construction phase or, the operational phase of a development. The standards applicable to inform the planning and construction of ecotourism developments are: the Design and Construct Standard for Infrastructure and the Precinct Planning and Design Standard (PPDS).

The PPDS is the most recently developed standard; it provides benchmarks for a range of key performance areas including: precinct location site and planning, energy efficiency and conservation, water conservation and management, solid and other waste management, resource conservation, chemical use, waste water management, stormwater management, social commitment and economic commitment.

Use of Green Globe standards provides for recognition of best practice through certification, the awarding of a logo, and promotion to the industry and market. Certification requires a commitment to on-going appraisal of operations to ensure the consistency and superior quality of the product to the industry, authorities and tourists. To receive certification, a project is first required to undergo benchmarking whereby various environmental measures are assessed against baseline figures and evidence that the design documentation details performance requirements and systems that meet them. This information is assessed by an independent assessor and if baseline or best practice is achieved in the majority of benchmarks, certification is granted (usually following planning approval to ensure essential elements are met.

3. The drivers for creating sustainable communities and ecotourism developments

The “big picture” drivers for sustainable master plan and ecotourism developments have arisen due to a wide range of global issues including climate change, finite fuel resources, population increase, rising sea levels, over-consumption of resources and social inequity. Aspects particularly relevant to Australia that are driving sustainable development include depletion of the ozone layer, scarcity of fresh water, increased incidence of bushfires, erosion, deforestation, salinity and expanding population in urban areas.

There are drivers for the sustainable development of master plans and ecotourism resorts at every level of government. The federal government is responding to international policies and treaties, such as the Kyoto Agreement. State governments are responding to issues, such as land releases and rezoning to accommodate the growing population and to the need to encourage employment generation to support it. Local councils are driven to demand sustainability be incorporated into developments through the need to plan for and ensure the future viability of their local community and region.

There is growing demand by the community for higher quality developments that consider the environment and the community’s economic and social needs. Developers of sustainable master plans and ecotourism developments are gaining market advantage by responding to this need. They may also gain planning permission sooner, and avoid extensive litigation, if it is demonstrated to the local planning authority that the development meets the needs of the region at the present time and in the future. Incentives such as tax deductions, grants and rebate schemes are encouraging developers to implement sustainable practices.

The desire to future-proof assets by planning for future rises in utility costs is driving owners of buildings and ecotourism developments to incorporate sustainability initiatives into their developments.

Building industry participants, such as architects and builders, are increasingly driven to address sustainability issues in their work in order to win more work and to differentiate themselves from other companies in the market. For example, it is common for tenders, especially for ecotourism projects, to require a project team or builder to demonstrate their environmental credentials and experience in sustainable design or construction in order to win work.

Stakeholders of companies are increasingly aware of environmental issues and growing pressure from them is driving companies to demonstrate their corporate social and environmental responsibility, to transparently report it and to continually improve performance.

4. The benefits associated with creating sustainable communities and ecotourism developments

Planned communities and tourism resorts are typically located on previously undeveloped sites and often, in the case of tourist resorts, are remote in location and have minimal existing connections to the region. Sustainable communities and ecotourism developments aim to minimise the impact of the development on the environment. For example, integrating Water Sensitive Urban Design initiatives can reduce the flow of potentially polluting surface water runoff into local natural watercourses during storm events.

For ecotourism projects there are often net gains in biodiversity of the site and surrounds through landscape conservation and enhancement programs. In the case of urban regeneration projects, the existing biodiversity on the site can actually be improved, for example, the rehabilitation of an industrial site to parkland.

Residents of the local region benefit from the creation of sustainable communities and ecotourism developments as they have the capability to attract investment to the area, generating employment and providing social amenities, such as health, education, recreation and leisure facilities. Owners and tenants of buildings within sustainable communities and owners and operators of tourism resorts benefit from the lower operating costs associated with sustainable design and technology.

5. The barriers to creating sustainable communities and ecotourism developments

A significant barrier to creating a sustainable community or ecotourism development is the traditional focus of the building industry on speculative development based on short term rewards. Developers are often not prepared to finance the sometimes additional cost of incorporating sustainability initiatives if their customers do not perceive a value in it and do not recognise that they will reap the long term benefits.

There is insufficient legislation enforcing sustainable development and planning controls can be inconsistent at the various levels of government. Insufficient stakeholder consultation and active engagement in the planning process can be a barrier to sustainable development if the needs of the local community are not adequately assessed and incorporated into the design.

The separation of responsibilities during the developmental phases of a project is a barrier to sustainable development. For example, designers and builders are not typically involved in the handover of a building or site to the users which could mean that it may not be operated as the designers intended. There is a risk that the sustainability principles and initiatives determined during the planning phase may not get carried through into the site's operation and management, leading to inefficiencies that could potentially result in a greater impact on the environment. Finally, there is a general lack of education amongst all those involved in masterplanning and ecotourism developments including developers, owners, operators, financiers, government, designers, builders, residents and visitors, as to what sustainability is, what the benefits are and how a sustainable community is defined and delivered.

6. The costs and savings associated with creating sustainable communities and ecotourism developments

There can be higher upfront capital costs associated with the creation of sustainable communities and ecotourism developments. These costs may be due to the installation of environmental technology, such as a photovoltaic array or due to an integrated design process. The capital cost of environmental technology is often offset over its lifetime by the savings in utility costs, such as the savings in energy costs as a result of using a photovoltaic array for energy generation instead of fossil fuels, which are predicted to increase dramatically in cost in the next decade.

There are other savings that are more difficult to quantify, such as the improved indoor air quality that may result from the selection of a low Volatile Organic Compound (VOC) floor covering or the social capital gained from engaging in community consultation. An integrated design process involving the early engagement of consultants and their participation in a collaborative planning and design process can result in higher upfront fees due to the extended time commitment. These costs can often be offset by the integrated design and services solutions and improved system efficiencies that result from closer collaboration and communication between the disciplines.

The certification of an ecotourism development will add minimal costs to the project in terms of the benefits gained. Going through the certification process will add to the workload of the consultant team to provide evidence that key performance measures have been met; this could include additional reports and computer modeling.

7. Sustainable Built Environments' Sustainability Process

Sustainable Built Environments' ultimate environmental design aim for our built environment is to create buildings and communities that are: comfortable and healthy; require no additional energy or water, other than that produced on site; produce no waste in operation or construction, and are made of materials that are derived from fully sustainable sources. Whilst this is very difficult to achieve in practice, this goal acts as a theoretical lighthouse for the opportunities that are considered in any of our projects.

7.1 Sustainability Matrix

Sustainable Built Environments (SBE) considers all of the sustainability aspects related to a building, site or community when undertaking a development project. Particular consideration is given to: energy conservation, water consumption, waste minimisation and reduced resource consumption, sustainable transport, emissions minimisation, enhanced biodiversity and land use efficiency, enhanced social issues and amenity, and viable management practices. For example, under the sustainable transport category, we would assess the opportunities for a site based on: reducing reliance on the private car, reducing the CO2 emissions due to transport, prioritising personal mobility networks, promoting safe transport connections and creating permeable links throughout the site and to neighbouring communities.

7.2 Embedding Sustainability into the Development of Sustainable Communities and Ecotourism Developments

SBE often acts as the sustainability champion of a development project on behalf of our client. We are responsible for advising the client and guiding the project team in integrating sustainability principles into the development and for developing a framework that will ensure that the sustainability vision for the site is not compromised and that sustainability targets and predicted outcomes for the development are carried through all of the developmental phases and successfully achieved. Outlined below are some mechanisms that can be applied in order to embed sustainability into each stage of the development of a sustainable community or ecotourism development.

7.3 Opportunities for integrating sustainability into the planning phase

Opportunities for integrating sustainability into the planning phase of a sustainable community or ecotourism development are as follows:

- Identify a site where development will result in the lowest impact on the environment
- Commence an integrated planning process involving the developer, planner, project manager and local planning authority
- Assess the opportunities, constraints and risks related to implementing sustainable initiatives on the site
- Engage stakeholders and the community actively in the planning process
- Research the needs of the local community and region
- Develop a sustainability vision for the project
- Develop sustainable design guidelines for the site
- Integrate sustainability into local planning controls
- Develop an integrated brief for the design team
- Undertake preliminary life cycle costing

7.4 Opportunities for integrating sustainability into the design phase

Opportunities for integrating sustainability into the design phase of a sustainable community or ecotourism development are as follows:

- Commence an integrated design process involving the developer, planner, project manager, design team and local planning authority
- Engage stakeholders and the community actively in the design process
- Develop a Sustainability Strategy consisting of broad objectives for the project, set preliminary targets and determine proposed actions to achieve the targets.
- Form alliances with relevant industry representatives, universities and non-government organisations (NGOs)
- Test the proposed masterplan or ecotourism development against the Sustainability Strategy to determine progress against targets
- Undertake a peer review or value management exercise to increase efficiencies
- Insert "green" clauses into the Specification
- Undertake further life cycle costing

7.5 Opportunities for integrating sustainability into the construction phase

Opportunities for integrating sustainability into the construction phase of a sustainable community or ecotourism development are as follows:

- Integrate sustainability requirements into the Request For Tender for builders
- Insert "green" clauses (incentives and/or penalties) into builders' contracts
- Facilitate education and training courses for builders in the installation of sustainable materials, products and technology
- Initiate a feedback loop between the builders and designers to ensure lessons are learned

7.6 Opportunities for integrating sustainability into the operation and maintenance phase

Opportunities for integrating sustainability into the operation and maintenance phase of a sustainable community or ecotourism development are as follows:

- Ensure adequate time and resources for commissioning of building services
- Develop a monitoring plan to ensure continual improvement
- Initiate a feedback loop between the builders, designers, operators and users to ensure that the buildings and site are managed as the design team envisioned
- Develop a Building User's Guide to explain the sustainability features and their optimal operation

- Carry out a Post Occupancy Evaluation to determine actual sustainability performance and user satisfaction

8. Case Study: Huntlee, Hunter Valley, New South Wales

Huntlee is located between the historic Hunter Valley towns of Branxton and North Rothbury at the northern gateway to the Hunter Valley, the oldest wine region in Australia.

