SUSB-LCA ver. 1.0 (Sustainable Building Life Cycle Assessment ver. 1.0) is a program to calculate LCE (Life Cycle Energy), $LCCO_2$ (Life Cycle CO_2) and LCC (Life Cycle Cost) through a building life cycle in order to evaluate the environmental performance of a building, so that it allows comprehensive and quantitative assessment of the effect of $LCCO_2$ reduction. In addition, it is able to compare LCE, $LCCO_2$, LCC of buildings applied with environment-friendly techniques with those of existing non-applied buildings and to compare the effects of LCE, $LCCO_2$, LCC reduction after the application of eco techniques. The major functions of the program include calculation of LCE, $LCCO_2$, LCC through a building life cycle and comparison of environmental load values according to the application of eco construction techniques, and specifically, LCE, $LCCO_2$, LCC can be calculated by entering material volumes used for the construction of a building to be assessed, energy consumption during its operation and waste quantities at its demolition.

2.2 Assessment Method

SUSB-LCA ver. 1.0 assessed the environment load of a structure through its life cycle classified into construction, use/maintenance and removal/demolition: The stage of construction included construction material production, construction material transportation and construction work of a site, and inter-industry relations analyses were carried out to measure CO_2 released during the construction material production; The stage of use/maintenance was divided into use of a building and its maintenance stages, and it was analyzed by considering the assessment period and the life of the building, based on the annual energy consumption; And, the stage of removal/disposal was divided into removal of a structure and disposal of the removed wastes. Figure 1 is the overview of environmental load assessment for buildings, which was conducted by SUSB-LCA ver. 1.0(Shin, S.W. 2007).

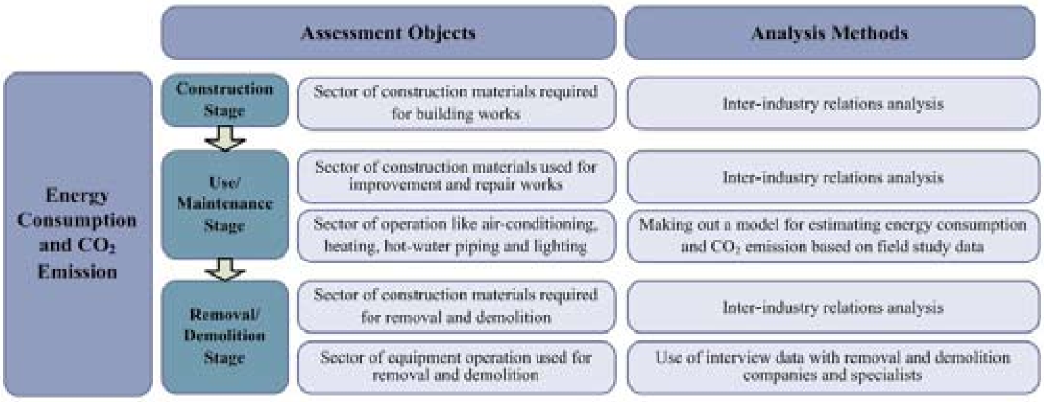

Figure 1 Environmental Load Assessment of SUSB-LCA ver.1.0

2.3 Construction Stage

The construction stage was divided into 3 sub-stages, construction material production, transportation and construction work. The production stage ranged from the time when raw materials are gathered to produce building materials to be used in the construction work stage to the time when producing building materials; The transportation stage meant the time during which produced building materials of various kinds are transported to construction sites; And, the construction work stage ranged from the starting point of construction of a first building to the completing point of construction. The construction stage was also divided into 3 kinds of works, construction work, public work and facility work, and the energy consumption and CO_2 emission were found out per work kind: The construction work included sub-works of 17 types including temporary, pile, reinforced concrete, masonry, waterproofing, tile, stone and steel works; The public work was composed of 3 types of sub-works, retaining wall and waterproof, pile, and appurtenant public works; And, the facility work included 17 sub-works including facility, piping of machine rooms and gas piping works.

The energy consumption and CO_2 emission in the stage of construction material production were calculated by applying a unit of a construction material, which was drawn by inter-industry relations analyses, to the material volume to be used for buildings. SUSB-LCA ver. 1.0 showed greater ability of data update, compared to other environment assessment programs for buildings[3], thereby allowing user's convenient update and modification of inter-industry relation analyses which were conducted in the construction material production of the construction. In addition, users were able to add or remove wanted types of construction, public and facility works and are able to select easily construction materials used in existing or newly added works to calculate their energy consumption and CO_2 emission.

2.4 Use and Maintenance Stage

In the stage of use, energy sources used for air-conditioning, lighting, cooking and so on were classified into electric, heating and gas energy when evaluating. To be specific, the heating energy was divided into district, central and individual heating in terms of heating method and into LPT, heavy oil, light oil, kerosene, and so on by heating source types, so that the emission of CO_2 was calculated by finding the use amount of the sources and inputting it to the program. SUSB-LCA ver. 1.0 presently sets up the heating type in the case of district heating as follows: LPG (65%), heavy oil (25%), incineration heat (9%) and light oil (1%). And, the ratio can be configured by users.

The energy consumption and CO_2 emission in the maintenance stage can be calculated, based on the life of a structure, by using data on repaired and replaced volumes of building materials owing to their wear-out, damage and destruction and by using breakdowns of oil and electric power used for repair and replacement works. For user's convenience, SUSB-LCA ver. 1.0 sets up the estimation basis of the energy consumption and CO_2 emission used in the maintenance stage as $6.24MJ/m^2$/year and $0.59kg\text{-}CO_2/m^2$/year, respectively. The energy consumption and CO_2 emission can be also estimated, as said above, with consumed materials, oil and electricity.

2.5 Removal and Disposal Stage

The stage of removal and disposal included removal and demolition of buildings ending their lives and transportation to handle building wastes, which means the stage ranges to the transportation of wastes generated from the removal of buildings to places for recycling or filling-up, and the recycling of building wastes was left for future consideration. The objects of analyses were materials and equipment used for the removal, and vehicles, oil and electric power required for the transportation of wastes. The stage of disposal was divided into 2 cases, loading and uploading, and the energy consumption of vehicle's returning to a waste generating place from a disposal area was assumed to be the half of the energy consumption of the loading case.

Table 1 The Classification of Environmental Load Assessment of SUSB-LCA ver. 1.0

Stage	Classification	Sub-Classification
1. Construction	1) Construction material production	① Construction work ② Public work ③ Facility work
	2) Construction material transportation	① Transportation
	3) Construction work of a site	① Construction site ② Public work ③ Gardening ④ Power consumption
2. Use/Maintenance	1) Use of a Building	① Power consumption ② Heating energy ③ City gas consumption
	2) Maintenance	① Improvement and repair stage
3. Removal/Disposal	1) Removal	① Removal
	2) Disposal	① Loading ② Returning

3. Assessment

3.1 The Overview of a Building Assessed

The building assessed was an apartment with 35 stories above ground and 3 stories below, with the total area of 14,424 ㎡, of which construction was complete in May 2004. It was a reinforced concrete structure and had a district heating system. The breakdowns showing construction materials used in the construction stage of the building and the actual energy consumption for the last year were examined to estimate $LCCO_2$. Table 2 shows the overview of the building.

Table 2 The Overview of the Building Assessed

Building Overview	· Apartment with 35-story below ground and 3-story below · RC Structure · Total Area: 14,424m^2 · Building-to-Land Ratio: 59.22%
Assessment Conditions	· Assessment Period: 60 years · Service Life: Existing Building (40 years) Environment-friendly building applied with high-strength concrete (60 years) · Heating: District Heating

3.2 Application of High-Strength Concrete

3.2.1 Overview

The building, as the object of this study, was a residential and commercial complex with 35 stories above ground and 3 stories below of RC structure, and there were total 13 buildings from A to M. Among them, the building I was selected to be applied with reinforced concrete, and the height of the building was 104.8m and that of a story was 2.9m. To compare and review the volume of concrete and reinforcing bars, only vertical structural members (Column, Wall, Core Wall, Wall Column) were considered. The compressive strength of the concrete of the vertical structural members was divided into 4 types depending on the stories, as shown in Table 3.

Table 3 Re-Design of High-Strength Concrete

	Previous Design	Re-Design of High-Strength Concrete
27～TOP	24MPa	40MPa
20～26 Stories	27MPa	40MPa
10～19 Stories	30MPa	40MPa
Basement～9 Stories	35MPa	40MPa

3.2.2 Reduction of Required Materials by the Application of High-Strength Concrete

Applying high-strength concrete of 40MPa to the stories with the compressive strength of 4 types (24, 27, 30, 35MPa), structural analyses were carried out. As a result of the analyses, the reduction ratio of concrete and reinforcing bar of the vertical members was 8.8% and 30.3%. In case converting the percentage to that of the entire concrete and reinforcing bar used for constructing the building assessed (Building I), it became 5.7% and 19.7%. The volume of concrete and reinforcing bars for reinforced concrete works of the construction work was thus reduced according to the reduction rate calculated in such a way. The reason of material cut-down is thought that the section of vertical members was decreased due to the use of high-strength concrete. In particular, the reduction rate of reinforcing bar was higher than that of concrete. On the other hand, the use of cement was increased in the case of high-strength concrete application, thereby emitting much more CO_2, compared to the case of non-high strength concrete. There have been several proposals to solve such a problem: for example, partial replacement of industrial wastes like blast furnace slag. This study thus substituted blast furnace slag for 20% of the entire cement.

And the compressive strength of this chapter, 40MPa, is the lowest limit of the compressive strengths ensuring at least 60 years of a building life in durability assessment tests for neutralization.

Table 4 The Reduction of Volume of Concrete and Reinforcing Bars by Applying High-Strength Concrete (40MPa)

		Previous Design	Design of High-Strength Con'c Application	Reduction Rate (%)
Vertical Members	Concrete(㎥)	11377.30	10374.10	8.8 ↓
	Steel (ton)	545.33	379.94	30.3 ↓
Total Members Horizontal + Vertical	Concrete(㎥)	17596.06	16589.57	5.7% ↓
	Steel (ton)	1667.94	1339.44	19.7% ↓

3.3 Results of $LCCO_2$ Assessment

Based on the breakdowns of building materials used in the construction stage of the building assessed and actual energy consumption for a year, the emission of CO_2 through a life cycle of the building including construction, use and maintenance, and removal and disposal stages, on the assumption that the life of the building is 40 years, was calculated. Then, comparing assessment results of the existing building and those of the environment-friendly building applied with high-strength concrete, the effect of $LCCO_2$ reduction was found out per stage and in the entire process.

3.3.1 CO_2 Assessment Results in the Construction Stage

Figure 3 shows the results of CO_2 calculation per stage for the assessed building applied with high-strength concrete. As shown in the figure, CO_2 emission in the construction stage of the case applied with high-strength concrete (40MPa) was reduced by nearly 4.12%, compared to the case applied with existing concrete (below 35MPa). Such an effect of CO_2 reduction is due to the decreased cross-section of vertical structural members by the application of high-strength concrete. Consequently, it shows that those techniques which can reduce building materials, like using high-strength concrete, are effective to decrease $LCCO_2$ of buildings.

In addition, high-strength concrete improves durability of buildings, so reducing maintenance costs in the operation stage. To be accurate, the aspect of maintenance should be also considered in estimating CO_2 reduction thanks to high-strength concrete, but this study purposed to assess $LCCO_2$ in terms of material reduced by using high-strength concrete, not considering effects of CO_2 reduction in the operation and disposal stages. In other words, the CO_2 emission in the operation/maintenance and removal/disposal stages was same as that of the existing case applied with non-high strength concrete (35MPa).

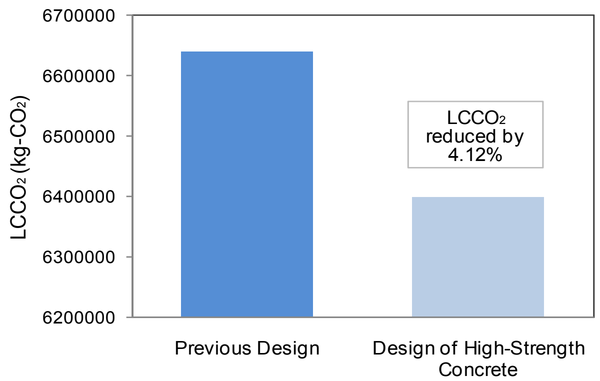

Figure 3 CO_2 Assessment Results in the Construction Stage

3.3.2 CO_2 Assessment Results through a Building Life Cycle

Figure 4 shows the results of $LCCO_2$ estimation for the assessed building applied with high-strength concrete. As shown in the figure, the $LCCO_2$ emission in the case using high-strength concrete (40MPa) was reduced by about 1.21%, compared to the case applied with existing strength concrete (below 35MPa). To be quantitative, the $LCCO_2$ emission of the 2 cases, one applied with the compressive strength below 35MPa and the other one with high-strength concrete, 40MPa, was calculated to be 22,820,631,10kg and 22,545,639.01kg. It is hoped that further assessment on environment-friendly performance of buildings will be possible through such estimation of $LCCO_2$ emission with application of new eco architecture techniques.

4. Assessment of Economical Efficiency

This study calculated the reduced volume of concrete and reinforcing bars after using high-strength concrete and evaluated effects of the reduced materials on the $LCCO_2$ emission of buildings. In this chapter, the reduced emission of carbon dioxide was converted to the present price traded in carbon exchange stations in Europe, for the purpose of assessing economical efficiency.

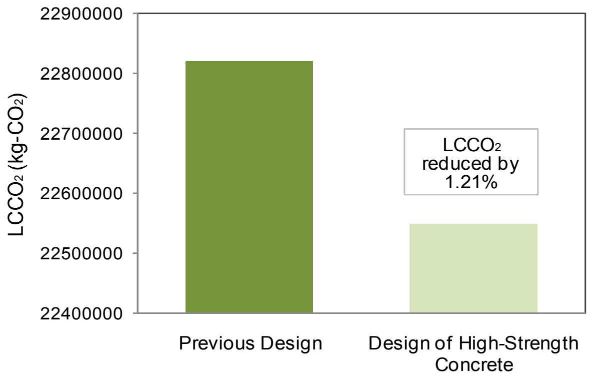

Figure 4 $LCCO_2$ Assessment Results through a Building Life Cycle

Table 5 shows the $LCCO_2$ assessment of an existing building using concrete with compressive strength below 35MPa and of a building using high-strength concrete (40MPa). As shown in the table, the $LCCO_2$ emission of the existing building and the other building was 22,820,631kg and 22,545,639kg. In case applying the reduction rate of $LCCO_2$, 1.21%, which was calculated in "3.3.2 CO_2 Assessment Results through a Building Life Cycle," the reduced volume was 274,992kg, which was found out to reach 2,760 thousand US dollars.

Table 5 Assessment of Economical Efficiency by Reduced CO_2

$LCCO_2$ Emission (kg-CO_2)	
Existing Building	22,820,631
Environment-Friendly Building	22,545,639
Reduced Volume (kg-CO_2, Reduction Rate : 1.21%)	274,992
Economical Benefits (Thousand US Dollars)	2,760

5. Conclusion

The purpose of this study was to assess effects of $LCCO_2$ reduction and economical efficiency thanks to the application of high-strength concrete, so various conditions of each stage, construction, use and maintenance, and removal and disposal, were entered to the program, SUSB-LCA ver. 1.0 and results drawn from the program were comparatively analyzed. The findings from the analysis are as follows:

1. In case using high-strength concrete (40MPa), the volume of used concrete and reinforcing bars was apparently reduced, thereby decreasing $LCCO_2$ released during the stage of construction material production. But, the higher strength concrete has, the more cement and aggregates are required. It is thus needed to design a proper mixture configuration.
2. The reduction rate of $LCCO_2$ emission of a tall building using high-strength concrete (40MPa) was 4.12% in the construction stage and 1.21% through the entire process.
3. The economic value of reduced CO_2 after using high-strength concrete in the building assessed was calculated to be 2,760 thousand dollars.
4. As this study purposed to assess $LCCO_2$ emission in terms of materials reduced by applying high-strength concrete, the effect of CO_2 reduction in the stages of operation/maintenance and removal/disposal was not taken into account. It is being, however, planned to conduct further assessment on effects of CO_2 reduction considering operation/maintenance and removal/disposal stages, for the sake of more accurate estimation of $LCCO_2$.

Keywords: Sustainable building, rating tools, Green Star, LEED, India

Summary

A number of environmental rating tools exist globally which aim to push market transformation towards a sustainable future. In 1998, the World Green Building Council was formed with the mission to create a sustainable built environment through market transformation. Tools such as LEED (Leadership in Energy and Environmental Design) in the United States and BREEAM (Building Research Establishment Environmental Assessment Method) in the UK, are seen as leaders in the development of sustainability rating tool. The Green Building Council of Australia (GBCA) launched the Green Star suite of tools in 2003. Green Star has been based, in parts, upon combining the best from both the LEED and BREEAM tools and adapting them to the Australian context.

Of the new 'tiger economies' in the Asian region, India in particular is turning her attention to lowering overall environmental impact. As a new member country to the World Green Building Council, the Indian Green Building Council (IGBC) is developing its own built environment sustainability rating tools based on LEED. The IGBC's auspicing body is the Confederation of Indian Industries (CII).

This paper investigates the development and implementation of Green Star and outlines the issues and barriers which occurred during the process. Lessons learned from the development of Green Star suite of tools in Australia are expected to help create a set of the best rating tools for India and excel the uptake of the tools in that market. The study found numerous lessons of use to CII, and indeed any other country setting up their own sustainability rating tools.

1 Introduction

The IPCC Report (2007) documents the observations of climate change and states quite clearly that the warming of the climate system is unequivocal. Adaptation and mitigation options and responses to climate change include developing policy frameworks that integrate climate change considerations into design, land use policies and building codes.

It is well documented that the building and construction industry is a major contributor to greenhouse gas emissions and landfill globally (IPCC 2007, OECD 2008). Energy efficiency of the building stock is dependent by the construction and building efficiency regulations and best practice in the market place today. In a recent report released by Mckinsey Global Institute (Bressand et al 2008), global energy demand has been expected to accelerate over the next 20 years. Most of the demand would be by the developing countries, namely, China and India.

In Australia, the operation of inefficient and poorly constructed buildings is responsible for 23% of national greenhouse gas emissions (CIE 2007), a typical figure for most developed nations. The interim report of the Garnaut Climate Change review (2008) identified an important role for Australia in establishing a realistic approach to climate change, particularly with regard to mitigation of climate change. The Garnaut Report also focused on putting in place major reductions in emissions in Australia.

This paper presents the findings of a study prepared for the Victorian Building Commission by the Centre for Design at RMIT University. The purpose of the study was to provide support to the Confederation of India Industries (CII) arising out a Memorandum of Understanding signed between the Victorian government and the Confederation of Indian Industries (CII) in 2006. CII is India's building industry body currently responsible for developing a sustainable building rating tool, based on the USA's LEED system.

Established in 2003, the GBCA has been at the forefront of green building rating tool implementation and may now offer valuable learnings to others embarking on the implementation of new building ratings schemes. A literature review combined with personal interviews with past and present GBCA executives and senior stakeholders was undertaken to provide an insight into the underpinnings of rating tool development in Australia. Among them were GBCA founding board members, present members of the Green Star Technical Advisory Group, and industry representatives. Questions were tailored around the differences between Green Star tools and LEED, approaches taken by the GBCA, establishing industry support in Australia, lessons learnt and how India could fast track its own rating tool processes from these experiences.

1.1 International Green Building Rating Tools

Sustainability rating tools are frameworks to assess sustainability of the buildings or the built environment. They are typically developed to provide guidance and incentive towards more sustainable building practice and design. They ensure minimum environmental performance, benchmark environmental performance and establish best practice. They enable a means to measure and benchmark the environmental performance of the built environment, allow comparisons of environmental performance between buildings, provide independent third party certification of the sustainability claims of a building, provide a guide and a framework for building professionals and push market transformation and encourage improvements in the sustainability of the built environment.

Tools usually provide a score, or they may provide a simple pass/fail or compliance outcome. Most scores are in the form of stars as in the case of Australia (5 star for housing), or, they may be in the form of silver/gold or platinum rating (LEED in the US).

India is still in the early stages of developing its suite of building rating tools and is currently contextualising the US LEED rating system for Indian conditions. This adaptation is important as the physical, economic, technological and social environments in India are very different from that of the US.

In recognition of the need for a centralised organisation for green building, the World Green Building Council (WGBC) was founded in 1999 by the founder of the US Green Building Council (World Green Building Council 2007). Different Green Building Councils are set up under this umbrella organisation. GBCA and IGBC have both received support from the WGBC.

It is recognised that the development of new rating tools or the application of building rating tools in different regions remains a difficult task. Lui et al (2006, p. 374) outline the following:

- Expanding numbers of tools are developed with different scopes, emphases, functions, underlying assumptions as well as limitations relating to the specific conditions in their origin regions
- Duplications and overlap of tools
- Lack of transparency and an implicit assumption about the capabilities of user groups to choose appropriately can cause uncertainty and confusion
- Conditions and requirements for developing EB tools within a specific region are multifaceted and complex
- Difficulty of customizing existing tools into specific regionally appropriate formats without avoiding their inherent problems

2 Green Star

The Australian best practice rating tool is Green Star, administered by the Green Building Council of Australia (GBCA). GBCA's aim is to assist the property industry to reduce the environmental impact of buildings and improve occupant health and productivity, while showcasing innovation in sustainable building practices (GBCA 2006).

In the first few years since GBCA's inception the focus has been to set up a suite of tools for the Australian building and construction industry, and to raise the awareness of the tools. At the time of this study (September 2007), the GBCA had over 400 members and more than 400 projects registered for accreditation.

The original template for the Green Star suite of tools was created by Sinclair Knight Merz (SKM) for the Building Research Establishment in the UK. This template began as an Australian version of BREEAM, until the Green Building Council Australia commissioned its development as a working tool, with aspects of LEED to be incorporated as appropriate. The resulting suite of tools uses the core principles and structure of BREEAM with the points and star awards of LEED, contextualised to suit the Australian building industry environment.

The decision to develop a new rating tool system rather than adopt LEED or BREEAM in their original format was made for a number of reasons. At the time of Green Star's development, BREEAM and LEED were 10 and 5 years old respectively, and as such, an update was considered warranted by the Green Star development team. When reviewing the rating tools, the GBCA also formed the view that a single rating tool cannot adequately address all building types, and that a suite of tools adapted for different buildings within the Australian context would be more suitable.

2.1 The Structure of Green Star

In Green Star, the lowest denominator is points, groups of which form credits. Groups of credits form categories. Similar to BREEAM, the category score weighting system ensures that alterations to individual credits do not result in a change in the overall influence of its category. In other words, adding another credit item, or increasing the number of points a credit is worth within a category, will not affect the overall impact of that category in the overall score.

This feature enables variation of the tool across different Australian states. This is an important consideration in Australia where local climatic and environmental conditions can vary significantly across the country. This feature is not included in the LEED tool, but its importance is recognised and the USGBC are currently developing a bioregional weighting system to address this.

The design of the Green Star tool, its categories, and weightings have been developed by referring to the BREEAM and LEED models, with extensive consideration to a variety of scientific and stakeholder input. Table 1 shows the approximate weighting of each Green Star Category as it compares to LEED and BREEAM. The data demonstrates that the Green Star category weightings are more closely aligned to BREEAM than LEED.

Table 1: Comparison of Building Assessment Tool Category Ratings

Category	LEED	BREEAM	Green Star
Management	7	15	10
IEQ	22	15	17
Energy	24	12.5	20
Transport	6	12.5	9
Water	7	5	9
Materials	16	10	16
Ecology	13	15	12
Emissions	4	15	7
Total	99%	100%	100%

(Shown as a percentage of total allocated points)

Data source: Green Star Office Design V2 Technical Manual (GBCA 2006)

2.2 Technical Content Development Process

New rating tools are developed and existing tools revised over time in response to changes in market demands and specific requests from industry. Each new tool or revision is developed involving contribution from industry experts and stakeholders.

The process for developing a new tool, shown in Figure 1, commences with a 16-week period of review and development by a Technical Working Group, comprising of industry representatives. Once the GBCA complete the draft, it is released for stakeholder feedback before a Pilot revision is implemented.

The process of revising a tool is illustrated in Figure 2. Industry working groups are involved in the revisions, and Green Star applicants are invited to provide feedback throughout the process, ensuring that major stakeholders are consulted. Tool revisions also incorporate technical clarifications from the previous revisions[1].

3 The Accreditation Process

Compiling the documentation for a Green Star submission is a time consuming and thus costly task for the applicant. Once submitted, up to four GBCA Assessors review the submission. Where the documentation for applied credits is not met, applicants are given the opportunity for one re-submission, which is again reviewed by the GBCA Assessors. The process of accreditation is also time consuming and costly for the GBCA.

In hindsight, it may have been possible to reduce the level of documentation required in the development of the tool, but this holds the risk of compromising the quality of the final assessment. It has been suggested that the initial review could be done in-house with the assistant of a Green Star Assessor. This holds the advantage of having direct access to the project knowledge, so that issues encountered in interpreting the technical documents, and insufficient documentation, may be addressed prior to submission to the GBCA, reducing the GBCA's workload. An online user interface could also be considered to lessen this resource demand.

4 The Green Star Tools

It was recognised in the early stages of Green Star development that the design, construction, and ongoing operation phases of building life should be addressed within the suite of tools. Three different assessment tools: Office Design, As Built, and Existing were created to address this.

The documentation required to achieve a Green Star Office Design rating is arguably less rigorous than that required for Green Star Office As Built, and it can be easier to prove the intention of a project than it is to actually complete it as per its original intent. It is also often difficult to gather documentation from project participants after the project is finished. The GBCA recognise this and take the stance that the Green Star As Built rating is more prestigious than the Design rating. Unfortunately the difference between a Design and an As-Built accreditation is not widely recognised in the market. One of the positive outcomes of enabling a Green Star Office Design rating is that it may be achieved in time for development approval, and this has been adopted by some government departments as conditions for development of their own assets.

The Green Star Office Existing rating tool has recently been added to the suite and is designed to address building ownership and operation, in response to the recognised need to improve asset performance. The Green Star Office Existing tool remains focused on the physical features of the building, not the ongoing performance as is assessed under other rating tools such as AGBR and NABERS[2]. In this manner, Green Star remains distinct from and complimentary to these other tools.

5 Green Star Implementation

5.1 Industry Support

It was recognised that the support of industry is essential in the acceptance and subsequently the success of Green Star. To gain this support, industry was continually consulted and represented in all stages of Green Star development.

Importantly, private developers were involved in the early stages, and some of the largest property groups used the tool in pilot projects across the country. This was done in recognition that the key influences within the industry were these property developers themselves, and industry support was unlikely to happen if the tool is developed in isolation and without their involvement. Government groups have also been key supporters of the GBCA and continue to be involved in the GBCA through participation in Technical Working groups. However, there is also a recognised balance in the involvement of industry, government, and private company representatives. Whilst the contribution of each of these groups is valuable, care must be taken to ensure that individual agendas do not hijack the process or outcome.

---

[1] During the assessment process, it is sometimes evident that a project meets the intent of that credit but not in the manner outlayed by the credit criteria. In this case the applicant may submit a Credit Interpretation Request (CIR), which is reviewed by the GBCA Assessor and if accepted is published as a Technical Clarification, setting precedent for other applicants.

[2] ABGR and NABERS are Australian rating tools that measure building performance.

Figure 1: New Green Star Tool Development

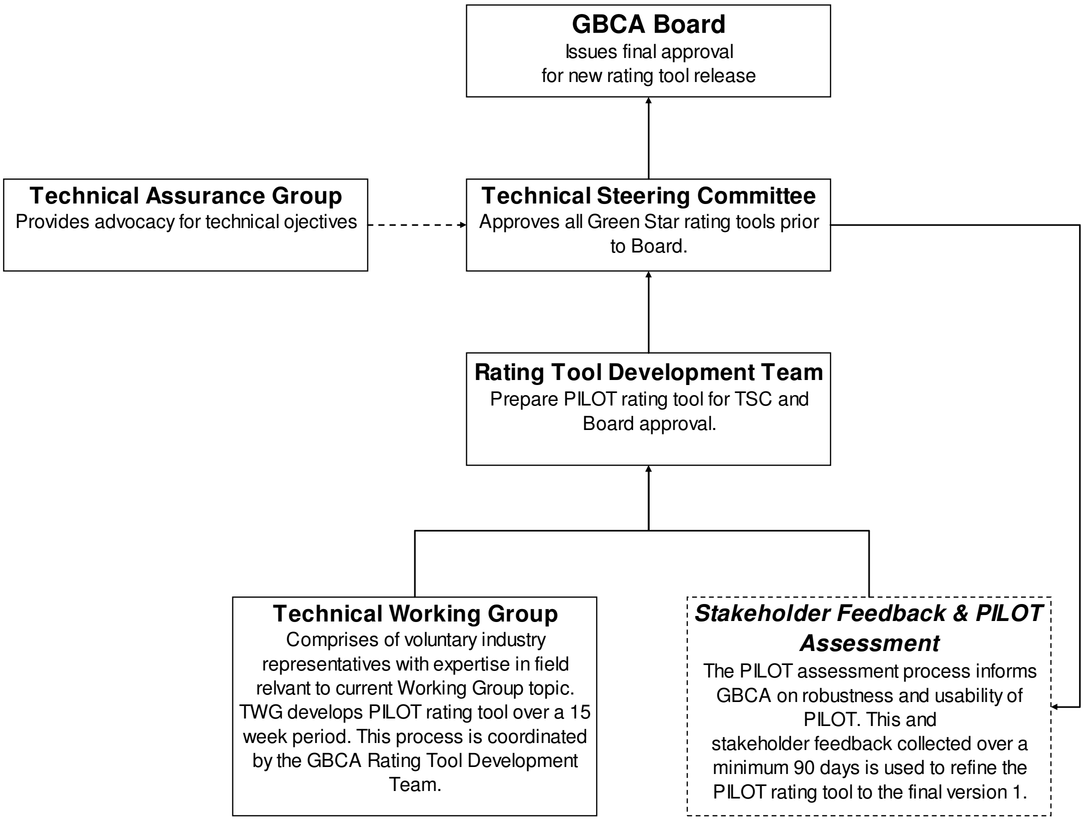

Figure 2: Green Star Tool Revision Process

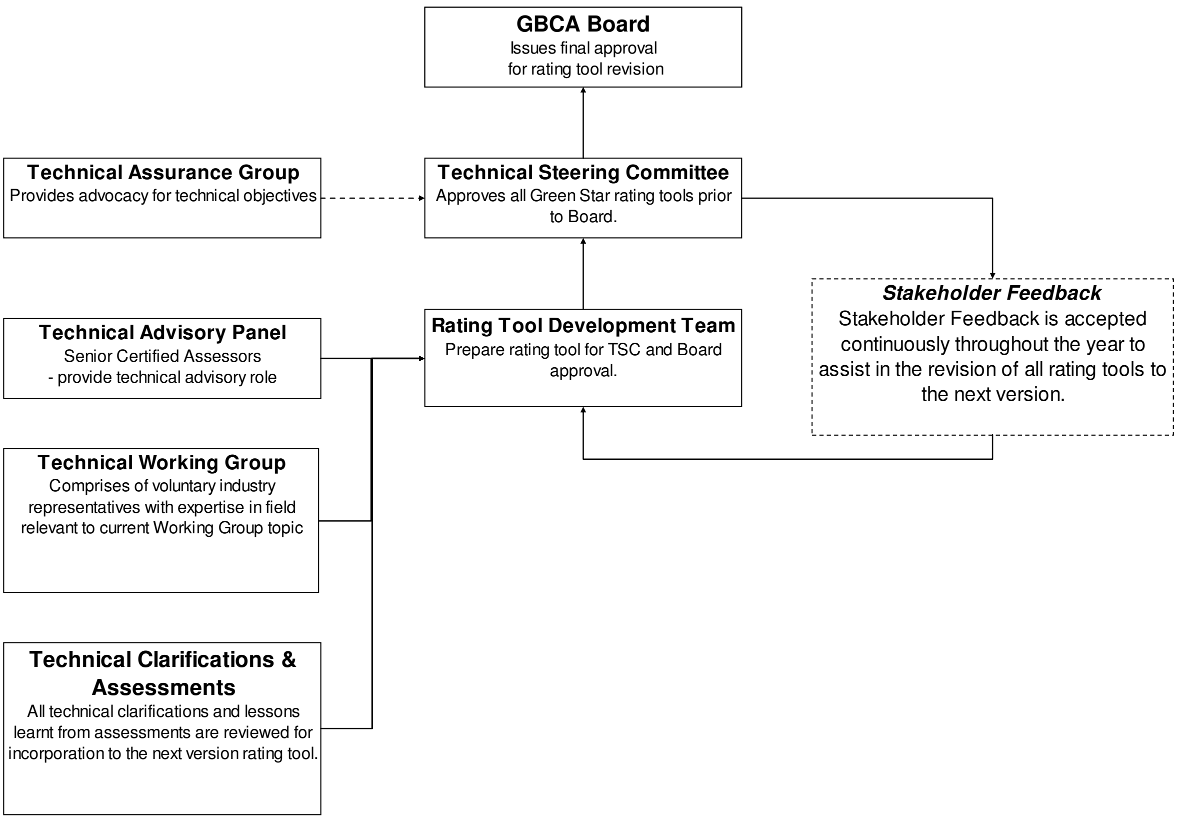

5.2 Market Uptake

The market uptake of Green Star in Australia was relatively smooth, largely because there was already recognition in the marketplace that a structured set of guidelines were needed to drive changes in the industry. Industry involvement and government support also assisted the process. A quick and comprehensive campaign to increase market awareness of the tool by presentations through conferences and other means of general industry education also greatly enhanced the rate of uptake.

One of the barriers to incorporating green building objectives into building projects has been the perception that green buildings are costly. This perception has shifted somewhat in the past few years with the increased availability of local examples where a business case can or has been demonstrated.

The availability of technical expertise at the commencement of the development program has also been identified as important in rolling the tools out in the market. While, there must be a strong base of technical knowledge behind the tool development, there also needs to be sufficient technical support available to those using Green Star for the first time.

6 Current Challenges for Green Star

6.1 Tool Revisions and Streamlining of the Green Star Suite of Tools

There is concern over the number of Green Star rating tools and there is a perceived need to streamline the suite. The US LEED model avoids having a multitude of different rating tools by flexibility in how the criteria are applied, so that many types of buildings can be assessed with the same tool. However, recently the US Green Building Council has recognised that this approach can lead to confusion, and is in the process of developing a guide to show applicants how to use the tool for different building types. With the current proliferation of tools at the GBCA, care needs to be taken that the distinction between them is maintained, particularly when it comes to Design/As Built/Existing ratings of buildings of the same class.

It is also important that as the Green Star tools are revised and fine-tuned over time. The release of new tools and revisions needs to be done in a timely manner so that people are not waiting for impending releases that are continually delayed. It is acknowledged though that as sustainable technology and practice become efficient and widespread, rating tools will need to change accordingly to reflect changes in the industry.

6.2 GBCA Strategic Direction

A common theme of recent climate change studies has been the building and construction industry's contribution to greenhouse gas emissions. The Green Star approach for reducing environmental impact through all stages of construction may position property well around the objective of meeting carbon-neutrality targets in response to climate change initiatives. It is appropriate that the GBCA determines its direction and role in this process.

There are also a number of other building performance rating tools in use in Australia to address operational performance of commercial buildings, and the residential industry. It is important that the GBCA maintains and continues to clarify the distinction between Green Star and other rating schemes, and works to maintain the synergy between the different schemes. The GBCA's position as an industry leader needs to be maintained.

The Green Star rating tools are currently targeted at the top 25% of buildings, and as such are aimed at best practice. In the past few months there has been increasing focus on the performance of existing building stock in cities, and various national and international groups are preparing to take on this issue. The GBCA are now facing the challenge of finding an effective way to expand Green Star for application on a much broader scale.

6.3 Resources

The GBCA's workload increased dramatically in 2007 following the announcement of new revisions of the Green Star Office rating tools. As Green Star becomes increasingly recognised in the Australian market, resourcing demands will continue to be an issue for the GBCA.

Resources are required in the areas of technical assistance and training, and as described in Section 3, the accreditation process is also demanding on the GBCA's time. The accreditation process must strike a balance between managing the legal and reputational risk of certifying projects that do not meet the requirements, and the resources required for the thorough interrogation currently demanded in the certification process.

7 Summary of Lessons Learnt

It is anticipated that the lessons learnt by the GBCA will be of use to CII and other Green Building Councils in the development of tools. The lessons identified throughout are listed below. They are not arranged into any order of significance.

7.1 Establish the Rating Tools Governing Body within the Marketplace

1. Establish connections and support from key industry and government groups early, and involve them in the creation of the Rating Tools and development of CII internal protocol.
2. Whilst developing the industry associations, be selective – avoid groups who may seek to 'hijack' the process to suit their own agendas.
3. Work quickly in the initial awareness campaign. Implement a quick and comprehensive campaign through conferences, industry education activities, and other means of general industry education. This can greatly enhance the rate of uptake and acceptance of the tool.
4. Prepare examples of the business case green buildings, with local examples where possible.
5. Work with and promote the building industry's need for green building practice.
6. The uptake may seem to start slowly, but be prepared for it to gather momentum quickly.

7.2 Protect the Brand

7. Ensure suitable legal protection to deal with unsuccessful submissions.
8. Ensure all appropriate copywriting and trademarking is in place, and regulate false advertising to protect the brand.
9. Be mindful of the need to differentiate the ratings, so that the variation between rating types is understood in the wider community.

7.3 Technical Adaptation of the Rating Tool for India

10. Consider the differences in conditions between the US and India, and make allowances to adapt the tool for local climatic, social, government, and other regional conditions that can influence the relative impact of building activities.
11. Consider a means for future adaptation to be built into the tool as regional building impact conditions change; such as a category weighting system.
12. Find a suitable balance in the level of documentation required to prove a case. Too much will be labour intensive and will discourage uptake, but it must be comprehensive enough to maintain the quality of the assessment and the brand.

7.4 Benchmarking

13. Be certain that the benchmarks for final ratings are reflective of the current building industry in India and are positioned to drive positive change.
14. Check benchmarking for individual categories and credits.
15. Consider the recognition of third party certification. This can greatly reduce the assessment workload, but care must be taken to maintain the standards (and protect the brand) of the rating tool.

7.5 Ongoing Technical Development of the Rating Tool

16. Develop a process for updating and adding to the proposed tool early. As a minimum it needs to:
    - Capture feedback from rating tool users;
    - Be thorough in its assessment technical detail;
    - Be implemented in a timely and efficient manner;
    - Engage stakeholders throughout the process.
17. Consider adaptations of the tool for different applications, whether it be to address different phases of the building lifecycle, or different types of buildings. However, ensure that this does not lead to the release of too many tools, causing confusion in the market.

7.6 Resources and Training

18. Ensure there is efficient and effective training available. Allocate resources to this as education will greatly enhance the rate of uptake and reduce future technical advisory resource requirements.
19. Develop additional resources online and in any other suitable means to reduce technical advisory workload at the CII.
20. Engage sufficient technical expertise early to ensure that as many issues are addressed in the development phase as is possible.
21. Anticipate a rapid uptake in the future, and if possible prepare extra staff to administrate the tool as demand increases.
22. Consider alternative options for assessments. This includes initial assessments in-house, external outsourcing and online or otherwise automated user interface.

8 Conclusion

This project set out to review and document the learnings of the Green Star rating tools developed and implemented by the GBCA. These lessons have been particularly analysed for the Indian context, however, these lessons can be applied to the development of suitable tools in other countries.

Literature reviews, primarily through desk research and interviews with key persons involved in the inception of Green Building Council and the development of the Green Star suite of tools were undertaken. It is anticipated that CII will be able to 'fast track' their tool development, documentation and processes.

In terms of its strategic role, the GBCA fulfils a need in the market place by nudging innovation and being the industry leader for best practice in building design and construction in Australia. A challenge that GBCA faces is meeting industry expectations in the development and constant finetuning of its tools in the face of sustainability challenges and technological advancement.

Lessons learnt include the setting up of appropriate governing structures with transparent feedback mechanisms from industry, ensuring there are appropriate procedures for protecting the brand, adaptation of tools sensitive to the cultural, climatic, government and industry structures in India, benchmarking to set baseline standards and directions for tool development into the future, appropriate technical support and communication structures to assist in tool development. Training and education to assist and enhance the rate of uptake of tools also need to be considered in parallel.

Keywords: building, office, exemplary, neutral, zero, emissions, methodology, Australia,

Summary

The ultimate goal for an office building is 'net balance carbon neutral', not only in operation but over its whole life cycle. Internationally there are a number of projects, legal frameworks, rating systems and projects pursuing this target. In the Australian context 'Towards Zero' has derived definitions, processes, technologies, strategies and an exemplary design in this pursuit. The team defined the project within a typical urban context and identified factors required to approach zero net emissions. A methodology was developed to implement leading architectural and engineering solutions in an integrated process taking into account that modern developers, owners and tenants understand the significant implications of a healthy and sustainable working environment on staff and corporate reporting. An exemplary design was developed for a typical Melbourne CBD site to prove that pioneering sustainable design can be successfully integrated architecturally. Each team member has been implementing the gained knowledge into their organisations educating respective staff and clients thereby producing more informed projects. Finally, recent advances and remaining challenges in the industry are identified.

1. Context

The project originated early in 2006 when the first office (base) buildings in Australia achieved the highest 6-Star Green Star (equivalent to L.E.E.D. in the US) Office Design V.2 rating by the Green Building Council of Australia. Investa Property Group, Spowers Architects and Connell Wagner Engineers looked at the 'next step' in the energy category i.e. a development's carbon-equivalent net neutrality, a concept that was already being pursued by projects internationally on mostly smaller scales. The client converted this idea into a project brief to:

- derive a methodology to identify key factors and processes to approximate zero net emissions in a typical Australian context,
- produce an exemplary concept design for a 45,000 m2 GFA (Gross Floor Area) office building on a site to be chosen in the Melbourne, Australia applying the generic methodology and
- inform and enhance the practices of all parties involved for their projects across the board.

For developments of this scale it is typical in Australia for developers to invest in a speculative proposal and adapt and finalize the design when a large scale tenant is signed up. After the initial lease the building is likely to have to accommodate a very different kind of tenant with different requirements.

Concrete Government emission targets with financial incentives for the property industry for significantly reducing its emissions footprint were not in sight during the project. Energy prices compared to developed world standards were very cheap while Australia generates some of the world's highest CO_2-e emissions per capita due to a large portion of brown coal fired power generation. Incentives through the short to medium running cost savings alone were low while respective public funding for respective research and demonstration is still minimal.

Only recently significant emission reduction targets have been promised within the framework of the Bali negotiations. The importance of raised building standards and building upgrades has been identified as a cost efficient key factor (Liana Downey et al 2008, and IPCC, Working Group III, Technical Summary, 2007) in the Australian climate change mitigation efforts where buildings account for 23% of national emissions (Centre for International Economics 2007).

2. Methodology

2.1 Definition of Zero Net Emissions

CO2-e (Carbon Dioxide equivalent) emissions of a building development are often only understood as operational emissions. For a more accurate net balance neutral view however the project team proposed the following aspects to be incorporated into the overall equation.

- Embodied energy/emissions through the construction process and materials
- Operational energy/emissions over the life time of the building
- Embodied energy/emissions through renovation cycle processes and materials (base building, fit-outs)
- Embodied energy/emissions through demolition and reuse/recycling/disposal processes

Other emissions such as sewage, waste, noise etc were not the prime focus of this project as the respective aspects are covered by the holistic approach of the Green Star rating system which was used as a complementary methodology using the highest (6-Star) rating of Green Star Office Design V.2 as target.

It is apparent that in order to speak of a true zero-net emissions building/development these emission 'handicaps' have to be compensated through an operational negative emissions or regenerative performance to a degree that the net emissions balance at the end of the anticipated life span is indeed zero. This also means that if the development exceeds the anticipated life span it becomes a 'positive' contributor to the public emissions balance.

The above is of course a simplification to illustrate the definition. In reality advancements in technology are likely to alter operational balance through a renovation/retrofitting cycle.

2.2 Generic Design Principles

The project team looked at key factors that affect the life cycle net emissions balance of the building. The scope focused largely on the architectural analysis with services and power generation complementing the strategies generically.

2.2.1 Base Assumptions

The following base assumptions were derived in order to optimize the scheme's passive properties:

Table 1 Generic Base Assumptions

<table>
<tr><td></td><td>A. Overall Building</td><td>B. Base Building Common Areas</td></tr>
<tr><td>Strategy</td><td>Daylight Optimisation</td><td>Daylight Optimisation + Natural/Mixed Mode Ventilation</td></tr>
<tr><td>Benefit</td><td>1. reduced artificial lighting energy use
2. reduced heat gains from artificial lighting
3. improved amenity, health and productivity</td><td>as per A plus
4. reduced energy consumption fans, chillers
5. interaction with outdoor climate</td></tr>
<tr><td>Design Guideline</td><td></td><td></td></tr>
<tr><td></td><td></td><td>Note 1: Natural/Mixed mode ventilation for the tenancy areas of this high-rise development was not factored into the base assumptions as comprehensive and tested double façade elements were considered capital-cost-prohibitive at the time as the Melbourne market returned significantly lower yields (up to AUD 400/m2NLA) than eg Sydney (up to AUD 1,200/m2 NLA).

Note 2: The Australian Building Codes do not regulate a maximum distance from view glazing or minimum daylight level/factor for work spaces.</td></tr>
</table>

2.2.2 Development of a Matrix of Building Typologies vs. Key Base Assumptions

Based on the brief of 45,000m2 GFA Spowers developed site-independent architectural typologies. These consist of towers, slabs, spine-wing and atrium types. They are further broken down into various subtypes with different organizations of common areas vs. office space complying with BCA egress requirements. The developed types (which do not yet represent actual building shapes) were then assessed generically against the base assumptions.

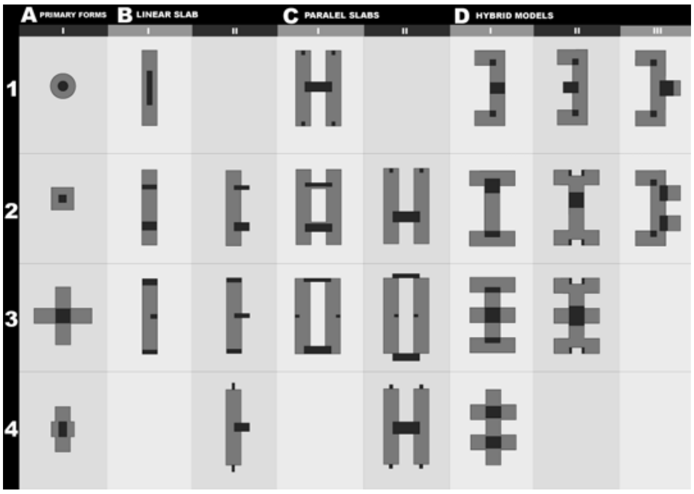

Figure 1 Extract from Generic Typology

	D1 (II)	D2 (II)	D3 (II)
Prefered Orientation	North/South	North/South	North/South
Optimum Site Dimensions	90m x 54m	90m x 54m	90m x 54m
Number of Floors Required	16	15	12
Gross Floor Area (GFA)	2592sqm	2748sqm	3396sqm
Nett Lettable Area (NLA)	2206sqm	2340sqm	2898sqm
Floor Efficiency	85%	85%	85%
Wall to Floor Ratio	58%	66%	53%
DAYLIGHTING			
Office 6m from Window	>60%	>60%	>60%

Figure 2 Extract from Analysis

2.2.3 Generic Building Section Based on Key Assumptions and Integrated Energy/Services Concept.

From the base parameters and typologies high-rise generic building sections were developed. These incorporated an 18m deep typical floor plate to allow not only for daylight/ventilation optimisation but also represented a framework for required flexible, large (> 2,000 m2) sub-dividable tenant floor plate organisation types. The typical section incorporates optimising strategies including daylight/artificial light, potential for cross-ventilation and efficient air handling and thermal mass utilisation. The floor plates can be connected vertically to facilitate communication, break-out spaces and vertical travel energy savings. Based on the generic architectural strategies engineering solutions were developed that included options for central/floor-by-floor air handling, on-site/off-site power generation, ground-air heat exchange and utilising thermal mass to balance the building.

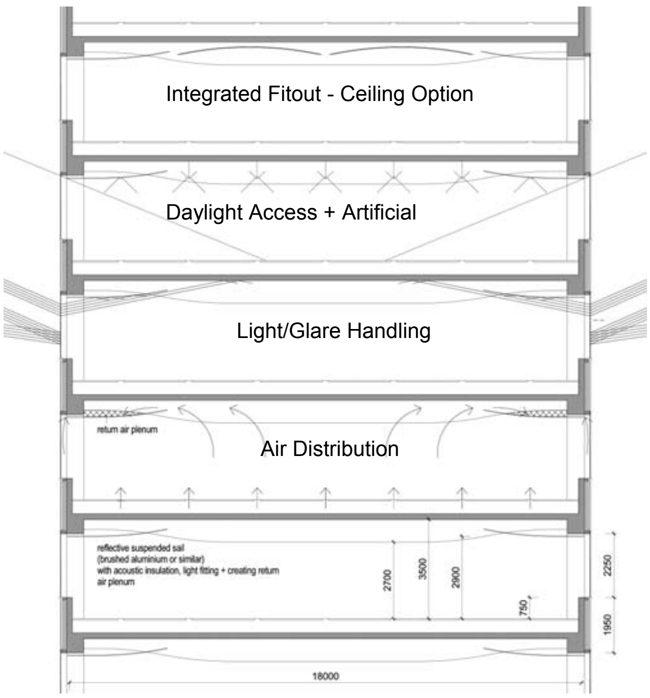

Figure 3 Generic Architectural Concept Section

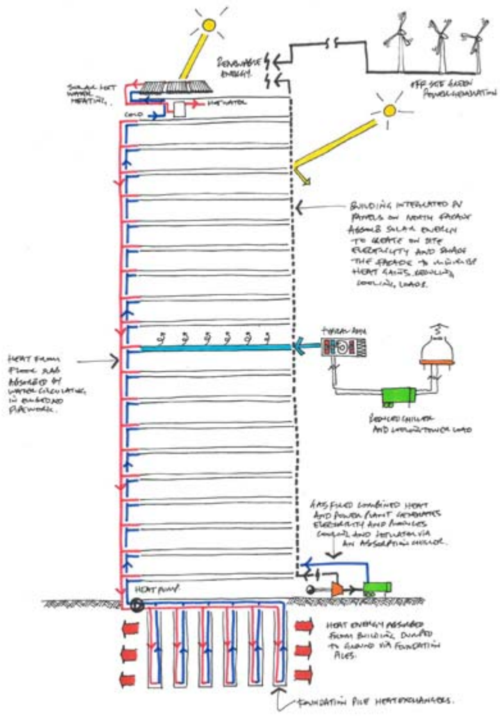

Figure 4 Generic Engineering Concept

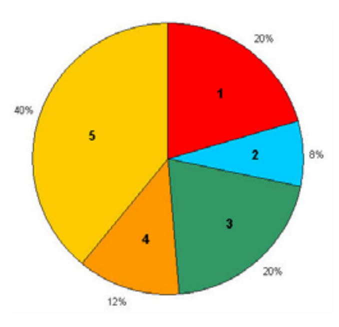
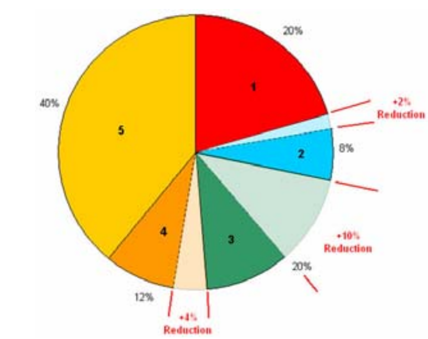
2.2.4 Base Building Load reduction Using the Australian Building Greenhouse Rating Methodology (ABGR)

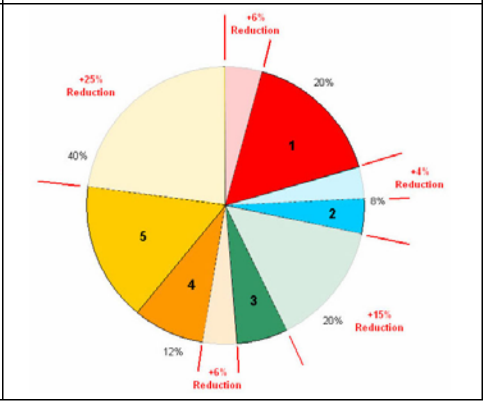
Base case for assessing the building's emissions balance was a projected ABGR rating of 4.5 Stars (116kgCO2e/m2) which represents a typical good practice large tenant brief. The following graph illustrates the incremental improvement through commercially viable and readily available (in Australia) technology. Note: The State of Victoria uses mainly CO2-intense brown coal for power generation which gets factored into the ABGR rating. Thus buildings in this state need to work harder for the same rating.

Table 2 Emissions Improvement Using ABGR Rating Methodology

.

4.5 STARS: 116 kgCO2e/m2 base case	**5.0 STARS:** 101 kgCO2e/m2 **(- 16%**	**5.0 STARS + 40%:** 61 kgCO2e/m2 **(- 56%)**
Variable Air Volume system 1 Boiler Energy 2 Chiller Energy 3 Fan Energy 4 Central Plant Pump Energy 5 Base Building Lighting & Small Power	10% Underfloor air distribution (UAD) 2% Improve chilling plant 4% Reduce pump energy	15% highly optimised UAD 4% Improve chilling plant 6% Reduce pump energy 25% Improved building light and power, open car park deck, naturally lit public spaces 6% Heating plant - condensing boiler
		






Further load reduction needs to look at strategies, technologies and synergies that have not been adapted to the Australian/Victorian environmental and commercial large scale context such as

- Space saving super insulation such as vacuum insulation and triple/vacuum glazing
- Comprehensive façade systems allowing high-rise natural ventilation and resulting load reduction
- High-rise daylight re-direction systems that minimise artificial lighting cooling requirements
- Large scale ground-hydronic heat exchange systems or phase change material storage (performance data from the Australian-first CH2 project was not available yet)
- Large scale hydronic slab activation (when tenant is not known at early design stage the option of exposed/activated elements can not be guaranteed within the overall ESD strategy of the building.)

The following options were studied and to be incorporated with the tenant on board to ensure acceptability.

2.2.5 Co-Generation

A conventional natural gas co- and tri-generation plant is a typical leading technology for minimising CO2e emissions even to reach the highest Green Star Office Design V.2 rating. However, it is logical that in order to achieve a net zero CO2e emissions balance (even just on an operational base) needs to incorporate some form of renewable power generation. The crucial question here is generation on-site vs off-site (including the question of green power top up).

A number of on-site options (including Photovoltaic systems, integrated or mounted, Wind Turbines and Bio Fuel) were considered and compared to regenerative off-site options (Wind, Solar, Bio fuel) as well as investment into 3rd party companies (Wind, Solar, Bio Fuel, 'Clean Coal', Geothermal) to demonstrate the principal implications for the client.

To illustrate the issue the following sample calculation and comparison between building-integrated PV cells and off-site sun-tracking solar dishes with a single PV cell was conducted:

Table 3 Sample Calculation Building Integrated Conventional PV Modules vs. Heliostat Concentrator PV System Off-Site in Optimal Solar Location

Resulting building electric energy demand: 50 kWh/m2, year x NLA 35,000m2 = **1,750,000 kWh/year**		
Location	ON-SITE - Melbourne	OFF-SITE - Mildura (North West Victoria)
BCA Climate Zone	Zone 6	Zone 4
Mean dayly Solar Radiation	4.94 kWh/m2, day	6.1 kWh/m2, day
PV efficiency	12% (flat panel, nominal, eg BP4170)	19% efficiency (heliostat concentrator photovoltaic sun-tracking dish w. single PV cell, nominal eg Solar Systems)
Electr.generation/m2, a	218.87 kWh (fixed angle unobstructed)	423 kWh (sun-tracking)
PV area required	7,995 m2	4,137 m2
Panels/Dishes required	6,352 Panels (á 1.26m2)	32 dishes (á130m2)

While the calculation shows a nearly double efficiency for the large scale sun-tracking dishes in a sunnier climate the advantages of an on-site solution include direct usability, less grid-loss and infrastructure, potential provision of uninterrupted power supply to tenants, local peak reduction, potential elimination of building cladding materials, visibility and marketability must be considered. These issues are mostly the client's decisions and are important for the integrity of the project's philosophy.

2.2.6 Good Architecture

As the embodied energy/emissions in buildings represent a significant portion of their life cycle net-emissions balance it is important to ensure that the building is

- Attractive and flexible to maintain its appeal to tenants/users through changing requirements
- Efficient, to optimise (not maximise) the actual use of the building i.e. number of work stations, formal/informal meeting spaces and amenity rather than merely m2 NLA thus fostering a healthy and productive work environment.
- User-robust, well-aging and up-gradable to allow efficient refurbishment, disassembly and renewal as well as efficient and flexible services upgrades

For a successful design and construction process and feasible outcomes it was identified as important to integrate optimal building's passive properties with the most efficient complementary systems thereby maximising synergies to allow efficiency (elimination/down-sizing) of systems and plant space while optimising amenity.

3. Design

3.1 Brief

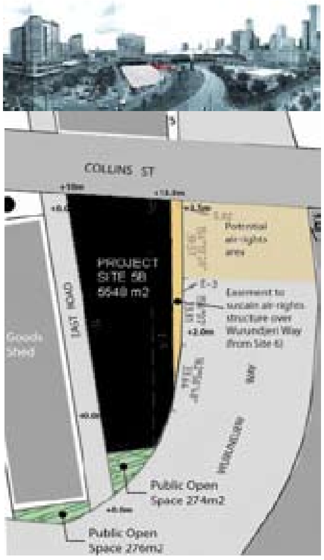
The building to be developed was to be of premium grade, incorporate 45,000 m2 GFA of largely column free, >2,000m2 NLA floor plates at >85% efficiency, with an optimum ratio of compactness vs. daylight/ventilation access. While it was to fulfil all base assumptions it was not necessarily to be ESD branded, i.e. with purposely visible features.

The speculative site was chosen in the Melbourne Docklands (Site 5B) immediately adjacent to the Western CBD. With its long sites East and West this only partially obstructed site does not have perfect solar access which was consciously accepted as it represented typical rather than ideal inner city conditions.

The generic typology overlay and analysis vs base criteria resulted in three applicable types a combination of which was chosen as actual base for the architectural design process.

3.2 Specific Concept Design

Solar and wind studies were undertaken to analyse the site's access to sun, daylight and breezes to further inform the footprint. Urban and architectural considerations of frontages and volumetric composition led to the modification of the building's typology into an actual shape.



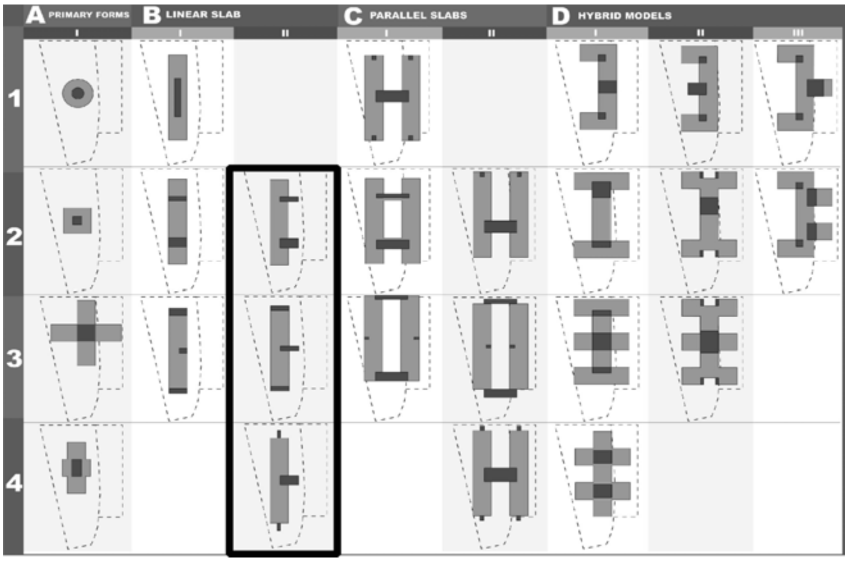


Figure 5 Site Location *Figure 6 Layout and Typology Overlay/*

Figure 7 Floor Plate Evolution

The concept design features East/West facing screens that modify the climate in terms of daylight, thermal radiation, acoustic shielding and air flow. These dominate the architectural presence and are broken up by multi-floor break-out spaces/sky gardens which indicatively show how typical floor plates can be connected and broken up to produce an interesting 3-D working landscape. These spaces can be naturally ventilated, operate at a wider temperature band and be used for informal meetings, as a casual work environment or for functions etc. The overall break-up into two major volumes facilitates marketability with potentially two addresses/foyers and easy floor plate sub-divisions.

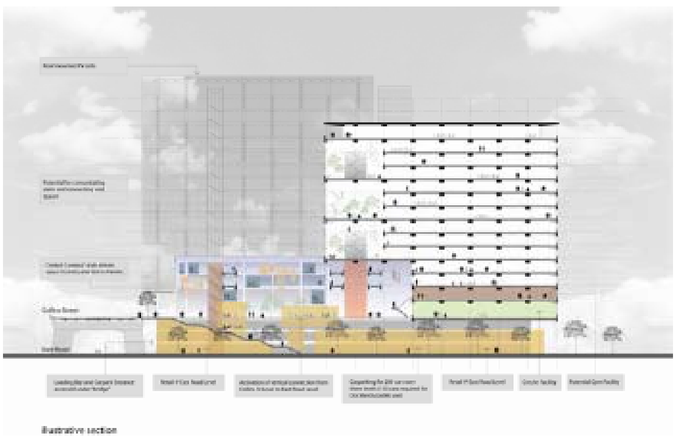

Figure 8 Artist's Impression (Collins St. View) *Figure 9 Exemplary Section*

4. CONCLUSIONS

4.1 Project General

To achieve zero net emissions over the entire life cycle of a project is an aspirational target that represents world's best practice. Strategies and technologies exist to realise this objective. A series of challenges have been identified for an Australian CBD context:

- Density, i.e. the access to sufficient renewable energy sources in a high-rise, dense urban environment
- Supply chain for innovative high-efficiency solutions including multiple suppliers
- Advanced façade engineering, component supply and respective warranties
- Yield structure in Melbourne which is low in Australian comparison.

The way forward can be facilitated through:

- factoring buildings efficiency in to the Australian carbon trading scheme
- comprehensive and future oriented valuation of high-efficiency buildings.

An informed and integrated inception and design process by an innovative design team is a pre-requisite to break through barriers of common practice in all fields of consulting, technical as well administrative and financial. Power generation and management concepts are important to consider early on. In particular, precinct-wide solutions as further investigated by members of the project team promise economies of scale and synergies that significantly improve the viability of pursuing a zero-net-emissions target. Furthermore the supply chain needs to be encouraged to connect to internationally leading technologies and innovation.

4.2 Industry Changes

Since the completion of the study mid-2006 significant developments have occurred. The Green Building Council has embraced (operational base building) CO-e net neutrality as the highest rating within the energy component of the Green Star Design V.3 rating tool. The change of government has effected the ratification of the Kyoto protocol and promised to install a carbon trading system by 2010. The current discussion (03/2008) in the industry revolves around how to account for buildings in the carbon market as it is widely recognized that an up-grading of the building stock is amongst the most effective ways of emission reduction. Tenant demand/awareness has improved and more case studies with new technologies have come on-line.

4.3 Property Development Effects

Generating power is a fairly new part of project development and facility management in Australia. Strategies should be devised early on in a project as this affects the capital cost expenditure, valuation, design, ownership and maintenance/operational aspects of the facility. Multiple options range from 3rd party contracting through specialised companies to developer-investment, ownership and operation.

In the development context of this project bringing the tenant on board of the zero strategy is crucial. Green Leases and contractual arrangements to fairly share costs and benefits between developer, owner and occupier are essential. There may be a tenant education process involved to ensure they understand and value the significance over the term of the lease regarding staff procurement and productivity, corporate sustainability reporting and the eminent effects of factoring the CO2-e emission balance into the electrical power equation.

One of the most important learning experiences from 'Towards Zero' has been the value of taking an intellectual approach to the conception and development of major commercial office buildings.

Using the backdrop of a proposed new tower at 1 Richard Johnson Square, Sydney, Investa gathered its project team to examine how this new building could minimise its carbon footprint. This was achieved via a presentation on 'Towards Zero' demonstrating the thought processes which were applied. All project consultants were asked to consider evolving new technologies in building design and materials, how they impacted on other aspects of the development and how they could each collectively contribute to producing a world class premium asset.

Key factors considered were; the proposed building's typography and position in the Sydney CBD, advances in glazing technology, on-site power generation and water recycling and mechanical services innovations.

As it was found in the initial 'Towards Zero' study, the zero emissions target may be elusive; however, it is achievable. But 'Towards Zero' is more than simply identifying green and greener innovations, it is an attempt to marry the goal of zero emissions with design excellence, ever increasing tenant demands and the need for commercially acceptable terms. No element was blindly pursued in isolation of other elements. This synergistic approach has lead to a more cohesive outcome.

Furthermore this project has been used as process and design model to educate staff. This has led to better comprehension of project briefings and design processes needed to facilitate optimal outcomes.

4.4 Engineering Effects

The methodology which was developed is considered to be readily applicable to projects which seek to achieve net zero emission outcomes for both new and existing buildings which will become increasingly important in a carbon constructed world.

The principles of minimising the energy usage in commercial buildings through the application of good passive solar design and the design of energy efficient lighting and air conditioning systems are well known. The challenge in a zero energy commercial building is to optimise the application of these principles without compromising the requirements of the building to accommodate contemporary workplace layouts which are sought by companies in Australia i.e. large floor plates with minimal columns.

'Towards Zero' has balanced the requirements to optimise daylight and views with the need to deliver these large flexible floor plates.

Once the passive and active elements of the building have been optimised to reduce the energy usage (and resultant green house emissions), the greatest current challenge is to cost effectively provide the energy required for a high rise building using renewable energy sources. There are technical challenges such as the availability of north facing facades and roof areas for photovoltaic cells and the ability to locate wind turbines on respective commercial office buildings in the city. The financial challenges become easier to overcome as the cost of energy goes up and the cost of renewable technologies continues to decrease.

There remains the strategic question of whether it is more appropriate to deploy the renewable technology on the building being constructed or refurbished or whether the financial resources are better spent generating the power in a remote environment with more suitable climatic conditions for the respective renewable power. This needs to be examined on a project by project basis and the potential marketing benefits associated with mounting the renewable technologies on the building to be balanced against the potential decrease in output associated with localising the renewable generation technologies in a sub optimal location.

Also, embodied energy/emissions of new construction vs. retrofitting has become a significant factor in the assessment of projects.

4.5 Architectural Effects

The typologies derived in 'Towards Zero' have become part of the 'tool box' for early project stages. Base assumptions and principles have been adopted into the client briefing and concept design processes. Since the project Spowers have achieved ISO 14001:2004 certification to ensure quality, continuous improvement and the transfer of acquired knowledge into projects across the board. Power generation has become a typical option to consider on respective projects. As for Investa, 'Towards Zero' has been used as educational case study for staff and raised the bar as showcase for clients.

Precinct approaches have been designed on following projects showing respective higher efficiencies and the potential for cost-effective inclusion of renewable energy sources.

Last not least the project has highlighted the possibilities for investments into leading building typologies.

4.6 Further Research

It is important to investigate the possibilities 'towards zero' on new projects. The complimentary step however should be applying and adapting the methodology to existing buildings and deriving processes and strategies to upgrade the typical building stock across Australia respectively to prepare the respective stream for meeting the projected emission targets.

THE EFFECT OF ROOF COLOUR ON THE OUTDOOR TO INDOOR TEMPERATURE DIFFERENCE IN PASSIVELY COOLED NON-AIR-CONDITIONED BUILDINGS

Eric PETERSON Ph.D[1,2]

Keywords: cool roof, passive cooling, building simulation

Summary

A recent study has highlighted the importance of roof colour on the heat gain of a building. For non-air-conditioned buildings a key parameter for the effect of roof colour is the temperature difference between the outside and inside, $\Delta T = T_{outside} - T_{inside}$. The previous study assumed that the temperature difference approaches zero in well-designed passive buildings, but now we detail how ΔT depends on the quality of passive cooling design. The present study considers day-time occupied school buildings evaluated in ten different Australian locations. We employ USDOE EnergyPlus software for these simulations with the DesignBuilder user interface. Our main finding is that ΔT approaches zero for very good passive cooling designs, and is very negative (by more than 5 K) for dark coloured buildings that are not otherwise well designed for passive cooling. We suggest that ΔT may be positive during early morning occupation, if night purging and thermal mass is effectively managed.

1. Introduction

Energy efficient building design is gaining global recognition as a key pathway to combat climate change [1, 2]. The benefits of radiation control coatings (e.g. a white roof surface reflecting short wave solar radiation) are currently not fully recognized in building energy codes as an alternative or adjunct to thermal insulation R-value requirements, especially for warm climates [3]. Radiation control coatings are perhaps better described as "insulators" or "thermal diodes", as they tend to be more effective in restricting heat flow in one direction (e.g. an aluminum foil at the roof underside is effective in restricting downward heat transfer). Clearly a better understanding of the effect of radiation control coatings will inform sustainable development in the tropics of the world, where the most rapid industrialization is currently underway [1].

In tropical buildings without air-conditioning careful building design, often involving building simulation, is required to ensure thermal comfort for occupants. For a passively cooled building a measure the effectiveness of this design is the temperature difference, $\Delta T = T_{outside} - T_{inside}$. This temperature difference, for example, depends on the solar reflectivity and thermal emissivity of the roof surface, the thermal mass and ventilation of the building, but also the internal loads of lights and people [4]. The significance of building simulation is confirmed by new building codes [5] which allow alternative solutions within a given annual energy intensity limit.

For permanently air-conditioned buildings in hot climates the temperature difference $\Delta T = T_{outside} - T_{inside}$ usually is positive, i.e. there is a continuous heat gain that needs to be removed the air-conditioning system. For passively cooled buildings, on the other hand, daytime solar heating and internal heat sources tend to make the outside to inside air temperature difference ΔT negative, i.e. passive buildings usually have a temperature above ambient to reject heat.

One could evaluate occupant comfort by conducting full year (8860 hour) simulations and then summarize the proportion of occupied hours that indoor temperature is deemed to be acceptable. But in the present study we provide hourly simulations for the difference in temperature between outside and inside, ΔT, on one single hot day with a recognized hot weather design temperature. We then suggest ΔT be subtracted from the constantly varying outdoor temperature to provide an order-of-magnitude estimate of the indoor thermal comfort conditions.

2. Building Models

The present study models a day-time occupied school building as shown in Fig. 1, in 10 Australian locations for both a “dark” red tile and highly reflective “white” roof and wall [the walls are shown dark for both buildings, but the properties have been simulated as stated].

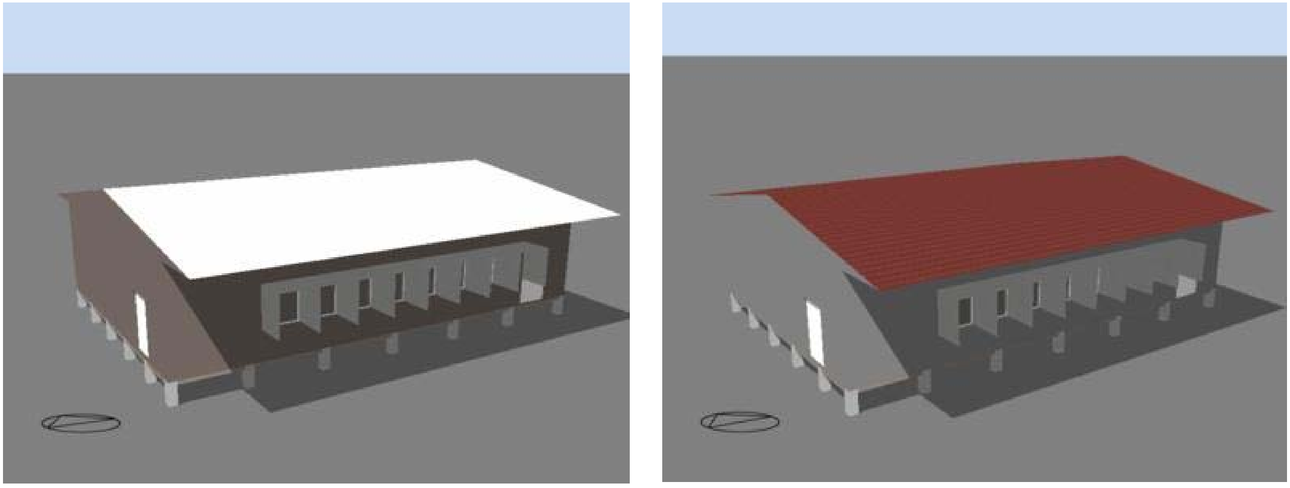

Figure 1 *Simulation case study: Lightweight one room school building with white and dark clay tile roof.*

Table 1 outlines the design conditions taken from ASHRAE [6]. Our simulation assumed clear sky solar radiation on 15th January (the height of summer), with the ambient temperature following a sinusoid with the minimum at 3 AM and the maximum at 3 PM. These values are normally applied in air-conditioning cooling load estimates and conventionally used to specify equipment capacity.

Table 1: 99.6% maximum dry bulb design temperatures and coincident minima used in the simulations

	max T [°C]	min T [°C]	Latitude°	Longitude°	Elev [m]
Townsville airport	33.2°	26.7°	-19.25	146.75	6
Brisbane airport	31.1°	23.7°	-27.38	153.10	5
Sydney city	30.7°	24.8°	-33.87	151.20	66
Canberra airport	32.7°	19.7°	-35.30	149.18	577
Melbourne city	34.7°	25.1°	-37.82	144.97	113
Hobart city	28.0°	19.9°	-42.88	147.32	57
Darwin airport	33.9°	27.1°	-12.40	130.87	30
Alice springs airport	34.7°	25.1°	-23.80	133.90	541
Adelaide city	34.7°	25.1°	-34.92	138.62	101
Perth city	34.7°	25.1°	-31.95	115.87	20

In the present study we evaluate a building with a gable roof consisting of two 87 m^2 roof areas - one sloped 10° north the other 10° south. The east and west gable ends are 6 m^2 each, and the wall areas are 49 m^2 north, 32 m^2 east, 49 m^2 south, and 32 m^2 west. There is 126 m^2 of indoor plasterboard ceiling area and also a 45 m^2 outdoor plasterboard area under the roof overhang. It should be said that the plasterboard ceiling reduces/delays heat gain from the roof to the occupied zone. The roof is assumed to be clay tile 25 mm thick with no bulk insulation provided other than the effect of specified surface reflectivities and emissivities. Walls of the building and vertical gable ends of the roof space are assumed to be metal clad with plasterboard walls inside, and foil linings are included only for the "white" case. Clear single glazed windows are externally shaded with 1 m overhang and projections. Windows total 13 m^2 north facing and 13 m^2 south facing. The floor of the indoor area is elevated above ground where outdoor air flows freely. The floor has been specified as linoleum on plywood over a 150 mm air space with timber sheeting, and given extra reflective foil lining only in the "white" case. The internal load due to fluorescent lights is at 8 W/m^2, controlled to exploit natural daylight from windows. Three air changes per hour indoor natural ventilation were assumed during occupancy 8 AM - 6 PM, and 0.5 air changes after hours. Roof ventilation was set at 1.0 air change per hour to represent well-ventilated construction at roof level. The building population of 24 people is 0.19 per m^2, with metabolic load of 108 Watts/person = 20.5 W/m^2.

For both the nominal "dark" and "white" case we have set roof and wall thermal emissivities to 0.9. The solar reflectivity, on the other hand, has been set to 0.3 for the "dark" case and 0.7 for the "white" to represent degradation after some dust and dirt has settled on the roof surface. In the "white" case we also set the emissivity of the tile underside to 0.05 to represent a single side of reflective foil lining.

Using the DesignBuilder software two alternative materials specifications were created, and subsequently 20 simulations were run in the EnergyPlus engine supplied with DesignBuilder [as per reference 7].

3. Results

Townsville conditions are used to illustrate the results of the simulations (Figs. 2 and 3). Figure 2 shows the roof cavity and room air temperatures together with the outdoor temperature and Fig. 3 the room loads. It is apparent that the temperatures vary significantly with roof colour. In particular Fig. 2 shows the room below a dark roof is substantially hotter than the room below white roof.

Further simulations may investigate the impact of higher mass constructions, to establish if room comfort conditions could be improved further. Nonetheless, it is clear from the lightweight construction high internal load example that radiation control barriers appreciably reduce indoor space temperatures. The results from Townsville can be compared in Table 2 among the ten Australian locations simulated.

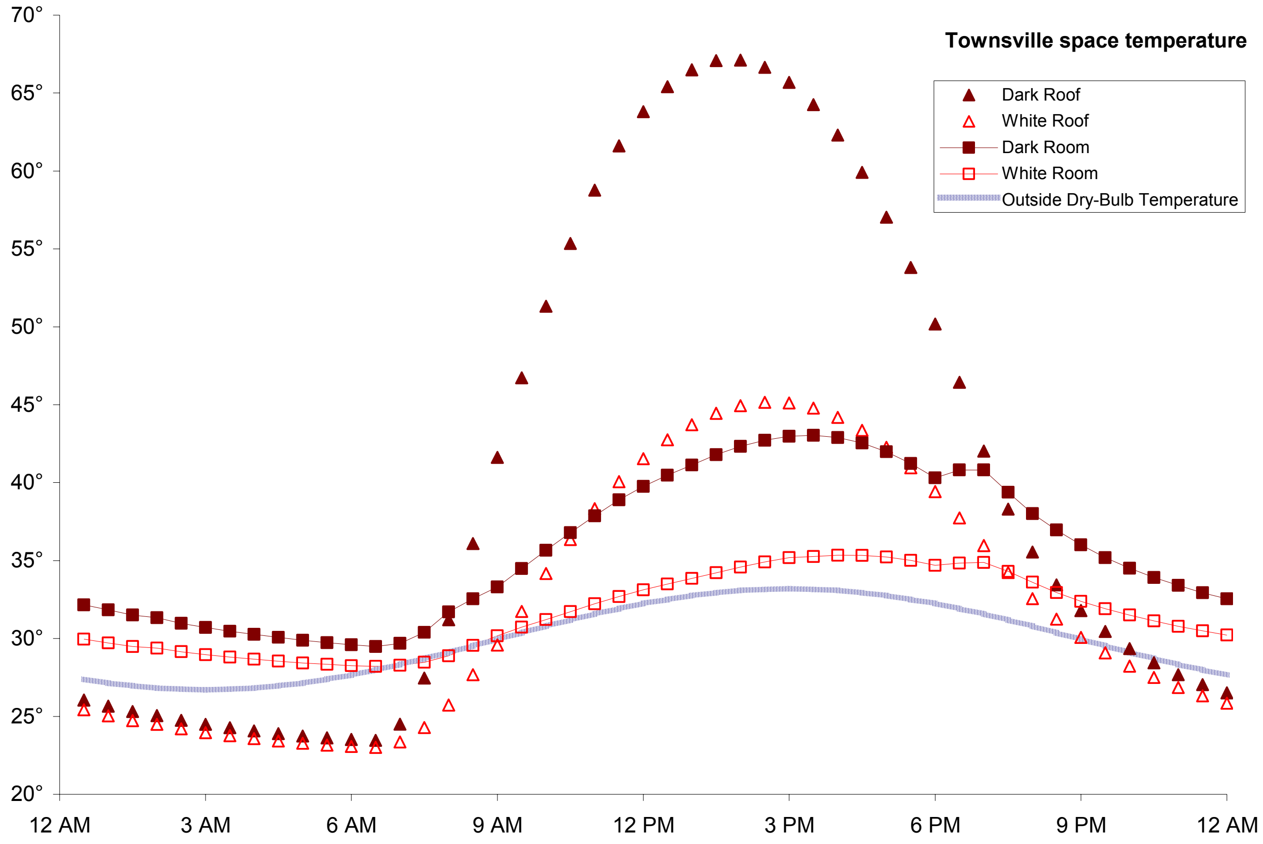

Figure 2: Temperatures in roof space and room below plasterboard for the dark and white school building during 99.6% design hot weather conditions in Townsville.

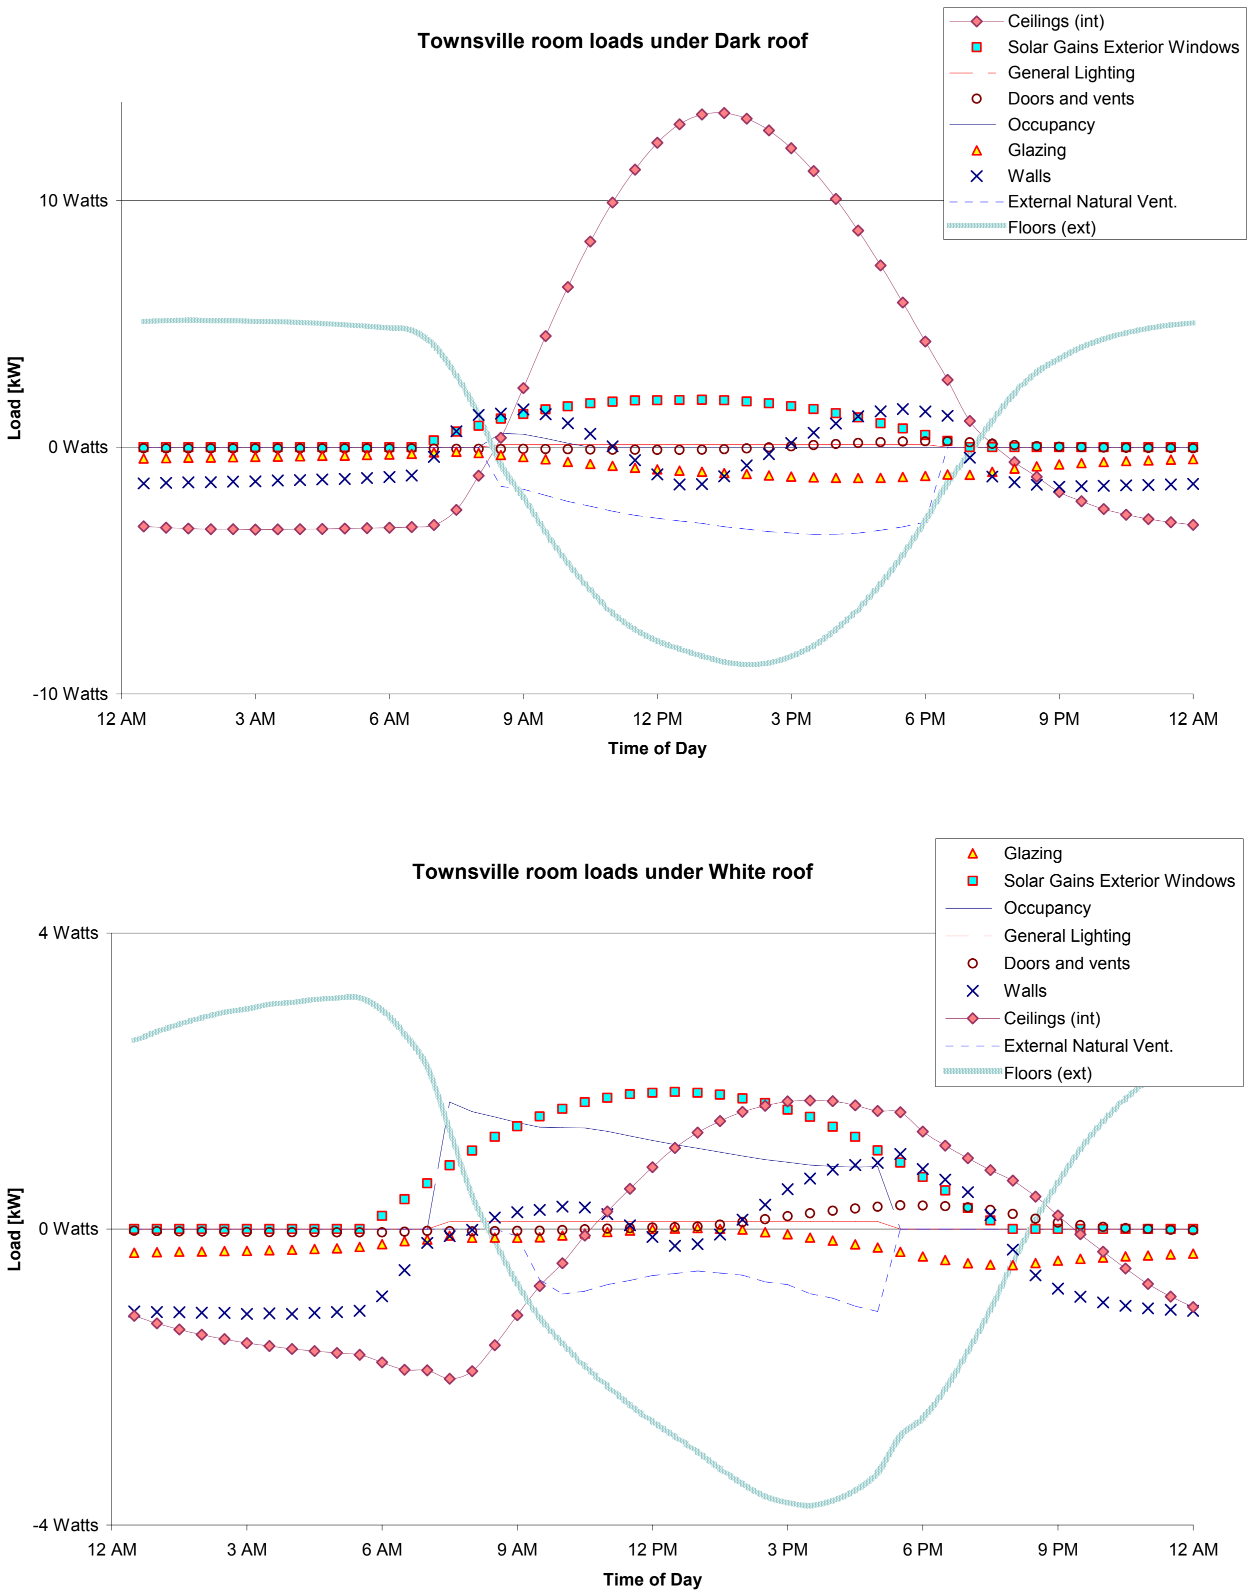

Figure 3: Heat transfers internally and through the fabric of the room of the Townsville school building. (a) The "dark" case; (b) "white" case. The difference between all of these loads translates into space temperature changes (see Fig. 2), mitigated by thermal mass.

The average outdoor to indoor air temperature difference values, ΔT, of the naturally ventilated light weight buildings with day-time occupation 9 AM through 5 PM are tabulated in Table 2 outdoor temperature. The building receives a net-cooling-benefit of about 6 K by changing the un-insulated roof and walls from "dark" to "white" and by adding foil into the wall cavities and under the roof and floor. For the above temperature reductions to be achieved it is important that the high solar reflective roof also maintains a high thermal emissivity to the sky and low thermally emissivity to the ceiling below.

Table 2. Average outside to inside temperature difference $\Delta T = T_{outside} - T_{inside}$ for the roof space and room in simulated lightweight school buildings for ten Australian cities (9 AM to 5 PM).

City	Net Cooling Benefit changing from Dark to White	Dark roof ρ=0.3 (Outdoor air – Ceiling space)	Dark building ρ=0.3, Outdoor –Room ΔT [K]	White roof ρ=0.7 (Outdoor air – Ceiling space)	White building ρ=0.7 Outdoor –Room ΔT [K]
Townsville	6.4	-27.9	-7.7	-8.5	-1.3
Brisbane	6.6	-28.8	-8.1	-9.0	-1.5
Sydney	6.6	-29.6	-9.4	-10.0	-2.8
Canberra	6.6	-26.7	-6.8	-6.7	-0.2
Melbourne	6.5	-25.9	-6.5	-6.2	+0.0
Hobart	5.9	-27.3	-7.6	-8.0	-1.7
Darwin	6.0	-25.6	-6.9	-7.1	-0.9
Alice Springs	6.6	-24.2	-5.5	-4.5	+1.1
Adelaide	6.5	-26.1	-6.6	-6.4	-0.1
Perth	6.6	-26.3	-6.8	-6.5	-0.2
Average [K]	**6.4**	**-26.8**	**-7.2**	**-7.3**	**-0.8**

Besides indicating a building's passive cooling capability relative to the ambient temperature, our simulation results enable reading of Fig. 4, taken from a previous study on the effect of roof colour [4]. The present study considers passively cooled buildings where there may be negative $\Delta T = T_{outside} - T_{inside}$. Generally we find from Table 2 that the average ΔT from 9 AM to 5 PM is of order of -6 to -9 K in the case of dark un-insulated building, but near zero for the white building with reflective foil cavities.