The Huntlee site spans two Local Government Areas; Cessnock and Singleton. The site consists of cleared agricultural land previously used for stock grazing, timbered areas that are regrowth woodland following logging associated with the former colliery activities, land that has been previously used as a coal mining site and conservation land.

The Huntlee site was identified as a major urban release area in the Lower Hunter Regional Strategy. In 2007 a Concept Plan was prepared for the $1.8 billion development of this 1,748 hectare site. The Huntlee project will create a major new centre in the lower Hunter Valley over a period of around twenty years with a projected population of 18-21,000. The development will comprise approximately 7,500 residential lots, 160 hectares of commercial and employment lands, neighbourhood centres, education, healthcare and community facilities and associated infrastructure (including upgrades to local road and bus networks, sewerage and water infrastructure etc.). In addition, the project involves the dedication of 876 hectares of high conservation land on the site and a further 4,988 hectares of conservation land in other locations in the Lower Hunter Region. The Concept Plan was submitted to the NSW Government as a Part 3A Planning Application in late 2007.

Sustainable Built Environments Pty Ltd (SBE) was engaged by the client, Huntlee Holdings Pty Ltd, to develop a Sustainability Strategy with the aim of embedding sustainable development principles into the planning and early concept design process. The goal was to carry these principles through subsequent design and construction phases, ultimately ensuring the sustainable management and operation of the site. The Strategy was also developed to meet the Director General's Requirements for an assessment of the development's potential greenhouse gas emissions and a strategy outlining how they may be reduced.

The process began with a comprehensive background literature review of reports, studies and plans, a site visit and meeting with the project team and client. SBE discussed the sustainability vision for the scheme, outlined the opportunities on the site for integrating sustainability initiatives and obtained feedback. Building on information gathered during this process, SBE developed a draft Sustainability Strategy. The Strategy commences with a definition of sustainability and its context and role in the proposed Huntlee scheme, a definition of the nature of a sustainable community and the vision for the development in terms of principles. A number of sustainability objectives were nominated and opportunities for integrating ESD initiatives into the scheme to achieve these goals were outlined for a range of sustainability aspects (e.g. energy efficiency, water conservation, sustainable transport, resource use, biodiversity, social amenity, management). Finally, preliminary targets covering all of the sustainability aspects for the scheme were outlined with the intention of refining and further quantifying them in subsequent design stages. SBE presented the draft Sustainability Strategy with the aim of obtaining feedback. This was then integrated into the final Sustainability Strategy and technical report which formed part of the Part 3A Planning Application.

The planning process for Huntlee has not yet progressed to detailed design and engineering stages which will come later in Project Applications and/or Development Applications for subdivision, works and buildings. It is envisioned that the Sustainability Strategy will be reviewed, revised and refined over time to reflect the more detailed planning and design solutions associated with future stages of the development process as well as to reflect the outcomes and recommendations of specialist studies. Future tasks to embed sustainability in the development phases may included the development of sustainable design guidelines or Development Control Plans, use of sustainability rating tools to guide design and measure performance and "green clauses" in the site and building works Specifications and builders' contracts, the development of Building User Guides, monitoring, Post-Occupancy Evaluations etc.

The commencement of works is scheduled for February 2009 depending on relevant approvals being obtained.

9. Case Study: Alila Villas, Ulawatu, Bali, Indonesia

Alila Villas Ulawatu is a mixed-use tourism development currently under staged construction. The site is spectacularly located on a terraced plateau on limestone cliffs that edge the southern tip of Bali. The site is arid and subject to seasonal drought. This part of Bali is distinctively different from most of the island where vegetation is lush and spring water abounds; the site is arid and marked by a grand vista of the ocean and seasonal drought. It is valued traditionally as hunting and grazing ground.

The vision for the project was to develop a resort that was not only designed to be of luxury standard, but also to exhibit best practice environmental practice and management. The development includes a hotel with full leisure facilities including bar, restaurants, day spa, fitness centre, boutique, meeting facilities, library, and swimming pool. The 14.4 hectare development site also includes: 29 villas for private ownership but managed by the development; 36 hotel villas; a pool for each villa; a gallery; landscaping, paths, roads and infrastructure.

The project developers engaged a multi-disciplinary team with the vision and ability to create an environmentally sensitive and responsible project, that demonstrated best practice for Bali and internationally. Following sketch design stage, SBE was invited by the project architects (WOHA Designs) to provide ESD advice, with particular focus on gaining recognition for the project's achievements through certification.

SBE reviewed the project against the key performance indicators of the Green Globe Design and Construct Standard (GG D&C) to develop an ESD Opportunities Study detailing further opportunities and strategies to improve sustainable performance. One of the main things added to the project brief through this process was the development of targets for resource use so that the project could be benchmarked against baseline Earthcheck™ indicators. The GG D&C methodology provides a checklist of key performance areas for sustainable practices and design including: sustainability design approach, energy efficiency and conservation, potable water consumption, solid waste production, social commitment, resource conservation, site, and waste water management. The key areas for construction provide for a comprehensive construction environmental management plan that: encompasses the key performance areas of the design stage; requires targets for energy, water and waste reduction be developed and monitored, and that a social commitment to local employment is made.

The checklist of key performance indicators was used through design development as a sustainable quality management tool to record the strategies in place, and those to be investigated further, and to assign responsibilities to the project team.

Some of the challenges encountered were finding a sustainable timber supply and sourcing efficient hot water systems. One of the great achievements of the project has been to access renewable energy by supporting the development of a nearby wind farm. The built form of the project responds sensitively to the landscape and refers to local traditions and construction techniques while embracing a modern style. Degradation of biodiversity and loss of topsoil due to former grazing and periodical burning will be mitigated through reforestation from a developed list of indigenous plants and seed collected from the site, resulting in greater biodiversity. The intention is to regenerate a more complex gallery forest to connect to existing nature network, and to enhance and maintain topsoil by using local techniques of low terracing, living fences and conserving fodder plants. Local customs and culture have been considered in the approach to the site and initiation of construction works.

Lessons learnt from this project have included the difficulty of developing design targets for a complex precinct development and maintaining the project team's enthusiasm for providing evidence once tender documents had been completed. Nevertheless, the project's construction has included extensive environmental management with monitoring of resource use through construction.

Operational environmental management systems will provide the opportunity for the environmental impacts due to the operation of the Alila Uluwatu Villas to be reduced, monitored and improved over time. The project is at benchmarking stage of the certification process.

10.Case Study: Ythan Springs Resort & Spa, Warburton, Victoria

The Ythan Springs Resort and Spa is to be located on 19 hectares on the middle ranges of the south facing slopes elevation of Mount Victoria and Mount Donna Buang. The site is within an area of conservation and botanical significance and of regional zoological significance for the Upper Yarra Valley and Dandenong Ranges. Flora and Fauna Studies confirm a mixture of intact vegetation, regenerating native vegetation and exotic vegetation with four species of regional significance found on the site.

The resort developer has enthusiastically pursued the development of a deep green tourist facility that incorporates innovative systems to manage and conserve energy and water use. SBE prepared an ESD Opportunities Study in early 2003 to assist in developing: the sustainable vision for the project, targets for performance, and strategies by which to achieve the targets. As there was no formal methodology available at the time, SBE used our sustainability matrix and the core principles of *The Natural Step* to define best practice approaches to sustainable tourism development. Community consultation was undertaken in an endeavour to create community links with the project.

The design process included extensive environmental studies and assessments of the site, community consultation, and energy and water modeling. Passive solar design has been optimised to the hotel and villa type accommodation, however, the largely southern orientation of the site has focused the design on strategies to optimise building fabric and utilise thermal mass.