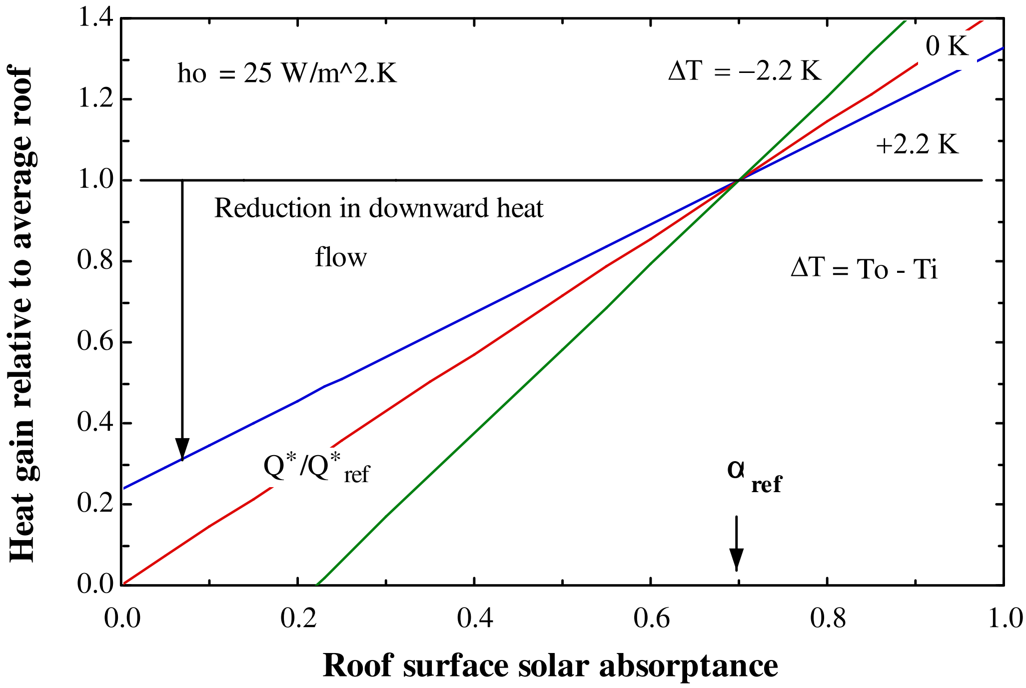

Figure 4 Effect of solar absorptance on the roof heat gain relative to an average roof with α = 0.7 solar absorptance (Note solar reflectance ρ = 1 - solar absorptance α for opaque surfaces).

Figure. 4 from the prvious study shows [4] how a reflective roof colour reduces the heat gain of buildings in the tropics. That study estimated ΔT = +2.2 K as a population-weighted annual average for air-conditioned building in northern Australia, and speculated that $\Delta T \approx 0$ K would a conservative approximation of passive cooled case buildings.

Discussion and Conclusions

This study has focused on a comparison between school buildings with dark and white roofs without bulk insulation. The results suggest that significant improvements to the building energy efficiency or comfort level can be achieved with the selection of an appropriate roof colour (white for hot climates) and the inclusion of reflective air spaces. For the building with white roof the temperature difference between the ambient and the room air temperature approached zero, which suggests ΔT = 0 K may be an appropriate base-case for "well-designed" passively cooled buildings. Poorly insulated buildings with dark roofs, on the other hand, may have a substantially negative ΔT (i.e. the inside room temperature is substantially higher than ambient), which suggests that the benefit of lighter roof colour was understated in the previous study for passive buildings [4].

The present study has succeeded to quantify the effectiveness of passive cooling with a “cool roof” and walls that include reflective foil but use no bulk insulation. Very good solar shading was applied to both the “dark” and “white” buildings. In both cases the electric lighting was reduced when sufficient natural day lighting was available. In future research it would be interesting to re-run the “dark” vs. “white’ simulation with double glazed low e-glass, more sophisticated ventilation schemes and some use of bulk insulation. But most important would be to quantify how ceiling bulk insulation restricts the passive cooling of the buildings in hot climates.

Keywords: integrated water cycle management, WSUD, water sensitive city, city as a catchment

Summary

The municipality of the City of Melbourne is committed to conserving water and protecting the beneficial uses of its waterways through stormwater quality improvement projects. Viewing the '*city as a catchment*' enables water management decisions to be understood in terms of the overall contribution to achieving water conservation and water quality targets across a municipality.

City as a catchment is one of the fundamental principles of a water sensitive city and seeks to minimise importing potable water, and exporting wastewater, from and to areas outside of the boundaries of the city. Instead it optimises the use of water resources within a city, recognising the natural catchment relationship, but working within the artificial city catchment (including its roads, roofs, and impermeable surfaces).

Understanding the quantity and location of water flowing through the municipality, and the pollutants being carried with these flows helps local government to initiate and assess sustainable water management projects. Sites across the city can be categorised as a 'source' (eg: sites that can harvest stormwater such as a road, or harvest rainwater such as a building with large roof) or a 'sink' (eg: large water-using business or park). Quantifying a water balance and stormwater pollutant budget enables links to be made between these sources and sinks. Demand management practices and harvesting alternative water supplies is crucial to achieving more sustainable water management practices.

Applying the *city as a catchment* philosophy to the City of Melbourne's management of water is an adaptation strategy done in response to climate change. It provides a basis for moving towards an informed city as an ecosystem approach that encompasses greenhouse mitigation and habitat protection and stretches beyond single municipal boundaries.

1. Introduction

An emerging challenge for urban communities is to incorporate design strategies that provide resilience to future uncertainty associated with drought and climate change, while catering for increased demands placed on the supply system due to population growth.

The concept of *city as a catchment* strives to close the loop on the urban water cycle within a catchment, and in this project within the municipality boundary of the City of Melbourne. *City as a catchment* espouses that government and urban water managers will minimise the use of potable water and optimise the use of alternative water resources across a catchment in a 'fit-for-purpose' capacity that is shaped by a carbon sensitive approach. Stormwater discharged to receiving waters should be treated to improve its quality and minimise its impact on the ecologic health of these systems.

Committing to the principle of *city as a catchment* provides a basis for the development of an implementation plan to strategically integrate sustainable water management practices into the urban landscape. Implementation plans will strengthen organisational commitment to sustainable water management by implementing WSUD across all their assets (including parks and gardens, building and roads). Local governments influence needs to extend beyond adoption within the public domain, through the regulation and provision of incentives to facilitate the uptake of WSUD in the private domain (including commercial and residential sites). It requires institutional capacity as a prerequisite to accomplishing integrated water management at all scales of urban design and development.

This paper explores the water balance and pollutant budgets for the City of Melbourne, water management targets and implementation to achieve the targets. For more information refer to *City as a Catchment* report (EDAW, 2008) and *Total Watermark – City as a Catchment Strategy* (City of Melbourne 2008).

For the remainder of this paper the term 'City of Melbourne' refers to the 3650 ha municipality area under the jurisdiction of the City of Melbourne council and located at the bottom of the Port Phillip Bay catchment including waterways Victoria Harbour, Yarra River, Maribyrnong River and Moonee Ponds Creek.

2. Climate Adaptation

The City of Melbourne has recently released a draft *Climate Change Risk Assessment and Adaptation Strategy* that sets out the likely local climate changes including rainfall decreasing between 2-4% by 2030, higher evaporation, reduced stream flows of between 3-11%, more frequent and intense storm events, and higher sea levels and associated groundwater levels.

The draft *Climate Change Adaptation Strategy* recommends that stormwater harvesting is one of two key high value adaptation measures that Council can undertake to assist in both flash flooding events and insufficient water supply. Stormwater harvesting is a central platform of the city as a catchment philosophy.

It is identified that progress from the water industry in applying rainfall data in modelling program to reflect climate change is needed as a priority to ensure we are best providing for future rain events.

3. Water cycle management targets

The City of Melbourne has committed to a range of integrated water cycle management targets directed at water conservation, stormwater quality and wastewater minimisation. The baseline year selected to calculate water volumes and pollutant loads is 2000. The percentage reduction targets are measured against this baseline year data.

For stormwater quality improvement the City of Melbourne has drawn on State best practice targets that were introduced in 1999 for the mean annual load reduction in litter, sediment and nutrients. To reach an 80% reduction in mean annual load of total suspended solids (TSS) and a 45% reduction in mean annual load of total phosphorus (TP) and total nitrogen (TN) Council has committed to a 20% reduction in mean annual load of TSS and a 15% reduction in mean annual load of TP and a 30% reduction in mean annual load of TN generated across council managed assets by 2020. At a municipal wide level the TSS:TP:TN targets are 20:25:40 by 2020.

The City of Melbourne's water saving target sets a 40% reduction per resident in mains water use by 2020, a 40% reduction in total water demand that is attributable to council activities, and 50% reduction in water use per employee for commercial/industrial by 2020 (Total Watermark, 2004). This will total an absolute saving of 22% allowing for 120% population growth to occur by 2020.[1]

4. Water balance and stormwater pollutant budget

The water balance calculated for the City of Melbourne has been separated into council, residential and commercial demands (sinks) and different sources of urban runoff to provide insight to the potential for harvesting stormwater to meet a proportion of the total demand across the municipality.

Water Sinks

Figure 1 shows that commercial practices place the greatest demand of 72% on mains water supply (18,243 ML/yr) followed by residential at 22% (5,541 ML/yr) and council at 6% (1,585 ML/yr) of demand. Even though Council's demand represents a relatively small proportion of the total, Council has an important role to play in providing leadership in the community.

88% of mains water is discharged to sewer as wastewater (22,510 ML/yr) from the municipality. Demand management practices and programs design to stimulate their uptake across the commercial sector are critical to conserving mains water and reducing wastewater flows. A total of 11% (2,959 ML/yr) of mains water is used for outdoor purposes (including residential garden watering and irrigation of public open spaces). Irrigation of public open spaces represents 65% of the demand placed on mains water supply by council managed assets which equates to 4% of municipal-wide demand. Ample stormwater is available to meet the municipality's mains water demands such as irrigation requirements by tapping into catchment drainage that flows adjacent to parks and gardens.

[1] *The above targets are all proposed at the time of writing and available for consultation. The targets will be considered by the Council of the City of Melbourne prior to the SB08 conference and may be confirmed or modified accordingly.*

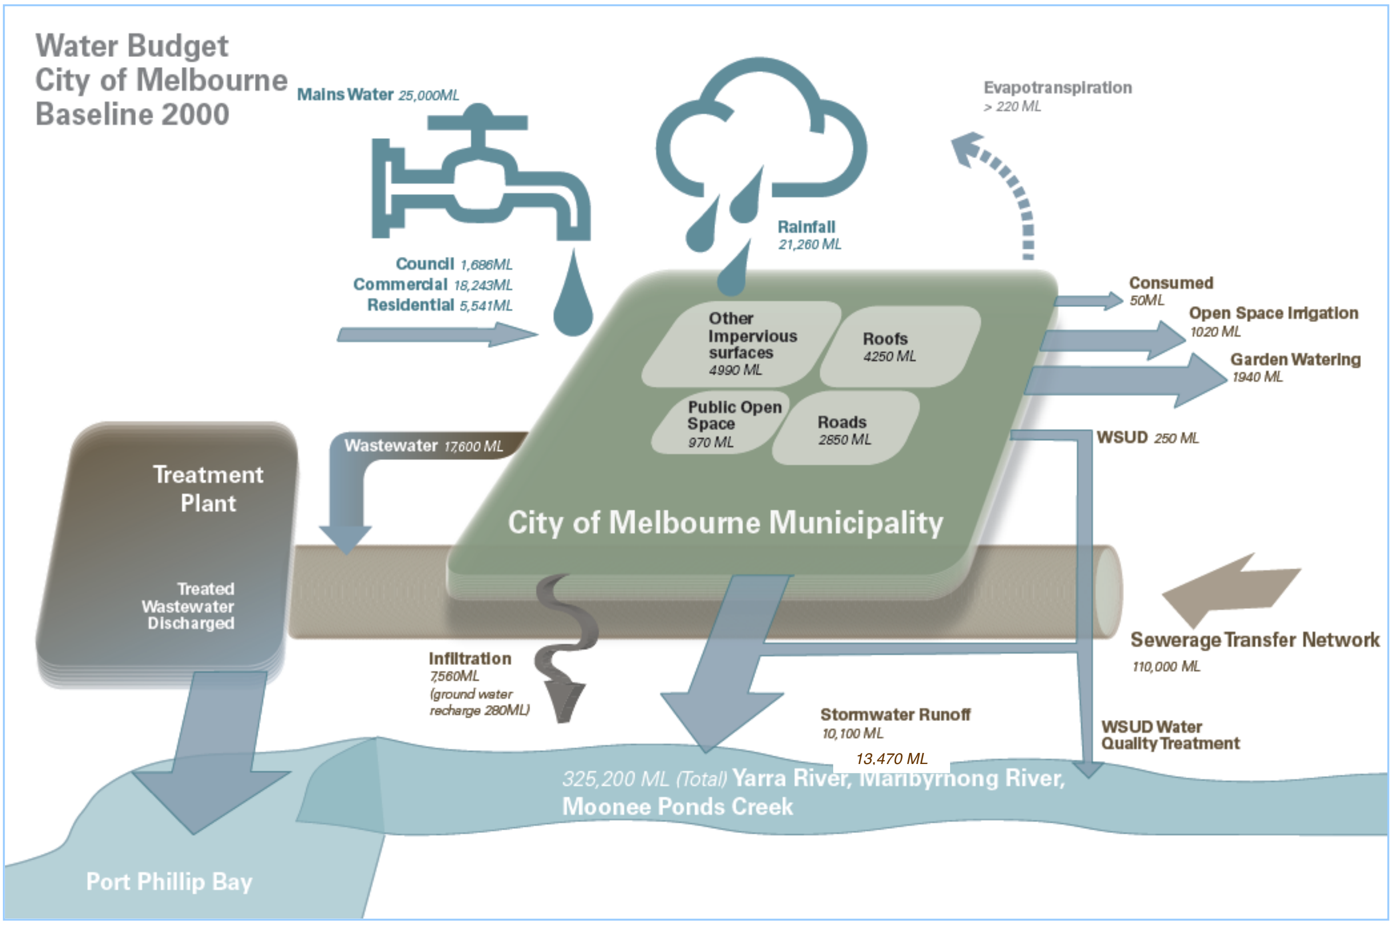

Figure 1. Water balance for the City of Melbourne

Water Sources

The mean annual rainfall volume across the municipality is 21,260 ML, of which 63% (13,470 ML) is discharged as surface runoff, 1% (220 ML) is returned to the atmosphere via evapo-transpiration processes and 35% (7,560 ML) infiltrates into the underlying soils. 1% (280 ML) of the infiltrated runoff contributes to groundwater recharge across the municipality.

Across the City of Melbourne existing stormwater harvesting projects (undertaken on both privately owned land and in the public domain) collectively remove about 2% (250 ML) of runoff (and associated pollutants) discharging to waterways. This water is predominantly used to supplement mains supply for irrigation of parks, gardens and sporting facilities, toilet flushing, and wash down of enclosures at the zoo.

A total of 4,230 ML/yr of roof runoff is generated across residential and commercial sites providing an abundance of water that could be harvested and used for garden irrigation, toilet flushing, hot water and laundry purposes. Private impervious areas and roads are other sources of runoff that could be harvested to provide a valuable supply.

Whilst the water budget shows that harvesting rainwater and stormwater could meet 70% of local potable water needs on paper, it is limited by available sites for storage. Using large sites in the CoM as a case study, it was demonstrated that the harvesting potential averages about 43% of the needs of the site with storage sizing based on an 80% reliability. Typically 90% of rainfall volume is attributed to frequent events smaller than the 1 in three month annual recurrence interval (ARI). Smaller rainfall volumes are easy to harvest because the equipment (such as tanks or storage pond, lakes) to hold this volume of runoff can be relatively small.

These opportunities; rainwater tanks, stormwater harvesting and wastewater recycling; to source water are readily available within the municipality. The COM adopts an alternative water source hierarchy for for use across the municipality, as set out in Table 1. The hierarchy seeks consideration of demand management strategies in the first instance followed by local sources, before offsetting any shortfall from sources outside of the municipal boundary or wastewater harvesting (which typically has high energy demand implications).

The water hierarchy reflects that alternative water sources have unique reliability, energy cost, environmental risk and economic profiles.

Table 1 Water Management Hierarchy for the City of Melbourne

Water source	Advantages	Challenges	Recommendations
Water Management from within the local catchment			
Demand Management	▪ Cost efficient ▪ No treatment ▪ Reduces wastewater ▪ Provides resilience to climate change	▪ Relies on behaviour change from all household or workplace members	▪ Demand management measures to be underway and demonstrated prior to alternative water sourcing
Roof runoff	▪ Multiple water cycle benefits (mains water conservation and reducing stormwater volumes and pollutant loads discharged to environment) ▪ Minimal treatment required as roof runoff is considerably cleaner than other alternative sources of supply ▪ Provides resilience to climate change	▪ Volume of supply to meet competing demands ▪ Reliability of supply ▪ Potentially higher pollutant concentrations conveyed to receiving waters from other landuse practices across catchment because runoff is not diluted with cleaner roof runoff (treatment of stormwater quality from sources, such as roads, is important to counteract this potential issue)	▪ Decentralised system requiring minimal infrastructure and maintenance. ▪ Greatest water conservation and ecosystem protection benefits achieved when used for indoor demands such as toilet flushing ▪ Also viable for other purposes such as garden irrigation when other sources are not a practicable supply option
Stormwater runoff	▪ Multiple water cycle benefits (drinking water conservation and minimising stormwater discharge to the environment thereby reduce pollutant loads to receiving waters) ▪ Provides resilience to climate change	▪ Reliability of supply ▪ Land uptake for treatment and storage requirements in confined spaces ▪ Dependent on committed on-site management.	▪ Decentralised system – preference is to supplement open space irrigation. ▪ Water not harvested should be treated to improve water quality and manage flows prior to discharge to receiving waters ▪ Provides landscaping values
Wastewater	▪ Multiple water cycle benefits (water conservation and minimising wastewater discharges to receiving waters) ▪ Provides resilience to climate change ▪ Constant supply	▪ High energy expenditure for treatment to meet end use water quality requirements ▪ Limit direct pathway for ingestion to minimise risk ▪ Storage requirements if supply-demand do not match ▪ Possible increase in salt and nutrient levels in supply, irrigation rates need to be well managed to ensure excess runoff does not enter waterways and impact ecological health ▪ Least greenhouse efficient approach	▪ Broader sustainability impacts should be considered (such as, energy and sodicity) especially if treatment facility is not currently available
Water Management from beyond the local catchment			
Sewer Mining extracted from Melb Water Sewerage Transfer Network	▪ Multiple water cycle benefits (water conservation and minimising wastewater discharges to receiving waters) ▪ Minimal storage requirements ▪ Provides resilience to climate change ▪ Constant supply	▪ High energy expenditure for treatment to meet end use water quality requirements ▪ Limit direct pathway for ingestion to minimise risk ▪ Possible increase in salt and nutrient levels in supply, irrigation rates need to be well managed to ensure excess runoff does not enter waterways and impact ecological health ▪ Least greenhouse efficient approach	▪ Broader sustainability impacts should be considered (such as, energy and sodicity) especially if treatment facility is not currently available
Stormwater from Yarra River, Maribyrnong River and Moonee Ponds Creek	▪ CoM is at 'bottom of the catchment' and is able to draw water without negative environment or habitat implications ▪ Minimal storage requirements ▪ Constant supply	▪ Surface waters are saline in CoM and if extracted, would need to be desalinated before use (high energy use) ▪ License requirements to ensure appropriateness of extraction ▪ Least greenhouse efficient approach	▪ Energy and treatment considerations of desalinating need to be carefully accounted for if this is to be pursued.
Mains water	▪ Inexpensive supply (because externalities remain unaccounted for and supply was heavily subsidised by government in its establishment phase) ▪ Existing infrastructure is accessible and regulations/approval process are well understood ▪ Most greenhouse efficient approach	▪ Reliant on single source of supply that is vulnerable to drought ▪ Population growth and urban consolidation across Melbourne is placing greater pressure on mains supply ▪ Climate change will result in less runoff due to higher temperatures and lower soil moisture levels ▪ No ecological protection 1. issues associated with environmental flows downstream of water supply reservoirs, and 2. no means to reduce stormwater or wastewater discharges to the environment	▪ Mains water is an important part of the water supply mix, but where possible, other alternative sources should be sought first. ▪ Demand management already undertaken in water management hierarchy to reduce water use ▪ Harvest alternative sources of water to conserve mains water and complement potable water use.
Groundwater	▪ Minimal storage requirement ▪ Can be sources close to end-use	▪ Groundwater shallow and saline in CoM and Yarra Delta region (SKM (2006)) ▪ CoM located on unconsolidated quaternary alluvium deposits and hence very low storage potential for ASR. ▪ Groundwater, if extracted, would need to be desalinated (high energy use) ▪ License requirements to ensure appropriate extraction ▪ Climate change will impact on groundwater flow and quality due to sea level rise	▪ Not considered a viable solution for the CoM due to the shallow and saline nature of the groundwater.

Water Pollution

For stormwater runoff volumes generated from different land use types across the municipality pollutant loads are quantified. Table 2 shows that land use types responsible for the greatest pollutant loads are roof areas for nitrogen loads, and roads and other impervious surfaces for total suspended solids.

Table 2 Stormwater pollutant budget for the City of Melbourne

	City of Melbourne managed assets			Private ownership			Total
	Roads	Public open space	Nature strips	Roof	Other impervious surfaces	Pervious areas	
Flow (ML/yr)	2,850	970	115	4,250	4,990	325	13,466
Total Suspended Solids (kg/yr)	875,000	12,500	1,470	108,000	860,000	4,230	1,861,200
Total Phosphorus (kg/yr)	1,660	99	12	591	1,450	34	3,845
Total Nitrogen (kg/yr)	6,740	920	107	10,000	11,500	310	29,577

The greatest water pollution reductions made to date in the City of Melbourne have resulted from rainwater harvesting which diverts stormwater and its pollutants (primarily nitrogen) from the waterways. Rainwater harvesting projects by Council have included Queen Victoria Markets, childcare centres, and sporting pavilions. The private community has generally embraced rainwater tanks with their increasing prevalence in households, industrial premises and large entertainment venues.

In addition to rainwater tanks, stormwater management projects are now being realised on the ground. With the generous support of Melbourne Water, ten projects to date are treating stormwater quality prior to discharging to receiving waters; these projects may involve more than one treatment measure such as the street pit trees located in the Docklands and in Little Bourke Street and also includes large and small scale wetlands, and biofiltration systems.

The stormwater pollution budget for the City of Melbourne shows that private impervious surfaces, roof areas and roads generate the greatest volume of runoff across the municipality. Land uses responsible for the greatest loads of pollutants in the City of Melbourne are:

- *Roads and other impervious surfaces for total suspended solids.*[2]
  The generation of total suspended solids is very high in the City of Melbourne for both Council land and non-Council land. TSS is primarily generated from roads, and is therefore very high in the City because of its highly urbanised nature and road coverage.
- *Roof areas for nitrogen loads*
  Like TSS, nitrogen in stormwater is generated from roads, footpaths and driveways, however one of the other primary generators is roofs (as roof water picks up atmospheric pollutants which largely includes nitrogen). Nitrogen is particularly relevant for non-Council land because of the large amount of roof space.

[2] based on updated stormwater flow concentration parameters used by Coomes (2007) using Fletcher (2005) recommendations

5 Achievements to date

Quantifying and understanding targets for the City of Melbourne enables implementation plans to be developed that define the fundamental building blocks and interim targets that can be realistically achieved over time. Simultaneously considering management targets for different aspects of the urban water cycle highlights where complimentary benefits are found. Table 3 summarises the flow management benefits achieved through the implementation of WSUD practices to date (demand management practices refers to permanent fittings and fixtures).

Since 2000 there has been a 34% reduction in the volume of mains water used across the municipality. This is largely due to the uptake and installation of demand management practices across council owned assets and residential areas. Reductions across council managed assets are 28% (refer to Table 3) which is attributable to demand management practices including improved irrigation practices in parks and gardens.

Table 3 Flow management benefits achieved across the City of Melbourne

	Water stream	Land ownership	Baseline 1999 Volume generated (ML/yr)	Current 2006/2007 Volume reduction (ML/yr)	Current 2006/2007 % reduction	2020 reduction target
Demand	Mains water supply	Municipality (total)	25,470	8,500	34%	22%
		Council	1,685	489*	28%	40%
		Private residential	5,541	1,142*	20% 39% per resident	40% per resident
		Commercial/industrial	18,243	6813	37% 48% per employee	50% per employee
Source	Stormwater	Municipality (total)	13,466	238	1%	9%
	Wastewater	Municipality (total)	22,510	6,424	29%	30%

*current water use accounts for a 6% reduction attributed to restrictions rather than to the installation of permanent demand management fixture and fittings

The highest proportion of mains water consumed is across the commercial/industrial sectors. Programs designed to address their high water consumption have been initiated since 2000; the benefits of which are assessed as part of future WSUD benefits. Indoor demand management practices have inherently contributed to a 29% reduction in wastewater generation across the municipality (shown in Table 3).

Four percent of the total pollutant loads for nutrients and TSS has been achieved to date through the implementation of WSUD projects. Table 4 quantifies predicted stormwater pollutant loads removal across the municipality through WSUD projects by 2020. This information was used to quantify viable 2020 water quality targets and establish a strategy for implementation with works identified to achieve the targets.

Pollutant load removal across the private residential sector is entirely attributed to the uptake of rainwater tanks. These reductions are considered minimum volumes given that tank uptake is based on rebate data from the water retailers and these data sets do not capture all tanks installed private properties.

Table 4 Stormwater pollutant load removal and predicted percentage removal by 2020

Pollutant	Land ownership	Pollutant generation baseline year 1999/2000	% removed by 2020
TSS	Total	1,861,200	20%
	Council	888,970	15%
	Private residential	291,669	46%
	Commercial/industrial	680,561	16%
TP	Total	3,846	23%
	Council	1,771	17%
	Private residential	623	59%

6 Towards innovation

The City of Melbourne has a strong foundation on which sustainable water management objectives can be built. To date, strategies have included finding ways to save mains water through efficiency, design and behaviour changes; minimising wastewater disposal to sewer through demand management, and recycling where practicable; treating stormwater to meet water quality objectives for harvesting and reuse and/or discharge to waterways; protecting groundwater from contaminants and disruption; and managing catchment hydrology, particularly for aquatic habitats.

The City of Melbourne has designed and established a tool to help staff to get a more operational understanding of how WSUD projects improve water quality. This has taken the form of a 'ready reckoner' that staff are able to use in the earliest days of conceiving projects. As seen by the examples below, water quality improvements are expressed in points which reflect the proportion of pollutant removal it can achieve, and enables useful comparisons in the function and costs of different WSUD treatments.

Using the language of 'points' has created a simpler feel for staff in understanding water pollutant loads as it is commonly the lack of confidence of staff that is the biggest implementation barrier rather then the lack of skill and capacity of staff. A language of points has helped staff to compare WSUD treatments and costs and give a sense of scale to the challenge of meeting municipal stormwater targets.

Treatment	WSUD treatment area	Catchment Area Treated	Points (reflecting proportion of pollutant removal)	Approx Cost
1 small wsud street tree pit	1 sq. metre	260 sq. metres	1	$2,500-$7000 per tree in residential area (not CBD)
1 large wsud street tree pit	3 sq. metre	780 sq. metres	3	
1 raingarden	10 sq. metres	2500 sq. metres	10	$1,200-$2,200 per m2
1 swale	40 metres	1 ha	50	$50 - $300 per m2
100kL rainwater tank	1.3ML/year of roofwater	2500 sq. metres	1	$75-$400 per kL
porous paving	30 sq. metre	1000 sq. metres	4	$150 - $500 per m2
1 small wetland	1000 sq. metres	5 ha	100	$150-$200 per m2
stormwater reuse 7ML/year	400 KL storage	5 ha	80	

NB: Costs are based on the small number of projects done to date, and will be revised when additional data becomes available. It is likely that the costs will decrease as works become standard procedure.

It is acknowledged that some new works will be constructed in the City of Melbourne that will generate more stormwater and potentially lower stormwater quality. Therefore 'negative points' will be assigned by staff to works that increase impermeable area. For example, changing open space to an impervious surface will be -6 points, and changing open space to porous paving will be -1 point.

City as a catchment provides the platform for integrated water management which can then be applied to all works undertaken across the municipality using a range of tools and resources designed by the City of Melbourne including WSUD Guidelines, Draft Climate Neutral Sustainable Water Schemes Framework, and Draft Risk Management Framework for Sustainable Water Schemes. The integration of these key pieces of work will ensure all civic and external projects plan for more sustainable water needs and carry these through to implementation.

The City of Melbourne prioritises action for the *city as a catchment* strategy by:

Firstly, saving water and preventing stormwater pollution *at source by using non-structural techniques* including demand management strategies which engage, communicate and educate to bring about behavioural change. Other strategies include regulation, town planning controls and fiscal incentives.

Secondly, saving water and preventing stormwater pollution *at source by structural techniques* to treat and/or harvest alternative water supplies.

Thirdly, saving water and preventing stormwater pollution *in system by structural techniques*. Such infrastructure is installed within drainage/stormwater systems to manage stormwater quality and quantity before it is discharged to receiving waters.

These measures are preferable to treating and/or harvesting stormwater at the *end of pipe* where the quality of water and velocity of flow make sustainable water projects less efficient and effective.

Decision Making Guidelines

Decision-making guidelines have been set out to guide sustainable water management on a site-by-site basis. Some of the guidelines are listed below with the full list in *Total Watermark – City as a Catchment* (CoM 2008).

1. All City Sites as Catchments

All city sites (buildings, roads, open space) are to be considered holistically to contribute to sustainable water management across the municipality. Over time this will build resilience to the ongoing pressures of urban consolidation and climate change on water resources and aquatic environments.

2. Community Engagement

Community engagement is integral component of all projects and needs to include:

a) information sharing and feedback from relevant stakeholders and community about water options and potential issues;

b) community consultation to direct the scale of the project.

4. Hierarchy of Sustainable Water Solutions

A hierarchy of guiding rules have been set out to promote the adoption of sustainable water management practices across council managed assets, residential and commercial/industrial land uses.

The hierarchy establishes a general approach based on least cost, least energy intensive options in the first instance through to more complex solutions in which the water cycle benefits need to be considered in context of the projects affect on broader sustainability sectors. Water hierarchy decision guidelines are:

(1) **Protection of receiving waters** including waterways, harbours, bays or groundwater. Recreational, tourism and economic uses of waterways must not negatively affect their social or ecological values. To protect receiving waters:

a) all planning or building proposals need to demonstrate no net negative effect on receiving waters in terms of quality and/or quantity;

b) all road renewal projects and street tree replacement to promote passive irrigation where possible, and meet best practice stormwater quality standards by applying water sensitive urban design (such as, rain gardens);

c) all new building and other infrastructure in the municipality must treat catchment runoff to meet best practice stormwater quality standards by applying water sensitive urban design (this generally requires to the 3 month ARI peak flows to be treated);

d) infiltration into the water table is encouraged when treatment ensures water quality meets best practice stormwater quality standards through integration with WSUD (such as, rain gardens).

(2) **Demand management** conserves water and minimises the generation of wastewater:

a) all new building, other infrastructure and private open space works need to minimise water consumption through the installation of demand management fixtures, fittings, appliances and educational signage;

b) all refurbishments, upgrades and extensions need to minimise water consumption through the installation of demand management fixtures, fittings, appliances and educational signage; and

c) all council managed assets (including buildings, parks, gardens and sporting facilities) need to consider opportunities to retrofit demand management landscaping, fixtures, fittings and appliances.

(3) **Stormwater quality improvement** to protect receiving waters to be considered in all urban design:

a) treatment is to reduce total suspended solids, total nitrogen, total phosphorus and litter to best practice standards; and

b) WSUD treatments to be integrated in various stages of the water cycle, where appropriate, and recognising where existing water quality treatment is already occurring upstream.

c) WSUD treatments are to be modelled to demonstrate achievement of best practice water quality. Models for private land are requested to be provided to Council so that Council can acknowledge the contribution of private land to improving waterway quality.

OPPORTUNITIES FOR SEMI-DECENTRALISED WATER REUSE AND POWER PRODUCTION

Dominique HES Ph.D[1]

[1] University of Melbourne, Faculty of Architecture Building and Planning, dhes@unimelb.edu.au

Keywords: semi-decentralised water and energy production, sustainable cities

Summary

Semi-decentralised water and energy systems can function autonomously but are still connected to infrastructure such as mains water, sewer and the electricity grid. The system proposed here is both for the provision of fit for purpose energy in the form of heat and electricity, and treatment of waste water for the provision of recycled water for non-potable purposes. The purpose of this paper is to explore the potential for both these systems to reduce waste such as transmission losses and their ability to produce sufficient amounts of fit for purpose outputs, while looking at the potential of the two systems to be integrated synergistically.

The basis of this paper is a literature review presenting the argument of the consideration of semi-decentralised systems in high density developed areas. This showed that there are serious issues with the current approach to the provision of energy and water in our current centralised systems. There are transmission losses which for water are 12-30% and for energy are 1-9%, the systems are built to disassociate the user with the water and energy they are receiving while being so large there is limited ability to adapt and react to changes in requirements. Lastly because they focus on only one output – electricity and drinking water, centralised systems miss the opportunities provided by using other outputs at a level that is fit-for their purpose, with the potential of saving of 50% in energy production and 80% in water provision. It is within this last point that the main gains can be made.

1. Introduction

By semi-decentralised this paper means systems that function autonomously but are still connected to infrastructure such as mains water, sewer and the electricity grid. The system proposed here is both for the provision of fit for purpose energy in the form of heat and electricity, and the treatment of wastewater for the provision of recycled water for non-potable purposes, nutrient and gas recovery.

Decentralised water systems have been written about by numerous authors (see for example, Mitchell and White 2003, Crites and Tchobanoglous 1998, Weber, Cornel and Wagner 2007); while decentralised energy systems have been used for decades in areas where the expense of brining in grid electricity is too high. The purpose of this paper is to explore the potential for both these systems to provide efficient, when compared to centralised systems, amounts of fit for purpose outputs, while looking at the potential of the two systems to be integrated in a single synergistic system.

Firstly both the water and energy issues are framed followed by a discussion on the problems generated by centralised systems. Secondly, the opportunities for semi-decentralised systems are outlined with a view to the effective use of limited resources. Finally, options as discussed for brining both of these systems together.

Water

Decentralised wastewater systems are defined as "*systems that collect, treat and reuse or dispose of wastewater at or near its point of generation*" (Crites and Tchobanoglous 1998). They include single-home onsite systems and cluster systems that may serve many hundred of homes. Centralised systems are those that serve entire communities or multiple communities (Hamilton 2004: xxi).

Weber and associates make the argument for Semi-centralised Supply And Treatment Systems (SESATS) for mega cities in developing countries based on two aspects: shortage of potable water in those areas and the rapid and unpredictable growth of cities which results in the inability to plan and implement effective centralised water infrastructure (2007:349). Figure 1 shows the SESATS arrangements. Note the use of semi-centralised as opposed to semi-decentralised, for all general purposes the definition of this system: *"are combined treatment facilities for water, wastewater and (organic) waste which provide service water for household use and intra-urban irrigation for an entire district within a city"* (2007:350) aligns to the one presented by this paper. Their argument for the use of semi-decentralised systems is to protect the environment from pollution and to manage resources sustainably. Abu-Sharkha and colleagues also argue for semi-decentralisation as it provides the best of both worlds, local production with the security of grid connection (2006:86).

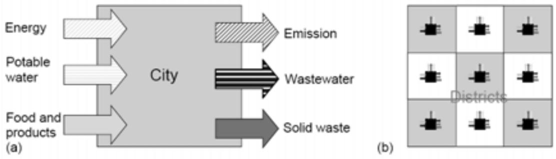

Figure 1 Comparison of centralised (a) and semi-centralised (b) systems (Weber et al. 2007:350).

For the purposes of this paper, the idea of clustering is important, that is finding an optimum amount of inputs and outputs based on technology used, type of development and types of inputs and outputs. It is different to a lot scale, or individual house level, and municipal scale, such as a catchment. Mitchell et al. (2001:616) spell out that this differentiation is needed for the discussion and understanding of a decentralised system: *"[a] cluster represents a group of uniform unit blocks that form a local neighborhood or suburb and the associated roads and public open space. The cluster can be used within the model to represent the spatial scale at which community supply and disposal operations may be managed."*

Energy

Within the city semi-decentralised systems are typically solar panels on a roof connected to the grid. There are many examples though of other systems such as wind turbines and Combined Heat and Power (CHP) systems. The definitions above for water and clusters can similarly be used to describe energy semi-decentralised systems.

2. Problems with current centralised systems and opportunities for semi-decentralised systems to address them

For both energy and water there are problems with the current centralised systems. These fall into four areas: transmission losses, waste through use of a level of energy or water above what is required for its purpose (called fit-for-purpose use), disassociation of the user with the system and the focus on the transmission system rather than the production system (Luising 2006, Langergraber and Mullegger 2006, Timmeren 2006, Timmeren et al. 2007a/b/c, Naji et al. 2006, UNEP 2004). These problems at their core mean that both water and energy resources are being used inefficiently.

Transmission losses

For water transmission losses occur in the forms of leaks and unaccounted for water. For energy it is the energy lost through the transport of the energy from the point of generation to the point of use. The Department of the Environment and Water Resources estimate lost or unaccounted for water to be 20-40% (Pers Comm Paul Starr DEWR, 2007) of the total amount used in buildings. For Melbourne this represented 49 billion litres last year (WaterSmart 2006). Leaks are thought to be a significant part of this at 12% of total water supplied (WSAA 2003:12), unaccounted water in addition is also water lost through meter slippage, theft, community service obligations etc. For energy the amount of electricity loss in transfer is around 1-9% of total energy production depending on the quality of the network (Jörß et al. 2003). Importantly, for the purpose of this paper, the further electricity is transported the higher the loss.

Fit-for-purpose use of resources

Fit-for-purpose use of resources, is the use of resources at a level of refinement appropriate for its task. As an example of the waste that is caused by using resources that have been produced to a level above what they are needed, a recent paper by Othman and Jayasuriya (2006) showed that Metropolitan Melbourne uses approximately 500 GL of drinking water for non-potable uses (Melbourne Water, 2005). The average household uses 19 - 25 per cent of its potable water supply for toilet flushing, and 35 per cent for garden watering (Water Resources Strategy Committee for the Melbourne Area 2001, ATSE 2004).

This is an inefficient use of high quality water and has led to the development of the water quality cascade (Chanan et al. 2003:2). The cascade includes fit-for-purpose water use but also water sources including potable water from the main centralised system, rain water, stormwater, grey water (showers, washing machines etc.), black water (toilets) and waste water from cooling towers. Through its use it is estimated that there could be a drop in the potable water consumed of 80% or more and reduce effluent discharge by more than 90 per cent (White and Turner 2003:6).

> *"The principle of the water quality cascade involves matching the end use of water with the quality of the water source, and utilising all water sources to meet water service needs"* (White and Turner 2003:3)

For example drinking water is not required for toilet flushing or watering the garden. When tested against the perception of risk from users, what as found was that "*customers do not necessarily want more water, rather* *they want the services that water provides, such as aesthetically pleasing landscapes, sanitation and clean clothes"* (Howe and White 1999).

For energy production, aside form the transmission losses there are significant losses in the production of energy, for coal for example, up to 70% of the energy is lost by the time it reaches the end user. Much of these losses are due to heat and the chemical conversion processes. Efficiently using the waste heat is one way of reducing the losses, but often where the power is produced there is not the demand for heat. Using a decentralised cogeneration system for example, where gas is turned into heat and electricity, can result in a doubling of the thermal efficiency and a significant reduction if carbon dioxide emissions. If natural gas is used then the production of electricity in this type of plant, emits less than half the greenhouse gasses per unit of energy produced than the most efficient thermal power station (Roarty 1999: paragraph 2).

Tanaka and Nasu (ndg:61-62) from the Japanese Ministry of Land Infrastructure and Transport, in their paper on a shift in Japan to 'A Recycling Society', describe the potential of using all of the synergistic opportunities afforded by recycling of water including use of the biosolids and production of energy. Again, relating to this need to use resources optimally by looking at the fit-for-purpose production of energy and water.

> "*Introducing source separation concepts in municipal wastewater management does allow adequate treatment of the different flows according to their characteristics. This is the key to technical solutions for the efficient reuse of water, energy and fertilizer*" (Otterpohl et al. 2002: paragraph 1)

Disassociation of the user with their water and energy system leading to overuse and misuse

> *"The lack of transparency and understanding about the value of water and energy and the systems that provide these resources has led to the overuse and mismanagement of both resources".* (Lofman et al. 2002: 73)

Due to the historic development of centralised systems which provide energy and water at the home and remove all waste away without any direct intervention by the occupant, there is a disassociation between the resource and the user. This means that if a resource needs to be limited extensive education and regulatory initiatives need to be put in place. These are expensive and need ongoing reinforcement, while they also assume that the restrictions are temporary. This does not encourage ownership of the problem. Several researchers have shown that by using more decentralized systems the user becomes more aware and responsible in their use of the resource leading to better management and reduces consumption (Naji et al. 2006, Lofman et al. 2002, Timmeren 2006).

Timmeren (2006:316) argues that if a system is within a decentralised system it increases the flexibility of the system while allowing for local response and adoption "*local decisions [and responsibility] with out abandoning the principle of scale size*", that is it links people to their responsibility allowing for better management. Further, you can identify costs and attribute these more precisely, you can anticipate market changes, transport costs are reduced, faults are identified more quickly and allows for smaller incremental investments with fewer risks. Finally, it allows the use of the outputs in a manner that is fit for purpose minimising the waste of resources.

Focus on the transmission system rather than the treatment system – response to error and ability to adapt

> *"The 'economy of scale' of central sewage pants is very often pointed out in wastewater management. However, this essentially correct fact cannot be seen isolated. In most urban areas wastewater collection and transport cause 70 to 80% of the total costs." (*Otterpohl et al. 2002:35)

For both the energy and water resource provision research has shown that most of the investment is in the transmission of the water and the energy. This is particularly true for water systems where one researcher concluded that the majority of the cost of a centralised water system is in non-productive transport, though is some areas much is done by gravity, there is still a great deal of infrastructure cost (Otterpohl et al. 2002). Rather than focusing on optimising the water treatment or energy production system much of the investment is on the maintenance of the pipes, transfer stations and other transmission systems.

Secondly this leads to two further consequences, the inability for rapid adaptation and often a delay in the response to errors. If a leak is found in your home you quickly turn off the water and get it fixed, if a leak is present in the centralised network, it may never be found, as shown by the 12% of wasted water discussed above, or if it is visible it often takes significant effort to be located and fixed. A semi-decentralised system with an on hand management system or person can identify problems, adapt to changes in influences on the system and can fix problems because of the reduced size and complexity of the system. It allows the "*real time connection to inputs and coordination and better harmony between input and outputs – supply and demand"* (Timmeren et al. 2007b:2).

Why inefficiency is a problem

The above problems are based on the assumption that there is a limited amount of energy and water resources. Further, this limited amount is being put under pressure from increasing populations combined with increases in demand and reduced supply. Melbourne's water supply will now be discusses as an example: water resources are scarce, climate change will have unpredictable impacts on it, but most agree that for Melbourne rainfall will decrease by 4 to 14% by 2020 (CSIRO 2005). Modelling and planning of the water resources are predicated on a rainfall of around 638.8mm per annum yet in the last ten years the average has been 557.7mm, a 13% drop (BOM 2007), leading to a rapid using up of water stored in catchment areas; in Victoria water storages have dropped from 80% in 2001 of capacity to around 30% in 2006 (Beeton et al. in DEH 2006:60). In the next 10 years, this change in rainfall together with an expected increase in consumption through population growth – over one million people by 2030 – (DOI 2002) will lead to a water crisis.

This paper argues that by addressing the problems listed above semi-decentralised systems should be considered in growing cities and in new developments. The next section identifies the types of semi-decentralised systems and their potential benefits for water and energy provision.

3. Opportunities with semi-decentralised systems to address problems

From the above it can be summarised that a semi-decentralised water or energy system can lead to a reduction in demand, reductions in investment costs for infrastructure, reduction in the cost of waste water treatment, takes up less overall space, improved chance of management and fine tuning, improve flexibility and the ability to react to changing conditions – say through incremental growth – and a more sustainable outcome through the more effective use of limited resources (benefits summarized from the work of: Hunt et al. 2004, Timmeren 2006:315, Hamilton 2004:6-7, Fane et al. 2004, Weber et al. 2007, U.S. Environmental Protection Agency 1997).

> *"The combined treatment offers new technical possibilities, such as mass and energy flows within the facilities, e.g. cotreatment of organic waste and wastewater and the direct use of biogas. These techniques lead to an increase in system efficiency and a decrease in the amount of residues to be disposed. Another characteristic is the proximity between consumer and treatment facilities, which allows short sewer and pipe systems, resulting in an economic reuse of water."* (Weber et al. 2007, p350)

The disadvantages to semi-decentralisation is that is needs more careful and thorough management, the economies of scale are often not there, though some of the authors cited above argue that it is more cost effective, Hamilton (2004: xxiii) concludes that it is depended to the situation and the context of the plant. Similarly Crites et al. (1998) suggest that decentralised waste water systems are not always the best solution, their research showing that it depends on the context but particularly if there is the opportunity for use of the various products in a fit-for-purpose manner, or where resources are under strain (for both water and energy it seems that climate change will be something that will increase this strain for many countries (IPCC 2007)). Depending on the system it may require a greater amount of cooperation by the residents, for example, by not using certain detergents, and the issues associated with change of ownership. Finally the responsibility of management of the system and ability to ensure it is running smoothly is highlighted as a potential problem.

As discussed above each semi-decentralised system needs to be designed and implemented based on the resources and needs of the sites, a outer suburban bungalow development will be different from a high density development in the inner city. Friedler and colleagues suggest that for water multi-storey residential buildings, in densely populated urban areas is where the potential is greatest (Friedler et al. 2005:222).