The project has been in a holding pattern for a number of years whilst proceeding through the planning process. SBE has recently applied the Green Globe Precinct Planning and Design Standard (PPDS) to provide an in depth master plan review by assessing the initiatives that have been integrated into the design and to determine the project's eligibility for certification.

The PPDS broad scale standard designed for use in the master planning and design of tourism infrastructure for medium to large mixed use precinct developments where stakeholders are seeking a measurable ecological performance outcome. The key performance areas addressed are: sustainable masterplanning approach, energy efficiency and conservation, water conservation and management, solid and other waste management, resource conservation (materials), chemical use, wastewater management, stormwater management, social commitment, 'Quality of Life' approach and economic commitment.

Some of the sustainable initiatives included in the development include: a consensus approach to design through consultation, comprehensive water conservation and reuse strategies to provide 74% of site's water needs with water harvested from the site, renewable energy using micro-hydro system, preservation of

Mountain Ash forest, water sensitive urban design, engagement with educational institutions, net gains for biodiversity. The development will provide economic gains to the community by acting as a drawcard for the area, providing job opportunities for an area with low employment, providing business opportunities and conserving the environment..

Due to the proactive approach taken to sustainability at masterplanning stage, Ythan Springs Resort & Spa has the potential to achieve baseline or best practice performance for all key area indicators with most of the strategies in place for certification.

Conclusion

Applying sustainable principles of integrated design at the initiation stage of masterplanning and ecotourism projects has the potential to reduce the environmental impact of the built environment while increasing its social capital and ability to meet future needs. An integrated design approach provides the opportunity for a more holistic built solution, as synergies between systems are more likely to be uncovered and utilised.

As best practice sustainable design principles include consideration of operational management and maintenance issues, it is ensured that systems to assess a development's performance against design predictions will be in place to allow for monitoring and on-going improvement. The information obtained through this process can be used to inform target setting for future sustainable developments and provide an example to industry of what can be achieved.

Keywords: Health Building, Indoor Environment Quality (IEQ), Post-Occupancy Evaluating Method (POEM),

Summary

Entering into the 21st century, Taiwan is facing the problems of pollution to indoor environment and harmfulness to dwelling health. The dwelling environments of buildings must all face the ever worsening of “indoor environmental quality” day after day, regardless of new or old. Especially in Taiwan’s hot and humid weather, with the high ratio of 97% in existing buildings, sick buildings create harmfulness that affects the quality of health in the indoor environment including sound, light, thermal comfort and air. It could also lead to the break out of diseases including Sick Building Syndrome (SBS), Sick Home Syndrome (SHS) and Building Relative Illness (BRI). In this study, the improvement of indoor environment was split into three phases: self-inspection, initial investigation and advanced building health examination. The tested items include the diagnosis and investigation to indoor environment of sound, light, thermal comfort and air, plus the assessment to domestic and foreign indoor environmental criterions, for the purpose of finding indoor problems to improvement. The improvement includes target setting, designing and planning, constructing and re-inspecting, and finally ensuring the effectiveness of improvement. The entire operation procedure can be used as the reference for expanding the promotion in the future.

1. INTRODUCTION

According to the evaluation in ecological housing of World Health Organization (WHO), we find out that buildings are not only protecting people from invasions, but also effecting users’ lifestyles and indoor environment quality (IEQ) in our daily life Nowadays in Taiwan, the ratio of the new to old buildings is about 3:97. So the indoor environments of buildings have lots concern in human health. And the increase correlation between the output value and human comfortably shows the importance of the health and comfort in buildings. The increase of existing buildings’ service life causes a lot of questions For example, the aging of equipments , functions and materials in buildings, or the deteriorating indoor environment influence human health, and so on…

Many potential hazardous factors may appear in the indoor environment of buildings, which present many risks to the health of the habitants. In a broader definition, people spend 90% of their time staying in the indoor environment. Thus, the quality level of indoor environment will definitely cause impact to people’s health. Inferior indoor air quality may cause discomfort and harm. Moreover, it may spread the contaminated mass to more people and offer a media space for the diffusion of contamination source. The health of general public will be seriously influenced.

2. Environmental Characteristics

2.1 Overall Environment

The climate type in Taiwan is subtropics. The northern part of Taiwan has the subtropical monsoon climate and southern part of Taiwan has tropical monsoon climate. Climate of Taiwan Island is influenced by warm humid air current and ocean current. Therefore, the island also possesses maritime climate. However, being adjacent to the Mainland China where the weather system usually shifting from the west to the east, the island is inevitably influenced by the continental climate. Moreover, although the geographical area of Taiwan is small, the central and eastern terrains are mountainous. Forty-six percent of the total area on the island is mountain terrains, hills, and terraces with heights over five hundreds meters above sea level. Central Range of Taiwan (Zhong-Yang), Mount Snow Range, and Mount Jade Range (Yusan) lie longitudinally on the island are mountain regions with heights over three thousands meters. Mt. Ali locates in the western region has height between one to two hundreds meters. These mountains have great influences to the climate in Taiwan. They affect the rainfall patterns and temperature variation in the mountain regions and lowlands, in additional, they divide the climate patterns to the southern, northern, western and eastern areas.

2.2 Characteristics of Micro-environment

This study is to diagnose different types of surrounding micro-environmental climates of indoor environmental quality, with four categories including city, rural area, ventilated, and non-ventilated. Each diagnosed cases are distributed in Taiwan as indicated in Figure 1.

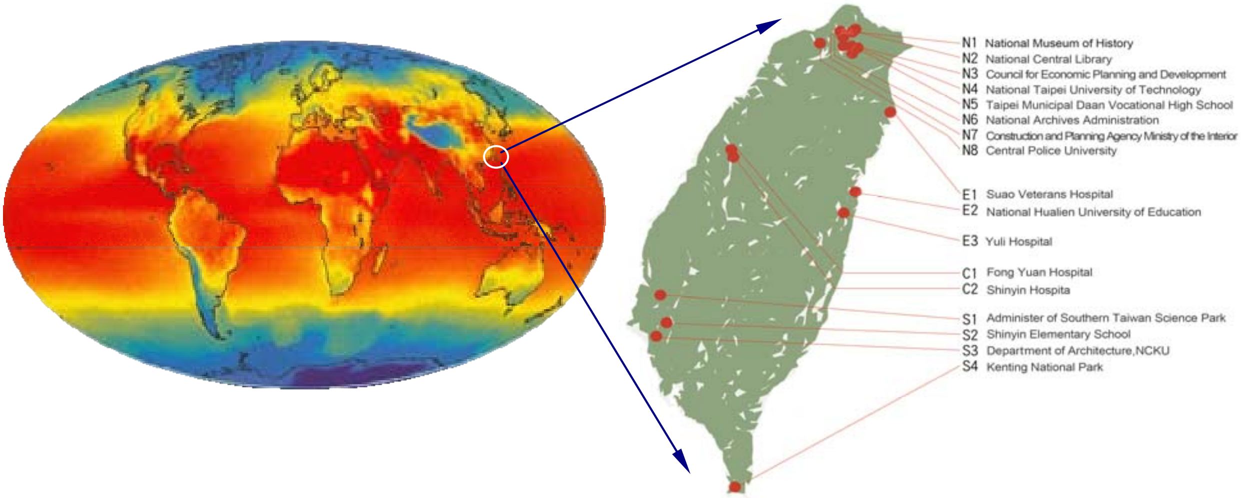

Figure1 Taiwan's location in the world & the diagnosed cases in Taiwan

3 Research Content

3.1 Diagnostic Procedure

Indoor environmental quality testing is divided into the following three levels: major issues and self-examination procedure, field inspection by building pathologist, and advance building health examination procedure. Working from the self-examination and field inspection to the final indoor health examination, this study scheme is initiated by individuals who have discovered environmental issues of their surrounding spaces and applied for an indoor environmental quality diagnosis. After completing field inspection and laying out the testing scheme, the building pathologist states the actions for improvements and goals in the final diagnostic reports (as in Figure 2).

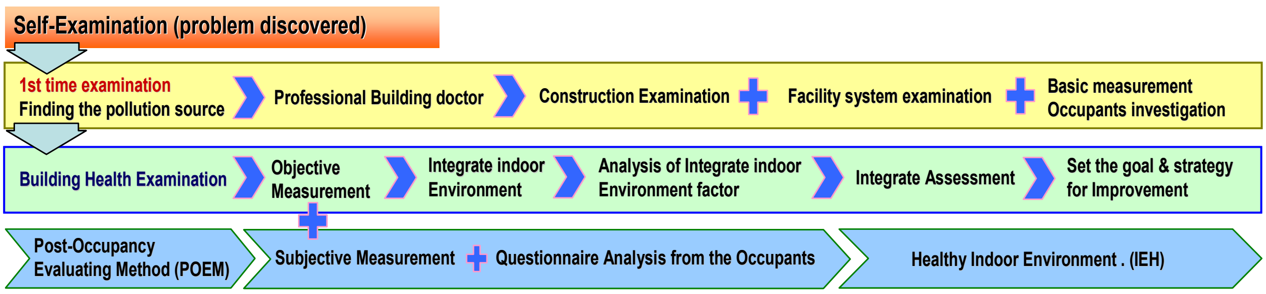

Figure2 Indoor Environment Examination Process

3.2 Selection and actual testing of indoor environmental items

This study adopted the standard operation process in improving the quality of indoor environment, which was created by previous studies. The actual quality of indoor environment was measured in order to understand the problems associated with the inferior quality, to draft measures of improvement and to undertake practical improvement work. Through confirming the goal of improvement, designing and planning, constructing and re-inspecting, it was concluded that the advancement of indoor environment quality was ultimately reached and the improved performance was assessed as well.