Livingston and associates (2004: 581), quoting Australian research, show that Australia scarcity of water is a major driver in the exploration of alternate and recycled water sources in major cities (Dillon & Ellis, 2004, Radcliffe, 2004, Naji and Lustig, 2006). They conclude: *"[t]he traditional approach to augmenting supply to meet growing demand is no longer regarded as a desirable option (Australian Senate, 2002), with growing awareness of the environmental impacts of such an approach*". Australia is not the only country though, as mentioned above Japan is looking at increased efficiency through becoming a recycling society. While in fast growing areas such as China the problem of insufficient supply, disposal and treatment in the next couple of years will be a crucial issue (Weber et al. 2007).

4. Types of potential water and energy systems

This section briefly outlines some of the technologies that could be used in a semi-decentralised system for the provision of either water or energy. The aim is to lead to a synergistic system where a combination of these technologies provides a holistic solution to the environmentally responsible provision of energy and water.

Water systems

Crites defines the elements of a decentralised wastewater management system as: wastewater pretreatment, wastewater collection, wastewater treatment, effluent reuse or disposal and biosolid and septage management (Crites et al. 1998:7). This paper is mainly concerned with discussing the water treatment aspect, though the other elements also have crucial roles to play in effective provision of fit-for-purpose water. For high density situations with little excess space the literature recommends anaerobic treatment systems (Timmeren et al. 2007c and Otterpohl et al. 2002). Depending on the regulatory context there will be a need to further treat the outputs from this system using either aerobic post treatment or advanced membrane technologies such as ultrafiltration/microfiltration followed by reverse osmosis.

Energy systems

Semi-decentralised energy systems are numerous, as mentioned previously these can be grid connected solar panels, wind turbines, and so forth. For the purpose of this paper generation using cogeneration systems are of greatest interest. Cogeneration uses gas as its source of fossil fuel, this can be natural gas but can also be methane or other biogas alternatives. As discussed previously using this type of system can halve the greenhouse impact per unit of electricity produced (Roarty 1999, Abu-Sharkha et al. 2006), furthermore, being close to the point of use heat generated can be used while minimising transmission losses. Depending on the context the heat could be used for heating of hot water, space heating or with an absorption chiller could be used for cooling.

The term cogeneration can refer to many types of systems depending on the input fuel, scale, use of heat and electricity. The main types for small scale use in a semi-decentralised system are: reciprocating engines; Stirling engines; gas turbines; and fuel cells. For the purpose of this paper the main criteria is the effective use of gas as the source of the energy. Madlener and Schmid (2003) studied nearly 5,000 CHP systems and found that 17-18% of them ran on landfill or biogas as the fuel. Considering the potential methane output from the water recycling system the potential starts to become obvious.

Being semi-decentralised the challenge will be in its interaction with the grid, as Lasseter (2002) points out it is possible for local generation with limited central control so that there is an even transition to stand-alone mode in case of power loss in the grid, the challenge is in how to re-synchronise once the grid is operational once again.

Energy water nexus

The central point of this paper is the need to use our limited resources more efficiently and this is possible by decentralising water provision and treatment and energy provision. There is a strong link between energy and water use, researchers such as Thirlwell et al. (2007) and others write about the energy water nexus – that is the direct link of energy and water – that is you need water to create energy and you need energy to collect, transport, treat and supply water. Improvements in efficiency in one leads to increase efficiency in the other similarly scarcity in one will lead to greater use of the other and ultimately scarcity and increased costs. For example, to produce one kilowatt-hour of electricity requires 140 litres of water for fossil fuels and 205 litres for nuclear power plants (Thirlwell et al. 2007:4).

This illustrates that we need to stop looking at our energy, water and waste systems as separate systems that are not affected by each other, this misses efficiency opportunities and does not represent the real world (Timmeren 2006: 315). Everything is interconnected and if you look at it from this perspective there are many opportunities that can be taken up. Looking at the issue from this perspective allows for the potential to develop more imaginative schemes *"for meeting the local requirements in a flexible manner with the small scale generators and consumers closely integrated."* (Abu-Sharkha et al. 2006:85)

5. Integrated system

Thus bringing together water treatment and provision with energy production in a semi-decentralised approach would seem to play to these synergies. Taking water, treating it, collecting the gas, nutrients and treated water and providing both fit-for-purpose water and energy. Increasing the capacity of the system by also adding green waste should also be considered. The research now needs to focus on the feasibility of these systems not only to provide adequate water and energy and the facilities that are needed to allow effective use of all of the outputs, particularly the heat and the nutrients. Further it is crucial to look at how the brining together of different technologies can be managed and the delineation of responsibilities and ownership.

> *"Decentralized systems turn out to be able to gain efficiency advantages as compared to fully centralized systems, particularly through the design of an integrated system of energy generation and supply, and through the connection of this system to a waste water treatment system coupled to nutrients recycling."* (Timmeren et al. 2007a:10)

Case study

The system advocated in this paper has been designed for a small residential (250 homes) and commercial/education area called the “EVA Lanxmeer” in Culemborg in the Netherlands. This system has not yet been built but it is expected that when it is operational that it will treat all of the effluent of the development and provide a total energy production 118 kWh/day, 37 is needed for the plant and the rest is available for use in the development. This combined with the reduced requirement for energy and water transport and losses is expected to save 194 kg/home/yr of CO_2 (Sidler et al. 2004). This is increased if the if the sludge is further used in the living machine this increases to 210 (Timmeren and Tawil, 2006). Given these figures it would seem that further work needs to be done on the energy outputs, as the system would need to be augmented with additional gas to offer ongoing supply, again this is why a semi-decentralised system is an optimum solution.

The EVA system is called the Sustainability Implant (Timmeren and Sidler, 2007), it is a technical and architectural solution developed specifically for the unique requirements of the site, it is shown in the chart below (Figure 2) and is made up of (Timmeren et al. 2007a:5):

> *“1. Gathering black water on the one hand and green household waste (and to some extent garden waste) on the other, and leading them into the system;*
>
> *2. The fermentation process, with biogas, effluent and sludge as its output;*
>
> *3. Purifying and improving the gas into natural fossil gas equivalent;*
>
> *4. Purifying the effluent until it has surface water quality;*
>
> *5. Composting sludge into usable garden compost.*
>
> *…*
>
> *6. Collection of separated waste flows (Retourette) and e-delivery goods of the district;*
>
> *7. Using the biogas in a combined heat power plant (CHP), CO_2 in glasshouses and purified water in the spa and vitality facilities.”*

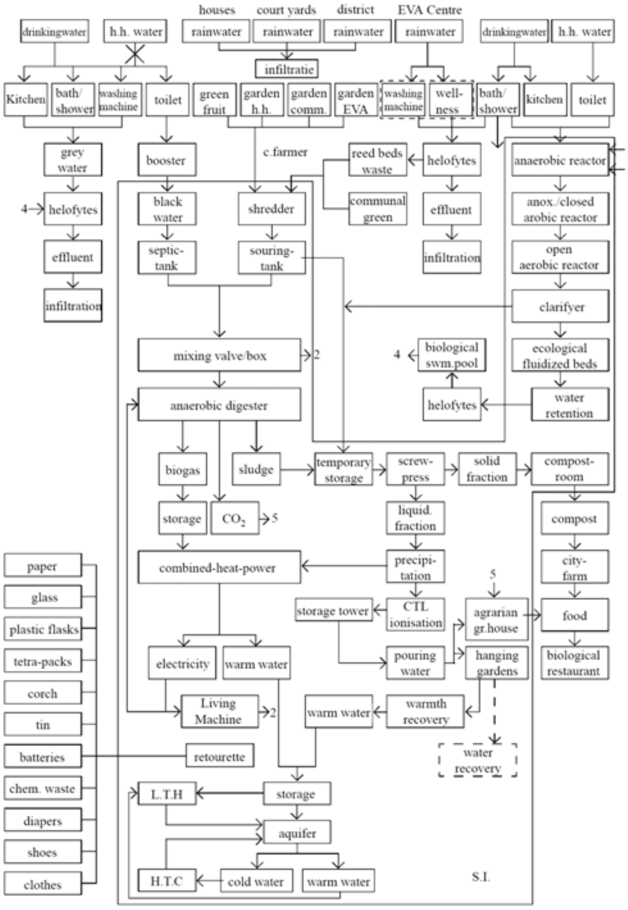

Figure 2 – Outline of EVA system (Timmeren and Sidler, 2007:31)

6. Conclusion

There are serious issues with the current approach to the provision of energy and water in our current centralised systems. There are transmission losses which for water are 12-30% and for energy are 1-9%, the systems are built to disassociate the user with the water and energy they are receiving while being so large there is limited ability to adapt and react to changes in requirements. Lastly because they focus on only one output – electricity and drinking water, they miss the opportunities provided by using other outputs at a level that is fit-for their purpose, with the potential of saving of 50% in energy production and 80% in water provision. It is within this last point that the main gains can be made in the efficient provision of energy and water while dealing with waste water and green waste.

Keywords: sustainable water management, greenhouse gas emissions

Summary

Reusing or harvesting water is a great way to reduce our reliance on potable water, but it can have environmental consequences. For alternative water sources, additional infrastructure and treatment are required resulting in extra greenhouse gas emissions. This raises the questions - are we emitting additional greenhouse gas emissions which contribute to global warming and climate change? Can we be water self-sufficient and climate neutral?

The City of Melbourne has developed a methodology to help deliver carbon sensitive water reuse (rainwater, stormwater, greywater and blackwater) projects. This methodology is consistent with the Australian Greenhouse Office approach, utilises life cycle thinking to ensure interactions with other social, environmental and technical issues, and has consistency in decision-making within the institutional arrangements over a range of scales.

To demonstrate the methodology it is applied to two projects; the first at the household level for the application of a rainwater tank connected to toilet flushing, and the second an analysis of City of Melbourne's new office building CH2 which contains a water mining plant.

1. Introduction

Urban water management is increasingly under pressure. The prolonged drought, climate change and increased population density strain our already stressed centralised water system. Traditionally, Australian cities have generally been able to rely on surface water runoff from large external catchments for all urban water demands. Such centralised approaches have been successful in water service provision to the community, producing a high quality potable water source, which is used for a wide range of end uses varying from drinking to garden irrigation. There is now a need to consider alternative water sources along with behavioural change and demand management measures to provide a sustainable water future.

Alternative water sources can be decentralised or centralised. The centralised system involves augmenting existing dam storages with desalinated water or non-potable water. Decentralised solutions include precinct water mining schemes, stormwater harvesting or rainwater harvesting.

The inclusion of alternative water sources requires additional infrastructure and energy. Energy is required during construction and operation dependent on treatment type and construction materials. As Victoria’s energy is predominately sourced from non-renewable carbon sources, energy usage contributes to the production of greenhouse gas emissions. As the City of Melbourne is striving for climate neutrality, understanding the interaction between alternative water sources and greenhouse gas emissions is a challenge.

Water and climate neutrality present an ultimate goal for the City of Melbourne. The challenge lies in the translation of these principles into meaningful solutions for government and business practices. Tools to understand complex water systems are developing to assist water management strategies (Jeffrey et al., 1999; Beck, 2005). Currently a knowledge gap exists in availability of such tools and their relationship to climate change.

This paper presents one of the decision-making tools for building a viable and livable city. The focus here is on the nexus between alternative water sources and energy usage. The tool enables consistency for sustainable water schemes to be implemented without resulting in a net increase in greenhouse emissions.

2. Urban Water Management

Urban metabolism traditionally views cities as resource consumers. Sustainability initiatives have been focused on reducing consumption, minimising impacts and “doing more with less”. Traditional centralised systems have serviced cities by the extraction of external resources – both for energy and water. Moving towards a resource generation model, where cities are creating resources internally enhances the city’s self sufficiency. The challenge arises in ensuring our decentralised solutions actually reduce the city’s carbon and water footprint. Urban metabolism and nature provides a model for sustainable solutions.

2.1 Built and Natural Environments

The built environment has benefited from engineering advances, providing essential services through the construction of centralised water, sanitation and drainage systems. These large reticulation networks, predominately underground, have provided a cost-effective, reliable and efficient solution for water services. The centralised management system ensures high quality assurance and protects public health. Yet, the hidden and invisible nature of the centralised system has removed the connection between the built and natural form.

Over the past century, cities have evolved around these centralised systems. Buildings were readily connected to the ever expanding systems providing water, sanitation and drainage services, and landscapes developed as desired, with water no longer a limiting factor. As such, landscapes unable to be supported in the previous natural climatic conditions have been introduced within modern cities. Likewise, water bodies have also been widely incorporated throughout urban environments. In light of recent threats to water services and supply, such practices are clearly unsustainable and a shift in thinking is required.

Reducing demand by eliminating wastage of potable water is the first step in sustainable water management, beyond this then alternative water systems are required to enhance the landscape and create a connection between natural and built forms.

2.2 Ecosystem approach to water management

Learning from other complex systems, particularly ecosystems, provides new approaches for future water management. Insights for alternative water sources revolve around flexibility, adaptability and a resilience to change.

Nature provides a model for complex systems that have proven resilient to change. Ecosystems are often complex, with a multitude of individual components working synergistically. By examining natural ecosystems, insights can be attained and many of the attributes translated to the built environment. For an ecosystem to operate effectively and efficiently, the individual components must be able to communicate efficiently, manage material, energy and waste flows (Mitchell and Campbell, 2004). Inherent to the robust 'operation' of most ecosystems, is the ability to be resilient to change. Translating these attributes into the built environment provides direction in the creation of sustainable water systems.

In order to create a sustainable water system that is resilient, it is desirable that the attributes and characteristics of the system are analogous to those in the natural ecosystem (Mitchell and Campbell, 2004). These include:

- movement from water supply to water service provision
- diversity of water sources, and
- flexibility in infrastructure.

Diversity of water sources provides a key element in creating a viable and livable city that is connected between natural and built forms. The City of Melbourne is employing these principles within Melbourne through policy development, framework to assist implementers and on the ground projects.

3. Framework for climate and water neutrality

The City of Melbourne is committed to sustainable water management as articulated through *Total Watermark* (2005) and the City of Melbourne's *Water Sensitive Urban Design (WSUD) Guidelines* (2005). The City of Melbourne is also leading in the adoption of a climate neutral organisation through *Zero Net Emission by 2020* to mitigate the impact of non-renewable energy sources. The interaction of energy use and subsequent greenhouse gas emissions with alternative water supplies is articulated through *Carbon Sensitive Water Saving Schemes* (2008).

3.1 Policy management framework

Greenhouse gas emissions are one element to consider for alternative water sources. The following is a simple process for considering greenhouse gas emissions arising from potential water saving projects:

- firstly, when planning, consider all opportunities for water conservation (because saving water will also reduce greenhouse gas emissions);
- secondly, consider opportunities for alternative sources of water, namely rainwater harvesting, stormwater and wastewater recycling. If an alternative source is to be used, then;
- thirdly, undertake assessment of greenhouse gases emitting from proposed alternative source.

The City of Melbourne has developed the following process to help deliver carbon sensitive water reuse (rainwater, stormwater, greywater and blackwater) projects.

A policy framework was developed and consists of:

1. Greenhouse gas audit - establishes a baseline and compare with existing centralized services. For the City of Melbourne this was conducted by examining Scope 1 and 2 emissions for water and wastewater services.

2. Reduce water use – through behavioral change and demand management measures
3. Sustainable water scheme – develop an integrated water sensitive strategy
4. Consider the onsite generation of renewable energy to serve the water reuse scheme.
5. Consider the purchase of renewable energy (or 'Green Power').
6. Consider the use of emissions trading/carbon offsets.

The framework provides an approach for evaluating greenhouse gas emissions for alternative water saving schemes. Geographical location of the water reuse scheme will dictate opportunities available for alternative water sources and alternative renewable energy considerations. Further information is available from the City of Melbourne's Discussion Paper, *Carbon Sensitive Water Savings* (2008) and Blunt and Holt (2007).

3.2 Carbon sensitive water saving schemes

In the development of carbon sensitive water saving schemes, the definition of direct emissions (scope 1), indirect from purchase energy sources (scope 2) and other emissions (scope 3) enable a clear understanding of emissions sources. Table 1 outlines typical examples of emission sources and their classification. To ensure consistency with National standards, the approach is consistent with Australian Greenhouse Office with emissions calculated use emission factors from the *Australian Greenhouse Office (AGO) (2005)*. The delineation of scope 1, 2 and 3 emissions enables a clear understanding of the boundary conditions. Scope 1 emissions are a direct result of activities, scope 2 are purchased with the efficiency of operation is important. Finally scope 3 are supply chain dependent. Clear boundary definition is important for responsibility of emissions.

Table 1. Definition of emissions and scope with selected examples

Emissions Sources	Examples
Scope 1 Emissions	**Direct emissions**
Fossil fuels	Natural gas, Petroleum, diesel, biodiesel – e.g. Water tankers
Fugitive emissions	Methane from wetlands, sewage treatment plants
Scope 2 Emissions	**Indirect emissions from purchased energy sources**
Purchased energy	Purchased electricity
	Purchased steam/heat
Scope 3 Emissions	**Other emissions**
	Embodied energy in water
	Embodied emissions in purchased materials

3.3 Alternative water sources

Treatment will be required to upgrade water quality for the appropriate end use. Typically water used within the City of Melbourne will be treated to a high standard reflecting the water reuse applications. A range of water sources is available for integrated water resource management as shown in Table 2. Greenhouse gas emissions will be dependent on the water source, water end-use and the treatment technology selected. The greenhouse gases in water treatment emissions are generated by:

- energy consumption, and
- biological degradation of organic matter that produces greenhouse gas emissions.

Table 2. Alternative water sources and indicative treatment required

Water	Treatment
Rainwater	Minimal treatment required. The hotwater system (e.g. gas boosted system) can be integrated to provide thermal disinfection; alternatively UV disinfection may be installed.
Stormwater	Best practice treatment required. Typically this is through the use of natural treatment systems such as bioretention systems or constructed wetlands.

	Mechanical systems, for example filtration systems, can also be used for stormwater treatment, particularly for large scale systems where limited space is available for treatment.
Greywater	Diversion devices can be fitted to subsurface irrigation systems with no treatment required. Greywater reuse treatment systems can be situated on a household scale for reuse. Moderate treatment is required to ensure pathogens are removed from greywater for non-potable water reuse.
Blackwater	High level of treatment is required to remove pathogens and biological components to ensure water is safe for reuse. Mechanical treatment systems are typically used in cities due to the limited space available.

4. The application of carbon sensitive water saving schemes

4.1 Case study - CH_2 Water Mining Scheme

The City of Melbourne's latest building, Council House 2 (CH_2), incorporates the best practice design for a green commercial building. It achieves a six star rating by the Green Building Council's rating system. The calculation is based on 600 employees for a net lettable area of 9,373 m^2.

Step 1. Baseline establishment

The CH_2 building is compared to a conventional commercial building for water consumption and derived greenhouse gas emissions. The net lettable area is the best indicator of water consumption within commercial buildings. CH_2's net lettable area is 9,373m^2. As a baseline assessment, a conventional building typically consumes 1.4 kL m^{-2} y^{-1} of water based on the net lettable area. This equates to 13 ML y^{-1} for the CH_2 building. This water consumption correlates to a total greenhouse gas emission of 11.8 t CO_2-e/y as shown in Table 3. The existing centralized water infrastructure system will not be reduced and hence only the operational energy is considered in this analysis, with the embodied energy of the centralized system excluded.

Table 3. Equivalent tonnes of CO_2 emitted from a conventional office building

Water	Equivalent $C0_2$ generated (tCO2-e/ML)	ML/y	Conventional building (tCO2-e/y)
Potable Water	0.173	13	2.25
Wastewater	0.875	11	9.59
		Sub-total	11.8

Step 2. Demand Management measures

The City of Melbourne has implemented best practice water management in the design of the CH_2 building. Water efficient fittings (AAA taps, fittings, dual flush toilets), pressure reduction valves and appliances are installed to reduce water demand.

The total demand is calculated as 10.6 ML/y. This is comprised of a 2.0 ML/y potable water demand for drinking, hand basins and showers. An additional water demand of 8.6 ML/y is estimated for the provision of non-potable water to toilets, irrigation, cooling towers and tankers (for irrigation) and street sweepers. Best practice water management in office buildings is 0.5 kL m^{-2} y^{-1} to 0.75 kL m^{-2} y^{-1} which corresponds to 4.7 – 7.0 ML y^{-1} and correlates well with City of Melbourne's water balance of 6.4 ML/y (excluding the demand for tankers and street sweepers – outside the building). The water balance figures are used to determine the greenhouse gas emissions for the CH_2 building.

The greenhouse gas emission from the potable water supply is 0.35 t CO_2-e/y as shown in Table 4. Note as wastewater is imported into the building for additional demands there is a reduction in wastewater (on a volumetric basis). All sludge and organic matter is returned to the sewer system for centralised processing. This is highlighted by the negative value for wastewater imported.

Table 4. Greenhouse gas emissions from CH2 building

Water	Equivalent $C0_2$ generated (tCO_2-e/ML)	ML/y	Water efficient building (tCO_2-e/y)
Potable Water	0.173	2.0	0.345
Wastewater imported	0.875	3.5	-3.06
		Sub-total	1.75

The non-potable water supply is technology and systems dependent with the greenhouse gas emissions calculated in Step 3.

Step 3. Alternative water reuse scheme

Step 3a. Technology selection

A blackwater reuse system is installed in the basement of the CH_2 building. Wastewater from the building and additional water from the sewer is treated to a high water quality. Solids are removed by an initial screening process, with finer pollutants removed by the subsequent ultra-filtration and reverse osmosis. Pathogens are effectively removed by the physical separation process. This physical separation process can adjust to meet demand.

Stormwater is harvested from the roof and collected for reuse within the building. This provides an additional water source to contribute to the non-potable water supply.

The reused water (consisting of treated blackwater and harvested stormwater) is fed to a 20 kL header tank before distribution throughout the building. The water is used for toilet flushing, irrigation, cooling towers, external irrigation (i.e. supplied to tankers) and street sweepers.

The energy requirements are accounted for by the treatment train components and include:

- Pumping from sump and sewer
- Ultra-filtration unit
- Reverse osmosis unit
- Hot water system for cleaning and disinfection, and
- The design estimates for energy consumption are 2.5 – 3.0 kW/kL treated water.

The plant operates for 8 hours a day over a typical work week (5 days). The greenhouse gas produced is 248 – 297 t CO_2-e per year as shown in Table 5.

Table 5. Equivalent Greenhouse gas emission from the operation of the water mining system

Energy consumption	Energy consumption (kWh per kL of treated water)	Equivalent CO_2 produced (t CO_2-e per y)
Minimum (kWh/kL)	2.5	248
Maximum (kWh/kL)	3.0	297

Step 3b – Distribution system

The distribution system consists of a header tank situated on the roof, dual supply reticulation and a pumping system. Reused water is pumped from the basement to a header tank. The water is pressurised by a second pump before delivery to the building.

The ongoing energy requirements are from the pumping system.

- Distribution pump (situated in basement) – 5.5 kW
- Pressurised pump (situated at roof) – 4.0 kW

The pumps are assumed to operate for 8 hours per day for a typical working work (5 days). After commissioning, real data can be utilised to refine this conservative estimate.

Table 6. Greenhouse gas emissions from pumping network

Energy consumption	Energy consumption (kWh)	Equivalent CO_2 produced (t CO_2-e per y)
Distribution pump	5.5	17
Pressurised pump	4.0	12

The embodied energy requirements are due to the additional materials for the headers tanks, dual supply reticulation and associated equipment. These components are summarised in Table 7. These components are assumed to be suitable for the life of the building (50 years) to enable inclusion with ongoing greenhouse gas emissions demands. The greenhouse gas emissions from the embodied energy contribute to 0.7% of the total emissions and are immaterial for the water mining plant, with the bulk of emissions being contributed from the operational energy requirements.

Table 7. Embodied energy for rainwater tanks and harvesting system

Item	Quantity	Mass (kg)	Embodied energy (MJ/kg)	Embodied energy (MJ)	Green-house gas emissions (t CO_2-e)	Green-house gas emissions (t CO_2-e/y)
Header tank	20 kL	1000	38	38000	15.2	0.30
Holding tank	30 kL	1500	38	57000	22.9	0.46
Rainwater holding tank	10 kL	500	38	19000	7.6	0.15
Dual supply reticulation network	Throughout building an additional 1300m of copper plumbing and fittings	1650	100	165000	66.2	1.32
					Sub-total	2.24

There is a net increase of greenhouse gas emissions from the water mining treatment system. A summary of the greenhouse gas emission is provided in Table 8. The majority of the emissions are derived from the treatment and distribution energy requirements. A net increase of 314 t-CO_2e/y will have to be generated or offset to ensure there is no net increase in emissions from water recycling.

Table 8. Summary of greenhouse gas emissions

Baseline assessment - Conventional building	
	t-CO_2e/y
Water	2.25
Wastewater	9.59
Sub-total	11.8
CH2 water efficient building	
Water (mains supply)	0.345
Wastewater imported	-3.06
Treatment	297
Distribution	30.8
Sub-total	325
Net increase	**314**

Step 4 – Onsite renewable energy

In all, CH_2 will use approximately 549,257 kWh of electricity per year for all its operational needs. If this were sourced only by conventional energy this would generate 764 tonnes of greenhouse gases.

However, CH_2 building has onsite renewable energy systems including:

- Electricity from co-generation - A gas-fired co-generation plant on the roof will be used to generate electricity and heat, reducing reliance on the public electricity grid.

  The co-generation plant will have much lower CO_2 emissions than coal-fired electrical generation and will provide 164, 777 kWh per year of electricity, meeting about 30 per cent of CH_2's electricity needs. This will save 229 tonnes of greenhouse gases.

- Solar photovoltaic cells - CH_2 will use about 26 square metres of photovoltaic cells on the roof to generate about 12, 775 kWh per year of electricity from the sun's energy. This energy will power the movement of the louvres used to shade the west façade. This will provide 2% of the buildings energy needs and save 17 tonnes of greenhouse gas emissions.

  This results in on-site generation of 32% of CH_2's electricity needs.

In addition the following technologies provide efficiencies that will result in greenhouse gas savings:

- Heat from co-generation - Heat from the co-generation plant (about 100Kw) will be used to help CH_2's air conditioning plant. This heat can be used directly for heating or, via an absorption chiller, for cooling. It is estimated the co-generation plant will satisfy 80% of the building's fresh air heating/cooling requirements just by using waste heat;
- Heat recovery - Heat is recovered from the air that gets exhausted out of the offices. CH_2's fresh air system uses no re-circulated air so fresh air from outside needs to be constantly heated or cooled to be supplied at 18°C. Through a simple heat exchange process, the temperature of the air exhausted from the space is used to help heat or cool the fresh supply air;
- Solar hot water heat recovery - About 60 per cent of the hot water supply will be provided by 48 square metres of solar hot water panels on the roof. On days with little solar heat gain, a gas boiler will heat water instead; and

- Wind turbines - Six wind turbines will extract air from the offices spaces through ducts on the north façade. The turbines, especially designed for CH_2, are 3.5m high and replace electric fans that would normally carry out the same function.

Step 5 – Purchase accredited green energy

In Step 4, it could be seen that 32% of CH_2's energy needs will be supplied by renewable sources. This leaves 68% of power for CH_2 still needing to be sourced by mains electricity. Management of CH_2 has decided to fully fund the mains electricity requirement with accredited Green Power$_{TM}$.

For the purposes of the requirements for this carbon sensitive water recycling policy, it is considered that 68% of the power needed for the recycling plant should be funded by Green Power$_{TM}$.

Step 6 – Carbon trading

The owners of CH2 have agreed to supply Green Power$_{TM}$ for all their 'mains' energy needs. Because of this, there is no remaining 'mains' energy that needs to be offset by exploring carbon off-set programs.

4.2 Case Study: Single allotment – rainwater harvesting

A single household allotment is investigated for the harvesting of rainwater and reuse within the block. This scenario is based on a small inner city redevelopment. The terrace house is bordered by properties on either side. Limited garden is available within the block with the harvested water used for toilet flushing.

The roof area of 45 m^2 is collected in a 1.5 kL tank. The tank is situated within the roof and the water gravity feeding to the toilets. This removes the requirements for any pumps. In situations where tanks cannot be installed in the roof, a pump will be required for distribution and increase greenhouse gas emissions.

The harvested rainwater will be used for toilet flushing (demand of 50L/d).

Step 1. Demand management

Reducing water demand by the installation of dual flush toilet (6/3L) also reduced greenhouse gas emissions. A water efficient toilet consumes 50 L/d (18.3 kL/y) for toilet flushing. Reducing water consumption reduces the transportation of both water and wastewater through the centralised networks. It also reduces the volume of water to be treated at centralised facilities.

Step 2. Alternative water scheme

The 1.5 kL tank provides stormwater for 87% of the demand, that is, 15.9 kL/y with the remainder supplied by potable water (2.4 kL/y). This reduces the overall greenhouse gas emissions to 16.4 kg CO_2-e/y. Wastewater is still disposed via centralised treatment facilities being transported to Werribee for treatment and release back into the environment. The energy requirements and consequent greenhouse gas emissions are calculated for the transportation and treatment.

The embodied energy is calculated for materials for the rainwater tank and additional plumbing. Additional plumbing is required for collection of rainwater and supply to the toilets. No treatment is required for this scheme beyond the settling achieved in the rainwater tank. As there are no mechanical systems or electrical motors attached to this system, no ongoing energy is required. The total embodied energy is 6890 MJ. The analysis estimates a life span of 50 years and thus the average greenhouse gas emissions are 55 kgCO_2-e/y.

As an example a summary of the greenhouse gas emissions from both the conventional and water efficient household is provided in Table 9. There will be a net increase of 18 kg CO_2-e/y in the greenhouse gas emissions, predominately from the additional materials required to construct the rainwater tank and additional plumbing required. This can be offset by the purchase of green energy (refer to Step 3).

Table 9. Summary of greenhouse gas emissions from rainwater tank for toilet flushing

Baseline assessment - Conventional	
	kg-CO_2e/y
Water	5.54
Wastewater	28.1
Sub-total	33.6
Water efficient terrace	
Water (mains supply)	0.41
Wastewater	16.0
Rainwater tank	24.8
Distribution	10.2
Sub-total	51
	kg-CO2e/y
Net increase	**18**

Step 3 – purchase green energy

It is recommended to purchase green energy to off set the net increase in green house energy. This water reuse scheme will have a net increased of 18 kg CO_2e/y and this can be offset by the purchase of green power.

5. Conclusions

For both case studies, there is a net increase in greenhouse gas emissions. The operational phase of the localised treatment is the most significant source of emissions. Even the household scale system with no operational energy requirements produces additional emissions.

Sustainable water management is critical to ensure the livability of the urban environment. Learning from nature directs our community to resilient water systems. For sustainable water systems, this translates to a move to water services, diversity of water sources and flexibility in infrastructure. As the complexity of water systems increases, understanding the interactions with climate change is critical to ensure consistency with planning decisions. The key outcomes of this stuffy include:

- Livable cities require a diversity of water sources with varying emission consequences. Augmentation of centralized water systems will result in additional emissions
- Carbon and water neutrality are complex. Consistency in decision making across spatial variations is required to ensure optimal environmental outcomes.
- Carbon footprinting provide a methodology to quantify emissions from alternative water sources
- Boundary definition of the system to be studied is critical - scope 1, 2 and 3 emission are recommended to be considered greenhouse gas emissions, and
- Community values and learning from complex systems may help to drive the integration of natural and built forms.

Carbon neutrality is a competing driver to deliver alternative water sources. This methodology enables consequences of water management decisions and their impact on emissions. By understanding, defining and managing the explicit interactions with the emissions, planning decisions can be consistent for water projects.

WATER BALANCE OF A GREEN BUILDING

SAM TROWSDALE, JEREMY GABE, ROBERT VALE

Landcare Research, Private Bag 92 170, Auckland, NZ

ABSTRACT

Monitoring results are presented as an annual water balance from the pioneering Landcare Research green building containing commercial laboratory and office space. The building makes use of harvested roof runoff to flush toilets and urinals and irrigate glasshouse experiments reducing the demand for city supplied water and stormwater runoff. Stormwater treatment devices also manage the runoff from the carpark helping curb stream degradation. Composting toilets and low-flow tap fittings further reduce the water demand. Despite research activities requiring the use of large volumes of water, the demand for city-supplied water is less than has been measured in many other green buildings. In line with the principles of sustainability, the composting toilets produce a useable product from wastes and internalise the wastewater treatment process.

KEYWORDS:

Green Building; Rain Tank; Compost Toilet; Stormwater Treatment, Tamaki Building.

INTRODUCTION

Landcare Research is a New Zealand Crown Research Institute primarily concerned with the terrestrial environment and sustainable development. When Landcare Research chose to relocate its Auckland office to a site on the University of Auckland's Tamaki Campus, staff wanted to demonstrate how it might be possible to build a new building that was more environmentally friendly than usual. This was made complex by the requirement for research laboratories, glasshouses and housing for the six million or so specimens in the national collections of insects and fungi.

The pioneering Landcare Research Tamaki Building won the Energy Efficiency and Conservation Authority's Energy-Wise Commercial Building award in May 2005 and it also received an "environmental hero" Green Ribbon Award from the Minister for the Environment. The building was designed to be energy efficient and make use of renewable materials and finishes that had a 100-year life.

The building's design also considered four urban waters: mains-, storm-, waste- and natural-. To minimise its impact on natural waters, it was designed to minimise demand for mains water and discharges of stormwater and sewage. This paper presents the measured operational performance of the building's water systems as an annual water balance (Figure 1) to show what has been achieved and to enable comparison of its performance with national and international practice. Context is provided by estimating the water balance of a similar building constructed using more conventional systems (Figure 2). The size of flow in the conventional water balance was estimated using the measured flow in the Landcare Research building. The annual period considered is the year ending 25 July 2007. The paper is structured around the building's *inputs* of water, *demands* for water and *outputs* of water.

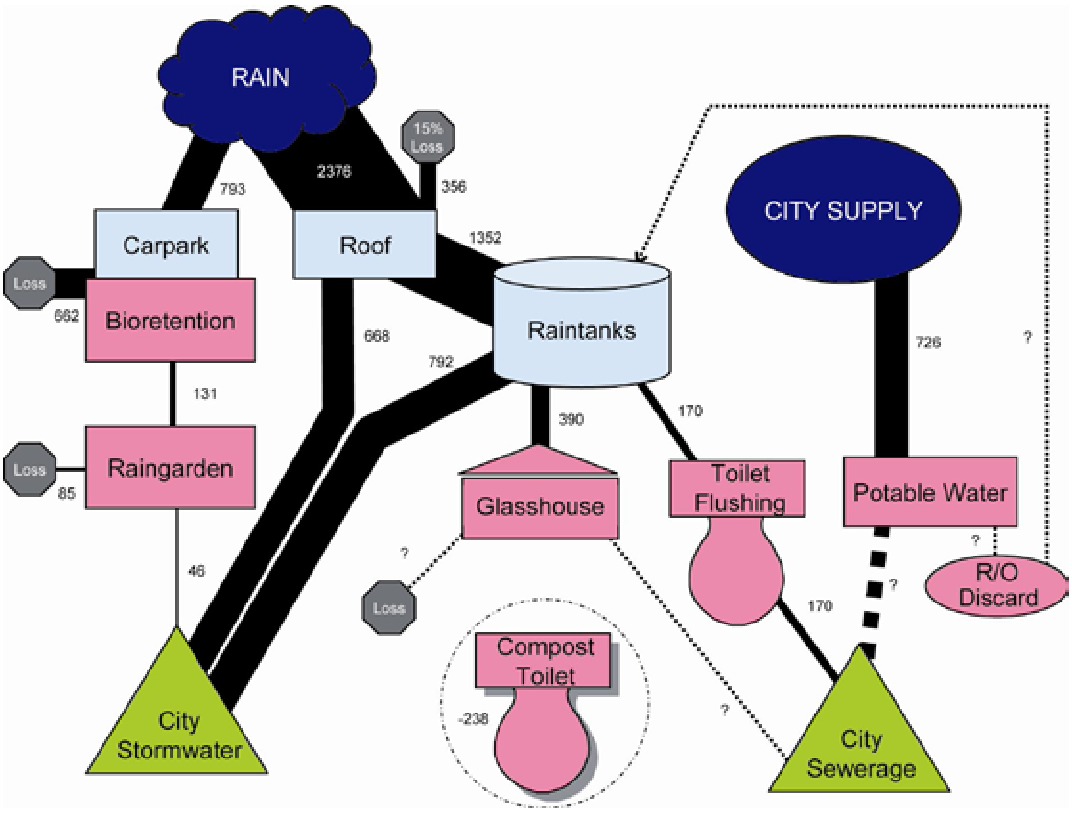

Figure 1 Water balance of the Landcare Research Tamaki Building. The thickness of the lines is proportional to the magnitude of flows, which are labelled and have the units m^3/ year ending 25 July 2007.

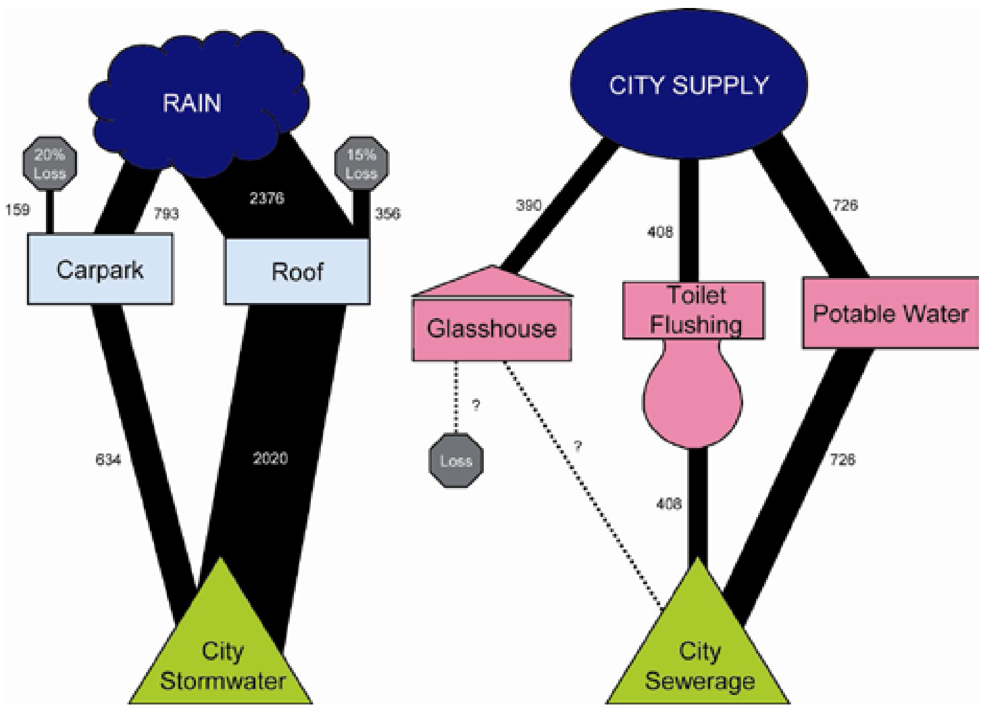

Figure 2 Water balance of a building similar to the Landcare Research building but using a more conventional system. The thickness of the lines is proportional to the magnitude of flows, which are labelled and have the units m^3/ year ending 25 July 2007.

INPUTS OF WATER

The inputs of water to the building include rainfall, harvested rainfall, and potable water supplied by the city's water main. The input size and method of measurement are presented before discussing their implications.

Rainfall

Rainfall is measured onsite using two (primary and backup), 0.2-mm tipping-bucket gauges. Data records are complete from 19 January 2005 to date. These data are further supported by climatic data collected at a weather station just 500 m from the building since December 1992. Auckland City experiences most rainfall in April to September (90-130 mm/month) and moderate moisture deficits (30-90 mm/month) from November through March. The total annual rainfall for the year ending 25 July 2007 was 1042 mm, similar to the long-term average rainfall of 1200 mm/ year (ARC 1999).

Water supply

The building is connected to the mains water supply. In addition, runoff from 1512 m^2 of roof area drains through a syphonic drainage system to three 25 000-L rainwater storage tanks connected in series. The first two tanks are connected at their base and are in hydraulic equilibrium. Water is pumped from these tanks to header tanks for use in the building. The third tank collects overflow. A mains backup is available for prolonged dry spells and for fire fighting. The volume of water running off the roof and into the tanks was 1352 m^3 in the period considered, assuming a 15% loss due to evaporation and storage on the roof. None of this water would be available for use if a conventional system had been used (Figure 2).

DEMAND FOR WATER

The core business operations of Landcare Research require laboratories and glasshouses that use a large volume of water. Rainwater harvesting, low-flow fittings and composting toilets reduce the water demand of the building (Figure 1 and 2).

Mains water

The building's potable water is supplied by the city mains supply. The local interpretation of the building code requires that hand basins, showers and kitchen appliances also be supplied by mains water. Low-flow fixtures and low-volume domestic appliances were used throughout. The building also draws on the city water supply to make water treated by reverse osmosis (RO), required for laboratory work such as washing glassware and making chemical solutions. The RO treatment process is a large consumer of water because only an estimated 30% (maximum) of the water used in the process is purified. The system has been configured so that the reject water can be sent to the rainwater tanks. The volume of reject water has not been measured.

The consumption of city mains water has been measured hourly by the building management system since May 2006. A total of 726 m^3 was used during the year ending 25 June 2007. No mains water was used to top up rainwater tanks. The number of full-time-equivalent (FTE) employees was 94 making the total mains water used 7.7 m^3/ FTE/ year. Normalising for floor area (4828 m^2), results in a mains water use of 0.150 m^3/ m^2/ year.

The well known green building rating systems LEED (US Green Building Council, 2007) and NABERS (Department of Environment and Climate Change [New South Wales], 2007) provide sections on water. This has led to a number of green buildings reporting measured water use (NABERS) or being the target of post-occupancy evaluation based on promises made in the design stage (Turner, 2006). These data are used to provide context to the measurements made by Landcare Research.

Turner (2006) collated actual measured water use in US buildings that have attained a LEED building rating (Table 1). For comparison, measurements have been converted from imperial to SI. Turner's method assumed 365 days per year based on the reported employee counts for the King Street Center building.

Table 1 Actual water use measured in green buildings (after Turner, 2006)

	LEED rating	m^3/ FTE/ year	m^3/ m^2
Landcare Research building, NZ	N/A	7.7	0.150
Viridian Place, Portland, USA (commercial office)	Certified	7.8	0.179
Anonymous office building, NW region, USA	Certified	24.5	0.187
Balfour Guthrie office building, Portland, USA	Silver	8.4	0.244
Hillsdale Public Library, Portland, USA	Gold	7.8	0.321
Seattle Central Public Library, Seattle, USA	Silver	6.0	0.329
King Street Center, Seattle, USA	Gold	7.4	0.338

The Landcare Research building has comparable performance to these LEED-certified buildings. The water use measured in m^3/ FTE/ year was similar in most buildings, with the obvious exception of the anonymous office building. The Landcare Research building performed best using the metric m^3/ m^2.

A total of 59 buildings have achieved a NABERS score for water use but only one building scored a 5-star rating (0-0.35 m^3/ m^2/ year). That was the Szencorp building at 40 Albert Road, South Melbourne, Australia, which has been dubbed "Australia's greenest building" (Szencorp, 2006) and has also achieved 5-star Australian Building Greenhouse Rating (Department of Environment and Climate Change [New South Wales], 2007) and 6-star Green Star (Green Building Council of Australia, 2007). The Szencorp building's annual measured water use (0.131 m^3/ m^2/ year) was very similar to that measured in the Landcare Research Building (0.150 m^3/ m^2/ year). Interestingly, the measured water use in the second highest NABERS-scoring building was much higher at 0.391 m^3/ m^2/ year, which rated it a 4-star (0.35-0.7 m^3/ m^2/ year) building.

The data show that the Landcare Research building is one of the best-performing green buildings in terms of mains water use, and that is despite the large water demand for laboratories and glasshouses. The key to achieving this performance was the use of composting toilets and rainwater harvesting, which are discussed in the following sections. Interestingly the volume of harvested rainfall was greater than the building's total water demand, meaning that there is the potential to perform better.

Harvested rainwater

Harvested rainwater is used to flush dual-flush toilets and urinals. It is also used to irrigate the glasshouse experiments. The building management system records hourly demand for stored rainwater for toilets and glasshouses independently. A total of 170 m^3 harvested water was used to flush toilets during the year ending 25 July 2007. The glasshouses were a large user of water, requiring 390 m^3.

There are five dual-flush toilets on the ground floor and manual-flush urinals in the male facilities on all three floors. There are four manual-flush urinals in total. Composting toilets were not practical on the ground floor because the building is situated on basalt rock, making excavation for the bins very expensive.

Composting toilets were installed on the first and second floors of the building, where seven individual toilet pedestals are connected to two Clivus Multrum (2001) composting bins. The bins are gravity-fed from the male and female toilets and use no water for flushing. Assuming a similar water use per toilet as the building's dual-flush toilets, the compost toilets reduced water demand by 238 m^3 in the period considered.

Cost savings by reusing rainwater

Landcare Research was charged NZ$4.76 per cubic metre of water that it drew from the city water main. Landcare Research paid NZ$3,456 for mains water supplied for the year in question. The reuse of rain water saved NZ$2,666. Clearly, cost savings would have been larger if the building had been fitted with more-conventional toilets and appliances. The maximum potential savings can be described as the total value of all harvested water in the year ending 25 July 2007 (1352 m^3). At city supply prices, this gives a total potential cost saving of NZ$6,436 per year.

OUTPUTS OF WATER

Traditional methods to manage urban stormwater and wastewater have been shown to cause environmental degradation, which has driven the development of more sustainable management techniques (Wong, 2007). Some of these techniques are used in the building and are described here.

Stormwater

Two-thirds of the roof area (1526 m^2) drains to rainwater tanks, which help to reduce the stormwater volume and peak discharge to the city infrastructure. The remaining third (754 m^2), mainly that on the research glasshouses, drains directly to the stormwater network. Of the water collected in the tanks, 560 m^3 was used in the building while 792 m^3 went into storage. Some of that storage was used to irrigate the site's gardens via a gravity-fed drip irrigator. The water is presumably evaporated, transpired by plants, or recharges groundwater. To provide detention volume during the rainy months, when there is a surplus of runoff water and the gardens do not require much irrigation, the tank was slowly drained to the city stormwater network. The total volume of water used for irrigation or drained was very similar to the amount drawn from the city supply; 726 m^3, meaning that the Landcare Research Building has the potential to be self sufficient in water.

A series of stormwater treatment devices manage the stormwater from the building's carpark. The building's 761-m^2 carpark was designed with a permeable surface as the first step in stormwater treatment. Constructed of compacted gravels, the surface had a "slow" (McQueen, 1983) infiltration rate. Mean saturated hydraulic conductivity, measured over 48 h using the twin-ring method, and following 48 h of pre-wetting, was 1.5 mm/h, with one-third of the test sites having nil infiltration and no site having more than 5-mm/h infiltration. The durability of the carpark surface and turbidity of runoff were below expectations. This type of surface is not recommended and on 13 July 2007 the surface was tarmac-sealed.

In an effort to control pollution at source, the 38-space carpark was designed to accommodate about half the number of cars as staff. Encouraging staff not to drive to work was supported by locating the building c. 800 m from a railway station and bus depot, providing cyclist facilities (covered storage and showers), and setting up an internal website to assist with carpooling.

The carpark drains to a bioretention strip, which in turn drains to a raingarden. The water that passes through the raingarden enters the local network of stormwater pipes, which delivers it offsite to a constructed stormwater pond and then to a local stream. The onsite stormwater devices are described.

The bioretention strip is 1.5 m wide and runs the length (30 m) of the main building. It meets sizing guidelines (USEPA, 1999), being about 8% of the catchment area. The strip is gently graded (1-3%) and runoff is designed to pond to an extended detention depth of c. 50 mm. The bioretention was planted with native groundcovers that do not require mowing and that will smother weeds to minimise maintenance. The planting was designed to filter sediment from stormwater by imitating the favourable physical characteristics of a grass sward. The plants included *Acaena microphylla*, *Fuchsia procumbens*, *Selliera radicans* and *Apodasmia similis*. A tussock edging reduces rain-splash onto the building and the dense *Scleranthus biformis* and *Selliera radicans* protect the soil surface from erosive drips falling from the building's overhang. In our opinion, the planting improves the site's visual landscaping. Untreated *Cupressus macrocarpa* sleepers fastened 30 mm above the ground by chemset bolts replace the typical curb-and-channel drainage system. These inhibit soil compaction by vehicles and encourage sheet flow delivery of water to reduce the likelihood of erosion and scour of the soils. Measurements show that during the study period, the bioretention discharged a total of 131 m^3 of water to the raingarden.

The raingarden has 18 m^2 of surface area and flanks the main entrance to the building. The northerly aspect maximises solar exposure and evapotranspiration. The key design features to improve stormwater treatment and retention include a deep (900 mm) multi-layered soil and delivery of water evenly across the upper surface. The raingarden was also planted with native plant species, which were chosen for their fine, dense and extensive root systems to maximise biofilms where biological activity is high. The *Muehlenbeckia astonii* and *Hebe speciosa* can tolerate annual clipping, which may be useful for harvesting bio-accumulated contaminants. Organic mulches were used to disperse the energy of stormwater, assist removal of contaminants, and suppress weeds until the native plants provide a dense cover. Just 46 m^3 of water was discharged from the raingarden to off-site treatment via the city stormwater network.

The annual water balance for the conventional building assumes a similar sized carpark that is tar-sealed and connected directly to the city stormwater network. A loss of 20% is assumed due to evaporation and storage on the carpark surface. In this case, the total annual volume discharging to the stormwater network was 634 m^3/ year, which is 1320% more than was measured when the treatment train was used. The estimate could be conservative given that the carpark is undersized for the building.

Figure 3 shows a well-characterised event that occurred on 24 January 2006, when 41.8 mm of rain fell in the 18 h between 3:09 a.m. and 5:45 p.m. Initial low-intensity drizzle was followed by heavy showers in which rainfall intensity peaked at 2.3 mm/10 min, and 10.1 mm/h. The event was large but not unusual. The 2-year return interval for the area is 70 mm in 24 h. Three weeks of predominantly dry conditions preceded the event, punctuated with only one small (<5 mm) rainfall event. With summer evapotranspiration rates of about 3 mm/d, it is expected that the stormwater devices had maximum water storage capacity available when rainfall began.

Once depressions in the carpark surface were filled and rainfall intensity was greater than the infiltration rate, it is likely that much of the rainfall onto the carpark became runoff. This runoff was stored in the mulch and soil of the bioretention strip for 4.5 h, during which time 7 mm of rain fell, before the bioretention started to discharge to the raingarden. A further 3 h passed, during which 2216 L of stormwater entered the raingarden, before the raingarden started to discharge. The total volume of water that fell on the catchment in the event was 31 800 L. The total discharge from the bioretention was 7889L and from the raingarden 3031 L, meaning that <10% of the water that fell on the catchment discharged to stormwater pipes. The peak flow was also attenuated. The peak flow measured exiting the bioretention device was 1.09 L/s and only 0.74 L/s from the raingarden.

The modelled conventional system had a markedly different hydrograph (black line on Figure 3). The peak flow was nearly three times greater at 2.8 L/s, there was little lag time between rainfall and runoff, and the total volume discharged was much larger (23 400 L). There is a well-documented decline in habitat and water quality of urban streams (e.g. Paul and Meyer, 2001) due to increased runoff from directly connected impervious surfaces, such as roofs and roads, hydraulically efficient drainage systems, compaction of soils, and modifications to the vegetation. This can result in increased flood flows (Leopold, 1968), stream erosion (Hammer, 1972), and decreased baseflow through decreased groundwater recharge (Schueler, 1994). The effects of the building's stormwater treatment devices are masked at the stream habitat scale by the numerous other urban stormwater inputs to the stream, but presumably if we all treated our stormwater we would limit the degradation of stream habitat.

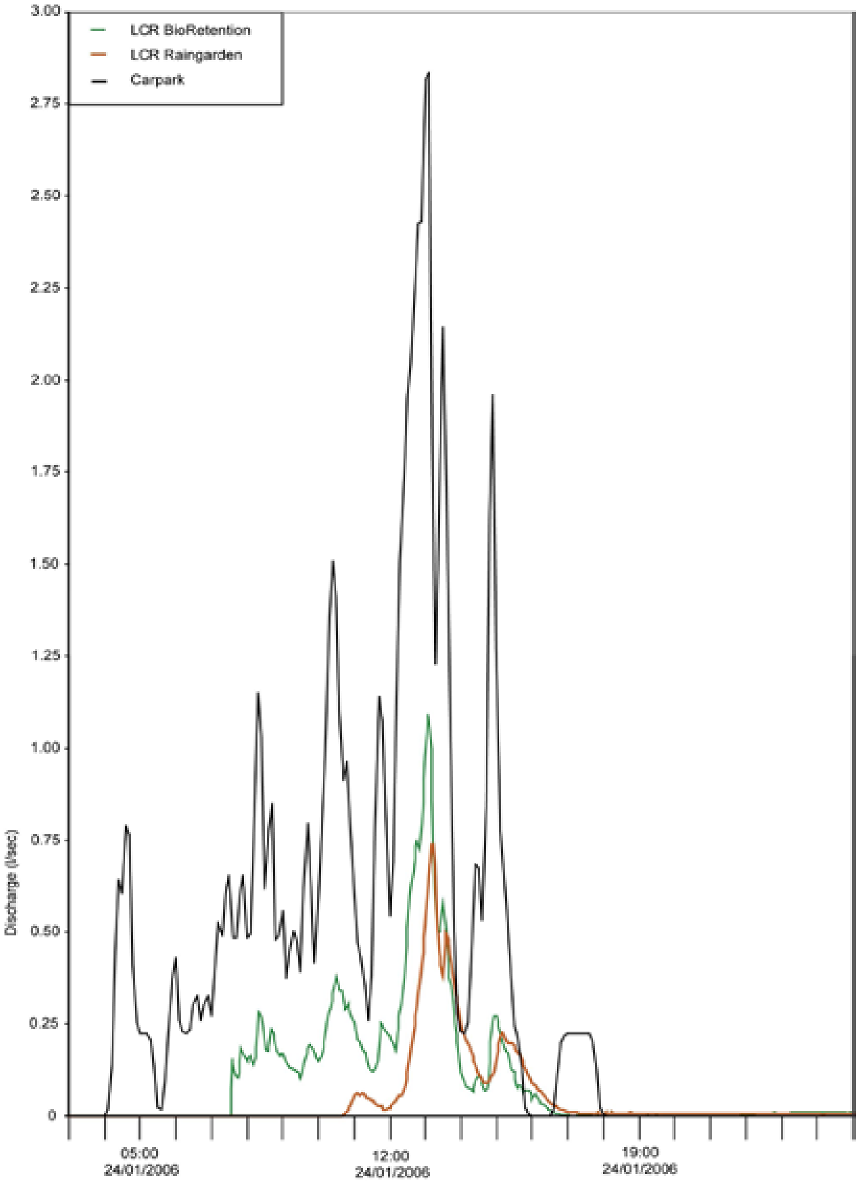

Figure 3 Hydrograph of discharge from the bioretention and raingarden at the Landcare Research Tamaki Building (brown and green lines respectively) and modelled discharge from a tarmac-sealed carpark (black line).

Wastewater

The dual-flush toilets and the urinals are connected to the city sewer system. The volume of water flowing from the flush toilets to the sewer was assumed to be similar to the volume used to flush the toilets (170 m^3). Grey water from the laboratories, hand basins, glasshouses and kitchen drains to the sewer via a local sediment trap and a 1000-L detention tank. The tank can be used to isolate the drain if necessary, for example if there is a spill in a laboratory sink. Landcare Research is charged to dispose of every unit of water supplied by the city, so the discharge of potable water was assumed to be the same as supply (726 m^3).

The key to minimising discharges to the city's sewer and wastewater system was the use of composting toilets. The composting bins are connected to the city sewer to allow liquid that has not evaporated to drain, but most of the inputs are managed within. In line with the principles of sustainability the composting toilets promote the use of a product typically considered waste. The composting toilets also better embody the traditional view of the indigenous Maori, who regard land-based disposal of human excrement and urea more appropriate than disposal to waterways (Durie, 1994).

The compost product has been shown to compare favourably to NZ Standards (NZS 4454) and commercially available composts where contribution to plant nutrition is claimed (Trowsdale et al., 2006), but the compost has yet to be used on site because of concerns about its safety. This is due in part to a lack of policy regarding appropriate handling and use of the material. While composting toilet systems have been used at the domestic scale (e.g. Vale and Vale, 2000), they are very rare in commercial-use buildings and to our knowledge these are the first compost toilets to be installed in a commercial-use building in New Zealand. Staff satisfaction of the composting toilets has increased during their 3-year operation and, in June 2007, 78% of staff said that they were completely or beyond-satisfied with using the composting toilets. This was the third highest ranked response in the building satisfaction survey.

CONCLUSION

The Landcare Research building has provided a successful demonstration of what can be achieved to address the urban water balance. Despite research activities requiring the use of large volumes of mains water, the building shows savings in the demands it makes on water resources and the wastes it emits to the environment. This was largely achieved by using composting toilets, rainwater harvesting, and stormwater treatment devices. Monitoring is ongoing to better understand and fine-tune the systems and provide data against which to benchmark building performance.

Downsview Park: A Sustainable Community in the Making

By: Tony Genco

Abstract

This paper will describe the history of the evolution of the Downsview Park project including the mandate and vision, the various steps that have been taken to move the implementation of the opportunity forward and the current tage now where the public is being reengaged in the form of advice on the development of the Sustainable Community Development Guidelines and the Urban Development Plan for the site. An analysis will be offered as to what sustainability has meant to the development of the opportunity to date and why sustainable development will become the only way that development can take place in order to truly create a society that we can all live in and truly prosper in. Downsview Park seeks to demonstrate how sustainability is achievable and through the development of indicators and other forms of accountabilities, the ability to integrate living, working, playing and learning all is in one place will be the hallmark of the new way of living in a modern world. It will describe how and why a federal crown corporation has been tasked with this responsibility to achieve this important and relevant outcome for the benefit of Canadian society.

When the Government of Canada announced the closure of Canadian Forces Base (CFB) Toronto in 1994 it stipulated, “the existing DND-owned lands associated with the Downsview site will be held in perpetuity and in trust primarily as a unique urban recreational greenspace for the enjoyment of future generations”.

Downsview Park is the name given to the whole sustainable community composed of 231.5 hectares [572 acres] that includes public open space, recreational, cultural, residential, commercial, institutional, sports and entertainment uses, all of which will be developed according to the principles of environmental, economic, and social sustainability. Downsview Park is also referred to as the Downsview Park Sustainable Community. More than 146 hectares (362 acres) of the total land area are earmarked for park and recreational activities.

Downsview Park will be a leading edge sustainable community. It will set 21st century standard for excellence in landscape architectural design, recreation, urban planning and sustainable development. The goal is to define the leading edge of green development, implement green technologies and promote green business and to offer in the City of Toronto, for the people of Canada, a wonderful place to showcase environmental social and economic sustainability on a self-financing basis.

Parc Downsview Park Inc. (PDP) is committed to sustainability in all its dimensions and environmental, economic and social sustainability are in evidence in the current and planned operations and activities of Downsview Park.

The lands where Downsview Park is located have a very rich history and have experienced a number of previous land uses. These uses, which have included agricultural production and a military base, have helped shape Toronto and Canada and have made Downsview part of some of the most important moments in Canadian affairs. The historical uses have also defined the physical environment of the park.

After the Second World War, the Government of Canada recognized the Downsview Lands strategic importance with its proximity to Toronto's industry and infrastructure. Downsview was considered by the government to be well suited as an air station and logistical support base because of the existing airfield and hangar facilities.

The idea of transforming the Downsview Lands into a national urban park was first advanced in 1994 as the closure of the military base was being contemplated. The lands were seen as a large underutilized tract of land, contained valuable old assets as well as some heritage buildings which could be renaturalized and developed as a national and international showcase for environmental, social and economic sustainability.

Parc Downsview Park Inc.'s (PDP) aspiration is to create a sustainable community, with a national purpose and identity, of great magnitude and prestige for all Canadians and to grow Downsview Park into a model for the world.

PDP is a federal Crown Corporation, established to design, develop and maintain Downsview Park. PDP's mandate stipulates that PDP is to be a self-financing and that all revenues received shall be applied to park infrastructure, operation and maintenance requirements in perpetuity. Accordingly, approximately 71 hectares (212 acres) will be dedicated to opportunities that complement the park while providing revenue to finance the construction, development and management of the Downsview Park Sustainable Community.

While PDP seeks to generate both capital and cash flow from the Downsview lands, it will be done in a way which adds value to the public open space. Further, PDP will ensure that the vision and values of Downsview Park are evident throughout the property in a seamless and integrated fashion.

PDP is now actively moving ahead with its ambitious plans to build the Downsview Park Sustainable Community. Administration of most of the land for Downsview Park was transferred to PDP in 2006. PDP now actively manages the land for the purposes of achieving its mandate. Those actions include constructing and maintaining the urban green space; maintaining, protecting and leasing real property assets; providing a varied program of activities for the public; providing facilities for public and private access; and cultivating relationships with current and future partners in the creation of Downsview Park.

In the early stages of Downsview Park's development, the Downsview Park International Design Competition was held to realize the vision of creating a unique urban recreational greenspace, with the goal of making Downsview Park internationally recognized as one of Canada's great urban parks and a model for 21st century park building and beyond. The objective of the design competition was to promote innovative design proposals that would respond to the social and natural histories of the site, while developing its potential as a new landscape, one capable of sustaining new ecologies and an evolving array of public uses and events.

The design competition resulted in an exceptional design team and concept for Downsview Park known as Tree City. The winning design did not propose itself as a traditional national park. Rather, the site provided an opportunity to think about what it would mean to create an entirely new definition of the urban landscape, one that had the potential to redefine humankind's relationship with nature. It is a fascinating and cutting edge design, which will give Downsview Park worldwide recognition. Downsview Park may have as much influence on parks for the 21st century as New York's Central Park did for the 20th century.

Sustainability is the one word which best captures the essence of the vision of Downsview Park. Sustainability is implicit in the mandate given to PDP by the Government of Canada and is at the core of PDP's interpretation of the mandate. That vision is to create a community that is a showcase of sustainability for the world.

The vision, as developed by the Board of Directors states: "Downsview Park is a unique urban recreational greenspace, a safe and peaceful place, developed according to the principles of environmental, economic and social sustainability, for Canadians to enjoy in all seasons. The park reflects Canada's mosaic brilliance and celebrates its past present and future accomplishments." PDP is committed to sustainability in all its dimensions and environmental, economic and social sustainability are in evidence in the current and planned operations and activities of Downsview Park.

Downsview Park will be a leading edge sustainable community. It will set 21st century standard for excellence in landscape architectural design, recreation, urban planning and sustainable development. The goal is to define the leading edge of green development, implement green technologies and promote green business and to offer in the City of Toronto, and for the people of Canada, a wonderful place to showcase environmental social and economic sustainability.

Sustainable Community Development Guidelines will define the influence of the park plan on the other areas of the Downsview Park Sustainable Community and provide an explicit framework for the development of the entire site. These vital guidelines will ensure that the entire site (the greenspace, the cultural and recreational lands, the residential lands, and the business/commercial elements) become one seamless and integrated community and a showcase of urban sustainability for the world to see and experience.

The Sustainable Community Development Guidelines also a land use plan and development policies; streets, blocks and community plan; an open space plan;

sustainable urban criteria; sustainable building standards; an energy utilization plan; a sewer and water reduction plan; a sustainable housing plan; a public participation and marketing plan; a financial needs assessment for PDP; and, new ideas for further investigation.

This past year, PDP refined the urban development plan for the entirety of Downsview Park. The Downsview Park Development Plan integrates the open space plan with the development plan to demonstrate the vision for the site. The Downsview Park Development Plan identifies various neighbourhoods across Downsview Park, each of which is anticipated to include a variety of land uses. The Downsview Park Development Plan is the subject of a 25-year financial model that demonstrates its economic viability.

PDP has preserved flexibility in the specifics of the Downsview Park Development Plan in order to maximize its ability to negotiate with partners to achieve the best possible result for Downsview Park in each situation, while striving to maximize the land retained by PDP. PDP's processes will be open and transparent as it encourages innovation and excellence from itself and those with whom it does business. Downsview Park will be built with everyone who shares its vision and values.

Public consultation has been a key planning principle in the development of Downsview Park because of significant local community and stakeholder interest and expectations for Downsview Park. As such, public consultation has played and will continue to play an important role in the successful development of Downsview Park, including development decisions. In the past, PDP has been acknowledged for consultation excellence and wants to maintain a high standard in the future.

PDP has hosted a variety of public consultation events and participated in public consultation events hosted by other organizations. In addition, the dissemination and exchange of general information have been facilitated through newsletters, articles, a Web site and a public consultation phone line. For example, public input into the park vision significantly influenced the competition brief for the Downsview Park International Design Competition in 1999 and more recently in the principles and concepts for PDP's Urban Development Plan and Sustainable Community Development Guidelines.

As it builds the Downsview Park Sustainable Community PDP is also forging partnerships, strategic alliances and strong, positive relationships with the local and surrounding communities, other governments and various organizations. Some of these relationships have been formulated through tenancies while others are executed through commitments to work together in future or through joint committees on broader initiatives.

Downsview Park today is a vibrant place where hundreds of thousands of Canadians are educated and entertained through a wide variety of community programs and seasonal events. These programs and events promote and broaden the awareness of the significant historical, environmental and cultural features that make Downsview Park unique. They have also established Downsview Park as a place for people of all ages to play, learn and enjoy in every season.

Summary

There are many tall-narrow buildings in the center of large cities in Japan. These buildings are of single span along the street and standing side by side with a narrow space between adjacent buildings. Many of these buildings were designed and constructed according to the old seismic codes and are insufficient in the seismic capability.

There are a number of technologies available for seismic retrofit, such as adding walls or steel braces, confining columns and beams with steel plates or carbon sheets. Yet these retrofit works have not been widely practiced mainly due to the following reasons: 1) the retrofit work requires a lot of expenditure, 2) the utility of the building is reduced if walls or steel braces are added, and 3) the use of the building is interrupted during the retrofit work.

In order to overcome the above shortcomings of the conventional retrofit methods, we have proposed a seismic retrofit method appropriate for tall-narrow reinforced concrete buildings, which can be applied from outside of the buildings. The proposed method is composed of, 1) drilling bore-holes on the columns from outside, 2) poring grout in the bore-hole, and 3) inserting reinforcing bars with anchor heads on both ends. The supplemental reinforcing bars, together with the existing hoops, are expected to work as the shear reinforcement of the columns and improve the seismic capability of the buildings.

This paper firstly introduces the concept and the application procedure of the proposed method. Secondly a static loading test to study the effect of the supplemental reinforcing bars is presented. Thirdly the construction workability of the proposed method in a space as narrow as 50cm is ascertained through the field tests. Fourthly a design example is presented. And finally the reduction in CO_2 and the construction wastes by the proposed method as compared to the conventional retrofit methods is demonstrated, which shows a favorable effect of the proposed method on the environment.

1. Introduction

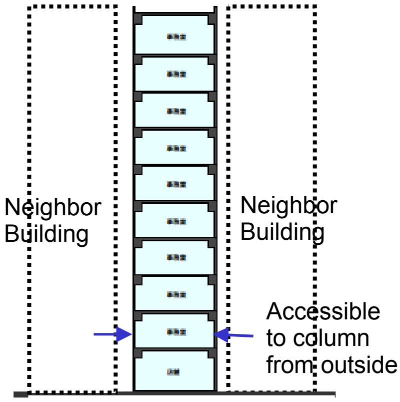
In order to make an existing building to be sustainable, the seismic safety is one of the first priorities for the buildings located in active seismic areas. In Japan as one of the most active seismic areas, many buildings designed and constructed according to the old seismic code are insufficient in the seismic capability. There are a number of technologies available for the seismic retrofit, such as adding walls or steel braces, confining columns and beams with steel plates or carbon sheets. Yet these retrofit works have not been widely accepted mainly due to the following reasons: 1) the retrofit work requires a lot of expenditure, 2) the utility of the building is reduced if walls or steel braces are added, and 3) the use of the buildings is interrupted during the retrofit work.

We have developed a new seismic retrofit method for tall-narrow buildings that are located in the center of large cities in Japan. The plan view and side view of a typical tall-narrow building are shown in Figure 1. It has a single span of 5~8 m along the street (short direction), and has several spans in the transverse direction (long direction). The same type buildings are standing along the street side by side with a narrow spacing with adjacent buildings. Both sides of the long direction are usually reinforced concrete shear walls, indicating sufficient seismic capability for this direction. The short direction, however, is basically a moment-resisting frame and has insufficient seismic capability if designed according to the old building code, and therefore requires seismic retrofit.

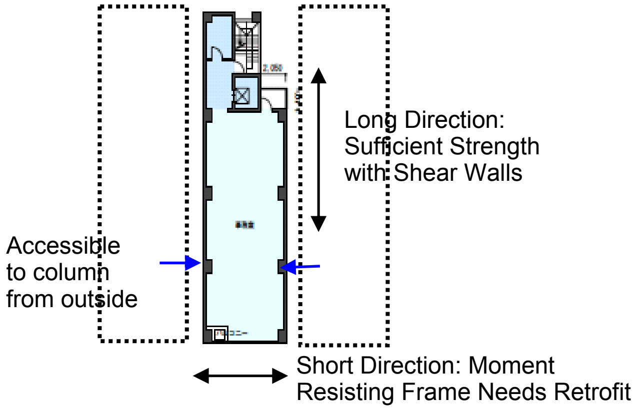
Tall-narrow buildings have special structural features such as: 1) the seismic retrofit is only needed for the short direction, and 2) as this direction is of single span, all columns, at least one face, are accessible from outside, in other words, they can be retrofitted only from outside of the building.

Taking advantage of these features, we propose a seismic retrofit method appropriate for tall-narrow reinforced concrete buildings, which can be applied from outside of the building. The proposed method is composed of, 1) drilling a hole on columns from outside, 2) poring grout in the hole, and 3) inserting reinforcing bars with anchor heads on both ends. The supplemental reinforcing bars, together with the existing hoops, are expected to work as shear reinforcement of the columns and improve the seismic capability of the buildings.

The proposed method may not be a perfect solution as a seismic retrofit, but we want to emphasize that this method is much easier than the conventional methods that building owners can accept it as a retrofit method.



Side View: Buildings are standing side by side with narrow space



Plan View: Building is Single Span along Street and Long in Perpendicular Direction

Figure 1 Typical Tall-narrow building

2. Seismic Retrofit Method

The problem associated with the columns of tall-narrow buildings which were designed according to the old building code is that the shear reinforcement is insufficient so that the columns may suffer shear failure during severe earthquakes, as shown in Figure 2. To prevent the shear failure of the columns, a retrofit method by adding shear reinforcement is proposed. The shear reinforcement as shown in figure 3 is a deformed bar with anchors welded on both ends. As the long direction has sufficient strength and stiffness due to the shear walls, only one short direction needs such retrofit. It makes the retrofit work much easier and applicable from outside.

The construction process as shown in figure 4 is composed of the following procedures:

1) Drill bore-holes on the columns from outside,

2) Pore grout mortar in the bore holes, and

3) Insert the reinforcing bars.

The bore-hole is slightly larger than the tip-anchor, and a larger hole is made in the surface part to accommodate the head-anchor. The added reinforcing bars, together with the existing hoops, are expected to work as shear reinforcement of the columns.

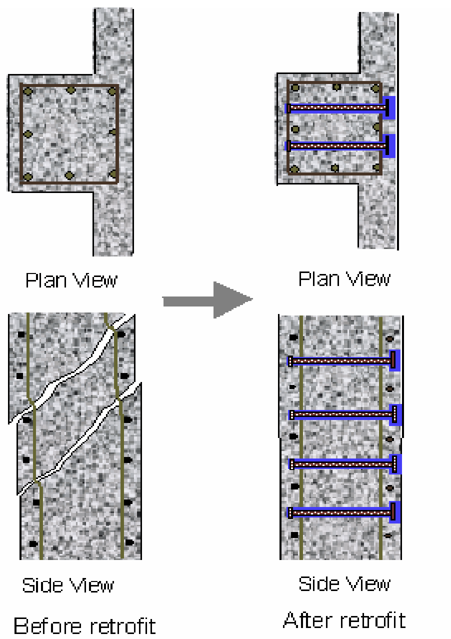


Figure 2 Concept of Retrofit: To Prevent Shear Failure of Column by Adding Shear Reinforcement

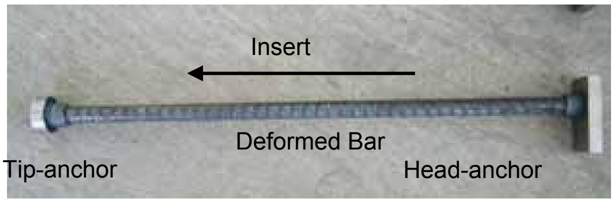

Figure 3 Deformed Bar with Anchors for Shear Reinforcement

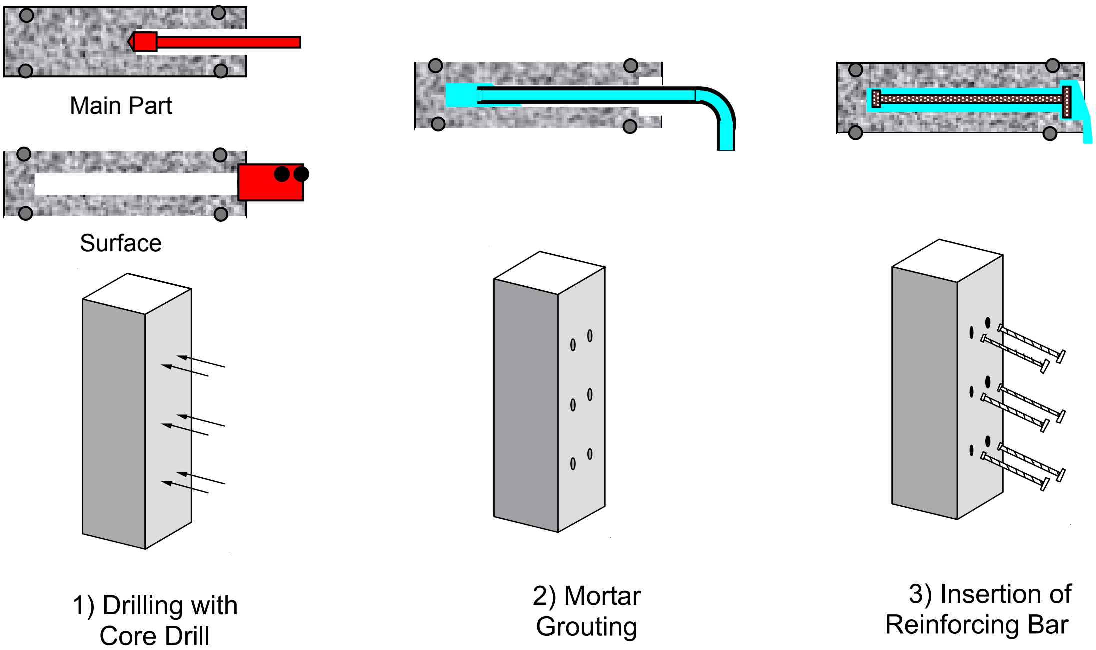

Figure 4 Construction Procedure

3. Static Loading Test

In the proposed method, the function of the supplemental reinforcing bars may not be the same as that of the usual hoop-type bars, especially their effect on concrete confinement may not be expected. The effect of the supplemental reinforcing bars was examined by static loading tests.

Real-scale column specimens with and without the supplemental reinforcing bars were subjected to constant vertical load and horizontal load reversals. Figure 5 shows the test set-up and one of the specimens. Table 1 tabulates several structural properties of the specimens. Test columns are composed of two test series of Round-bar Series and Deformed-bar Series, in which existing longitudinal and shear reinforcements are round bars and deformed bars respectively. The existing shear reinforcements are spaced with an interval of 30 cm and lateral reinforcement ratio is very small (about 0.1%), as compared to the current design practice. With the retrofit by inserting the reinforcing bars, the lateral reinforcement ratio increases to about 0.40%, where cross sectional area of the supplemental reinforcement is counted in the same manner for an ordinary hoop.

Figure 6 shows the force-displacement curves and damages at 2% drift. All specimens failed in shear, but the shear cracks are smaller and more distributed in the retrofitted columns. The test results are similar for the two series. The inserted reinforcing bars were observed to improve the energy dissipation capacity represented by loop area, as well as enhance the maximum load.

As prototype tall-narrow buildings are old, the objective of retrofit is not necessarily to strengthen these buildings to meet the current design practice but to prevent them from suffering serious damages and the occupants from losing their lives in the event of severe earthquakes. It can be said that the proposed retrofit method is likely to attain this objectives for both cases of Round-bar Series and Deformed-bar Series.

4. Application Test of Proposed Method in Narrow Space

As the proposed seismic retrofit is especially targeted to the tall-narrow buildings standing side by side, a special construction method, which can be applied in the narrow space between buildings, has to be developed. The minimum space considered for the construction was determined to be 50 cm. To minimize the construction noise to the neighborhood, a high-frequency diamond core drill was selected as a base machine. The core drill was modified to be handed in a space as narrow as 50 cm. The developed machine is shown in Figure 7. The motor is attached to the angle vertical to the drill axis to reduce the total length, and the bits are divided into pieces, which can be connected one by one as the drilling is going deeper.

The motor is attached to the angle vertical to the drill axis.

The bits are divided into pieces to be connected as the drilling goes deeper.

Figure 7 Core Drill Developed for Construction in Narrow Space

An application test was conducted using the column of an existing building. To reproduce a narrow space between buildings, a temporally wall was installed to leave the work space of 50 cm. The test column was of two stories with the height of 560cm, and its cross section was 65 cmx65 cm. Scaffoldings were installed, and the location of existing bars was censored and identified. The column and the view of the application test are shown in Figure 8. Three men are working as a team.

The application procedures after the above-mentioned preparation were composed of, guide-rail attachment and relocation, bore-hole drilling, grout pouring, and reinforcing bar insertion. Total 48 supplemental reinforcing bars with 13mm diameter were inserted at a vertical spacing of 25cm. The hole is 57cm in depth, and 30 mm in diameter for the main part and 80 mm for the surface part as shown in Figure 9. Three bit pieces were connected one by one as the drilling was going deeper. The average time needed to drill one hole is 6.0 minutes, and the total time needed for the application of 48 inserted bars, including all application processes after the preparation, is 25 hours. The working efficiency is about two insertions of the supplemental reinforcing bars per hour.

Figure 8 Model Column and Application Procedure

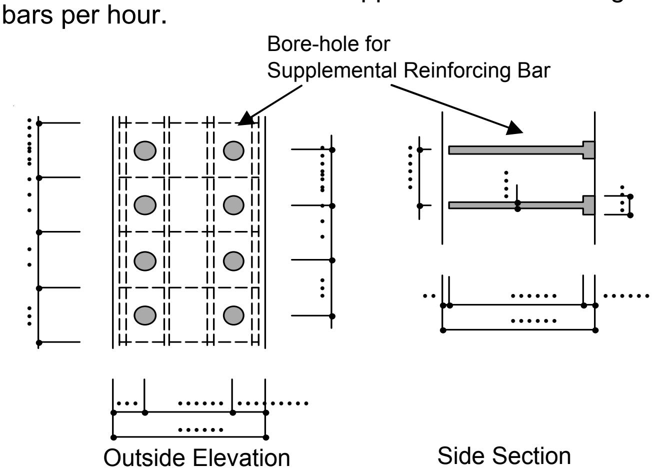

Figure 9 Bore-hole Arrangement on Test Column

5. Design Example

By taking an example building, seismic performance was compared for the pre-retrofit and the post-retrofit structures, where Japanese Standard for Seismic Evaluation and Guidelines for Retrofit was used. In this evaluation practice the seismic capacity was evaluated by index, 'Is'.

$Is = E_0 \times S_D \times T$

Where, E_0: basic structural seismic capacity index

= C (Strength Index) x F(Ductility Index)

S_D: modification factor due to structural irregularity

T : reduction factor for time-dependent deterioration

The model building is a 6 story reinforced concrete building as shown in Figure 10. It is a single-span moment-resisting frame for the short direction, while it has shear walls on both sides for the long direction. Figure 11 shows the cross section of the columns which have existing shear reinforcement of 9mm-daiameter round bar at the spacing of 30 cm. Shear reinforcement ratio is 0.071%, which is very small as compared to the current design practice. The seismic capacity was evaluated by the above method. The resulting 'Is' values are plotted in Figure 12. The 'Is' values of 1st to 4th stories are less than 0.6. Note that the Is value less 0.6 means unsafe for earthquakes.

The seismic strengthening with the proposed method was planed. For the 1st- and 2nd- story columns two reinforcing bars with 16mm in diameter are added at the spacing of 15 cm. For the 3rd- and 4th- story columns two reinforcing bars of 13mm in diameter are added at the spacing of 15 cm. The resulting shear reinforcement ratio becomes as much as 0.353% for the 1st- and 2nd- story columns, and 0.225% for the 3rd- and 4th- story columns. Totally 1600 reinforcing bars are needed.

The effect of the inserted reinforcing bars is assumed to be 0.8 of the ordinary hoop. The resulting 'Is' values after the retrofit are plotted in Figure 12. The 'Is' value exceeds 0.6 for every story, showing the sufficient seismic capability by the retrofit.

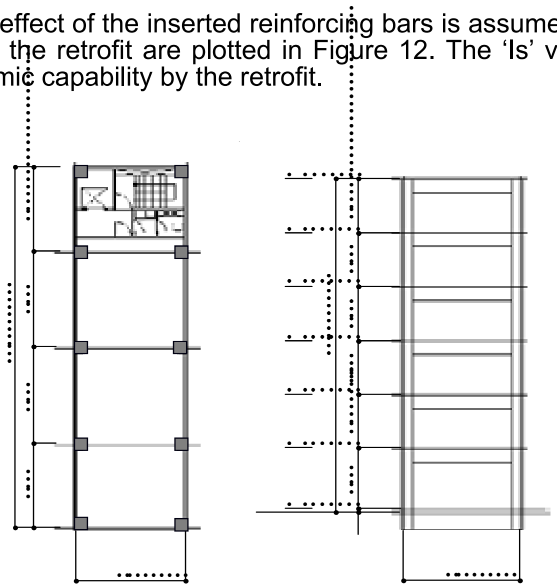

Figure 10 Model Building: 6 story RC

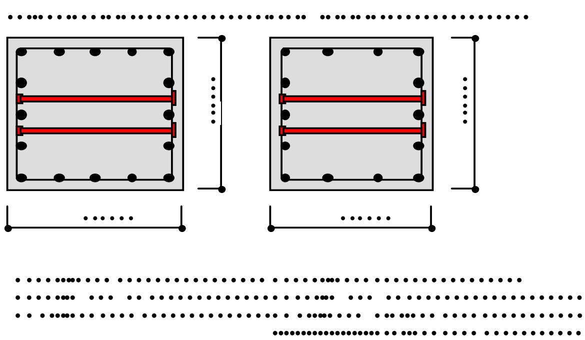

Figure 11 Column Section after Retrofit

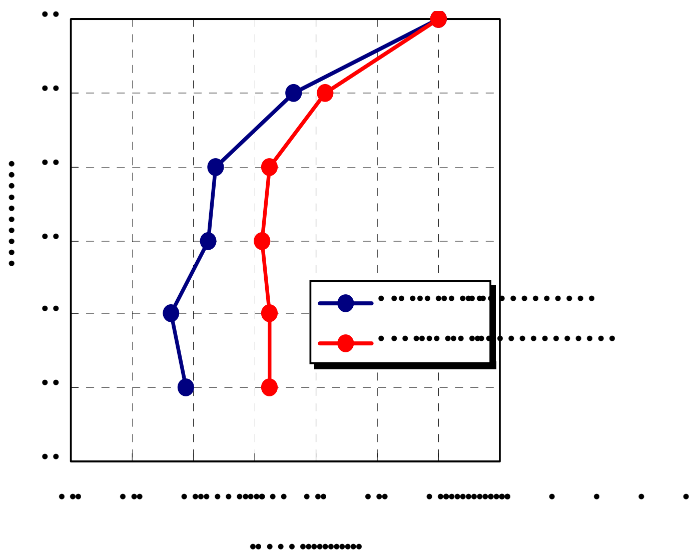

Figure 12 Seismic Capacity Index 'Is' Before and After Retrofit: Post-retrofit Is value exceeds the threshold value of 0.6 to satisfactory seismic capacity.

6. Environmental Effect

Among conventional methods for the retrofit of columns to prevent shear failure, a carbon sheet wrapping method is one of the most typical one. To apply the carbon sheet wrapping method, the interior finishing materials have to be removed to expose the column concrete. After the wrapping method is applied the interior has to be finished again. The proposed method of the supplemental reinforcing bars that is constructed from outside, the interior materials need not be replaced. Together with the reduced material usage in the proposed method compared to the carbon sheet wrapping method, the total CO_2 and wastes associated with the retrofit work can be significantly reduced.

Table 2 shows the comparison of the materials needed for the seismic retrofit, Table 3 compares the amount of CO_2 and other greenhouse gases, and Table 4 compares the amount of wastes. The reduction in CO_2 is 43% as shown in Figure 13 and the reduction in the wastes is 87% as shown in Figure 14, proving the proposed method to be environmentally friendly

Table 2 Material Used for Retrofit Work

	carbon sheet wrapping method	reinforcing bar method

6. Conclusions

A new seismic retrofit method for the shear reinforcement of a column is proposed. The largest feature of the proposed method is that it can be applied from outside of the building, so that it can solve shortcomings of the conventional seismic retrofit methods: The retrofit work can be applied while the building is in use, and it does not reduce nor limit the utility of the building.

The strengthening effect of the proposed method has been proved through the static loading tests. It can be said that the proposed retrofit method attains the objective of improving shear capacity of columns of round-rebar and deformed-rebar.

A case study of applying the proposed method to a model building shows that by applying the proposed method the seismic capacity of the building can be improved to exceed the threshold value for the seismic safety in the seismic evaluation practice.

Applicability of the proposed method in a space between buildings, as narrow as 50cm, has been proved. Based on the obtained construction efficiency data, cost estimation has become possible.

As the proposed method does not require removal and re-application of finishing materials, the CO_2 consumption and the amount of wastes can be reduced dramatically as compared to the conventional seismic retrofit methods.

The proposed method may not be a perfect solution as a seismic retrofit, but we want to emphasize that this method is much easier than conventional methods so that it is more widely accepted by the building owners. By proposing such retrofit method, we hope that the seismic retrofit becomes more available and leads to the safer built environment and the longer life of buildings.

Summary

Kwai Chung Estate in the Western New Territories of Hong Kong, was built in the 1960s at a time when the population was increasing rapidly and when there was a severe shortage of safe and secure housing. The original estate was home to 22,000 people in 42 seven storey “walk-up” Mark II and III blocks, with shared toilet and washroom facilities. They were built at a time of great urgency to cope with the needs of shelter for the masses when Hong Kong was emerging as a post-war industrial city. When they were built, they were a great improvement for those who were re-housed but by the late 1980s the estate was in poor condition, with an aging population and the basic living shared toilet and washroom facilities no longer met accepted standards. The estate was identified for redevelopment under the Housing Authority’s Comprehensive Redevelopment Programme.

1. Introduction

After the upheavals of the Second World War and the civil war in China, the Hong Kong Government was faced with a huge influx of migrants to the territory. The population of Hong Kong rose from 600,000 at the end of the war to over 2,000,000 in the early 1950’s and the growing number of people had no choice but to live in crude squatter settlements on hillsides, on boats in Typhoon shelters or in overcrowded tenements. Consequently they were very vulnerable to fire and other natural disasters.

These conditions were the catalyst for the Public Housing programme in the 1950’s, which began as an emergency programme struggling to cope with a growing demand and to address the chronic shortage of safe and secure housing for people on low incomes. The standards of accommodation in the first estates were very rudimentary by comparison with the modern comprehensive estates that are built today, but for homeless people, the shelter and security provided was a huge improvement on their previous conditions. Kwai Chung Estate, in Tsuen Wan New Town in the Western New Territories, was one of the earliest ‘Resettlement’ Estates built in the early 1960’s.

Though the population and the consequent demand for housing continued to increase, stability and prosperity in Hong Kong improved dramatically. Gradually, public expectations went beyond the desire for simple shelter. The type of accommodation provided in the early estates was becoming unacceptable and by the late 1980s Kwai Chung Estate was in poor condition, with an aging population.

2. The Old Kwai Chung Estate

Kwai Chung Estate provided homes for 22,000 people in 42 Mark II and Mark III blocks of reinforced concrete construction. These buildings were some of the earliest forms of public housing in Hong Kong and were eight storey walk-up blocks with single room flats and shared toilet and washroom facilities. Each flat was designed as a single room with no partitions and no water supply. Flat sizes were 14 to 21 sq. meters to accommodate 4-6 persons (2.3m^2 per person).

The old estate had no proper public transport facilities and the estate was split into small irregular sites by the road network which made access difficult. Car parking was insufficient and not segregated from pedestrians. Estate shops were scattered under the residential blocks and local open spaces were isolated and uncoordinated with minimum soft landscape work and recreational facilities.

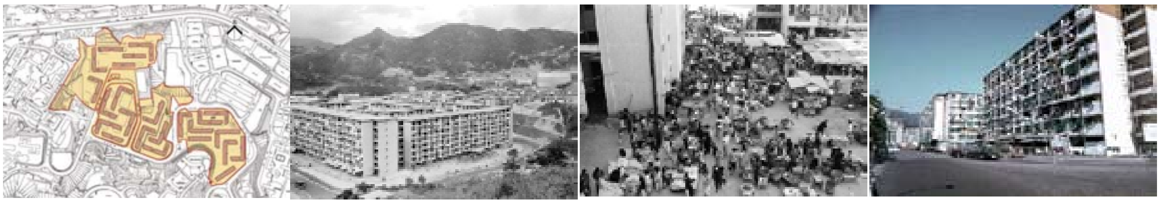

Figure 1: (From left to right) Kwai Chung Estate before redevelopment in 1960s. Master Layout Plan (top left), overview of the Estate, market bazaar, Mark III building

Public housing had been provided through several separate government agencies and in 1973 the new Hong Kong Housing Authority (HA) was formed to manage the programme more effectively. Clearer policies were developed and the experiences of the preceding 20 years led to a programme of more comprehensive and self-contained estates, each with its own public transport interchange, purpose built schools, shopping and market facilities and a wide range of social welfare services provided by both the Housing Authority and NGOs to cater for the diverse needs of a more complex community.