Prior to the indoor on-site comprehensive environmental test, an on-site test planning was drafted. The comprehensive environmental test items were roughly divided into five portions including sound, light, warmness, air and electric-magnetic. Tabular presentation of data is an easy way of condensing many items. Tables must carry numbers in the text (Table 1) and caption.

Table 1 This indoor environment of research assesses the datum.

Project	Factor	Unit	Datum					
1 Acoustics environment	Sound Level	dB(A)	Office		Museum		House	
			56 (IEI)		corridor 56	Show room 45	50 (IEI)	
					(EPA)

	HCHO	ppm	0.1				(TW-EPA)	
	TVOC	ppm	3				(TW-EPA)	
5 Electronic environment	Electronic	V/m	10kHz～100kHz：87 50Hz～60Hz：4170～5000				(TW-EPA)	
	Magnetic	μT (1000nT)	12kHz～200kHz：4.6～6.25 50Hz～60Hz：83.3～100				(TW-EPA)	

3.3 Experiments and questionnaire

This work focuses on comparing the physical environment in different places around Taiwan, which could be observed to determine the differences causing by micro-climate in different places. A summary of the building ID numbers, test dates, locations, rates of occupancy, construction styles, and HVAC systems of the test buildings are given in Table 2.

Table 2 The details of 18 test buildings.

	Northern of Taiwan.							
ID number	N1	N2	N3	N4	N5	N6	N7	N8
Construction / Floor	RC/2F	RC/2F	RC/B1	RC/7F	RC/4F	RC/3F	RC/6F	RC/B1

Note.

This study included several space types as follows: office room, housing space, activity space, exhibition space and so on. We use long time (24hr) measurement to find out the status of indoor environment factors in different periods.

Codes of ventilation type:
MSAC: Multi-Split-A.C.
CACS: Central A.C system.
WTAC: Window type A.C.
AHU: Air Handling Unit.
FCU: Fan Coil Unit.
FAN: Fan.

In order to analyze effectively the relationship between the physical environment of different using type places, and the mental sensations of the occupants, the field-measurement'' and ``questionnaire'' were carried out simultaneously in this study. The measurements are composed of eight factors including carbon monoxide conc. (ppm), carbon dioxide conc. (ppm), air-borne dust conc. (mg/m^3), air velocity (m/s), air temperature (℃), relative humidity (%), noise level (dB(A)) and illuminance (lx). An automatically successive measurement was applied to sample eight physical factors in 24 hrs continuously, as shown in Fig. 3. The outdoor quantities are also monitored. The sensors were installed at the breathing zone (FL +90±120cm). In the questionnaire, the purpose is to investigate the level of satisfaction with the indoor physical environment during the sampling period. The satisfaction response was represented by a five-grade scale. The psychological response of occupants, working in the investigated spaces, was obtained by questionnaire as the field-measurement proceeds. The questionnaire was filled in by the researchers via the interviews with the occupants.

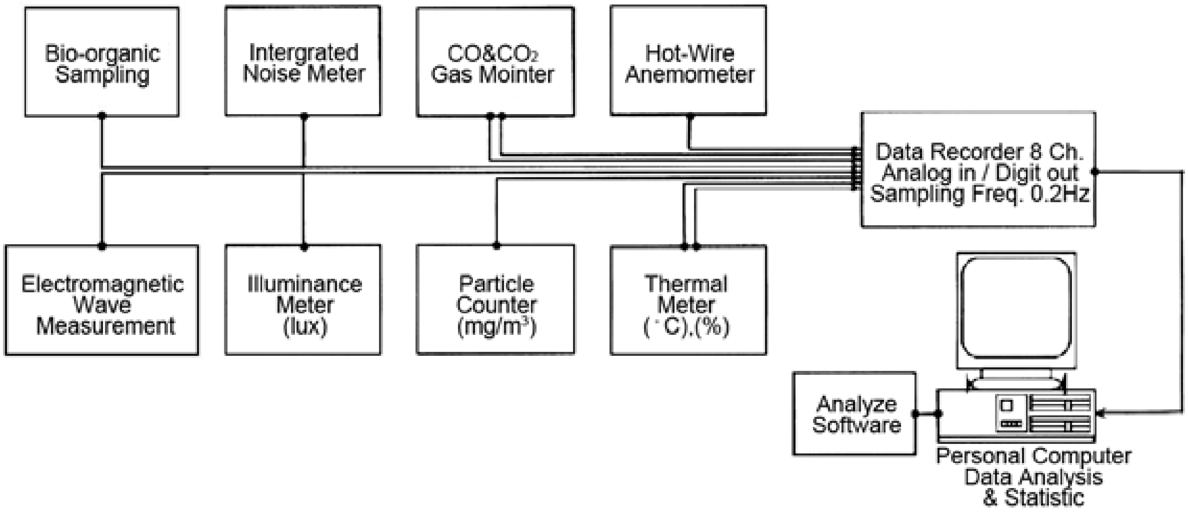

Figure.3. Schematic diagram of the field-measurement apparatus.

4 Research a result

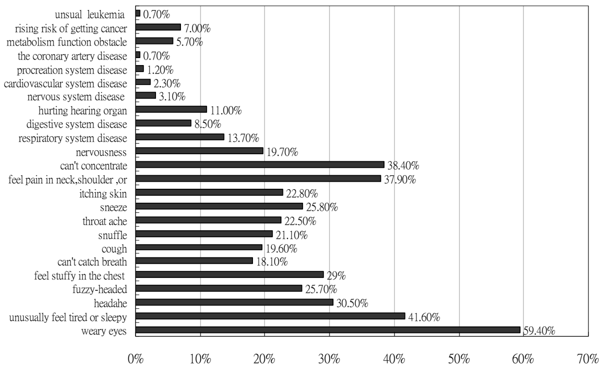
4.1 Case evaluation and user's feedback inquiry before improvement

The improvement to indoor environment must eventually aim at the assurance of user's health. Hence, it is necessary to collect the information on the indoor use status, the degree of complaints to indoor environment and the symptoms caused by indoor environment. As such, the questionnaires were drafted prior to initial inspection and the survey was conducted focusing on four key points.

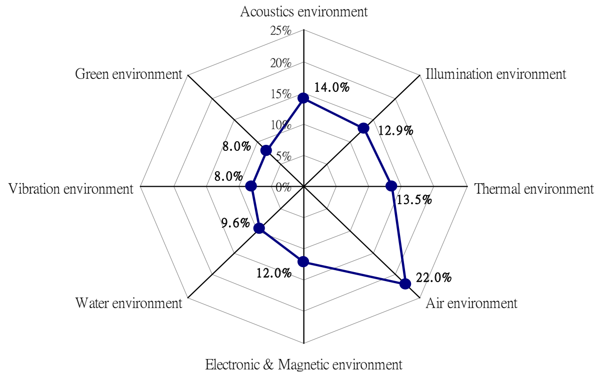
Examining the features of the samples, from the structure of sex, the percentage of male (40.34%)is lower than the female's (59.66%); from the structure of age, primarily in the range of 30 to 39(33.22%), followed by 40 to 49(31.56%), 20 to 29(17.94%), 50 to 59(12.96%), and the percentage of the age above 59(2.66%)and below 20(1.66%) are rather low; in the status of smoking, a high percentage up to 85.33% of the users do not smoke, current percentage of smokers is 8%, 6.67% of them already quit smoking; in addition, 85% of the users maintain normal living condition (85.02%) and balanced meals (84.23%). However, there are as high as 68.62% of the users under pressure. Probably take place in the indoor personnel's discomfort symptom. in figure 4(1).

Users' reaction to indoor environment problems is shown in figure 4. The project included the diagnosis and physical improvement of the indoor environment. For diagnosis, three different stages were implemented, including self inspection, the preliminary walk-through, and the detailed inspection of the building from a healthy environment standpoint. For environment measurement, there were components of indoor acoustics, illumination, thermal comfort, air quality and electromagnetic field. The process for conducting physical improvement started by setting the goals of improvement, and followed by planning, design, construction, and re-assessment after completion. It is also the purpose of this study to establish a reference manual for future projects.