However, when compared to the standards of housing in the new estates built by the new Housing Authority, Kwai Chung Estate fell far short of expectations. In 1988, the HA introduced its Comprehensive Redevelopment Programme (CRP) and Kwai Chung Estate was then included in this programme.

3. The Need for Redevelopment

Since the public housing programme had began in the 1950s, housing standards had risen significantly. By the late 1980s, space standards had increased from 2.3m^2 per person to 5.5m^2. There had been a growing demand for housing and for changing eligibility criteria which exacerbated demand still further. Increased demand meant making better use of the land available and as a consequence development densities were rising and by the 1980s, developments of 2,500 persons per ha were the norm.

Larger flats and more flats in each new site meant that buildings were increasing in height from the seven storey walk up designs of the 1950s to buildings of over twenty storeys in the 1960s and 1970s and to 35 storeys in the early 1980s. By the time that the CRP had been announced, the Housing Authority was planning even higher blocks of 39 storeys with even larger flats. The improved standards of facilities, and more comprehensive estates naturally led to far greater site planning constraints.

The condition of the buildings in Kwai Chung Estate had deteriorated badly, maintenance demands were growing, and the blocks had no lifts which were causing greater problems for the aging population. Non self-contained flats with shared toilet and washroom facilities had been phased out in new estates from the late 1960s and conversion of this type of building into self-contained units was not practical when considered alongside the demands of rising standards, increasing production and greater development densities.

The old estate also had no planned public transport facilities, and the existing streets split the estate into small irregular sites and made access between them difficult. Car parking spaces were insufficient and not well planned nor segregated from pedestrians. Local open spaces were also isolated and uncoordinated with minimum soft landscape work and recreational facilities. Shops and other support services were scattered under the blocks and were a world apart from the new comprehensive shopping centres that were being built in new estates.

4. The Objectives

Planning for redevelopment commenced in early 1990. The objectives were to improve the standard of accommodation for the population, rejuvenate the community, optimise redevelopment potential, improve the road network, pedestrian access and public transport facilities, and provide modern and comprehensive shopping, social, recreational and community facilities for residents. Regeneration of ageing districts serving the people living in the area and retaining and rejuvenating community identity, is the main goal of redevelopment.

5. The Planning and Design Concept

The redevelopment was planned in phases. The CRP concept was to enable the Housing Authority to redevelop its older estates more speedily and more efficiently. It allowed a larger scale of redevelopment compared to the slower and relatively inefficient "pump primer "approach that had been tried in the late 1970s and early 1980s, when individual blocks were built in older estates. One of the main principles of the CRP was to recognise that communities had been established in older estates and hence redeveloping around those communities was seen to be an essential component of the success of the programme.

The redevelopment of Kwai Chung was therefore based on the need to re-house as many of the existing residents as possible in the same estate and if that was not possible, then in the same district. The CRP therefore relied on the construction of large reception estates to enable the first groups of residents to be moved out and allow the redevelopment to proceed.

What are now widely regarded as the parameters essential to achieve sustainable development goals, were the key parameters at the time of the planning of the redevelopment of Kwai Chung Estate and the following approach on social, environmental and economical considerations was used: -

5.1 Social considerations

5.1.1 Minimising Social Disruption to Residents

Under the CRP, an overriding principle has been to maintain many of the characteristics and essential components of the of the existing community by in-situ rehousing, reprovisioning and retention of facilities. Essential facilities, such as temporary car-parking and a market, were to be built in advance, adjacent to phase 1 and maintained throughout the redevelopment period.

Efforts were also made to retain and integrate an existing religious shrine, schools, youth centre and the premises of the local *Kai Fong Association* [Neighbourhood Community Accociation] in the master layout plan of the new Estate.

Figure 3: (From left to right) Existing school and factory building, the Kai Fong Association [Neighbourhood Community Association], Youth Centre, religious shrine, retained in the neighbourhood of Kwai Chung Estate.

Kwai Chung estate was over 25 years old and consequently with established communities and important social networks in place. The elderly residents in particular, wished to stay in the estate because of these long standing networks and because of their association with the various complementary social welfare services which provided care where required and regular opportunities for them to conveniently meet friends.

5.1.2 Establishing a Civic Hub

The design was based on a “civic hub’ concept which was strategically located to provide essential facilities and create a focal point in the estate. This ‘civic hub’, together with the podium garden, acts as a natural meeting point, with a wide range of easily accessible estate facilities where residents meet and socialise.

The central ‘civic hub’ comprises of a 3-storey central air-conditioned shopping centre with a total floor area of 5,800 sq. metres, an air-conditioned market with stall area of 800 sq. metres, 744 car-parking spaces, 112 light goods vehicle parking spaces and 75 motorcycle parking spaces. A covered public transport interchange is now centrally located along with the educational and social welfare accommodation; kindergartens, a day nursery, clinics and Residential Care Home for the Elderly, as the essential supporting facilities for the residents

5.2 Environmental Considerations - A Green and Healthy Living Environment

In the planning of the original Kwai Chung Estate, which was part of a programme for fast track emergency housing, there was no clear theme for the planning of play and recreation, with no provisions for sheltered seating nor formal planning of passive and active recreation. Though there had been estate improvements over the years, the estate lacked green spaces and external areas were fragmented and predominantly concrete paved with play and recreation facilities which fell far short of the standards of new estatesin the 1980’s.

A large housing estate such as Kwai Chung, has a significant impact on the district as a whole and hence play and recreation spaces for the district were planned in consultation with the Leisure and Cultural Services Department (LCSD) of the Hong Kong Government and with the local District Council. Two sites have been specifically designed in consultation with the LCSD as local open spaces for the use of the residents of the district and will be under their management upon completion. Landscaping, play and recreation within the estate follows the HA’s comprehensive guidelines and they have been built at-grade (in phase 5) and at podium level (in phase 3 and 4) and are all linked to other estate facilities and domestic buildings.

The overall area of open space has been increased in the redevelopment from about 4.8 ha to 6.5 ha. An area has been excised in consultation with the Government and a playground has been re-provisioned, as a District Open Space. About 30% of the estate area has been landscaped with over 100 old trees retained and about 150,000 new trees and plants provided in the new Estate. Environmental and landscape features include a bamboo garden, planting on the podium and a well landscaped noise barrier.

Figure 4: The footbridges connecting Phase 4 and Phase 5; and the Bamboo Garden in Kwai Chung Estate Phase 5 with Phases 3 and 4 beyond

The open spaces in the estate have been strategically located and integrated with the main pedestrian circulation networks. Active and passive recreation areas, including badminton courts, basketball courts, volleyball courts, table tennis tables, children's play areas, and a Tai Chi court, have been provided as part of the overall landscaping design of the estate. These open spaces, together with the main podium plaza, provide greatly improved opportunities for the residents day to day recreational needs and for formal planned community activities.

5.3 Economic Considerations

5.3.1 Optimising Site Potential

The HA has routinely formulated its design briefs in close consultation with Government but over time the supply of land has become more difficult. In the late 1990's there was a critical shortage and demand for flats for rent and flats for sale had been increasing dramatically. The Government set annual production targets for both the public and private sectors, with 50,000 flats per annum required of the public sector.

Steps were taken to maximise the development potential of new HA developments and there was a gradual alignment with private sector practices. Phases 3 and 4 of the redevelopment were designed with a podium to accommodate the new transport interchange, a new modern shopping centre and car-parking for estate residents and for shoppers. Residential blocks were built above the podium with recreation space and landscaping on the podium decks. This approach allowed an increase in number and size of flats, improved the extent and standard of the estate facilities and at the same time provided greater opportunities for landscaping.

The redevelopment has optimised the site potential with a plot ratio of 5.5 providing 430,000 sq. metres domestic gross floor area. The number of new flats in the redevelopment has increased from 8,850 to 14,543 and the population from 22,000 to 40,000, yet still allowed for an impressive upgrading of the whole estate and hence a much improved living environment. The flats are also generally larger and to a much higher quality than those in the old estate. The mix of flat types and flats sizes has been more finely tuned to fit the profile of the estate residents, with flat sizes ranging from 17 sq. metres to 47 sq. metres, suitable for 1 person, and families up to a household size of 6 persons to cater for changing demographic needs.

5.3.2 Improving Pedestrian Accessibility, Road Network and Transport Provision

The old housing sites were fragmented, with level differences and consequent accessibility difficulties. The sites were small and split by the local road network and so did not allow sufficient development opportunities. The space required for some of the improved and more comprehensive estate facilities required larger sites and this, along with the need for clear and simple communication links through the estate, provided the opportunity to simplify and realign the road layouts, thereby improving the traffic flow, and at the same time allowing the optimisation of the overall development potential.

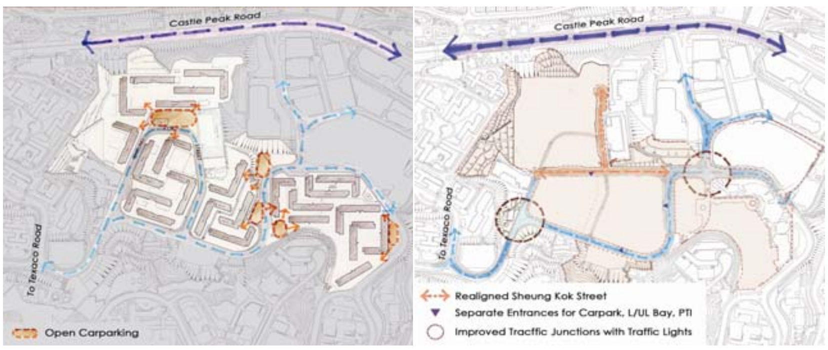

Figure 5: The road network before development (at left) and after redevelopment (at right)

The redevelopment has created a predominately vehicular free environment, with a well planned pedestrian network with footbridges and lifts which provide above grade connections throughout the estate between domestic blocks, schools and the "civic hub". A link has also been provided to the Tai Wo Hau MTR station so that there is now a quick, efficient and convenient link to Kowloon and Hong Kong Island and the KCRC and West Rail connections to the New Territories.

6. Social Aspects

6.1. Local Rehousing

Under the CRP, the redevelopment was to allow for in-situ rehousing, reprovisioning of open space and retention of existing facilities and features as far as possible, so was to be implemented in stages. As a first step, residents on the site of Phase 1 were to be moved to a new reception estate in Kwai Shing Estate so that the construction of new blocks on the site could begin. The new blocks in phase 1 would eventually re-house people from other parts of the estate and trigger the overall redevelopment in a planned and sequential manner. Phase 1 of the redevelopment was completed in early 1998.

Figure 6: Phase 1 completed in 1998 (left). Small Household Block completed in 1999 providing housing for elderly residents (right)

6.2 Retention of Existing Heritage and Community Buildings

The existing religious shrines, youth centre, schools and *Kai Fong Association* [Neighbourhood Community Association] were essential local heritage and community facilities which had to be retained, so the new estate was designed to accommodate them. Temporary arrangements for vehicular and pedestrian access to these locations was provided to maintain proper functioning of activities during the redevelopment.

6.3 Updating of Development Parameters, Social and Policy Changes

During the last 10 years of the redevelopment programme, there were substantial changes in the development parameters in response to adjustments in public housing policy, such as intensification of development potential, introduction of quality initiatives, cessation of flats for sale through the Home Ownership Scheme (HOS), and enhanced design features to emphasise the identity of the Estate.

In February 1998 the government began to look at the opportunities for increasing land supply for housing by redeveloping old HA factory sites. There were four 7-storey factory buildings completed in the mid 1960's next to Kwai Chung Estate. These factory buildings were under-utilised and in 1999 were selected for redevelopment to become part of the new Kwai Chung Estate. Relocation of affected factory tenants was to be resolved before redevelopment, so special ex-gratia allowances were made to assist them to re-establish their businesses in other accommodation.

6.4 Housing for the Elderly

From the start of the housing programme, family sizes have reduced and estate populations have naturally aged. The HA had been extending its support services for the elderly since the early 1970's, but because of the high housing demand, accommodation for elderly was only provided on a shared basis. By the late 1980's the demand was acute and the HA built more self-contained small flats for 1 to 2 persons in its main residential blocks of the time, the Harmony blocks. New blocks of small flats were designed to be linked to the main residential blocks and make use of their lift and utility services. These Annex blocks, as they became known, became the most common way of providing small flats.

In the mid 1990s the HA embarked on a programme of special developments for the elderly with self–contained small flats for single persons and couples, with recognised accessibility standards and appropriate support services provided by the Non-government organisations. These buildings were known as "Small Household Developments" and a programme of 25 such projects was launched in 1995 with flats of 17m^2 to 22m^2 for single persons and couples, built up to 20 storeys in height. One such block with 240 self-contained flats was built in Kwai Chung by arranging a site swap for a small but under-utilised playground next to Kwai Chung Estate. Later housing for the elderly in the final phases of the redevelopment was provided in 17m^2 flats in the 40 storey residential blocks as part of the standard flat mix along with family flats, and in Annex Blocks in phases 3 and 5 of the estate.

This redevelopment project has therefore had to respond to new policies and priorities that have arisen in the community during the design and construction programme, spanning almost two decades.

7. Environmental Aspects

7.1 Layout Design

The design of the estate and the disposition of the buildings, has made use of environmental studies to model the local wind environment and traffic noise in the area to help to plan the estate facilities more effectively. The domestic blocks are located away from the noise sources as far as possible; some blocks located adjacent to the public roads are on the podium, which serves as a noise barrier to reduce the impact of traffic noise. Noise barrier walls at appropriate locations along estate boundaries have also been provided.

7.2 New Construction Technology

When Kwai Chung Estate was included in the Comprehensive Redevelopment Programme, the HA embarked on a major programme to improve construction quality and efficiency. Though standards had improved between the 1960's to the 1980's there had been very little change in the way that buildings were built, despite the considerable increase in height of buildings, from 7 to 35 storeys.

Construction was very labour intensive in-situ concrete construction with a reliance, to a large extent, upon semi-skilled or unskilled labour. Quality was a major concern. Housing production targets were increasing and hence the increased stock of housing, led to growing management and maintenance responsibilities. The construction industry was a major employer and site safety and working conditions were a cause of concern. The HA was a major government developer and began to look at new practices to improve working conditions and site safety, quality, efficiency, and waste management.

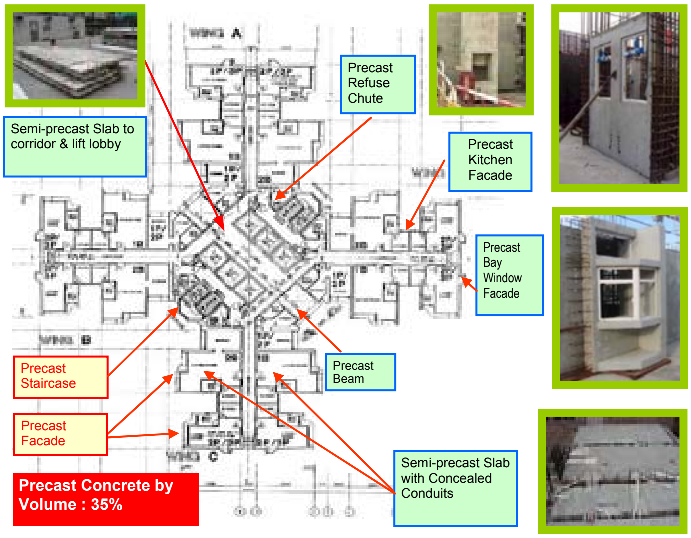

Figure 7: Precast Elements for the New Harmony Blocks constructed in Kwai Chung Estate

Prefabricated construction techniques had been tried over the years and by the late 1980's the HA embarked on a new approach in the design and construction of its buildings using modular design concepts and mandatory prefabrication. This started with pre-cast concrete components and was later extended into the fitting out of flats, with dry construction lightweight concrete partitions, door assemblies and kitchen fitments. The intention was to reduce wet trades, reduce the reliance on unskilled or semi-skilled site labour and introduce factory production as far as possible. Precast elements amounted to approximately 30% of concrete works by volume and included facades, staircases, refuse chutes, and later, features to emphasise the identity of each estate.

The last project, at the Kwai Chung Flatted Factory site, has used prefabrication more extensively, including structural elements, and components amount to over 60% of construction volume. These techniques have had a major effect on the Hong Kong construction industry and led to the development pre-cast concrete components industry in Hong Kong and latterly in southern China, which benefits the industry as a whole.

An Automated Refuse Collection System (ARCS) was also implemented for collection and handling of domestic refuse in a totally concealed environment where the refuse is automatically extracted by vacuum to centralised containers, thereby minimising nuisance caused by spills and smell. The system is one of the largest ARCS in Hong Kong and can handle a capacity of about 34 tonnes of refuse per day with 2 to 3 nos. of 10-tonne capacity containers for daily storage.

8. Economic Aspects - Continuous Provision of Basic Facilities

In order to maintain basic facilities such as shops, car parking and transport ffor the residents and the public in the vicinity, a temporary market and carparking was provided on the future district open site adjacent to phase 1. New roads were constructed in stages and remained in-use throughout the redevlopment period.

9. Continuous Community Engagement

A continuous dialogue with local residents is an important part of the redevelopment process. After public consultation at planning stage, efforts were made to seek local comments during and after completion. Resident's Surveys were carried out after occupation to obtain feedback and the findings showed that over 80% of the residents were satisfied with the estate as a whole, in particular, with the planning and design of blocks and estate facilities.

Continuous improvement is also on going after in-take. A working group formed by Members of the Kwai Tsing District Council, a representative from the Incorporate Owners of the nearby HOS court, and representatives from Housing Department conducted regular meetings over about 2 years to work out common objectives for improvements. A lift tower and footbridge were eventually planned, and are now under constrcution, to serve Kwai Chung Estate, Tai Wo Hau Estate, and the schools.

In order to promote public participation in "greening", a Community Participation Scheme was launched in mid 2007 in the new estate. The Scheme is to provide young plants to the participants approximately 6 months before completion of the Estate. The plants are to be grown at home or school and to be transplanted in the estate. The idea is to engage the community in the longer term to enhance commitment to the well-being and up keep of the estate and will be part of a series of activities to be arranged to generate more interaction and dialogue with the local community.

Figure 8: Community Participation Scheme – Action Seedling held in Kwai Chung Estate

10. Implementation and Project Cost

The first stage comprised of three 39 Storey Harmony Blocks with 2,400 flats which were completed in 1998. These blocks are adjacent to the District open space which had been built on the site used as a temporary car park and market until the car parking facilities in phases 3 and 4 were completed in 2005.

The second stage was the construction of the Small Household Development for the elderly and two New Cruciform Blocks (NCB) originally intended for sale. The NCB were fully fitted apartments, larger than flats for rent, with 10 flats per floor, rather than 20 flats per floor for typical rental housing. Prior to completion, the HA cancelled its flats for sale scheme and the buildings were eventually transferred the Government for use as disciplined services staff quarters.

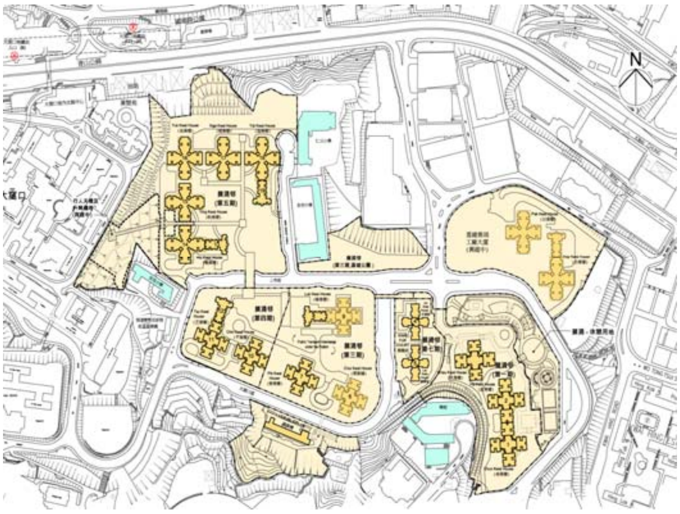

Figure 9: Master Layout Plan of the completed Kwai Chung Estate, with the civic hub at the centre.

The third stage shows the re-alignment of road network, intensification of production that was necessary towards the late 1990's when phases 3 and 4 were developed with a podium design to accommodate the "Civic Hub". The shopping centre, public transport interchange and car-parking were built beneath the podium and residential blocks built above, with social welfare facilities, and landscaped passive and active recreation facilities to cater for all ages. Social welfare support services were located at the above grade pedestrian access levels in phase 4. Residential buildings were five 40 storey modified New Harmony One blocks, and two 30 storey Annex Blocks, with small flats for single persons and couples. This stage also shows the new direction for the HA, where efforts has been made to give the buildings a clear identity of their own. Though standard building types are an efficient and cost effective way of building mass housing, there were concerns that public housing estates were becoming monotonous and not contributing positively to the urban landscape. Consequently, design teams modified the detailing of the buildings and developed unique colour treatment for each site within an overall colour theme.

The fourth and final stage was for the construction of five 40 storey New Harmony One blocks and two 30 storey Annex Blocks with small flats for single persons and couples, catering predominantly for the elderly or small families. This stage also shows the drive towards greater identity, with more modelling on the facades than those in phase 3 and 4 and a slightly different, though sympathetic, colour scheme.

Functional and cost-effective materials , such as acrylic paints for external walls and internal corridor walls, homongeneous floor tiles to common domestic floor areas , were used to ensure rational use of public resources. The final project cost for the redevelopment is estimated at HK$3,958M and is within the project budget of HK$4,974M. Average unit cost for the domestic flat is about HK$5,000/$m^2$ construction floor area.

11. The Completed Estate

Residents are now living in modern self-contained flats with a much improved estate environment, a high standard of landscaping, and ample sitting out areas for the elderly and play facilities for children. The redevelopment has allowed for more effective land use and enhanced traffic flow in the area. Key facilities were maintained during the redevelopment and out of the original 22,000 tenants, 7,000 were eventually re-housed in the new estate.

Figure 10: New Harmony type blocks above the podium in Kwai Chung Estate Phases 3 and 4

Pedestrian access has been improved by footbridges, escalators, lifts and a comprehensive covered walkway system. There is a connection to the nearby Tai Wo Hau MTR station, for convenient and quick access to Hong Kong and Kowloon. A public transport interchange is now at the core of the estate, with a wide range of shopping, social and community facilities, which have created a new focal point at the civic hub There are greatly enhanced recreation facilities and new district open spaces to serve the wider area.

The redevelopment has regenerated the area with the preservation of mature trees, religious shrines, and schools and revitalised landscaping and recreation and play facilities to serve the estate and the district. The environment of the completed estate and improvements for the district as a whole together with the community engagement programme, have fostered a renewed community identity, encouraged greater social interaction and provides for the needs of a vibrant and diverse community, with a greener, safer, healthier and more comfortable living environment.

After 12 years of work and close attention to local interests, Kwai Chung Estate has been one of the largest CRP projects with homes for 40,000 people.

Acknowledgements

The redevelopment of Kwai Chung Estate was a long term project with the contribution of a large number of individuals and organisations. We are grateful for the support from the project management team, planning team, landscape team, Housing Management team and of course, the building contractors, including China State Construction Engineering (Hong Kong) Ltd., Hip Hing Construction Co. Ltd., Yau Lee Construction Co. Ltd. who provided information on construction technology. Special thanks to ARCA Ltd. for contributing photographs for the Paper. The Project management and design teams were:

Project Managers: NM Chan, SH Ho, Irene Cheng, Chris Gabriel, Hong Kong Housing Department
Deputy Project Manager: Polly CP Young, Hong Kong Housing Department
Architects: CW Ko Chief Architect 1, Hong Kong Housing Department: Phases 1 and 2
ARCA Ltd: Phase 3
MLA Architects (HK) Ltd: Phase 4
P & T Architects and Engineers Ltd: Phases 5 and 7

A SECOND CHANCE FOR OLD BUILDINGS

Keywords: life cycle buildings, sustainable, transformation, recycling

Summary

In the Netherlands, both the office market and housing market show a mismatch between supply and demand, quantitatively and qualitatively. In 2007 almost 14% of all offices are vacant, i.e. 5.9 million square meters. At the same time we see a shortage of about 1 million dwellings. A building must be able to be changed over its life cycle to adapt to the inevitable evolving needs of it's end users. The first real challenge is how to make adaptable buildings without creating unnecessary redundancy. The second challenge is the re-use of old vacant buildings because the available area for erecting new ones is very scarce in the Netherlands. In this matter, old buildings deserve a second chance in their life cycle. We need to be able to measure the transformation potential of office buildings both at location and at building level. To this end, we have developed what we call a 'transformation potential meter' (Geraedts, Van der Voordt, 2003, 2004). The meter has been tested since 2004 in practice by a number of market players, and by students of architecture. This has allowed the transformation potential meter to be evaluated and refined in 2006. Two new steps - the financial feasibility scan and the risk assessment checklist – have also been added. In this paper, we describe the principle of the new transformation potential meter.

1. Prospects of vacant office buildings

According to experts from the world of professional practice, the transformation prospects of the current offering of office buildings depend primarily on the following three factors:

1 *Duration of vacancy:* The longer an office building is unoccupied, the readier the current owner will be to convert it so that it can be used for another purpose.

2 *Reason for vacancy: market, location or building:* When an office building is unoccupied because of market factors, transformation would not seem to be an attractive option from the owner's viewpoint if the market is strengthening. If the location is unsuitable for office purposes and/or the building does not meet (or no longer meets) the requirements for office use, transformation may be a good idea. If the vacancy is due to building-related factors, the transformation potential is highly dependent on the extent to which the building can be converted by design interventions into an attractive residential property meeting the requirements and wishes of local target groups. Financial feasibility and permission to modify the zoning plan are critical factors for success in this context.

3 *Municipal policy:* When the office building in question lies in an area that has been prioritised for residential use by the municipal authorities, transformation into residential housing would seem to be an obvious solution since this is in line with municipal policy. If on the other hand the building is in an area earmarked for (re)development for office use, renovation and reuse for office purposes would seem to be more appropriate.

2. Demand for housing

Transformation of unoccupied offices into housing only makes sense if the dwelling units produced meet a need. The supply must be in line with the demand, as regards both the location – which should be a residential environment – and the features of the building (an office building will in general be converted into a block of flats comprising individual dwelling units). Since nearly a quarter of people looking for housing are under 25 (including many students), transformation into low-cost accommodation may be a good choice. Where high-rise office buildings are concerned, transformation into accommodation for families with young children is less appropriate. Conversion into flats for senior citizens might be a good choice here. Tests of the ability of a transformed building to meet the desires and preferences of potential target groups may be based on the results of various studies of the factors determining the choice of dwelling (see e.g. De Jong, 1997; Priemus, Wassenberg and Van Rosmalen, 1995). Where possible and appropriate, such studies differentiate between the various target groups concerned. The type and size of the housing, an attractive, safe dwelling environment and affordability are important criteria for all target groups. The main differences concern such matters as price and quality level, preference for a family house or a flat, and the desire to live in a lively environment with plenty of facilities or in a more peaceful environment.

Table 1 Relevant aspects on demand side residential accommodation

Location (environment)	Building (residential)
1. Tone	**1. Dwelling type**
a Nature of built environment	**2. Access**
b Social image	**3. Dwelling size**
c Liveliness	a Number of rooms
d Amount of green space	b Living room
2. Amenities	c Kitchen
a Shops	d Bedrooms
b Restaurants, bars etc.	e Sanitary facilities
c Schools	f Storage space
d Bank/Post Office	**4. Arrangement of dwelling**
e Medical facilities	**5. Level of facilities**
f Recreative facilities	**6. Outside space (garden etc.)**
3. Accessibility public transport	**7. View from dwelling + privacy**
a Distance to bus stop	**8. Environmental aspects**
b Frequency and times	a Heating
c Distance to tram or underground	b Ventilation
d Frequency and times	c Noise
e Distance to railway station	d Exposure to sun and daylight
f Frequency and times	e Energy consumption
4. Accessibility by car	f Materials used
a Distance to motorway	**9. General conditions**
b Congestion level	a Accessibility
c Parking facilities	b Safety
	c Flexibility
	d Adequate management
	10. Costs
	a Purchase price/rent
	b Other costs

If one wishes to use a Quick Scan to determine whether an unoccupied (office) building is suitable for transformation to residential accommodation for one or more specific target groups, a demand profile must first be created for each target group. This is also necessary when looking for a suitable building for a specific target group. The five target-group profiles shown in Table 2 have been defined on the basis of the dwelling preferences of the persons concerned.

3. Transformation Potential Meter

The information collected about the transformation prospects, the housing requirements of potential occupants and the target-group profiles has been used as a basis for a number of checklists that can be used to appraise the potential of the stock of unoccupied office buildings for transformation into residential housing. This appraisal takes place in a number of steps, from more superficial to more detailed and specific. Step 0 is the inventory of the unoccupied office space. Step 1 is a Quick Scan of the transformation potential of this stock, with reference to a limited number of veto criteria which fall under the headings Market, Location, Building and Organisation. Failure of a building to meet these criteria means that it does not have sufficient transformation potential and thus leads to a NO GO decision. Step 2 is a more detailed feasibility scan, which shows with reference to appropriate criteria which features of the location and the building lend themselves to transformation and which do not. This then leads in step 3 to the assignment of an overall score expressing the transformation potential of the building(s) in question on a scale varying from non-transformable to highly suitable for transformation. Depending on the results, this leads either to a NO GO decision or to further refinement of the feasibility study in two subsequent phases: step 4 (financial feasibility scan) and step 5 (risk assessment checklist). Depending on the nature of the project involved, step 5 may come before step 4. The transformation potential meter is particularly intended for use in the initial phase of the plan development process, from the first quick scan to the taking of a well-based decision as to whether or not to proceed with the project.

Table 2 Five target-group profiles with preferences for inner-city transformations

Target group 1: Starters	Target group 2: Starters
Young, low-income singles Shared accommodation **Location (dwelling environment)** 1. Urban environment 2. Plenty of amenities **Building (features of dwelling)** 3. Unit in group of 3-7 occupants 4. Bedsit, average 22 m2 5. Shared sanitary facilities 1 shower/toilet per 4 units 6. Shared kitchen with table for meals 7. Shared outside space (garden, etc, 1.5 m2/unit) 8. Shared cycle storage 9. Shared washroom 10. Total 50 m2; useful floor area 35 m2 **Costs** 11. Max. rent 160 - 220 Euro	Young, low-income singles Semi-independent accommodation **Location (dwelling environment)** 1. Urban environment 2. Plenty of amenities **Building (features of dwelling)** 3. Semi-independent unit with shared facilities 4. Bedsit, average 22 m2 5. Sanitary facilities for 2 persons 6. Kitchen for 2 persons 7. Shared outside space (garden, etc, 1.5 m2/unit) 8. Shared cycle storage 9. Shared washroom 10. Total 50 m2; useful floor area 35 m2 **Costs** 11. Max. rent 220 - 320 Euro
Target group 3: Young, two-income	**Target group 4: Senior citizens 55+**
Young couples with two incomes **Location (dwelling environment)** 1. Urban environment 2. Plenty of amenities 3. Suburban (more space, green) 4. Easily accessible by car 5. Good parking facilities **Building (features of dwelling)** 6. Big luxury flat 7. Own outside space (garden, etc.) **Costs** 8. Max. rent 550 - 750 Euro 9. ditto 750 - 1000 Euro for top flat 10. Purchase 100,000 - 200,000 Euro	Low to modal income **Location (dwelling environment)** 1. Safe dwelling environment (social safety) 2. Shops, daily amenities and public transport within walking distance (<500 m) 3. Urban environment 4. Suburban (more space, green) **Building (features of dwelling)** 5. Preferably not on ground floor 6. With lift in building 7. Preferably not with internal staircase 8. At least 3 rooms 9. Living room 25 - 30 m2; bedroom > 11.5 m2 10. Direct link living room, bedroom, bathroom 11. Extra attention to acoustic insulation 12. Adaptable for disabled occupants **Costs** 13. Max. rent 400 Euro 14. Purchase 75,000 - 110,000 Euro
Target group 5: Senior citizens 55+	
Above-modal income **Location (dwelling environment)** 1. Safe dwelling environment (social safety) 2. Shops, daily amenities and public transport within walking distance (<500 m) 3. Easily accessible by car 4. Good parking facilities 5. Some like urban, some like suburban **Costs** 17. Rent 550 - 1100 Euro 18. ditto > 1100 Euro for top flat 19. Purchase 110,000 - 500,000 Euro	**Building (features of dwelling)** 6. Preferably not on ground floor 7. With lift in building 8. Preferably not with internal staircase 9. Access via entrance hall, not via gallery 10. 4 - 5 rooms 11. Living room 30 - 40 m2; big kitchen 12. Direct link living room, bedroom, bathroom 13. Amply sized bathroom 14. Balcony or roof garden 10 - 15 m2 15. Extra attention to acoustic insulation 16. Adaptable for disabled occupants

Step 0: Inventory of market supply at district level

Before starting to use the transformation potential meter proper, an inventory should first be taken of the market supply of office buildings in a given municipality that have been unoccupied in the long term or may be expected to become unoccupied in the near future. Information for this purpose may be obtained from literature surveys, data from estate agents or the investigator's own observations. If adequate information is already available about a given unoccupied building, this step can be skipped.

Step 1: Quick Scan; first impression, assessment with veto criteria

The instrument offers the user the possibility of performing a quick initial appraisal of the transformation potential, which is not very labour-intensive and does not require much data. This quick scan makes use of eight veto criteria that fall under the headings Market, Location, Building and Organisation.

Table 3 The various steps of the Transformation Potential Meter

Step	Action	Level	Outcome
Step 0	Inventory market supply of unoccupied offices	Stock	Location of unoccupied offices
Step 1	Quick Scan: initial appraisal of unoccupied offices using veto criteria	Location Building	Selection or rejection of offices for further study; GO / NO GO decision
Step 2	Feasibility scan: further appraisal using gradual criteria	Location Building	Judgement about transformation potential of office building
Step 3	Determination of transformation class	Location Building	Indicates transformation potential on 5-point scale from very good to NO GO
Further analysis (optional, and may be performed in reverse order if so desired):			
Step 4	Financial feasibility scan using design	Building	Indicates financial/economic feasibility Sketch and cost-benefit analysis
Step 5	Risk assessment checklist	Location Building	Highlights areas of concern in transformation plan; GO / NO GO decision

A veto criterion is a criterion which if satisfied (if the answer to the relevant question is 'Yes') leads to immediate rejection of the idea of transforming the office premises in question into residential accommodation. Further detailed study is then no longer necessary. This is thus an effective means of picking out promising candidates for transformation quickly from the overall potential market.

Table 4 Step 1 – the Quick Scan with veto criteria

ASPECT	VETO CRITERION	DATA SOURCE	App rais.
MARKET			
1 Demand for housing	1 There is no demand for housing from local target groups	Estate agent or municipality	
LOCATION			
2 Urban location	2 Zoning plan does not permit modification	Zoning plan/municip. policy	
	3 Serious public health risk (pollution, noise, odour)	Estate agent or on site inspection	
BUILDING			
3 Dimensions of skeleton	4 Free ceiling height < 2.60 m	Estate agent or on site	
ORGANISATION			
4 Backer for transformation plan	5 There is no enthusiastic, influential backer	Local investigation	
5 Internal veto criteria of property developer	6 Does not meet criteria for region, location or accessibility	Property developer	
Not able to meet specific criteria	7 Does not meet criteria on size and character of building	Property developer	
6 Owner/investor	8 Not willing to sell office building	Owner	

The veto criteria apply to all target groups. Veto criteria 2 and 3 at location level concern the situation of the building within the urban fabric. If for example the office building is located on an industrial site where serious public-health hazards have been discovered, or if the municipal authorities do not allow any modification of the zoning plan at this location, there is little point in taking the investigation of the transformation potential any further.

Step 2: Feasibility scan based on gradual criteria

If the results of the Quick Scan indicate that there is no immediate objection to transformation (no single question is answered 'Yes'), the feasibility of transformation can be studied in greater detail with reference to a number of 'gradual' criteria, i.e. criteria that do not lead to a GO / NO GO decision but that express the transformation potential of the building in question in terms of a numerical score. Taken together, these criteria allow a more rounded picture to be built up of the feasibility of the transformation project under consideration.

Table 5 Step 2a – Feasibility scan on location level using gradual criteria

LOCATION			
ASPECT	**GRADUAL CRITERION**	**DATA SOURCE**	**App rais.**
FUNCTIONAL			
1 Urban location	1 Building in industrial estate or office park far from town centre	Town map	
	2 Building gets little or no sun	On-site inspection	
	3 View limited by other buildings on > 75% of floor area	On-site inspection	
2 Distance and quality of amenities	4 Shops for daily necessities > 1 km.	On-the-spot investigation	
NB: *The quality of amenities can be described*	5 Neighbourhood meeting-place (square, park) > 500 m.	Ditto	
in terms of number, variety and level	6 Hotel/restaurant/snackbar > 500 m.	Ditto	
of services provided.	7 Bank/Post Office > 2 km.	Ditto	
	8 Basic medical facilities (practice, health centre) > 5 km.	Ditto	
	9 Sports facilities (fitness, swimming pool, sports park) > 2 km.	Ditto	
	10 Education (from kindergarten to university) > 2 km.	Ditto	
3 Public transport	11 Distance to railway station > 2 km.	Town map	
	12 Distance to bus/undergr. > 1 km.	Map/transport services	
4 Accessibility by car and parking	13 Many obstacles; traffic congestion	On-the-spot investigation	
Obstacles	14 Distance to parking sites > 250 m.	Inspection/new design	
Congestion: 1-way traffic, no parking, tailbacks *Accessibility by car/parking*	15 <1 parking space/100 m2 dwelling surface	Inspection/new design	
CULTURAL			
5 Tone of neighbourhood *NB:*	16 Situated on or near edge of town (e.g. near motorway)	Map or estate agent	
Assessment depends on target group, e.g.:	17 No other buildings in immediate vicinity	Map or estate agent	
young people not in	18 Dull environment	On-the-spot	
monofunctional neighbourho	19 No green space in neighbourhood	On-the-spot	
55+ not on edge of town	20 Area has poor reputation/image; vandalism	On-the-spot and local press	
	21 Dangerous, noise or odour pollution (factories, trains, cars)	On-the-spot	
LEGAL			
6 Urban location	22 Noise load on façade > 50 dB (limit for offices 60dB)	Municipal authorities	
7 Ownership of ground	23 Leasehold	Estate agent	

The feasibility scan at location level (Table 5) comprises 7 main criteria, subdivided into functional, cultural and legal aspects, and 23 sub-criteria. The feasibility scan at building level (Table 6) comprises 13 main criteria, subdivided into functional, technical, cultural and legal aspects, and 13 sub-criteria. An answer 'Yes' to any question indicates somewhat lower suitability for transformation – though not severe enough for out-and-out rejection. At the end of the scan, the Yes's are added up to obtain the overall transformation potential score – the lower the better. This is described under step 3 below. It may be noted that the criteria vary somewhat, depending on the target group under consideration. For example, students will prefer to live in the city centre where there is more night life, while young families with children will tend to opt for a peaceful suburban environment.

Table 6 Step 2b – Feasibility scan on building level using gradual criteria

BUILDING			
ASPECT	**GRADUAL CRITERION**	**DATA SOURCE**	**App rais.**
FUNCTIONAL			
1 Year of construction or renovation	1 Office building recently built (< 3 years)	Year of construction	
	2 Recently renovated as offices (< 3 years)	Year of renovation	
2 Vacancy	3 Some office space still in use	Representative body	
	4 Building unoccupied < 3 years	Ditto	
3 New dwelling units	5 ≤ 20 -person units (50 m2 each) can be made	≤ 1000 m2 useful area	
	6 Layouts suitable for local target groups can't be implemented	Design sketch	
4 Extendability	7 Not horizontally extendable (neighbouring buildings)	On-the-spot investigation	
	8 No extra storeys (pitched roof; insufficient load-bearing capacity)	On-the-spot investigation	
	9 Basement cannot be built under building	On-the-spot or Estate agent	
TECHNICAL			
5 Maintenance	10 Building poorly maintained/looks in poor condition	External visual inspection	
6 Dimensions of skeleton *Module of façade determines placing of walls*	11 Depth of ffice building < 10 m	Estate agent/inspection	
	12 Module of support structure < 3.60	On-site or estate agent	
	13 Distance between floors > 6.00 m	On-site or estate agent	
7 Support structure	14 In poor/hazardous condition	On-site inspection	
8 Façade *External spaces dependent on target group* *Protected monuments: limits on adaptation*	15 Can't be made to blend with surroundings or module > 5.40 m	On-site or estate agent	
	16 Façade/openings not adaptable	On-site inspection	
	17 Windows cannot be reused or opened	On-site inspection or new design	
9 Installations/services	18 Impossible to install (sufficient) service ducts	On-site inspection or new design	
CULTURAL			
10 Character *cf. Location, 'Tone of neighbourhood'*	19 No character in relation to surrounding buildings	On-site inspection	
	20 Impossible to create dwellings with an identity of their own	On-site inspection or new design	
11 Access (entrance hall, lifts, stairs)	21 Unsafe entrance, no clear overview of situation	On-site inspection or new design	
LEGAL			
12 Environment *Exposure to sunlight, air and noisepollution, hazardous materials*	22 Presence of large amounts of hazardous materials	On-site or municipality	
	23 Acoustic insulation of floors < 4 dB	On-site or new design	
	24 Very poor thermal insulation of outer walls and/or roof	On-site or municipality	
	25 < 10% of floor area of new units gets incident daylight	On-site inspection	
13 Bouwbesluiteisen; bereik-baarheid; vluchtwegen	26 No lifts in building (> 4 storeys), no lifts can be installed	On-site or estate agent	
	27 No (emergency) stairways	On-site or new design	
	28 Distance of new unit from stairs and/or lift ≥ 50 m	On-site or new design	

Step 3: Determination of the transformation class

The results of the feasibility scan can be used to calculate a transformation-potential score for the building in question, on the basis of which the building can be assigned to one of five transformation classes ranging from 'ideal for transformation' to 'not suitable for transformation'. The total scores for the location and the building are determined by multiplying the number of Yes's in the respective tables by a weighting factor, which has provisionally been chosen as 5 for the location and 3 for the building to reflect the greater relative importance of the location in these considerations. The maximum possible score for the location is thus 23 x 5 = 115, and that for the building 28 x 3 = 84, to give a grand total of 115 + 84 = 199 (see Fig. 1).

Total Location (= nr. of Yes's):	**8**	x		Total Building (= nr. of Yes's):	**11**	x
Default weighting:	5	=		Default weighting:	3	=
Score Location:	**40**	**A**		Score Building	**33**	**B**
Maximum Location (23x5):	115			Maximum Building (28x3):	84	

Figure 1 The total transformation-potential scores at Location and Building level are determined by multiplying the number of Yes's in the Appraisal column by the default weighting factor

The minimum score is zero, which would indicate that no single feature of the location or the building is considered unsuitable for transformation. On the basis of the transformation-potential score, the building can be assigned to one of five Transformation classes. Buildings in Transformation Class 1 (score lower than 40), are highly suitable for transformation to residential accommodation, while those in Class 5 (score higher than 161) are totally unsuitable for transformation. All five Transformation classes are given in Table 7.

Table 7 Transformation classes for office buildings; in the example shown, a total score of 40 + 33 = 77 corresponds to Transformation class 2 (transformable)

Transformation score	Transformation class		
Location + Building = 0 - 40	1 = Excellent transformability	**Total Score A + B:**	**77**
Location + Building = 41 - 80	2 = Transformable	Min. score Loc. + Build. =	0
Location + Building = 81 - 120	3 = Limited transformability	Max. score = 115 + 84 =	199
Location + Building = 121 - 160	4 = Very poor transformability		
Location + Building = 161 - 199	5 = Not transformable	**TRANSFORMATION CLASS:**	**2**

Determination of the transformation class of a building completes the first three steps of the transformation potential measurement. If the results indicate that the building lends itself to transformation (i.e. that it falls into transformation class 1 or 2), the analysis can continue in two additional steps, aimed at studying the financial feasibility of the transformation project and carrying out a risk assessment for use in further planning.

Step 4: Financial feasibility scan

If the transformation project is not financially feasible, there is no point in taking the plans any further. The financial feasibility depends among other things on the acquisition costs, the current condition of the building, the amount of renovation or modification work required, the number of dwelling units that could be created in the building and the project yield in the form of rental income and/or sales prices. In order to determine the financial feasibility, answers must be obtained to a number of questions concerning both the project costs and the expected revenue. On the revenue side, we need to know how many dwelling units can be created and for what target groups they are intended. These questions can only be answered if a sketch has been made of the intended layout of the building after transformation. The financial feasibility can be raised by increasing the size of the building, e.g. by adding extra storeys on top, or by the inclusion of commercial functions alongside the residential ones. On the expenses side, it is necessary to know the acquisition costs for the premises, including the cost of the ground. Building and installation costs are also an important factor. What is the current condition of the building? Which parts can be reused, and which will have to be demolished? What is the ratio of façade surface area to gross floor area (GFA)? To what level should the building be finished? To what extent can the existing stairways, lifts and other means of access and façade proportions be maintained? Caused by limitations of the length of this paper the financial feasibility scan will not be presented in detail.

Step 5: Risk assessment checklist

When the Quick Scan indicates that the office building in question has transformation potential at both the location and the building level and the results of the initial financial feasibility analysis are also encouraging, work may proceed on the subsequent development phases. It is of great importance to be aware of the possible bottlenecks and risks that can occur during this process. Two checklists, based on experience gained in a large number of projects, that can prove useful in this context have been developed.

4. Conclusions

Practical trials of the Transformation potential meter in practice have revealed its utility for mapping the potential of given office buildings for transformation into residential accommodation in a number of steps from global to more detailed. It was found, however, that a number of veto criteria included in the original version of the meter were too stringent. Some buildings that failed to pass these criteria on paper were found in practice to lend themselves well to transformation to residential accommodation. For example, a project size of less than 20 dwelling units (2000 m2), a building that was still partially occupied, a duration of vacancy of less than three years or an age of less than three years for the building in question were not necessarily reasons for rejecting the idea of transformation. It was moreover found to be highly desirable to combine the first three stages of the Transformation potential meter (Quick Scan, feasibility scan and determination of transformation class) with a financial feasibility scan and a risk assessment (the readiness of the municipal authorities to approve any changes in the zoning plan required for success of the project is one of the points that needs to be thoroughly explored in advance in this context). Additional literature review is required to cover the international state of the art of the topic discussed in this paper.

Keywords: Energy efficiency, buildings, policy instruments.

Summary

Energy supply capacity has increased roughly half of the consumption growth experienced in Brazil between 1990 and 2000. Such growth is noticeable in all sectors and shows a clear trend to further increase in the upcoming years. Buildings are major players in this scenario, as residential and commercial building stocks are responsible for 48% of electricity consumption in Brazil.

Brazil is among the few countries with severe deficiencies in energy efficiency (EE) standardization for buildings, and local buildings waste significant opportunities for energy costs savings for not appropriately considering bioclimatic principles or energy efficient technologies. Earlier studies made evident the huge conservation potential (30% in existing buildings and 50% in new ones) resultant of this poor combination of design/construction decision-making.

The national energy conservation programme (PROCEL) was created in 1985. Between 1986 and 2004, it saved (avoided energy generation) around 20.000 GWh. A labeling system for energy efficient appliances was established through a Federal Act in late 1993. Ten years later, PROCEL launched a building-specific action (Procel-Edifica), with an action plan that encompasses six major activities, including bioclimatic requirements, regulation/legislation procedures and energy efficiency indicators for several building typologies. A draft for a regulation is currently open for public comment and is expected to enter into force in 2007, being initially voluntary in character and compulsory after five years. Additionally, some cities have also begun to discuss laws regarding mandatory solar energy use, triggering a strong debate among designers, specialists, contractors and the municipality.

This paper aims at tracing a historical overview of the evolution of energy efficiency actions and policy instruments developed for the building sector in Brazil, emphasizing those most recently implemented or discussed, such as the proposed national energy efficiency regulation, as well as the main challenges to overcome.

Background on energy conservation actions in Brazil

In general terms, electric energy consumption in Brazil grew until year 2000 (Figure 1). In 2001, due to the combination of failures in long term planning and lack of investment in the supply side, and the increasing consumption led to a severe energy crisis and rationing, that finally triggered the approval of an energy efficiency (EE) law after more than 10 years of considerations in the Congress.

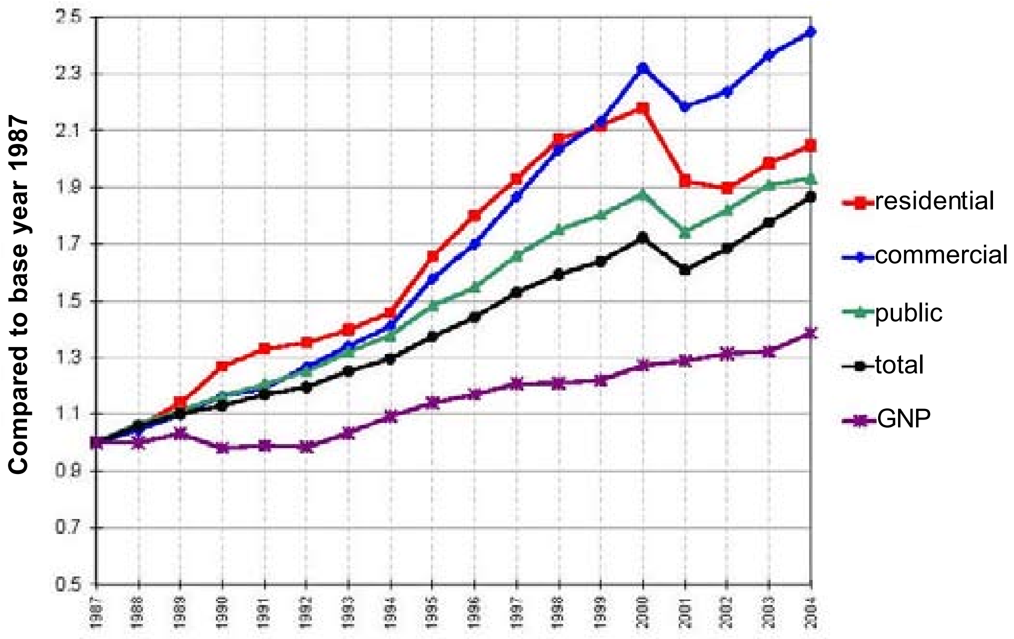

Figure 1 Electric energy consumption and GNP (base year 1987). Source: Balanço Energético Nacional | National Energy Balance 2005)

In Brazil, residential (22%), commercial (14%) and public (8%) buildings are responsible for 44% of total electricity consumption (MME et al, 2007). Among the set of energy efficiency initiatives that in some extent today influence the Brazilian building sector, some of them gathered in Figure 1, at least the following three deserve to be highlighted:

- PROCEL (Brazilian Program for Electricity Conservation) and created by Inter-ministries act MME/MIC nº 1.877, Dec 30th 1985, and maintained and converted into a federal government program by Decree of the Ministry of Mining and Energy (MME), of July 18th, 1991.
- ANEELs Resolution 242/98 (July 24th, 1998) and Law 9.991 (July 24th, 2000) that obligated the collection of private resources to be applied in energy efficiency programs in all sectors (demand side) and regulated distribution of such resources, including R&D projects.
- The Energy Efficiency Law (Law 10.295, 2001), defined the Brazilian Policy of Energy Conservation and Rational Use. The EE law instituted the Management Committee of energy efficiency levels and indicators (CGIEE), determined definition of specific indicators and regulations to be approved after public consultation - for appliances and, years later, for buildings; and the correspondent penalties for non-compliance. This energy efficiency regulation for public, commercial and service buildings refers to PBE (Brazilian Labeling Program) labeled equipment and was developed under the auspice of a PROCEL sub-program (PROCEL Edifica) and approved as in 2007 as a voluntary instrument, to become mandatory after five years.

Table 1 - Energy and CO_2 savings estimated/verified for a chosen set of energy efficiency instruments currently enforced in Brazil.

Instrument	Energy Savings	CO_2 savings[1]	Period
PROCEL (MME/MIC nº 1.877, Dec 30th 1985)	21.753 GWh/year[2]	6,5 to 12,2 million tCO_2/year (estimate DDE/SEPD/MME)	1986-2005
Law 9.991 (July 24th, 2000)	1.954 GWh[3] (DDE/SEPD/MME[4])	not available	2000- 2006
Energy Efficiency Law (Law 10.295, 2001)	Real figures not available. Duffie (1996) estimated savings potential around 12% between 2000 and 2020.	0,38 million tCO_2/year (estimate DDE/SEPD/MME, 2006)	2001-
Performance Contracting (before PROESCO)	18% (public sector) to 19,5% (industrial sector) (Source: ABESCO[5], 2002)	not available	2002
Proinfa[6]	not available	2,9 million tCO_2/year (estimate DDE/SEPD/MME, 2006)	2002-

1.1. The oil crisis and PROCEL creation

In Brazil, the oil crisis in 1973-74 and 1979-81 created the perception of energetic scarcity and elevated prices, justifying investments in increased national oil production, energy conservation and higher efficiency in the use of oil derivates and in the diversification of alternative energy sources.

The strategy adopted in the reformulation of energy offer policy considered the intensification of oil prospecting; increase in the country's production; launching of an ambitious nuclear program aiming at technology transfer in this area and the construction of several nuclear plants for generation of electricity, that however did not produce significant results in terms of energy supply at the time; creation of Proálcool (National program for ethanol production and use) for production of anhydrous alcohol to be mixed to gasoline, exploring the idle capacity of sugar industries; and, in the electricity sector, continuity to the hydraulic basis expansion for electric energy generation, that resulted in an energy surplus in the 80's.

In practice, except for the reduction in gasoline consumption resultant from Proálcool, the other mentioned efforts did not provide effective results by 1980. In 1981, the federal government launched CONSERVE, a program that had as objective to stimulate conservation and substitution of combustible oil used in industry. This program constituted the first significant effort towards energy conservation in Brazil. Several energy efficiency protocols were produced, with effects on industrial sectors like cement, steel making and paper/cellulose. Verified results however clearly pointed to a predominant focus on energy substitution, instead of the desired energy conservation: 79% of the operations approved by the BNDES (Brazilian Bank for Development) for the CONSERVE program between 1981 and 1985 aimed at energy source substitution, with intensification of the use of electricity, while the initiatives for energy conservation represented only 21%.

This was possible because of the economic recession in 1981, which reduced electricity demand and made some inactivity possible in the installed capacity of the electric energy generation park. To use this exceeding capacity, EGTD (energy guaranteed for a certain period of time) was created to guarantee energy supply at prices 30% lower for the industrial sector until 1986, facilitating amortization of investments on equipment installation or conversion. Obtained gains were considerable, however with the crescent use of electricity for industrial thermal purposes, promoted partly by CONSERVE, partly by the Eletrotermia program. What was actually verified was the responsibility transfer on energy conservation to the electric sector.

The growth in electric energy demand for industrial thermal purposes put pressure the sector's supply capacity, which was in deep financial crisis. The adopted strategy was the implementation of an electric energy conservation policy, which in turn resulted in the creation of PROCEL (Brazilian Program for

6 Programa de Incentivo ‡s Fontes Alternativas de Energia ElÈtrica (Proinfa), created by Law 10.438, of April 26th 2002.

Electricity Conservation) in 1985 that constituted the first systemic initiative for the promotion of efficient use of electric energy in Brazil.

PROCEL was created in December 1985 by the Ministries of Mining and Energy and of Industry and Commerce (Inter-ministries act MME/MIC nº 1.877, Dec 30th 1985) and managed by an executive secretariat supervised by Eletrobrás, to integrate actions for electricity conservation across the country. In July 18th 1991, PROCEL became a Federal Government Program through a Decree of the Ministry of Mining and Energy (MME) of July 18th 1991, having its scope and responsibilities broadened.

PROCEL has gone through several phases, including stagnation between 1990-1991, due to investment discontinuity and administrative reforms in the federal Government. Other actions were carried out such as establishment of a 10-year plan and guidelines, and creation of support groups composed by national and international institutions, but only 6 action lines were actually implemented: 1. labeling of more efficient electric appliances; 2. energy diagnosis, auto-evaluation and energy optimization in industrial and commercial installations; 3. technologic R&D for insertion of more efficient equipment; 4. public lighting (basically by lamp substitution); 5. information programs, education and promotion increasing access to information to all society levels; 6. legislation and regulation for energy conservation (Jannuzzi et al, 2004)

Finally, between 1999 and 2002, PROCEL functioned as technical support instance for ANEEL (National agency of electric energy) for the analysis approbation, and implementation of wastage avoidance programs with application of 1% of utilities' net annual operational revenue.

Investments made used resources from RGR (Global reversion reserve), a federal fund composed by resources from energy (concession) companies and provided by ELETROBRAS for projects elaborated by utilities based on policies established by PROCEL, like demand controllers, tariffs, and public illumination, always in a complementary investment mode (counterpart in proportion to investments made). Results are impressive (savings around 18 times the investment made between 1986 and 2005), however reliability of some of them (e.g. publicity campaigns; diagnoses and studies; educational programs) is low, given the limitations or even absence of evaluation methods.

Brazil has mature and comprehensive programs, there is favorable legislation, but still in need of new, complementary instruments. There is a huge, unexplored potential for energy efficiency. Barriers perceived at the time of efficiency programs implementation (e.g. low, subsidized tariffs; lack of information; incipient technology; inadequate legal structure; depleted resources; lack of qualified professionals; resistance from utilities companies…) are now mostly overcome and no longer impeditive. On the contrary, market transformation gained momentum and market is now clearly driven by motivators such as cost reduction (for consumers, producers and distributors); increase in economic efficiency (reduction of energy intensity); improvement in commercial balance (reduction of diesel oil and LPG importation); and reduction of environmental impacts (Porto, 2006).

Is has become clear that legislation and legal procedures to support energy efficiency programs have significantly advanced, with remarkable results for the society, like the 60% increase in annual investment values for end-use energy projects. Results (investments and obtained savings) demonstrate that such programs are advantageous in comparison to system expansion. It is therefore necessary to define more rigid and standardized procedures to results accountancy, aiming at giving more credibility to the process as a whole (Jannuzzi et al, 2004).

2. More recent regulatory marks

2.1. The Brazilian Labeling Program (PBE): PROCEL, CONPET[7] and the energy efficiency law (Law 10.295, 2001)

The Brazilian Labeling Program (PBE) results from a cooperation protocol among the Ministry of Industry and Commerce and the Brazilian Association of Electric and Electronic Industry (ABINEE), with intervention of the Ministry of Mining and Energy. PBE promotes equipment efficiency through labels that inform consumers on the energy consumption. Implementation of this program is based on Technical Groups established for each type of equipment. Models are distributed into classes according to their energy efficiency, determined by specific laboratory tests. Despite its success in enhancing performance of energy consuming appliances, PBE's comparative labels (associated to CONPET label, in the case of gas water heaters) incentive efficiency increase of the best models in the market, but still do not prevent that low efficiency products be manufactured or commercialized. The Energy Efficiency Law (Law 10.295) therefore bridges this gap, as it excludes from the market equipments not complying with the minimum performance levels required.

Impressive results have been collected by the energy efficiency programs, like PROCEL (energy savings of 22.095 GWh/year; summing up to R$ 15,6 billion of avoided investment) and CONPET (320 million liters of diesel oil savings/year; 860.000 t CO_2 avoided per year; 19.000 t of particulates avoided per year).

The Congress passed the Energy Efficiency Law (Law 10.295) after more than 10 years of considerations, only in 2001, when a severe energy crisis hit the country. Despite its success in enhancing performance of energy consuming appliances, PBE's comparative labels (associated to CONPET label, in the case of gas water heaters) incentive efficiency increase of the best models in the market, but still do not prevent that low efficiency products be manufactured or commercialized. The Energy Efficiency Law (Law 10.295) is supposed to bridge this gap, as it excludes from the market equipments not complying with the minimum performance levels required, even though showing a more limited potential to avoid emissions (0,38

[7] CONPET (1981): Brazilian program for rational use of oil and natural gas derivate products.

million tCO_2 avoided/year), if compared to the potential of labeling programs (PROCEL+CONPET: 6,5 to 12,2 million tCO_2 avoided/year), as shown in Table 1.

2.2. The 1% obligation law (Law 9.991, 2000)

It is very unlikely that initiatives in energy efficiency (EE) and energy research and development (R&D) in Brazil would have taken place without the regulators' enforcement of compulsory programs in 1998 and later with the implementation of Law 9.991/00 by the National Congress (Jannuzzi, 2005).

In 1995, with the inclusion of the electric sector in the de-statization programs, the Federal Government looked for mechanisms to ensure that the private sector would invest in energy efficiency (Haddad, 2002). The energy distribution sub-sector then received the attribution of using part of the operational revenue in energy efficiency programs, through concession contracts and specific legislation (ANEEL's "1% resolution" (1998) and Law 9991 (2000), that determined the application of 1% of annual operational revenue in efficiency actions, for each utility company and according to an annual calendar established by ANEEL (Jannuzzi et al, 2004).

In 1998, ANEEL, the energy sector regulator, issued the ("1% obligation") resolution[8] mandating utilities to invest a minimum of 1% of their net annual revenues in EE (end-use / supply-side efficiency) and R&D programs. From 1998 to year 2000, utilities were responsible for the formulation and implementation of EE and R&D programs. This procedure privileged the selection of projects of most interest for the utilities, with very short paybacks and potentially limited social impacts (Jannuzzi, 2005). In 2000, a national law (Law 9.991/00) was approved and *(1)* changed the allocation of the resources from the "1% obligation" and created a national fund - CTEnerg, in charge of investing in public interest energy efficiency and energy R&D; and *(2)* determined that utilities could only implement end-use energy efficiency programs, eliminating the possibility of application of such resources in projects in the supply side from the investment cycle of 2000/2001 on.

In 2001, under the severe energy rationing experienced in Brazil, ANEEL directed almost all resources to public illumination energy efficiency programs and fluorescent compact lamps donation to low income consumers. It became clear that conservation costs per kW reduced/made available were far below the traditional reference generation costs, estimated in US$ 1.000/kW (Jannuzzi et al, 2004). During the year 2004, the "1% obligation" suffered its first political attack and resources were diverted away from EE and R&D.

3. New agents – the industry of energy efficiency

Activation of the energy efficiency market presumes participation of several agents, initially stimulated by governmental actions and, in a second moment, spontaneously. In this sense Brazilian ESCOs have followed (though not integrally yet) the American market model (sharing gains to make their own costs feasible and assuming clients risks) of offering specialized engineering services in projects for reduction, optimization and energy efficiency in energy processes and uses. In this kind of partnership, it is used a methodology based on Performance Contracts, that guarantees savings to the client that make the needed investments feasible. Performance contracting results (2002) are shown in Table 2.

Table 2 - Performance contracting results (Source: ABESCO, 2002).

Sector	Nr. projects	Investment million R$	Average savings %	Payback period (yrs)
Industrial	57	14,4	19,5	3,0
Commercial	35	5,4	18,5	2,4
Public	25	3,7	18,0	1,2
Total	117	23,5	18,8	2,2

In 2006, a specific credit line (Programa de Apoio a Projetos de Eficiência Energética (Proesco) was created by BNDES (Banco Nacional de Desenvolvimento Econômico e Social) to facilitate financing of projects and performance contracts developed by ESCOs, helping to overcome the major barrier faced by the Brazilian energy efficiency market, which is responsible for R$ 200 million every year.

PROESCO offers alternatives for the market as a whole, creating new business opportunities for utilities, efficient equipment manufacturers, energy consuming companies, and mainly for Energy Services Companies. Financing is available for end-use and ESCOs activities support projects, and focuses on projects capable to prove their contribution to energy savings (equipment using more efficient technologies). This ensures positive results at acceptable payback periods.

8 ANEEL Resolution 242/98 (July 24th, 1998), which aprimorated the concession contracts clauses (1% obligation) and stipulated that 25% of the resources callected through the utilitiesí 1% obligation would be applied in efficiency actions on the demand side, being at least 10% of them directed to the residential sector; 10% to the industrial sector and 10% to public buildings. Regarding the remaining 75% (supply side), 30% (connected grid system, i.e regions South, Southeast and Centerwest) and 10% (regions North and Northeast) should be applied to projects adressing improvement of systems load factor.

Items eligible for financing (up to 72 months) are: studies and projects; construction and installations; equipment and machinery; specialized technical services; information, monitoring, control and supervision systems.

According to the type of client, PROESCO offers two operating modalities:

- For ESCOs Supporting Projects: risk shared between BNDES (share limited to 80%) and the accredited financial institutions or indirect operation, when the financial agent fully assumes the amount financed and the credit risks
- For Projects from Final Users of Energy: direct operation (carried out directly with BNDES) or indirect operation (carried out through accredited financial institution). Projects under shared risk modality will be presented to BNDES bearing an analysis from the accredited financial institution, after performance of the technical viability certification by a qualified institution.

A traditional financing procedure, in which the ESCO acted as service provider and the client was in charge of fundraising, was used between PROESCO's creation last year and mid 2007. In June 5th 2007, BNDES started a partnership with a federal bank (Banco do Brasil) that makes possible that the credit be granted directly to ESCOs, increasing agility and capillarity of the program's operations.

4. Brazilian Energy efficiency regulation

The regulation is voluntary for the first five years and applies for totally, partially or non-conditioned buildings, aiming at enabling energy-labelling of office, commercial and public buildings with net area over 500 m^2 or supply tension over 2,3 Kv.

Five efficiency levels (form A to E, being "A" the most efficient) are specified for envelope, lighting systems and air conditioning. Research to fundament the regulation requirements concluded that lighting responds for 12-57% of energy consumption, and together with HVAC systems (25-75%) and equipment (6-38%) are the major players to close the energy consumption equation for office buildings in Brazil. Weights for lighting, HVAC and envelope were initially established as, respectively, 30%, 40% and 30%. Non-conditioned areas have to be simulated to demonstrate that comfort conditions are maintained for at least 95% of the occupied period. As a requirement for certification eligibility, the building must count on a sub-metering system by energy end use. Minimum requirements for certification at the highest level are also defined and other initiatives that might contribute to increase the building's global energy efficiency are recognized by a bonus point.

Energy efficiency regulations usually provide at least one of three compliance paths: prescriptive, tradeoff and performance demonstration, being the two latter ones usually a comparison between design and reference cases (Lamberts; Carlo, 2006). While the prescriptive approach limits physical properties of the building envelope materials and assemblies, the performance demonstration option requires use of building simulation tools. The Brazilian proposed regulation includes both compliance paths. For the performance compliance path, minimum functions for building simulation software are presented (MME et al, 2006).

Gathering the energy use data, and constructive, materials and components characteristics that could be considered representative of major building typologies (reference prototypes) is a daunting task, particularly considering that Brazil does not count on reference databases like RECS (for residential buildings) or CBECS (for commercial buildings) available in the United States, or similar sources in other countries. Only based on these reference performance levels, tied to the national building context, it will be possible to establish minimum efficiency requirements. The reference prototypes as the starting point that set alignment for the energy conservation measures (ECMs) to be applied for theoretically more efficient alternatives. The progressive application of ECMs tends to increase a certain building's efficiency level and their effectiveness is evaluated through simulation of thermal-energy performance. Several pieces of software are available and through cross-referencing simulation results with prototypes and possible alternatives, an energy consumption scale will be gradually delineated and allow for initial classification of buildings and to relate scale intervals to ECMs applied in each alternative. As energy efficiency is not given by energy consumption alone (Lamberts; Carlo, 2006), the proposed EE regulation combines consumption to life-cycle energy costs analyses.

5. Concluding remarks

Voluntary labeling schemes have been applied in Brazil for more than 20 years when the National Labeling Program was created in 1984. This voluntary program made possible the reduction in electricity consumption of the models available to the Brazilian consumers. Besides this mechanism, since 1994 the PROCEL Label (Selo PROCEL) is issued annually to the more energy efficient appliances and equipment within their categories. It aims to stimulate the national manufacturing of more energy-efficient equipment and to enable consumers to compare the energy use of the models they are considering. In 2006 the introduction of a mandatory minimum energy efficiency standard for residential refrigerators started to be discussed, which should be implemented early in 2007.

It is however unlikely that energy efficiency (EE) and energy R&D initiatives in Brazil would have taken place without the regulators' enforcement of compulsory programs in 1998 and later with the implementation of Law 9.991/00 by the National Congress. Power sector reforms in Brazil provided the opportunity to enhance support and in fact increase significantly the level of funding in these areas. The regulatory requirement introduced since 1998 has increased by several times the amount of investments in energy efficiency through PROCEL (Brazilian Program for Electricity conservation). Whilst PROCEL, the national electricity conservation program initiated in 1985, invested an annual average of US$ 14 million during 1994-2003, utilities' compulsory investments averaged US$ 57 million per year during 1998-2004 (Jannuzzi, 2005).

However, legislative acts alone are not a sufficient condition to ensure that resources are being used efficaciously to maximize the public interest in energy-related services. In spite of the increased investments, no independent ex-post evaluation of the programs implemented has been carried out as yet to determine impacts in terms of avoided capacity and energy savings.

Significant experience has been acquired by the regulator and utilities in terms of managing EE and R&D portfolios, there are, however, three main areas that require attention to improve the performance of the Brazilian "1% obligation": 1) the administration, governance and coordination of the resources and efforts (amongst utilities and CTEnerg); 2) the need to improve collaboration and pooling of more resources into the compulsory EE and R&D activities; and 3) program monitoring and ex-post independent evaluation (Jannuzzi, 2005).

During the initial years of the "1% regulation" (1998-2005) ex-ante evaluation of EE programs was done by PROCEL. ANEEL then transferred this evaluation to some State regulators, to bring this activity back to its own staff later on. In 2005 ANEEL contracted external consultants to evaluate the proposed utilities' annual EE programs. The ex-ante evaluation of utilities' R&D programs was initially done by ANEEL staff. In a second phase ANEEL contracted the National Research Council (CNPq) to review the R&D proposals. More recently (2003), ANEEL contracted Universities and Research Centers for this task (Jannuzzi, 2005).

Despite Brazil's mature and comprehensive programs and favorable legislation, there is still a huge, unexplored potential for energy efficiency and a clear need for new, complementary instruments. Barriers perceived at the time of efficiency programs implementation (e.g. low, subsidized tariffs; lack of information; incipient technology; inadequate legal structure; depleted resources; lack of qualified professionals; resistance from utilities companies…) are now mostly overcome and no longer impeditive. On the contrary, market transformation gained momentum and market is now clearly driven by motivators such as cost reduction (for consumers, producers and distributors); increase in economic efficiency (reduction of energy intensity); improvement in commercial balance (reduction of diesel oil and LPG importation); and reduction of environmental impacts (Porto, 2006).

Energy efficiency poses a series of challenges in the broader Brazilian context:

- Define and align governmental action instruments (PBE, Procel, Conpet)
- Orient application of available resources (PEE, Sectoral funds)
- Orient refinement of the legal and regulation system;
- Facilitate constitution of a sustainable market for energy efficiency;
- Promote permanent mobilization of the society

Finally, transformation of the energy efficiency market demands:

- encouragement to energy efficient equipment, buildings, systems and production processes;
- support for energy sources replacement;
- orientation of governmental purchasing power;
- support for technical losses reduction;
- incorporation of energy efficiency in energy sector planning.

Regarding the building sector, specifically, the EE regulation, constitutes the major achievement. Even though it was included in the EE law issued in 2001, it took six years to have the regulation's first draft, launched in the end of 2006 and already altered twice before the consultation started. The proposed regulation is dedicated to commercial and public buildings, which sum up to 22% of total electricity consumption in buildings. Ex-ante projections of savings are not available yet, but are expected to be around 15 to 20%. The next step is to develop a version for the residential sub-sector, responsible for other 22% of electric energy consumed in Brazilian buildings and that, together with commercial building, has shown the steepest growth curves after the rationing in 2001.

INFORMATION EMBEDDED BUILDING' FOR SUSTAINABLE LIVING

Tomonari YASHIRO Dr.Eng.[1]

[1] Institute of Industrial Science, University of Tokyo, Tokyo, Japan, yashiro@iis.u-tokyo.ac.jp

Keywords: building management, life cycle traceability, energy use monitoring, ubiquitous technology

Summary

For promotion of sustainable living by rational building management, stakeholders of building need to be assured to acquire holistic data &information necessary for environmentally conscious decision-making in building management. However, in reality, stakeholders are not always able to access to the information, because some building related data are not collected, some are fragmented and some are deleted. This paper proposes the idea of 'information embedded building': it is a building that assures stakeholders to ubiquitously access to data &information whenever and wherever they need. This paper illustrates the technology developments that realize the idea of 'information embedded building'. Those include;

- Life cycle based traceability system for building components using RFID technology
- Network based energy monitoring system accessible by various stakeholders
- Personalized portal site system as a gate to access to holistic and customized data &information package of his/her building

The paper presents background and motivation of technology developments above. The application of the developed systems proves that they have potential advantage to assure ubiquitous accessibility to holistic range of building related data & information that are indispensable for rational building management to enhance environmental sustainability of built environment.

1. Introduction

Generally, the quantity of existing building in one country is enormously larger than the capacity of new construction of building in that country. For instance, Japan has totally 8 billion m2 building stock while it produces some 0.2 billion m2 new buildings. Therefore, for environmental sustainability of built environment, enhancement of environmental performance of existing buildings by improvement of building management is significant as well as that by increase of newly constructed sustainable buildings.

Various professional and non-professional stakeholders, such as owners, residents & occupants, investors, suppliers, managers, architects, engineers etc.,perform significant role in the process of building management. If they are well informed, stakeholders could make more rational decision-makings from the aspect of environmental sustainability of building.Contrarily, if they should not be well informed, the decision-making could be irrational. For instance, old-fashioned equipments are being replaced to improve energy use efficiency in building. However, in many cases, energy use is not reduced as is expected because inefficient operation of building equipments. If data relating to operational efficiency of equipments are available, managers of building would improve operation method and try to identify real energy use demand before they replace equipments. Thus, the availability of necessary data &information for building management is one of the key factors for environmental sustainability of existing buildings.

Regrettably, in reality, stakeholders are not always assured to acquire data & information promptly when and where they need, because some building related data are not recorded nor collected, some are fragmentally stocked by different agents, and some are missed and deleted. Consequently, difficulty in availability and accessibility of data and informationis is one of the barriers for enhancement of environmental performance by rational building management.

Here the idea of 'information embedded building' is emerged as a measure to breakthrough the barriers. By the introduction of information embedded building, stakeholders are able to access data & information whenever and wherever they need them. This paper aims to propose the idea of information embedded building and illustrate the examples of technological systems developed by author based on the idea.

2. The idea of information embedded building

Figure 1 illustrates the idea of 'information embedded building'; it is a building that assures stakeholders to ubiquitously acquire building related data &information whenever and wherever they need. Acquirable data & information includes;

- Technical detail and specification of building and its components
- Maintenance record of building and its components
- Monitored performance data of building such as data on energy use, indoor air quality etc.(real time based if necessary)

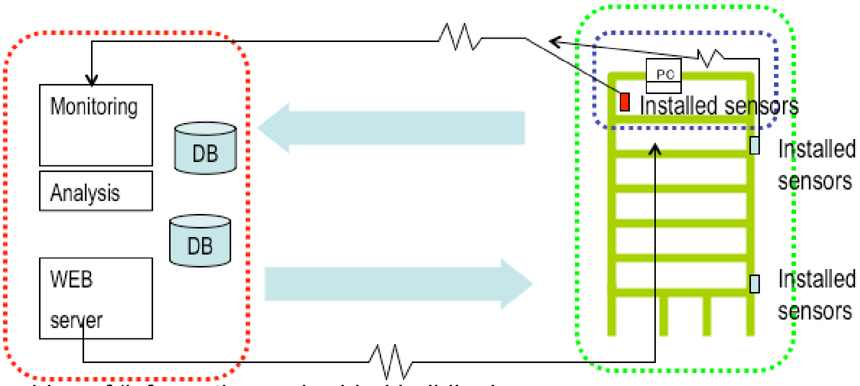

Figure 1 The idea of 'information embedded building'

The wording of information embedded building is a metaphor; It does not mean information is literally and physically embedded in building. Rather, it is a building in terms of which stakeholders of building are accessible to database at any time and at any place through embedded devices such as RFID etc. The device is a kind of access gate to the database stocked in the physically distant located servers. But for stakeholders who read, look, generate, edit and send data & information have a feeling that data & information is extracted from the embedded device. Information embedded building also means the building in terms of which stakeholders can collect performance data through ubiquitously installed digital sensors.

In order to realize the idea of information embedded building', the author developed the systems that ensure stakeholders accessibility to 'embedded' data & information. Those include;

- Life cycle based traceability system for building components
- Network based energy monitoring system of building
- Personalized home information portal site

3. Life cycle based traceability system for building components

3.1Background and motivation

Building can be recognized as a set of materials and components. Therefore, environmental sustainability of building is affected by those of installed materials and components. However, it is quite usual that residents, owners of building and professions who commits in the process of building management have difficulty to access to the information to identify the following issues.

- Technical specification and EPD of building materials and components and equipments
- Recommended maintenance method
- Previous maintenance record (home log book data)
- Fabricators, suppliers, operators, servicers who is responsible for fabrication, installation and maintenance of part of, or whole building

The difficulty of the identification of the issues above causes inappropriate treatment and use of components and equipments, delayed and inefficient repair & maintenance works, and poor traceability. Especially it should be noted that repair and maintenance works would be still less-productive by extension of lead-time if issues above is not identifiable.

3.2Developed system

Figure 2 illustrates the system developed by the author and collaborators. Here RFID device is embedded in the installed components and equipments. Professional and non-professional stakeholders can access to the database from the site at any time through the network between embedded RFID and servers. The database includes the information to identify the issues listed in 3.1. Contents of database can be input by various stakeholders who commit in the process of life cycle operation of building components and equipments from fabrication to the end-of-life of them. Stakeholders in downstream can utilize information input by those in upstream of life cycle stages. For example, residents can easily access to the updated user manual, directory of maintenance service providers and previous maintenance record. Maintenance service providers can access to the information on technical specification, maintenance manual, invisible construction details including interactions and interfaces with other components and previous maintenance records. In addition, contents of database input by downstream stakeholders are usable by upstream stakeholders. For instance, suppliers of equipments and components can identify where their products are actually installed and can contact users if they should recognize technical failures in fabrication or installation.

Thus, the ubiquitous accessibility to the database assures prompt data input by various stakeholders and immediate utilization of database whenever and wherever the stakeholder need. In a sense, the system can construct give-and-take basis data & information sharing by stakeholders, while it assures intensive protection of confidential information for specific stakeholder by advanced access control technology.

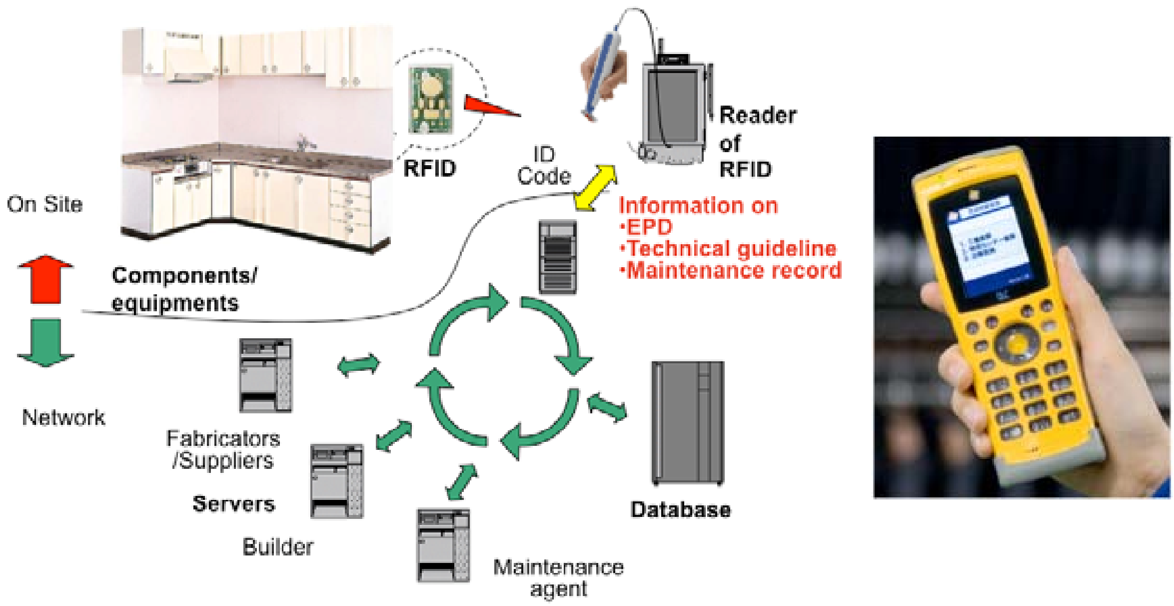

Figure 2 Life cycled based traceability system for building components and equipments using RFID

3.3 Potential benefit by life cycle based traceability system for building components

The life cycle based traceability system using RFID is now experimentally applied by nonprofit organization in Japan (Centre for Better Living). The trial experiments generate empirical lessons for application of the life cycled based traceability system for building components and equipments using RFID. It has proved that traceability system can easily form 'invisible' link between suppliers and users of components. It means that suppliers could have a chance to support users directly and to enhance the environmental sustainability of building.

The application of the traceability system has demonstrated the potential advantages to facilitate sustainability oriented building operation and maintenance by assurance of prompt information acquisition for various stakeholders of building.

4. Network based energy monitoring system

4.1 Background and motivation

A building can also be considered as a system in operation and provides a number of services to its users as well as conditions appropriate for living, working, etc. The environmental sustainability of the building relates to the services and conditions provided to occupants. A building provides the services by inducing energy, water, and various resources for its operation as well as generating atmospheric emissions, wastewater, wastes, etc.

As many previous literatures point out, there exist serious gap between the designed potential of energy performance of building and the reality of energy use. One of the reasons of the gap is weak feedback in building management process due to difficulty in data availability/accessibility in terms of energy use and indoor air quality. Thus, there exit the need to develop technical tool by which stakeholders of building know the real time energy use of whole building, or part of the building where he/she lives and works.

Building Energy Management System (BEMS) assures data availability/accessibility in terms of energy use in building. However, BEMS is mainly applied relatively larger office buildings which only occupy less than 10% of total floor areas of building stocks. Comparatively, smaller and middle sized buildings less than some 5 thousand m2 total floor area do not have resident professional energy manager, a very few stakeholders of those buildings can access to the data on real time basis energy use and indoor climate conditions that is the basis for living and work style with lower energy use intensity. In another word, it is probable that owners and residents who are active and positive for sustainable living actually behave irrationally against their purpose simply because of difficulty in data availability/accessibility in terms of energy use and indoor climate conditions. The gaps between sustainability oriented intention of occupants and the real consequences of energy use are expected to be minimized by introduction of technical tool that provide data on energy use and indoor climate conditions.

By incremental concern to global warming, policy makers advocates restricting comfort of indoor quality, For instance, Japanese government appeals to general public to keep mechanically conditioned indoor temperature higher than 28 deg C from the aspect of total peak demand control in summer time. But 28 deg C with high humidity is not comfortable to occupants; in a sense, the government's appeal is a request of compromise in well-being of occupants of building. The appeal could be emergency measures but could not be sustainable measures from the aspect of peoples' acceptance. There exist number of wasteful energy use in operation of building. Avoidance and minimization of those wastes should be the first measures before down grade of indoor environment quality. However, to avoid and minimize those wastes, energy use data availability/accessibility is essential. Thus, there is a need of cheaper technical tool that enables to provide energy use data and indoor climate data to stakeholders.

This is the background and the motivation why the author and collaborators has developed network based energy monitoring system which mainly target the smaller and medium sized buildings where BEMS is not applicable or where technical support by resident energy manager is not available.

4.2 Developed system

Figure 3 illustrates the web based energy monitoring system developed by the author and collaborators. The network system links devices such as current transformers (CT) that digitally quantify energy use in designated part of building (rooms, blocks, floors etc.), as well as sensing devices to measure characteristic of indoor climate (temperature, moisture content, CO_2 gas content etc.) All data is automatically collected through open web based network sources in terms of protocols and database architecture. Operating software is frame-worked with modulared and compatible with almost all conventional devices. Consequently, installation of the system as is illustrated in Figure 3 is relatively cheaper because any devices that is already installed in building is usable and thus additional investment is relatively lower than previous energy monitoring systems of building which applies large scale well performed but closed system composed of specific devices.

Any stakeholders can join in the circle of users of the network based monitoring system. Users can get the collected data and analysis report depending on his/her concern. In addition, owners and building managers can easily define benchmarks through the comparison with other similar buildings.

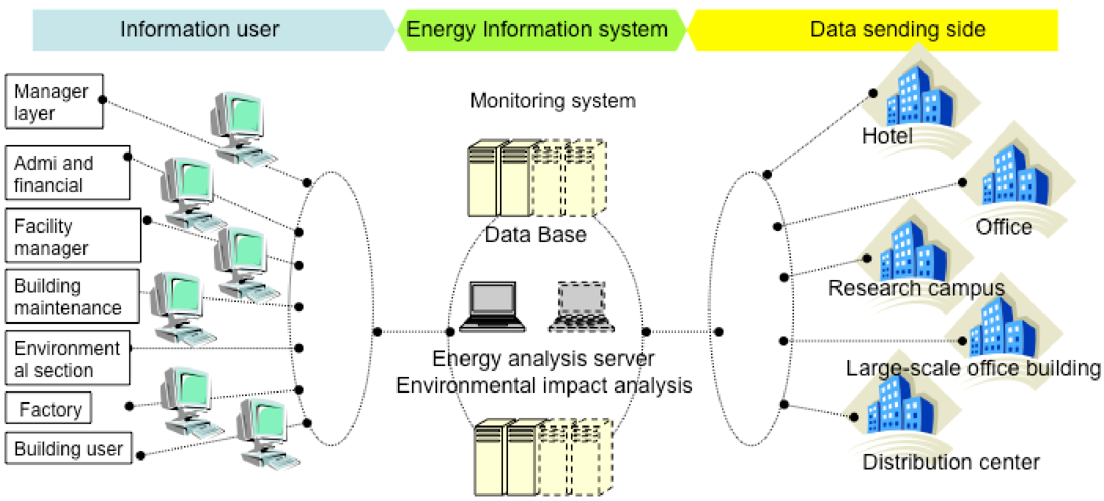

Figure 3 Outline of network based energy monitoring system

4.3 Potential benefit by energy monitoring system

The energy monitoring system is now installed and used in over 20 buildings. In many cases around 10 % reduction of energy use has been realized for five years since the installation of the monitoring system. The energy use reduction and associated reduction of CO2 emission from the building has been achieved only by improvement of operation. It includes;

- Promotion of voluntary activities by residents and occupants who became knowledgeable by provision of energy monitoring data (in other words, notice on how much energy they used respectively)
- Rationalization of ventilation by concurrently monitoring of indoor environmental sensing data (Figure 4)
- Improvement of COP performance of equipments by balancing real demand and capacity of air conditioning machines

Figure 4 illustrates the example of concurrent analysis of impact by mechanical ventilation control using energy monitoring system. Install monitoring system identified that too much mechanical ventilation is operated. Thus, building managers tried to change in operational mode of mechanical ventilation by watching real time base data of indoor CO2 concentration and energy use. It is a sort of concurrent and continual do-check-action process; If CO2 concentration is too high, ventilation is increased. Contrarily CO2 concentration is acceptably low, mechanical ventilation is decreased.

If developed energy monitoring system is used over two years, energy demand model can be constructed. Once energy demand model is established, proactive operation that optimizes COP performance over time. Actually industrial collaborator with the author invented optimization of building's operation over time; In such cases, more intensive energy use reduction should achieved by proactive operation of energy uses.

The experimental application of the energy monitoring system proved the potential benefit of building operating energy reduction by identification of inefficiency of energy use in building and by promotion of commitment by stakeholders.

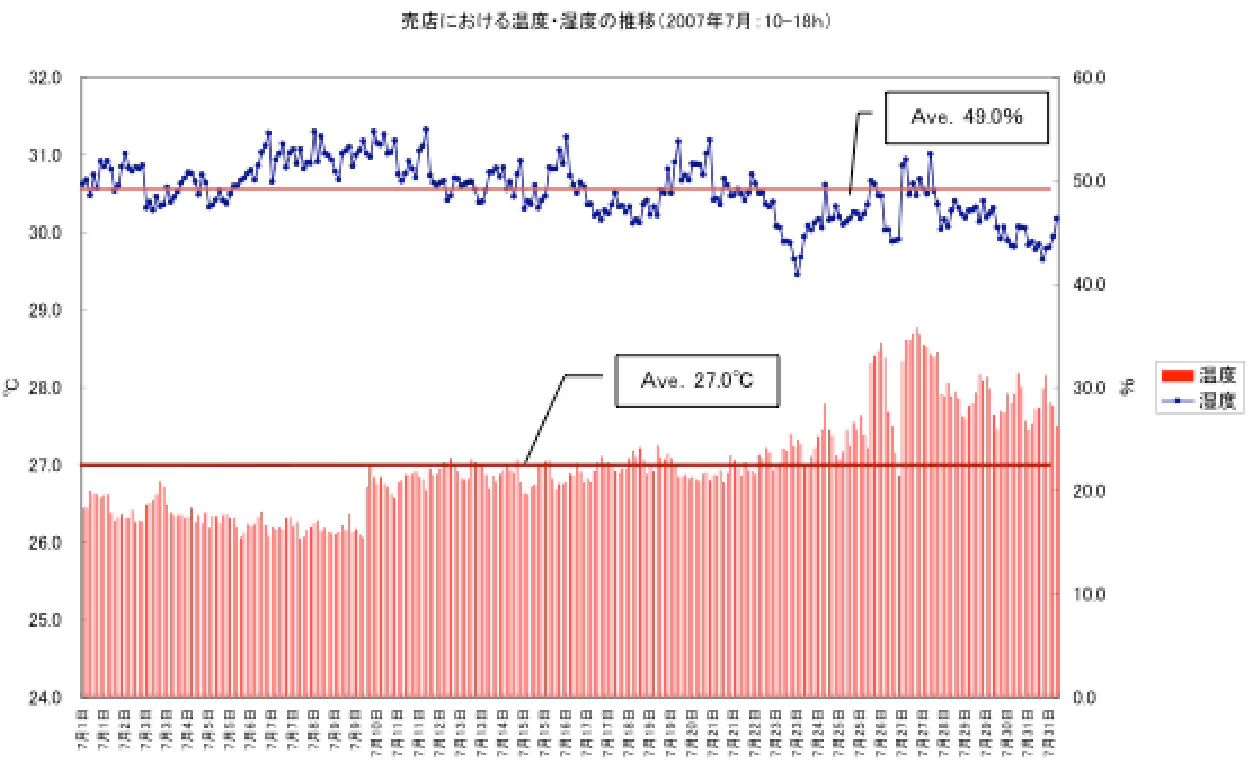

Figure 4 Example of on concurrent analysis of impact by mechanical ventilation control using energy monitoring system

In addition, developed energy monitoring system is usable to evaluate real effectiveness of new building technologies. For instance, performance of passive solar house is delicate and can be too sensitive to unpredictable factors. To realize potential benefit of well-designed passive solar house, it is desirable to introduce concurrent and continual do-check-action process like the process illustrated in Figure 4.