Ranking the influence to human health by the items of indoor environment, the sensitivity to the air in the environment is the highest (22%), Acoustic (14%), Thermal (13.5%), Illumination (12.9%) and electric-magnetic (12%), these factors also draw a lot of attention, as shown in figure 4(2).



(1) Indoor personnel's discomfort symptom.



(2) Environmental factor.

Figure 4 Probability take place in the indoor personnel's discomfort symptom and the user counts every environmental factor attention degree.

Referring to this result, it can be concluded that while performing survey for cases, the visible environmental factors shall be specially watched or more items shall be added for inspection. Synthesize in its room the bad reason of environmental quality is counted. In figure 5.

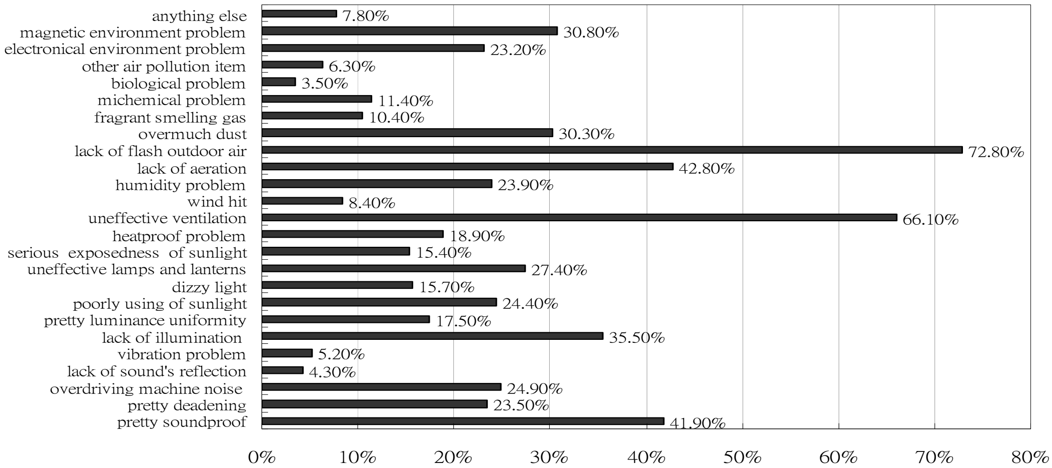


Figure 5 Synthesize in its room the bad reason of environmental quality is counted.

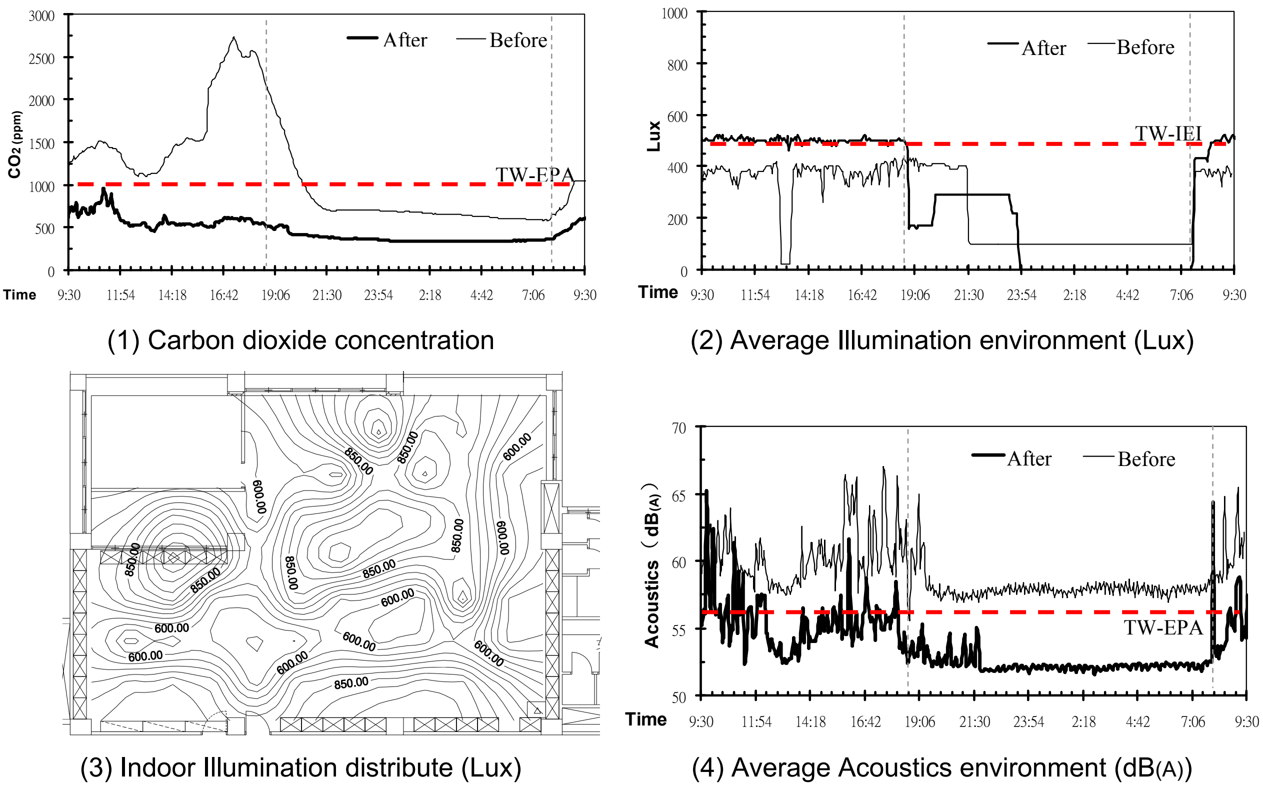
4.2 Diagnostics and user's feedback inquiry after improvement

Based on the climate differences in subtropical environment and in northern, central, and southern regions of Taiwan, this research investigates the environmental quality problems existed in different types of building and archive all the appropriate actions for improvement. The research then lists the localized construction items to be looked into in detail. The improvements should be discussed explicitly with the building management and pre-construction meetings should be held to reach an agreement prior to the construction. Things worth paying attention to such as the renovation to the interior environment should not destruct the existing building facilities itself. Instead, additional facilities or configuration should be added to achieve the improvement. In any event such that the improvement affects the building exterior or any regular usage, negotiation with the building management may be necessary. Part of the achievements after improvement are shown Figure6.

This research began from the viewpoint of health. Indoor environmental improvement is meant to ensure a healthy environment for the users. Hence, the user's usage behavior, degrees of complaint, and symptoms caused by surrounding environment are all essential information to be collected. Therefore, the users in the case studies are being inquired with questionnaire regarding usage purpose, health, and their emphasis in each interior environment after the improvement is implemented. The questionnaire is compiled to analyze the discomfort experienced with reference to the user's degree of emphasis on the interior environment. This analysis mainly focuses on the physiological discomfort and symptoms. It is discovered that user of the improved interior still experience illness such as dry eye or eyestrain, irregular fatigue or lethargy, dizziness, neck or shoulder muscle pains, and other symptoms. Greater percentages among the illnesses are headache, chest pain, dizziness, and neck or shoulder muscle pains. Occurrence of other discomforts is not as significant. The outcome with improvement is shown in Table 3:



(1) Carbon dioxide concentration

(2) Average Illumination environment (Lux)

(3) Indoor Illumination distribute (Lux)

(4) Average Acoustics environment (dB(A))

Figure 6 N7（Construction and Planning Agency）a model for improvement cases

5 Conclusion and Recommendations

Aiming at subtropical environment and the differences of climates in north, central and south Taiwan, this study discussed the indoor environment quality issues frequently occurred in each building features and planned appropriate improvement methods, further suggested items and content to be worked based on the individual condition.

The overall indoor environment quality in Taiwan's buildings was investigated and inspected, and the comprehensive conclusion is as follows: (1) Creating an IEQ efficiency zone of "green building design" for the existing private buildings. (2) Establishing indoor environment quality research and test process.(3) Drafting improvement techniques based on the specific conditions in each building.(4) The diagnostic result of indoor environment showed that the air environment was the primary problem.

DESIGN STRATEGIES FOR ADDRESSING CLIMATE CHANGE AND EXTREME WEATHER EVENTS

Tais Pereira BORGES MsC Arch

Sustainable Design, Science Design, University of Sydney, Sydney, Australia, Tais.Borges1@yahoo.com.au

Keywords: Design, Strategies, ESD, Climate Changes, Extreme Weather.

Summary

This work aims to address threats of climate change and EWE upon buildings, that are predicted to occur worldwide and in Australia in the 21st century and beyond.

The most relevant Extreme Weather Events (EWE) that are likely to happen more frequently in Australia are Extreme Temperatures and Heat Wave; Drought; Bushfire; Sea Level Rise and Coastal Erosion; Heavy Rainfall, Hailstorms and Flooding; Strong Winds and Cyclones.

Conventional design approaches are not sufficient to produce reliable future oriented outcomes. Even a perfect sustainable building will probably fail in coping with extremes such as sea level rise or bushfire. Environmentally Sustainable Design (ESD) is an essential approach to be used but together with other strategies that address climate change and EWE, reducing buildings' vulnerability.

The strategies identified in this paper for each extreme are particularly significant to designers and the civil construction industry, allowing them to deliver more reliable built environments now and for the future. All strategies require that designers take into consideration predicted weather data, not only historic climate records. It is extremely important to have knowledge of the kind of weather extremes a building in a specific location will face in the future, since its lifetime will be significantly affected by it.

1. Introduction

Buildings designed today will face a different reality during their lifecycle due to climate change and EWE. It is unlikely that buildings will be capable to deal with those issues. Probably, they will not succeed to deliver a desirable and comfortable place to live, work and entertain.

Unarguably, ESD can significantly reduce Greenhouse Gas Emissions (GHG) in any type of building, avoiding climate change and minimising ecological footprint. However, it is not immune to EWE. It will also face heat waves and extreme temperatures, intense and more frequent droughts and bushfires, possible heavy rainfall events and flooding, hailstorms and stronger winds.

Thus, it might be necessary to include extra design strategies to cope with EWE and new climate averages. Strategies that go beyond energy efficiency, water recycling and re-use, lifecycle, passive strategies and so on, an approach for managing vulnerability and assuring buildings' liveability.

The paper aims to highlight some important strategies for each main EWE that is likely to happen in Australia and other parts of the world, influencing design standards and the way architecture is conceived for the future. It provides designers with some practical strategies to be considered at the design stage in regards to climate change and EWE.

2. Architecture and Extreme Weather Events

Climate change predicts changes in magnitude and frequency of EWE as well as mean alterations of weather patterns leading to an exceeded design criteria and increased potential of damage to existing built environments. Thus, it is imperative to consider climate change impacts in the building stock which will be built in the next few decades to avoid extra cost associated with climate events, including catastrophes that may result in huge economic losses for the society.

The aim is to design and build weather proof buildings which cope with the climate now and changes in the future. Buildings should be robust enough to be protected against weather vulnerability, highly energy and water efficient, with longer lifetime, less environment impact and embodied energy along with more recycled materials.

Furthermore, these buildings should promote comfort and healthy indoor spaces. They must ensure liveability in extreme events and climate change conditions during their entire lifetime. Buildings should be supplied by renewable energy, specified with less water content and eco friendly materials. Finally, constructions should reduce waste during construction, operation, maintenance and demolition stages, causing minimum pollution and not harming biodiversity and ecosystems.

2.1 ESD Incompatibilities

Even though ESD principles are essential for dealing with climate change, some issues can be raised in regards to ESD coping with it, particularly EWE. Some passive design strategies may not be efficient or sufficient to keep a good internal environmental condition in extreme conditions. In addition, some technologies used in ESD might need more maintenance or replacement because of extreme events.

Some incompatibilities can be verified in passive cooling strategies such as natural ventilation. This strategy can exacerbate the indoor temperature in extreme temperatures and heat wave when extreme hot breezes cause thermal discomfort. In this case, mix strategies which integrate active systems may be a solution; however it consumes more energy and is less environmental friendly. In addition, extra shading or insulation might be necessary to comply with this kind of extremes, but it may jeopardise passive heating during winter.

Some ESD technologies such as photovoltaic panels may increase maintenance in extreme events like hailstorm. As a result, it would be costly to replace and consequently less environmental friendly as a result. A protection glass or mesh could avoid the damage, however it would decrease its efficiency.

Rainwater harvesting and recycling or re-use systems could be affected by the increasing risk of flash flooding and consequently vulnerability of water supply including drinkable water and soil contamination by sewage.

Landscaping can be used to control heat and humidity, used as a shading to avoid solar access and glare. It may be wind break against increased winds velocity and also employed as drainage system by permeable paving and green roofs minimising flooding effects. However, drought level restrictions would affect it directly. Lack of watering in drought conditions will increase dust and consequently poor air quality and more landscaping maintenance and plants replacement.

Robust constructions and structures are likely to be necessary to handle many EWE. Conversely, it means more concrete and materials, which result in more embodied energy, increased GHG, higher water demand in the construction process and consequently higher ecological footprint. It might have fewer openings and glass areas which could compromise passive strategies such as natural ventilation, daylighting levels and heating. Moreover, the excessive thermal mass could be more problematical to heat up, making passive heating unviable in winter.

3. Strategies for Addressing Extreme Weather Events

3.1 Extreme Temperature & Heat Wave

Mean temperature increase will influence specifications for energy efficiency in buildings. All elements such as insulation, shading devices, thermal mass and glazing should be dimensioned taking into account predicted temperature changes. Extreme temperatures and heat waves need to be addressed at the design stage.

Table 1 Australia's Future Temperature

IPCC's Emission Scenarios	Year 2030	Year 2070
Lower range (B1)		1-2.5ºC
Middle range (A1B)	0.6ºC-1ºC	
Higher range (A1F1)		2-5ºC

Darwin	11	44 (28-69)	89 (49-153)	230 (140-308)

[**Source:** Australian Greenhouse Office]

3.1.1 Strategies

Limiting natural ventilation during hot periods of the day is extremely important. Airtight building envelope also avoids ventilation during hot temperatures.

Extra shading devices and insulation will be necessary in extreme temperatures and heat waves. Thus, removable shadings devices or insulation would be a smart option.

Green roofs can insulate against heat gains and also absorb rainfall and storms acting as drainage system. Insulation should keep heat out in summer and heat in winter.

Thermal mass such as concrete, stone or tiled floors and brick soak up unwanted heat during the day. Increasing levels of insulation might be required for lightweight constructions. Also, surfaces that reflect heat in summer, like light coloured paints, are advised for both types of construction.

Larger floor to ceiling heights to allow additional cooling mechanisms that might be considered in the future. These systems should be very energy efficient, with low carbon emissions and preferably using renewable energy. Consider extra roof space facing north for adding photovoltaic panels for future energy demand.

Occupants should be educated to anticipate hot weather to manage the building accordingly. Providing a comprehensive manual is important for users to know how to operate buildings appropriately.

Appropriate deciduous trees for shading in summer and solar access in winter can be used but it may increase bushfire danger. In addition, water feature with minimal net water could be used to provide extra cooling in summer.

3.2 Drought

Rainfall and soil moisture decrease is predicted together with mean temperature increase. This combination leads to more frequent and severe droughts around Australia.

Table 3 Drought Prediction

Drought increase (%)	Year 2030	Year 2070
Australia	up to 20%	
Eastern Australia		up to 40%
South-western Australia		Up to 80%

[**Source:** Australia Bureau of Meteorology]

3.2.1 Strategies

It is essential to incorporate rainwater collection, re-use & recycling systems, and also to specify water efficient equipments on every new project. Design and specify materials and products which have less water content and use less water to install and to maintain.

Think carefully about water consumption of materials and building methods. Rainwater harvesting and recycling during the construction could minimise water demand on site. Particularly, in climate change conditions where higher temperatures will accelerate water evaporation and will increase water demand for many construction methods such as curing concrete.

Reservoirs and extra rainwater tanks could be incorporated to the building when needed. Rainwater collection should be estimated by the net water consumption over normal use for drought conditions plus climate change predictions. Leave space and spare connections for adding new rainwater tanks when the need arise in the future.

Be aware that even drought resistants plants today may be unviable in a future drought prospect. Thus, plants that last over 10 years should be carefully specified in relation to the future climate change prediction.

3.3 Bushfire

A combination of high temperatures, flammable vegetation, low humidity and very strong winds is highly linked to bushfire susceptibility (Ramsay et al, 2003). Bushfires are related mostly to dry seasons and climate change definitely will amplify its risks. Thus, it is extremely important to design buildings also surroundings to be less vulnerable.

Even though a given property is not in a ‘bushfire-prone area’, these strategies may be carefully analysed and applied when required in light of climate change conditions over the lifetime of a building.

Table 4 Extreme Fire Danger Rating Increase in Australia

Table 5 Numbers of Days of Very High or Extreme Fire Danger in Canberra

Canberra Today	Year 2020	Year 2050
23 Days	26-29 Days	28-38 Days

[**Source:** Climate Change in Australia]

3.3.1 Strategies for Landscaping

It is important to avoid construction in uphill topography because fire spreads faster. Earth mounds can be useful to deflect embers and wind-driven debris. Also, cut-and-fill and terrace the ground is used to avoid fire burning uphill, specially ground fire.

For instance, it is very important to choose a type of plant (trees and shrubs, ground cover and mulches) with low flammability characteristics. Plants without heavy litter dropping are recommended to avoid spreading ground fire.

Groups of plants acting as screen should be used to deflect wind driven attack. Plants that have dense foliage, low flammability and large size are ideal.

Create fuel-reduced area around buildings. It means clear space around buildings and non-combustible fences and walls. In addition, provide lawns and areas of cut grass, use mulches to maintain moisture content of vegetation.

3.3.2 Strategies for Building Design

The main objective is to reduce 'ignitions' by embers and burning driven by the wind, by heat radiation, by direct flame contact, and by wind damage.

Avoid litter and ember accumulation points, use non-combustible materials externally such as bricks, stone and metal or treated timber with fire retardant. Building design should be simpler, avoiding corners and re-entrants as much as possible. Furthermore, use non-combustible material for walls, columns and posts which support floors.

It is important that the roof structure can withstand gale-force winds. Also, roof space should be sealed and have sarking. Avoiding narrow roof gutters is very important as well as making it visible and accessible for maintenance. Roof light should be protected by screen or sprinkles or be made with special glass fire resistant (Ramsay et al, 2003).

Eliminating underfloor spaces using concrete on ground for example is a safer alternative than elevate wood floor. The building finished floor level should be higher than outside ground level and a non-combustible material should be used externally to prevent fire ignitions from debris in this vulnerable areas.

Attachments to a building such as verandas, decks, steps, landings, pergola and trellis may be vulnerable points of beginning a fire, so it may be prudent to avoid them, design longer eaves instead of pergolas or use non-combustible materials.

And last but not least, services should be designed as an additional instrument for successful bushfire management. Design for backup services such as dams, swimming pools, storage tanks, and rainwater tanks would maximise water supply for fire fighters in a bushfire event. In addition, gas cylinders should be located at a suitable distance from the building.

3.4 Sea Level Rise and Coastal Erosion

Coastlines may experience erosion, beach recession, sea inundation and flooding due to sea level rise, especially when combined with strong winds and storm surges (Minifie, 2007). Furthermore, prolonged and heavy rainfall events increase soil moisture making it more unstable, thus increasing chances of erosion.

Table 6 Sea Level Rise Prediction

	Mean Sea Level Rise by 2100
IPCC's Range	18 - 59cm
Ice Caps	10 - 20cm
Total	28 - 79cm
Australia East Coast	10cm
Total In Australia East Coast	38 - 89cm
* Actual Sea Level Rise Rate is 3.2mm year	

[**Source:** IPPC 2007 & CSIRO]

3.4.1 Strategies

A simple location choice avoiding vulnerable sites nearby coastal areas is a strategy itself. Undertaking an assessment risk about the location is important. Councils usually have risky areas demarcated.

Check viability of the development for insurance purposes at the chosen area. This makes insurance viable for the property.

Structures such as Palafittes, which are piles or stakes above rivers set into the sediment below the water allowing buildings to be built above flood levels, could be employed in flood prone zones. This concept could also be applied on dry land that may be subject to sea inundation or flooding due to future climate change.

Other strategies such as floatable homes could be used against flooding and sea inundation. It has been used in Holland where 26% of the country is located below sea level (Lijf et al, 2006). The homes are built in a concrete structure that floats with all services connected and operating normally during flood periods. Furthermore, constructions such as marines could be an inspiration for different infrastructures in cities vulnerable to sea level rise.

Other simple strategies may be applied to ensure safety, such as reducing slope angles. Appropriate vegetation on slopes has the ability to act as a barrier through its roots. Moreover, drainage systems are extremely important to avoid soil moisture saturation resulting in landslides.

3.5 Heavy Rainfall, Hailstorm and Flooding

Despite the decrease in mean rainfall, more heavy rainfall events are predicted, increasing the risk of flooding or flash flooding. Design for flood-proofing buildings means reducing potential damage on buildings by flooding in flood plain areas.

Table 7 Rainfall Estimates in Australia

Annual Precipitation	Year	Emission Scenario	Prediction
Central, Eastern & Northern Areas	2050	Low	-15 to +7.5%
	2050	High	-20 to +10%
	2070	Low	Around -15 to +7.5%
	2070	High	-30 to +30%

[**Source:** Australia Bureau of Meteorology & CSIRO]

3.5.1 Strategies

One of the most simple and effective flood proofing measures is to raise habitable floors in buildings and take advantage of the topography locating them higher than the flooding level, considering even higher levels due to climate change factor.

Any portion of a building or structure should be made by flood compatible materials which withstand immersion such as concrete, tiles, brick etc. It is important to clean and maintain all obstructions around the area to avoid extra rubbish on flood waters.

Drainage systems are really important to mitigate flood risk. For instance, Sustainable Drainage Systems composed by storm water tanks, rainwater harvesting and green roofs could be used as temporary storage minimising local flooding (Chell et al, 2005). In addition, permeable paving and landscaping areas would help draining extra rainwater.

The construction should be strong enough to resist lateral forces caused by impact of debris and uplift effect. Increased core walls and foundations could avoid flooded buildings to collapse under such forces.

Sewer system should be protected against flood damage because it can enter the building and contaminate ground and water supply. In addition, an adequate flood warning system and pre-planned evacuation measures are required to avoid greater risk of catastrophic damage. Ensure buildings have sites above maximum flood level and availability of flood free access for evacuation.

In regards to hailstorm, the areas which are generally most affected in building are roofs and windows. Thus, the strategy is to protect vulnerable points and specify stronger products such as resistant glass and roof tiles. Also, increasing the strength of roof fixings or roof replacement can significantly reduce to the potential damage. Insect inset screen can also add an extra protection for windows.

3.6 Strong Winds & Cyclones

Cyclones might increase power due to higher ocean's temperature and levels increase. Furthermore, cyclones can cause other extremes such as heavy rainfall, storm surges and flooding.

Table 8 Projections of Wind Speed in Australia

	Year 2030	Year 2070
Average Wind Speed	- 2.5% to 7.5% in Coastal Areas	
A1F1 Scenario		+15% some regions
B1 Scenario		Less than 10% everywhere

[**Source:** CSIRO]

3.6.1 Strategies

Design robust buildings which cope with extreme strong winds and is capable to withstand in case of loose parts of buildings such as roofs or trees blowing, hitting and damaging the building or even injuring people.

Roofs should be sufficiently anchored. Thus, specification and detailing are so important on the design stage. In addition, heavy materials such as brick, stone and concrete are more likely to manage this kind of extreme event.

Circular or polygonal building shapes are more suitable than rectangular or square plans. Also, symmetrical and compact floor plan is more stable. Orientation is also important; the smallest façade should face stronger winds.

Pitched roofs and roofs projections should be as small as possible to avoid suction. Openings should have strong closing/locking arrangements. Also, glass panels should be undersized and have extra outside protection such as metallic fabric mesh to avoid breakage.

4. Conclusion

This paper brings many factors together and issues to be addressed by designer using ESD while integrating in other strategies for coping with climate change and specially with EWE.

It is a general guide for designers to remember how important it is to make buildings liveable, comfortable and secure in light of climate change and extreme conditions during the 21st century and beyond. It gives practical strategies that can be considered straightaway in the design stage.

Designers or architects must understand that building designs must withstand the weather and it is a matter of considering climate change impacts over a lifetime of a building. It is extremely important to have knowledge of the kind of weather extremes a building in a specific location will face in the future.

Certainly, location assessment is deemed required for analysing all requirements and eventual vulnerability to possible climate change and extreme events predictions according to the lifetime of the building. The designer should be aware of it and choose appropriate strategies thinking in the future climate that the building may face.

Keywords: GBCS (Green Building Certification System), sustainability, apartment complex, design, construction

Summary

With an increasing demand for sustainable and environmentally-friendly buildings, Green Building Certification System (GBCS) has been in force since 2002 in Korea. The assessment categories of GBCS are largely divided into land use and transportation, energy · resources and environmental impact, ecological environment and indoor environment. A total of 6 types of buildings are dealt with in the GBCS. In particular, apartment complexes are the most common residential buildings in Korea, and it is anticipated that the number of applications for apartment complexes for the GBCS will continuously increase due to financial incentive programs that have been offered for certified apartment complexes since 2006. In this study, we aim to pick out the items requiring improvement for the green apartment complex. Twelve existing certified apartment complexes were selected. GBCS assessment results and actual conditions of design and construction were investigated and analyzed. The results showed that a total of 18 items that require improvement were identified in accordance with the average score-to-allotted point ratio. Relevant details that are expected to be helpful for the next design works were also presented.

1. Introduction

In the UNCED (United Nations Conference on Environment and Development) held in June 1992, UNFCC (United Nations Framework Convention on Climate Change) was adopted with the aim of reducing environmental problems caused by global warming. With the effectuation of the Kyoto-protocol, Annex 1 countries have been enforced to reduce the greenhouse gas emissions that act as a major source of global warming. It was reported that the building industry accounts for about 40% of the world's energy and resources consumption, 30~40% of its greenhouse gas emissions and 17% of the water used worldwide.[1] With the awareness that the building industry significantly contributes to environmental problems, attempts have been made in many countries to construct sustainable and environmentally-friendly buildings. In Korea, the Green Building Certification System (hereafter GBCS) has been in force since 2002. Especially, it is anticipated that the number of apartment complexes, which are the most common residential buildings in Korea, applying for GBCS has increased continuously because financial incentive programs for certified apartment complexes have been offered since 2006. Thus, it is important to establish a design guide to improve sustainability of apartment complex efficiently. In this study, we aim to pick out the items requiring improvement for the green apartment complex. Twelve existing certified apartment complexes were selected. GBCS assessment results and actual conditions of design and construction were investigated and analyzed. Then, items of which average score-to-allotted point ratios were low and relevant particulars helpful for the next design works were presented.

2. Outline of the GBCS

2.1 History and Operation Results of the GBCS

Since the GBCS for apartment complexes came into force in 2002, the GBCS for various buildings have been in force, such as residential and commercial building complexes and office buildings from 2003, schools from 2005 and retail and accommodation from 2006. Table 1 shows the history of GBCS. Certification types of the GBCS are divided into pre-certification and certification. Pre-certification is given for buildings in the design stage in accordance with the assessment results of their design documentations. Pre-certification is valid until the time of completion. Certification is given for the completed buildings and its

[1] Lee, P.J., 2002, Sustainable development and architecture, In Proceedings of the Joint Seminar on the Explanation of Green Building Certification System.

period of validity is 5 years. A total of 216 buildings were certified as a Green Buildings.[2] Table 2 shows the number of certified buildings from 2002 to 2006. It can be seen that the number of certified buildings in 2006 increases sharply. This is a consequence of the financial incentive programs being offered for pre-certified apartment complexes since 2006, allowing builders to add equivalent of 3% of the construction cost for the basic type to the price of a new apartment. Considering that the Price Cap System for New Apartments has been in force, this is considered to be a strong incentive.

Table 1 History of the GBCS

Date	Contents
1997~2000	- Drafts of green building rating criteria were announced by RCGBT (Research Council of Green Building Technology) supported by KOSEF (Korea Science and Engineering Foundation). - 3 certification systems were separately developed by KNHC (Korea National Housing Corp.), KIER (Korea Institute of Energy Research) and CrebizQM. - Trial certifications were conducted by MOCT (Ministry of Construction and Transportation) and MOE (Ministry of Environment) for the systems of KNHC and CrebizQM, respectively.
2000~2002	- Integration of 3 certification systems was determined by MOCT and MOE. - Integrated certification system was named as the Green Building Certification System. - KIER, HURI (Housing and Urban Research Institute) affiliated with KNHC and CrebizQM were designated as certification authorities. - The GBCS for apartment complexes was developed by KIER, HURI and CrebizQM.
Jan. 2002	GBCS for apartment complexes came into force.
Jan. 2003	GBCSs for residential and commercial building complexes and office buildings came into force.
Mar. 2005	GBCS for schools came into force.
Feb. 2006	Financial incentive programs for pre-certified apartment complexes came into force.
Apr. 2006	Revised GBCS for apartment complexes came into force.
Aug. 2006	KIEE (Korean institute of Educational Environment) was designated as the certification authority for schools.
Sep. 2006	GBCSs for retail and accommodations came into force.

Table 2 The Number of Certified Buildings from 2002 to 2006

Year	2002	2003	2004	2005	2006
	3	3	15	32	163
Building type	Apartment complexes	Office buildings	residential and commercial building complexes	Schools	
	172	30	7	7	

2.2 Assessment system of the GBCS for apartment complexes

The GBCS for apartment complexes was revised in Oct. 2005 in order to simplify the required documentations and add assessment items related to the remodeling of apartment complexes.[3] Revised GBCS has been in force since Apr. 2006. Table 3 shows the assessment systems used before and after the revision. Certification grades of the GBCS are divided into Excellent with 65 points or more and Best with 85 points or more.

Table 3 Assessment System of the GBCS for Apartment Complexes

Before revision		After revision		
Category	The number of assessment items (allotted points)	Category	The number of basic assessment items (allotted points)	The number of extra assessment items (allotted points)
Land use and transportation	11 (27)	Land use	5 (15)	3 (7)
		Transportation	3 (6)	1 (2)
Energy · resources and environmental impact	15 (41)	Energy	1 (12)	1 (3)

3. GBCS assessment results, actual conditions of design and construction and items requiring improvement

3.1 Outline of the Selected Certified Apartment Complexes

12 certificated apartment complexes constructed by 7 major construction companies of Korea were selected for this study. Among the 12 apartment complexes, 7 were pre-certified and 5 were certified. 3 of the pre-certified buildings were given the grade of Best, while 9 were within the grade of Excellent. Table 4 shows the outline of the selected complexes. There were few certified complexes by the revised GBCS at the time of investigation because it has been in force recently. Consequently, all of the selected 12 complexes were certified by the GBCS before the revision.

Table 4 Outline of the Selected Certified Apartment Complexes

3.2 GBCS assessment results and actual conditions of design and construction

Table 5 and Table 6 show the GBCS assessment results of the 12 selected certificated apartment complexes. The average total score and the average total score-to-allotted total point ratio of all the complexes are 74.82 points and 62.35%, respectively. Among all the categories, energy · resources and environmental impact category obtained the highest ratio of the average score-to-allotted points. On the contrary, ecological environment and extra categories obtained low ratios. In the case of the 3 complexes with the Best grade, the average total score and average total score-to-allotted total point ratio are 87.03 points and 72.53%, respectively. The average score-to-allotted point ratios of the categories of energy · resources and environmental impact and ecological environment are higher by about 20% than those of complexes with the Excellent grade. Table 7 shows the actual conditions of design and construction for each assessment item.

3.3 Items requiring improvement and relevant particulars for the next design works

3.3.1 Outline of the analysis

In this study, the average score-to-allotted point ratios of all the items were divided into five classes of A (Best), B (Better), C (Good), D (Worse) and E (Worst) for the purpose of evaluation. Classes A, B, C and D indicate that the average score-to-allotted point ratios are within the 80^{th}, 60^{th}, 40^{th} and 20^{th} percentile, respectively. E indicates that the average score-to-allotted point ratio is either equal to, or lower than 20% of those attained. The average score-to-allotted point ratios for A, B, C and D are higher than 93.83%, 81.33%, 55.56% and 48.35%, respectively (Refer to Table 6).

3.3.2 Land use and transportation

Among the allotted items with high points (3 points or higher), item 3 (gross floor-to-site area ratio) is categorized under the D class (48.37%/6 points). Among the allotted items with low points (2 points or lower), item 4 (interference in the right to sunshine of adjacent properties) and item 9 (connection of on-site pedestrian walkway to outside public walkway) were categorized under the E class (18.33%/2 points) and the D class (54.17%/1 point), respectively.

Considering the economical efficiency, it seems to be a little difficult to improve the item 3 and item 4. However, it is considered to be relatively easy to improve the item 9. As far as security problems don't arise, it is recommended to place as many gates as possible at the fence.

3.3.3 Energy · resources and environmental impact

Among the allotted items with high points, item 12 (Energy Performance Index[4]) and item 17 (reduction of CO_2 emission) are categorized under the D class (53.89%/12 points) and D class (54.83%/3 points), respectively. Among the allotted items with low points, item 15 (minimal use of furniture through the built-in wardrobe) and item 21 (use of rainwater) are categorized under the E class (38.33%/1 point) and the E class (25.00%/2 point), respectively.

Item 12 with the highest allotted point is a key to the sustainability. Among the items concerning EPI (Energy Performance Index), those items required improvement were selected based on the data of the 12 selected complexes. These items are the installation of windbreak space at the entrance of the unit and the building, external insulation, the installation of energy-efficient control systems of heating water pumps, the application of a heat recovery ventilation system, the installation of automatic power factor adjustment equipments for power condensers installed in a group and the installation of openings for daylighting and automatic lighting control systems for underground car parking. In the case of item 17, it is necessary to spread cogeneration and district heating systems nationwide. It seems to be relatively easy to improve item 15 and item 21.

3.3.4 Ecological environment

Among the allotted items with high points, item 28 (application of artificial landscaping methods considering ecological environment) and item 29 (garden-to-site area ratio) are categorized under the D class (49.76%/4 points) and D class (49.93%/5 points), respectively. Among the allotted items with low points, item 27 (on-site topsoil reuse ratio) and item 30 (connection to the outside green space) are categorized under the E class (13.33%/1 point) and the D class (52.08%/2 points), respectively.

It is considered that builders should take careful consideration of in items 28, 29 and 30 because they significantly contribute to the concept of a 'green' home for the residents.

Table 5 GBCS Assessment Results of the Selected Certified Apartment Complexes by Categories

Category	Allotted point	Allotted –to-total point ratio (%)	Total complexes			Best grade complexes			Excellent grade complexes		
			Average score	Average score-to-allotted point ratio (%)	Average score-to-average total score ratio (%)	Average score	Average score-to-allotted point ratio (%)	Average score-to-average total score ratio (%)	Average score	Average score-to-allotted point ratio (%)	Average score-to-average total score ratio (%)