5. Personalized home information portal site

5.1 Background and motivation

A building can be considered as a place to live and work. Provision and realization of better environmental performance of building in broader sense upgrades serviceability, comfort, health and quality of life generated by building is a critical factor for better environmental sustainability of building over life cycle of building. Occupants and stakeholders of building are expected to take proactive and voluntary action.

In order to promote rational decision-making toward sustainable built environment, stakeholders of building who commit in the process of building management should have whole picture of state of art of the building. As it is described in previous chapters, a building can be understood as a set of materials and component. It also can be understood as a system in operation.

For realization of better place to live and work, it is desired to integrate the information on the performance related to a set of materials and components as well as system in operation. Life cycle based traceability system for building components and energy use monitoring system can provide information on performance of building whenever and wherever stakeholders wish. However, those systems only provide a kind of snapshot views taken from specific interest of the stakeholders. Thus, it is expected some methodology is created to residents and owners of building by which they can build up whole picture from multiple interests by assembling and integrating data & information generated through specific interests.

Those data & information are not stocked and maintained by single party. Rather, those are stocked and maintained by various parties who have different motivation for utilization of data & information. However, the various parties need to note that those data &information relating to one house should be primarily belong to the owner or occupants of the house. They should understand that they keep the data & information of one house on behalf of the owner or occupants of the house. In reality, a few in conventional sectors in building industry think like that. So far majority in building industry still believe tacitly that they possess the data & information. Therefore, in order to build up whole picture of building, some social system need to be introduce to facilitate the collection of data & information from different parties with different interests.

Above expectation to the methodology development as well as needs to introduce the social system in terms of data & information collection and utilizastion is the background and motivation to develop Personalized home information portal site.

5.2Developed system

Figure 5 illustrates the idea of personalized home information portal site. Here, on behalf of owner or residents of a house, information manager request various parties who keep data and information relating to the house to provide those data & information to owners or residents. Weapon of information manager to the various parties to take consent of provision of data & information is volumetric number of owners and residents behind him/her who employee information manager as a representative of their interest.

Through the Personalized home information portal site, owners and residents can collect, see, keep and edit data & information which are kept by different parties such as architect, engineers, contractors and builders, building/facility managers, maintenance firms, energy suppliers etc. Accessible data & information through the portal site includes;

- Technical detail and specification of building and its components
- Legal status of house
- Land survey documents
- List of professions, contractors and suppliers
- Traceability related data available by Life cycle based traceability system
- Construction documents including audio visual records as well as logistic logs of building components
- Building permit documents
- Inspection report and certificate by third parties
- Maintenance record of building and its components
- Performance data of building (real time based if necessary) collected through energy monitoring system etc.

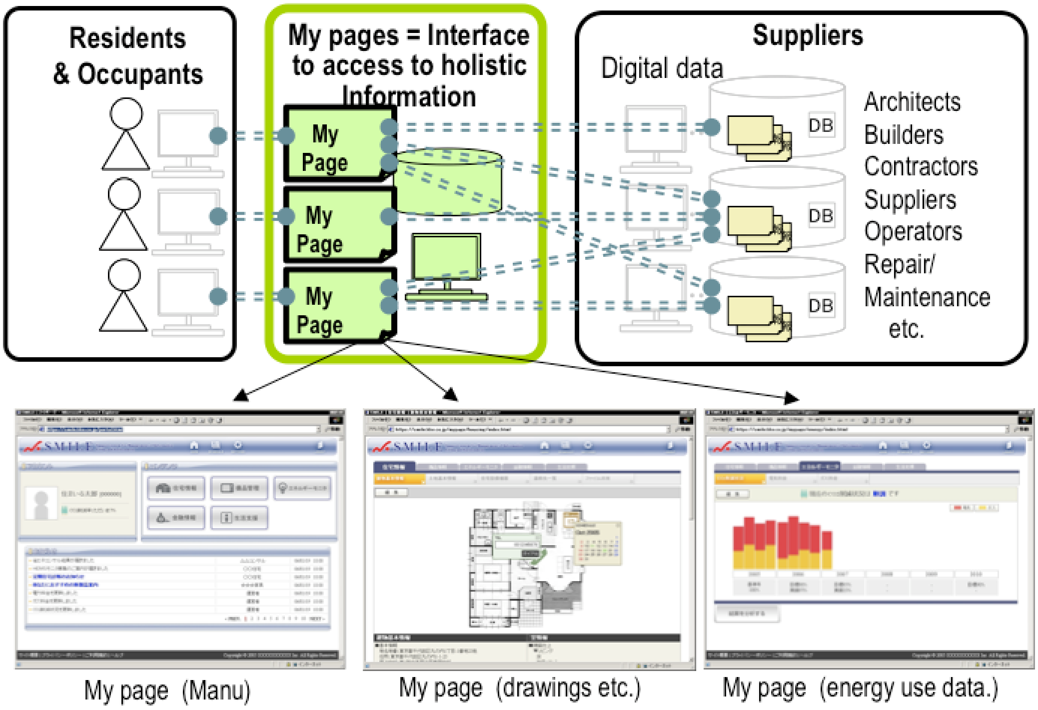

Figure 5 *Prototype of personalized home information portal site (http://www.kke.co.jp/smile/)*

5.3 Potential benefit by personalized home information portal site

The developed personalized portal site is now experimentally used by over 200 monitoring users and developers of the site is now getting the feedback from monitoring users. Through the process of experimental use, potential advantages of the portal site system have been identified. Those are;

- Enhancement of economic value of houses by assurance of traceability of houses. Consequently it generates motivation for intensive and continual investment on existing building stock
- Opportunity creation of supporting service for sustainable living; For instance, energy use data linked with schematic drawings and inventories of installed equipments generate the opportunity for effective energy use consultancy service.
- Improvement of productivity in repair and maintenance.

Concurrently, problematic issues of current version of portal site have been identified. Those are;

- Need to improve user interface for data input and data import.
- Need to prepare instructive manuals to assist non-building –professional users.

The personalized portal site system has a potential to improve the quality of life of residents with lower environmental impacts as well as to provide motivation for continual and proactive maintenance activities.

6 Concluding comments

The paper proposes the idea of information embedded building. By utilization and integration of available ubiquitous computing technology, the idea is technologically feasible. Whenever and wherever stakeholders of information embedded building can access to traceability related information, real time energy use data and building related data & information that are indispensable for well-informed decision-making in building management. For that reason, the idea of information embedded building could be generic paradigm for sustainable building.

A building can be seen as a set of building materials and components. It also can be seen as a system in operation with induced input and emitted output. Fundamentally it is place for living and work. The idea of information embedded building is applicable to these three aspects of building.

There is a gap between designed state of art of building and reality of building because a building could be affected by unpredictable factors. It is also because a building is a very complicated and integrated system so that there exist limitation of anticipation by simulation etc. In addition, it is because requirements to building is ever changing.

Consequently, to assure well being of occupants with lower environmental impact ,which is a source of sustainable building, continual management is essential to bridge the gap between dream in design and reality. Information embedded building is a set of silent and invisible technical devices , but it certainly contribute to bridge the gap by providing data & information to stakeholders whenever and wherever they wish, and to support more reasonable and well-informed actions by stakeholders.

Summary

Various technologies have been proposed for reducing carbon dioxide (CO_2) emissions and otherwise saving energy when buildings are in use. Architectural methods that take account of global environmental conservation are fundamental ways of mitigating the heat load of buildings. At the National Institute for Environmental Studies (NIES) Climate Change Research Hall (CCRH: ferroconcrete, 3 floors, 4900 m² total floor space), we collect a large amount of data on energy consumption, heating ventilating air conditioning (HVAC) operation, the indoor environment, weather etc., and use it to develop systems that automatically control HVAC and lighting, thereby achieving both environmental comfort and energy conservation. This data is also used to verify the effectiveness of the systems. We have now developed an environmental information system to help the occupants of buildings reduce the energy consumption. Our aims are as follows. We inform the occupants about such aspects of the indoor environment as temperature, humidity, energy consumption and comfort. Weather data allows them to decide whether to use natural ventilation or not. They can understand the campaigns of "Coolbiz" or "Warmbiz" and which air conditioning setting would be better as regards reducing energy consumption and operators can send the information to users to assist their efforts in this respect. The system collects data from HVAC on the BAC-net (TCP/IP) by using a web server (Windows IIS, DB: SQL) in real time. Using this information system, we can present forecast data to provide an optimal control indicator. By developing this information system, we are attempting to reduce CO_2 emissions and determine a sustainable lifestyle in the face of climate changing.

1. INTRODUCTION

In the 4th IPCC report Summary for Policymakers (SPM) [1] published in 2007, cost-effectiveness is shown to be the highest in the building sector, and aroused the interests in countermeasure technology in the building sector against global warming. Dr. Ikaga [2] reported that in 1990 about 30 % of the total greenhouse gas emitted in Japan could be attributed to the building sector. The emissions are related to design, operation, and reform in buildings, among which operation contributes more than half.

Moreover, industrialized countries are increasingly required to make an effort to reduce CO_2 emissions with a view to establishing a post Kyoto framework; there are some countries that have adopted a target of reducing CO_2 emissions by 70% or more as a national policy. It is a critical task to demonstrate how these government targets could possibly be put into practice through technical and political measures.

Among the series of measures regarding the building sector, the Building and Energy Management System (BEMS) is a key technology but has a specific problem that is not found with other control technologies. The problem with BEMS is that there is a very complex relationship between operators who are engaged in heat source management and residents / owners who are responsible for indoor management. However, advances in information technology have enabled high-speed calculation, and an information service system via the Internet is expected to be constructed at low cost and introduced rapidly, thus offering the potential for great progress.

In this study, we report an environmental information system for buildings that was constructed to resolve the above problems and its application to existing buildings. [3] [4]

1.1 Strategy of Predictive Control

In this study, there are two approaches to optimization with a view to realizing energy-saving operation, these relate to the indoor environment including comfort and equipment performance using control technology; therefore, calculation integrating both control technologies was needed. Measurements in buildings between 2004 and 2006 revealed that the control of the existing air conditioning systems operated based on the measured temperature but would not accept the room temperature within the optimum temperature range, and that the system tried to comply with a room temperature setting, therefore, the cooling and heating operation is mixed, leading to energy loss. [5]

In addition, energy-saving operation should have been adjusted for each region, taking into consideration the climate peculiar to Japan, namely hot and humid in summer and cold and dry in winter, but there has been no notion of optimization for each season. Moreover, adjustments are rarely made for problems caused by differences in information about building performance between the design and operation stages. Beyond these conditions, we established a procedure for optimizing operation taking building performance comprehensively into consideration, based on indoor environment and air conditioner settings with an energy-saving effect obtained according to an experimental result [6] (Figure 1). We developed tags for information management in BAC-net, representing a concept used for optimization calculation, and employed the following definitions for the calculation.

ENV0: External conditions (outside air temperature, relative humidity, sunshine hours, solar radiation on a south-facing surface)

ENV1: Heat source system (volume/amount of chilled and hot water, electricity, gas, and vapor)

ENV2: Indoor air conditioning system (volume/amount of chilled and hot water, motive power, and VAV wind supply)

INTE: Internal (lighting, heat build-up by equipment such as wall outlets, human bodies)

PERI: Building envelope performance (window performance, with/without the eaves)

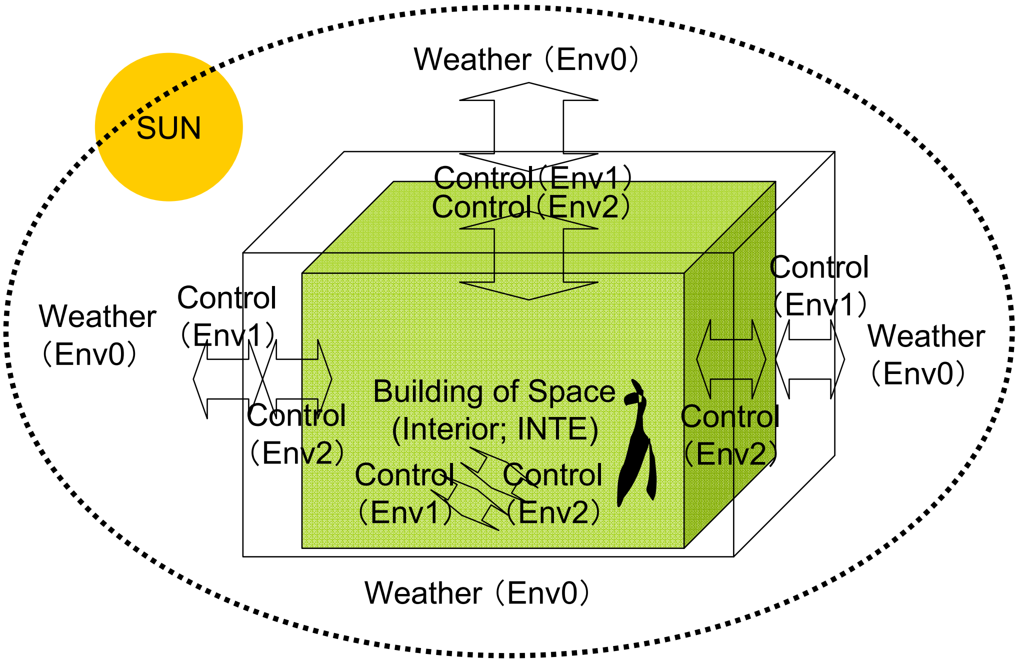

Figure 1: Control Model

Based on the weather forecast data, the difference between the indoor and outdoor heat balance is calculated over time. Then, guidance on daily air conditioning operation is established. The demand for indoor air conditioning is calculated to determine whether the system should be ON or OFF depending on the necessity of air conditioning operation.

As long as the external and internal environments are balanced, operation should be minimized. Natural energy such as natural drafts can be used. Also, in winter, the internal build-up of heat can be expected to contribute to substantial energy reduction.

1.2 Use of Prediction in HVAC Control

In this study, our optimization procedure is characterized by a virtual definition of the internal build-up of heat caused by outside conditions or indoor use (lighting, power consumption at wall outlets, and the number of persons present) as control parameters. For data collection, we have been using BEMS (Building Energy Management System, Yamatake, Savic-net EV, with a communication response of about 7 seconds) with combined use with BAC-net communication to obtain measured data at 10 min after every hour and since 30-minute integrated values [7) 8)]

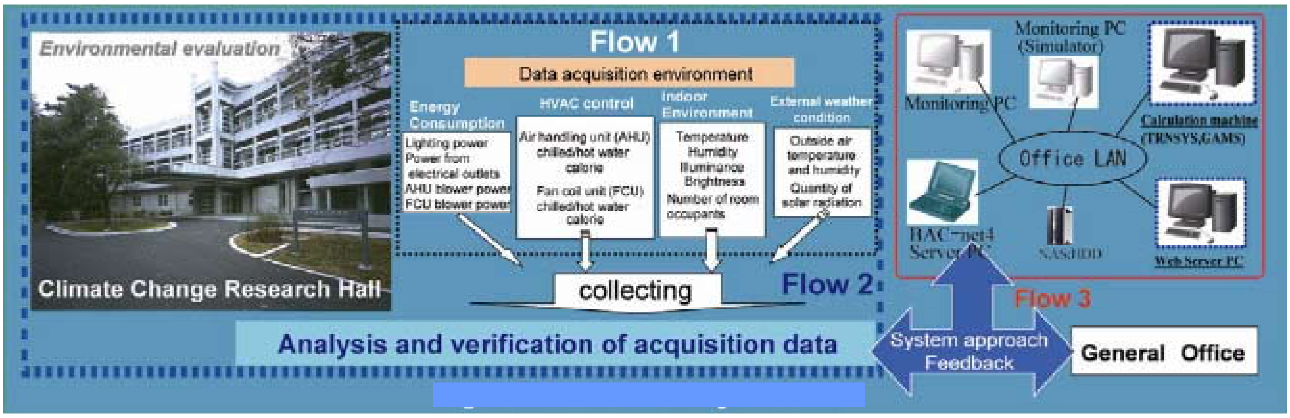

Figure 2: Communication flow of control system

1.2.1 Modeling AHU

The volume/amount of chilled and hot water, vapor, and VAV window supply are used as control parameters for air conditioning control. The indoor sensible heat load Hs and air conditioning system can be expressed as the following equation (1):

Indoor air conditioning system load (ENV2) = V x Ca x (tr - tv) …(1)

where, V is air flow; Ca is air specific heat = 1005J/(Kg/K); tr is room temperature and tv is diffused air temperature.

In this study, control was provided by the mathematical programming model Predictive Horizon Control (Ricker IMC) [9)], which operates as an energy-saving temperature and humidity control system during our development of the new control system.

1.2.2 Modeling Indoor Environment

Thermal load is calculated based on the convective heat transfer coefficient settings of six indoor surfaces including window, wall, and floor surfaces. The internal build-up of heat is calculated based on the lighting power, and power consumption at wall outlets.

Interior load (load0) = $Q_{AllS} + Q_{AllL} - Q_{AirS} - Q_{AirL} - Q_{Skin} - Q_{Vent}$ …(2)

where, Q_{AllS} is the indoor sensible heat load (kJ/h), Q_{AllL} is the indoor latent heat load (kJ/h), Q_{Skin} is the skin load (kJ/h), Q_{AirS} is the indoor ventilation sensible heat load (kJ/h), Q_{Vent} is the dragt (kJ/h), and Q_{AirL} is the indoor ventilation latent heat load (kJ/h).

In highly automated buildings that are equipped with newly developed cladding with high performance heat insulation, the heat load tends to be largely accounted for internal build-up of heat ; therefore, cooling operation is conducted in winter in the conventional control system (Figure 3).

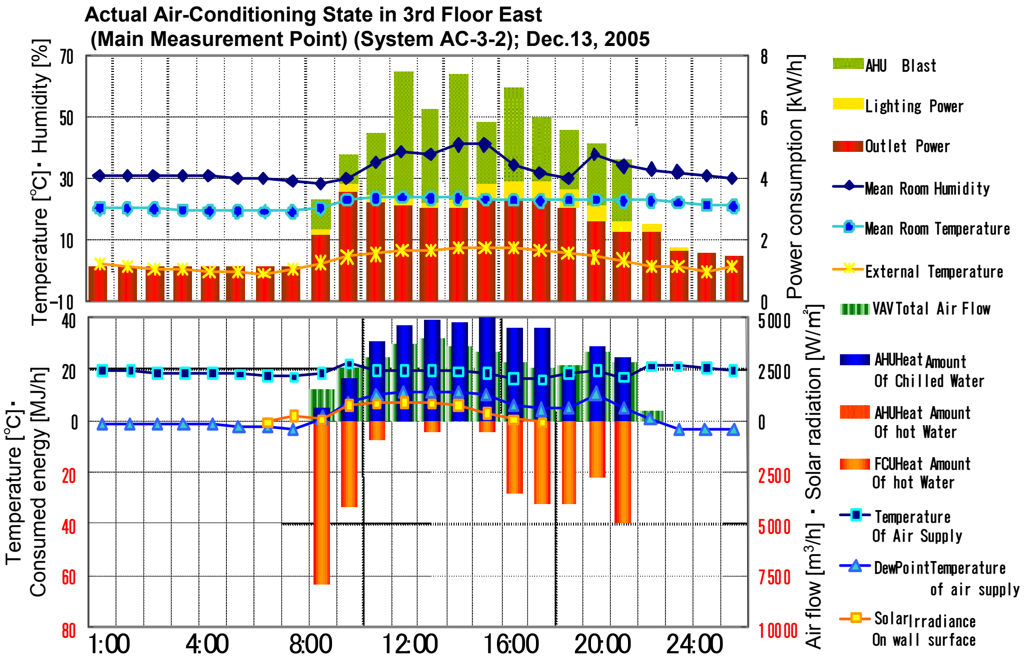

Figure 3: Conventional control on representative winter days

1.2.3 Modeling Plant

The amounts of chilled and hot water and vapor used in the heat source system are calculated according to whether the heat source system is ON/OFF and the COP setting, based on the energy consumption expected for the indoor air conditioning system.

1.2.4 Modeling Outdoor Environment

The ASHRAE comfort range[10)] is used to evaluate both the indoor environment and outside air temperature by calculating the dry-bulb temperature and absolute humidity using outside air temperature and relative humidity.

1.3 Methods of Building Energy Monitoring

The heat balance for sensible and latent heat can be expressed as Equation (3) by calculating sensible and latent heat.

The calculation is conducted continuously based on real-time information about the outside conditions.

$$env0 \rightarrow \{load1 \Leftrightarrow \{env2/ \{load0(INTE + PERI)\}^{l}\}^{m}\}^{n} \Leftrightarrow env1/load2 \leftarrow env0 \ldots (3)$$

->: Input of information

<=>: Equilibrium condition is ideal.

The guidance of heat source system operation is determined based on the processing requirement of the indoor air conditioning system.

Figure 4 shows the concepts of our control models. Different information is required for residents or energy managers, therefore, the model has indoor control parts, air conditioning parts and heat source control parts.

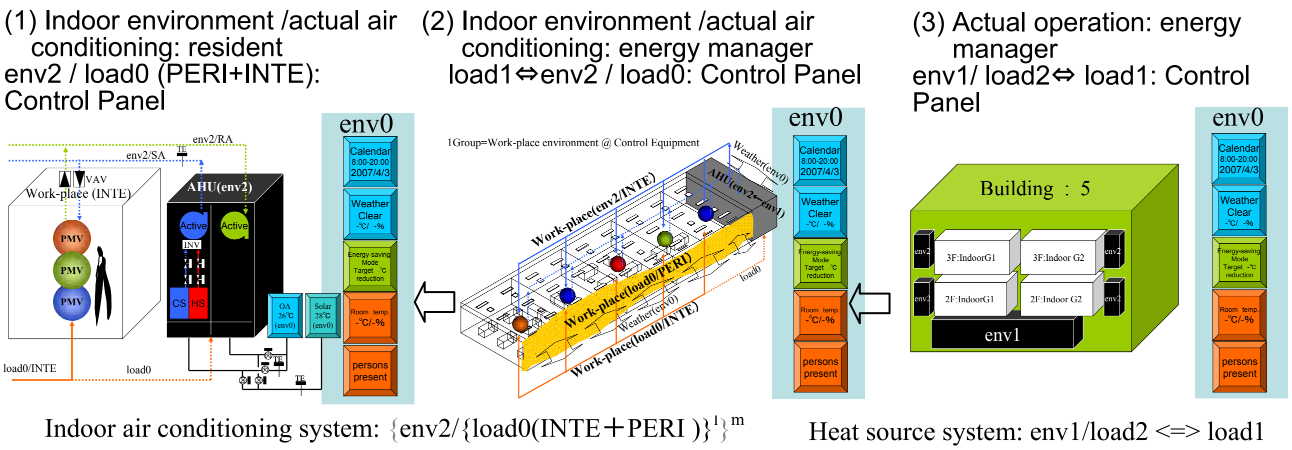

Figure 4: Concepts of control models

2. RESULT

2.1 Optimization of air-conditioning mode

Figure 5 shows indoor air-conditioning modes, including cooling, ventilation, and heating.

Room temperature corresponds to dry-bulb temperature, and room relative humidity is calculated using absolute humidity. Therefore, in both the calculation and the air conditioning system, identical data are obtained through real-time measurements and are calculated to evaluate the validity of air conditioning system operation by continuously monitoring the indoor/outdoor heat balance.

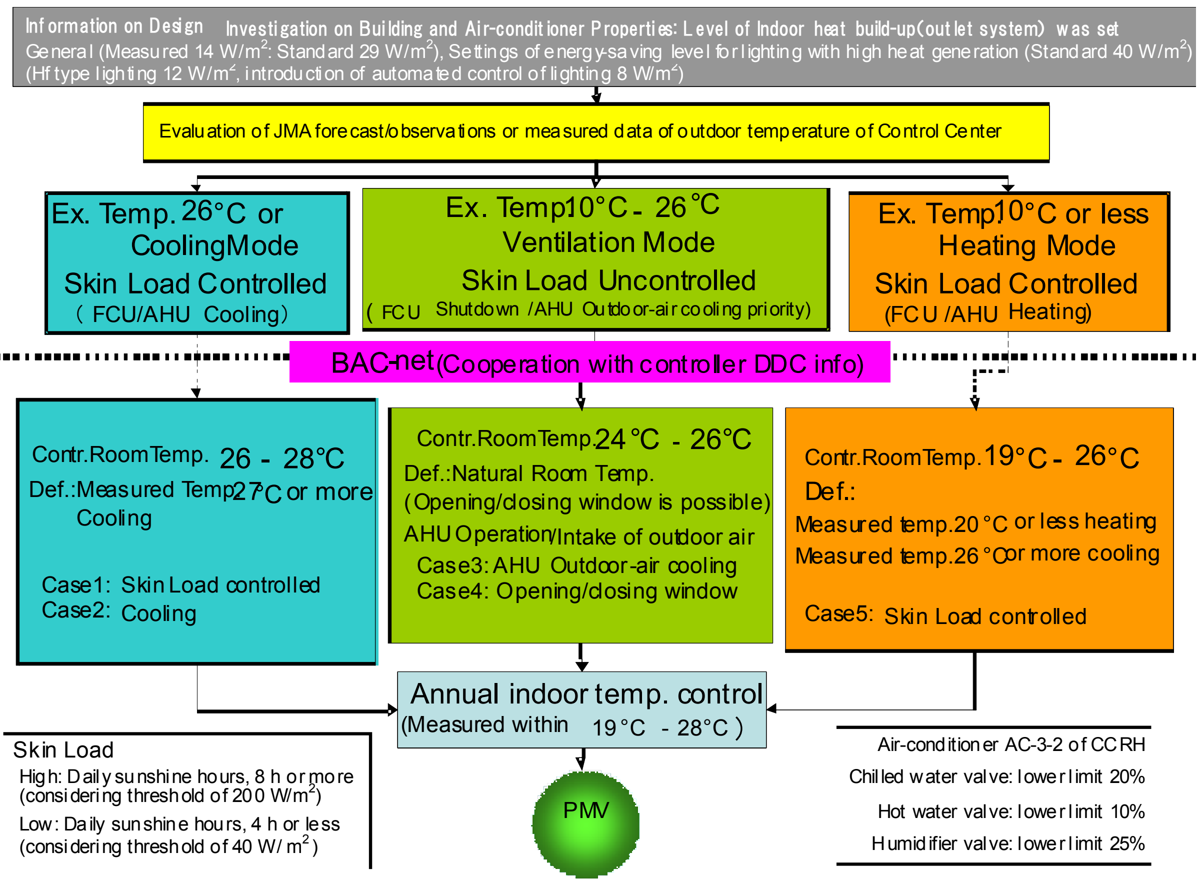

Figure 5: Determination of indoor air conditioning operation modes

In this study, we compared the energy consumption between the room temperature setting (25°C) and the experimental room temperature (27°C) and confirmed that our newly developed control system which provides cooling operation at 27°C or greater realized fairly good energy-saving operation. [6]

Conventional control in winter resulted in energy loss owing to the simultaneous consumption of FCU hot water and AHU chilled water at settings of both 23 and 24°C. When operating the new control with a conventional heating setting of 23°C or less, some AHU chilled water was consumed. Finally, a new control which provides heating for the room temperature of 20°C or less (no AHU chilled water consumption is allowed; room temperature setting at 20-26°C) realized energy-saving operation in which only indoor air was circulated (the air supply to the residential room was changed to the minimum value of 30%) and only FCU hot water was used (Table 1).

Table 1: Results of indoor air conditioning operation modes

	Cooling Mode				Ventilation Mode				Heating Mode	
	Case1		Case2		Case3		Case4		Case5	
	Skin load control		Cooling operation		Cooling by external air		With/without opening/closing windows		Skin load control	
	①	②	①	②	①	②	①	②	①	②
	Conventional control	New control	Conventional control	New control	Conventional control	New control	Conventional control	New control	Conventional control	New control
19°C									▲●	△
20°C									▲●	◎
21°C									▲●	○
22°C									▲●	○
23°C									▲●	●
24°C					▲	※	▲	△	○	●
25°C	▲	▲	▲	▲	○	※	○	◎	▲●	●
26°C	▲	○	▲	○	△	※	▲	△	▲●	●

28°C	△	△	△	△						

Energy-saving	Excellent ◎	Ideal operation for energy-saving is possible
	Good ○	Rather energy-consuming operation, but moderate comfort is maintained.
	△	Energy-saving operation, but comfort tends to be impaired depending on individuals who find it rather cold/hot.
Non-energy-saving	▲	Non-energy-saving operation where excessive energy is consumed for cooling
	●	Non-energy-saving operation where excessive energy is consumed for heating

2.2 Environmental Information System

In the commercial sector, energy-saving measures are adopted at the initiative of government, energy managers, or resident. Different information will be required for each of them. BEMS was originally a technology designed for energy managers, while a system for residents has been established in this study.

We developed a real-time monitor (Figure 6) that monitors external conditions, the indoor environment, and air conditioning settings to evaluate the optimization of the cooling, ventilation, and heating modes (Figure 5) by incorporating the results of the developed simulation control and experimental results. The monitor also provides the resident with information on energy saving of air conditioning and displays the power consumption of lighting and wall outlets. This information system might promote residents' energy-saving behavior.

In business buildings with a total floor area of 4000 m^2 or less, the system operates making use of natural drafts that occur when windows are opened and closed, thus reducing the air conditioning load. In addition, through sharing information between the residents and energy managers, smooth communication is realized when they reexamine an energy management plan and improvement of daily operation, leading to further energy-saving measures through information exchange.

As shown in Figure 6, a monitor screen shows real-time measured data on the PCs of individual residents through a TCP/IP network. 1-14 below show information service items. The system was developed based on Microsoft Windows OS XP (WEB server IIS pre-installed) using Visual Web Developer 2005 Express Edition, Microsoft! SQL Server 2005, Microsoft Visual Basic 2005 Express Edition distributed free by Microsoft.

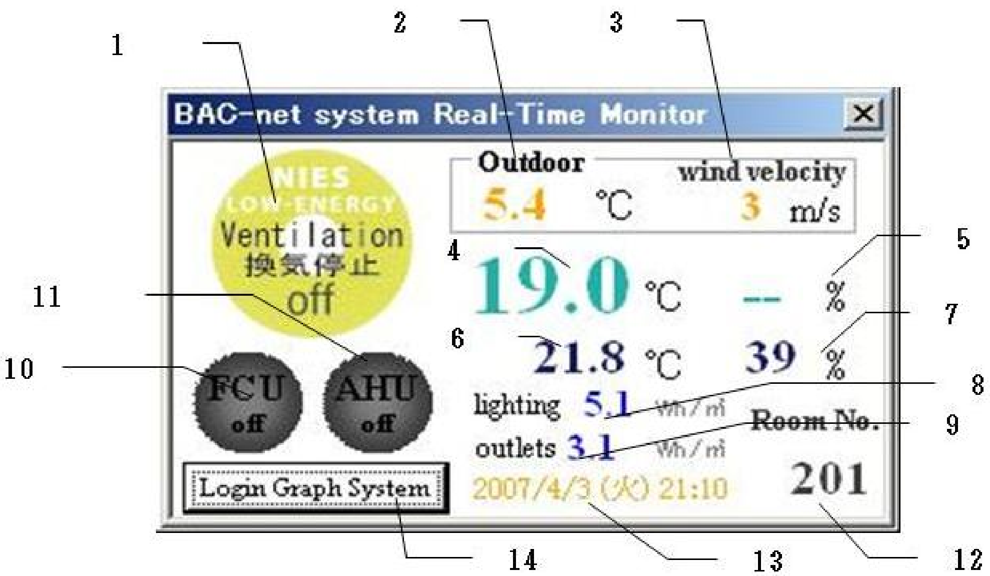

Figure 6 Example indication of indoor real-time monitor

1. Air-conditioning mode: Recommended air-conditioning mode
2. Outdoor temperature: Outside air temperature
3. Outdoor wind velocity : External wind speed
4. Indoor temperature setting: Indoor temperature settings
5. Indoor humidity setting: Indoor humidity settings (only for room where setting is available)
6. Indoor temperature: Indoor measured temperature

3. CONCLUSION

We showed that information providing guidance on the operation of an air-conditioning system could be prepared. This was achieved by calculating the indoor/outdoor thermal load using information on the current state of measures in the commercial sector with a view to introducing BEMS technology to improve operation in existing buildings. A building-local environment assessment monitoring system based on the results of a series of energy-saving measures.

In addition to information obtained from BEMS, we developed a control equation for continuously monitoring the indoor/outdoor heat balance. The information management system and control equation used in BEMS could be integrated by manipulation to provide real-time information. Improving the operation of the air-conditioning control requires to identify the optimum temperature range and air-conditioning ranges based on the actual room usages, and helps defining the guideline for improving the air-conditioning settings.

Appropriate energy-saving information should be provided for residents and energy managers, for example, by making use of such data as Automated Meteorological Data Acquisition System (AMeDAS) measurements delivered by the Japan Meteorological Agency in real time. Therefore, we prepared a prototype of an energy management information system (real-time monitor) for residents.

Substantial energy reduction requires the deliberate and efficient improvement of the operation of the heat source equipment and the introduction of more efficient equipment after the operation of the indoor air-conditioning system has been improved. This will probably lead to the practical implementation of measures designed to combat global warming in Japan, which is our primary goal.

Acknowledgment

TITLE: SIMULATIONS OF ENERGY INFLUENCE USING DIFFERENT CONTROL MECHANISMS FOR ELECTROCHROMIC WINDOWS

Andreas Jonsson Ph.D student[1]
Arne Roos Prof[1]

[1] Department of Engineering Sciences, Uppsala University, P.O. Box 534, SE-751 21 Uppsala, Sweden, Andreas.Jonsson@angstrom.uu.se, Arne.Roos@angstrom.uu.se

Keywords: anti-reflective coatings, smart windows, energy simulations, optical simulations

Summary

The use of electrochromic windows could lower the energy usage for buildings as earlier simulations have shown, but initially the windows would probably mainly be used as daylight sources and units for visual contact. The need for a control system for electrochromic windows is obvious. In this study a comparison of heating and cooling need of a building, using different control mechanisms, was investigated. From an energy perspective it is preferable to have the windows in their dark state whenever there is a cooling need, but this is probably not preferable from a daylight and visual contact point of view. In this study, four control mechanisms were investigated using computer simulations. The first control mechanism is only considering the heating and cooling need of the building – energy optimization mode. The second control mechanism is limiting the perpendicular component of the incident irradiation to avoid glare and to strong daylight – daylight optimization mode. The other two control mechanisms switches between the energy and daylight optimization mode in different ways based on user presence. The results show that the need for an occupancy based control system is clearly beneficial.

1. Introduction

Future energy saving requirements together with increased comfort desires are expected to lead to a demand for windows which can vary their transmittance to reduce the heating need during cold periods and reduce the cooling need during warmer periods (Selkowitz, et al, Platzer, et al).

As earlier studies have shown the use of electrochromic windows could lower the energy usage for buildings. If there is a need for cooling the smart window is usually set to a dark state to avoid the solar heat gain. When there is a need for heating the smart windows are set to a clear state to gain the solar radiation. In real situations this is probably not the best way to control the windows. The windows are there to let in light and to enable a view to the outside. Whenever someone is in the room the daylight aspect must be considered, both to let in a fair amount of daylight and also to avoid annoying glare.

The control mechanism is a key issue for electrochromic windows in general and should consider both daylighting and heating and cooling need. In this study four different control mechanisms are investigated using computer simulations. The "energy optimization mode" described above is then compared with other control mechanisms based on daylight and user presence. These simulations are compared with simulations for a regular solar control window as comparison.

2. Method

The simulated window in this case is an electrochromic device deposited on and enclosed in a plastic foil (Azens, et al, Granqvist) and for the simulations put in a double pain window combined with a low-e pane. This type of window can easily be created from most already installed windows, i.e. this type of window can be made available also for the retro-fit window market. The EC foil was laminated onto the inside of the outer pane. The two surfaces facing the gap between the panes had single layer antireflective coatings, assuming an refractive index of the coating of n = 1.31. The transmittance and reflectance spectra for the windows were calculated using the Fresnel formalism as described in Pfrommer et al. For the electrochromic layers, refractive indices have been taken from the Windows and Daylighting Group at Lawrence Berkeley National Laboratory. The Fresnel formalism was also used to determine the transmittance and reflectance of the complete window that were "constructed", according to figure 1.

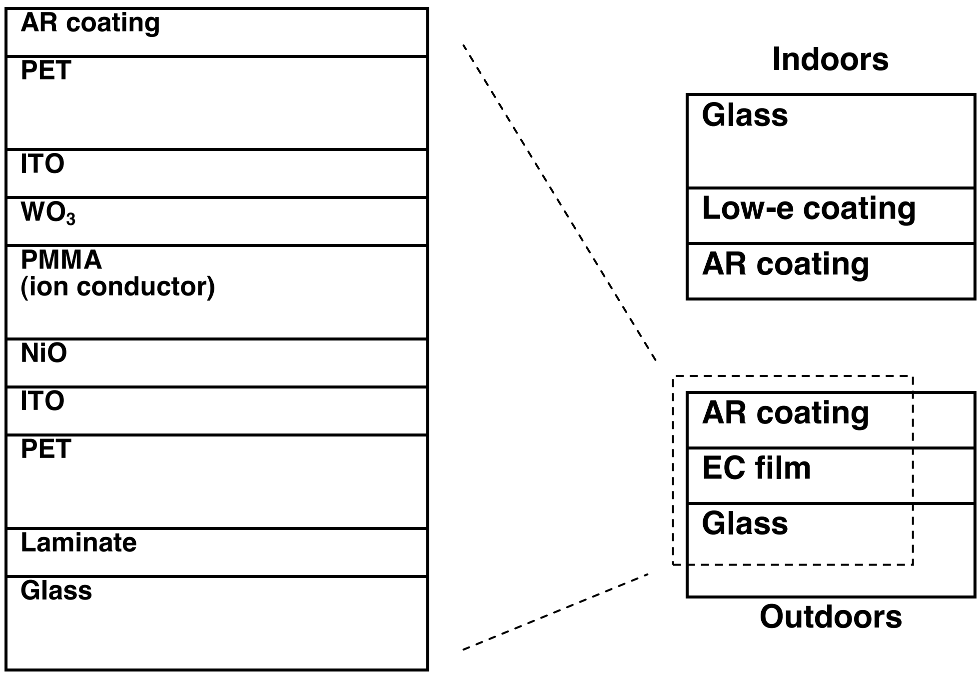

Figure 1 Schematic drawing of the simulated window configuration. To the left, the layers of the electrochromic foil. To the right, the double pane window with one low-e pane and a regular pane. (Not to scale.)

The simulation tool Winsel was used to estimate the energy balance of this smart window when placed in a building. Winsel is a tool for estimating how different windows affect the energy balance of a building. It can thus give an approximate value on how much energy that is needed to heat or cool a building depending on which windows are used. For this the program uses climate data such as outdoor temperature, direct and diffuse solar radiation and a few building parameters, such as balance temperature and a time constant for the building, i.e. how well the building can store heat (Karlsson, et al). The program calculates the energy losses due to the U-value together with the solar gain depending on the g-value.

For the energy calculations in this study an office building, with 5℃ as the balance temperature for heating and 14℃ as the balance temperature for cooling has been selected, assuming a well insulated building. The locations have been chosen to Stockholm, Sweden, and Miami, USA, and weather data were taken from Meteonorm.

Four different control strategies were investigated and compared. "Energy Optimization" means that the windows are then kept in the state which is optimized from a heating and cooling perspective. In the simulations the windows are then kept in a dark state whenever there is a cooling need. "Daylight optimization" means that the windows are in a state which should correspond to a level which is good from a daylight perspective. In the simulation this corresponds to when the perpendicular component of the incident direct sun light is 300W/m^2 or more, and then the transmittance of the smart window is regulated down to correspond to this level. This configuration of the control mechanism avoids the annoying glare caused by solar radiation when the sun is low in the sky. When the sun is higher or when there is only diffuse radiation the window is set to its clear state.

“Office hours” corresponds to having the window in “Daylight optimization” mode between 7:00am - 6:00pm and otherwise in “Energy Optimization” mode. “Presence detector” mode corresponds to having the window in “Daylight optimization” mode during half of the time between 7:00 am and 6:00 pm and otherwise in “Energy optimization” mode. This simulates the fact that many offices are unoccupied also during office hours. The different control strategies are summarized in table 1.

Table 1 Control strategies used in the simulations.

Control strategy	Explanation
Energy optimization	The windows are kept in the state which is best from an energy perspective.
Daylight optimization	The perpendicular component of the incident direct sun light is regulated to 300 W/m^2 whenever possible.
Office hours	“Daylight optimization” mode between 7:00am and 6:00pm and otherwise in “Energy Optimization” mode.
Presence detector	“Daylight optimization” mode during half of the time between 7:00 am and 6:00 pm and otherwise in “Energy optimization” mode.

3. Results

For the double pane smart window with antireflective coating on two surfaces the visible transmittance was calculated with Fresnel formalism to 66.7 %. The transmittance spectra for the solar spectrum can be seen in figure 2. Optical and energy parameters for the simulated windows can be found in table 2.

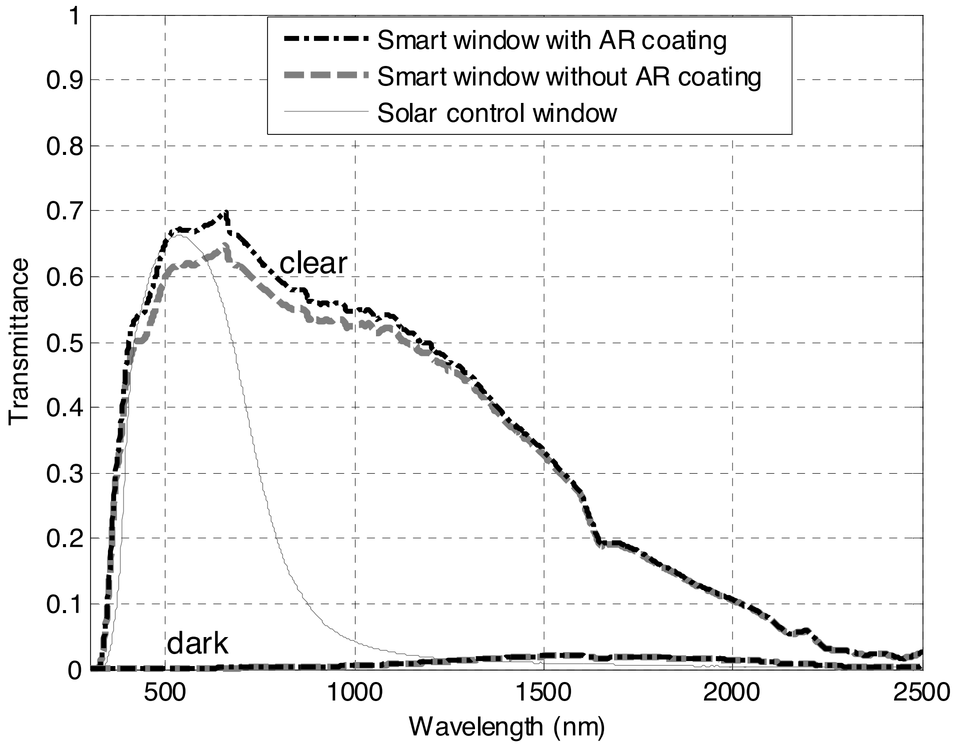

Figure 2 Transmittance of the simulated double pane window with one low-e and one electrochromic pane in dark and clear state.

Table 2 Window parameters for the simulated double pane window.

Parameter	Clear state	Dark state	Solar control
T_{sol}	53.7 %	0.51%	31.5 %
R_{sol}	12.7 %	7.40%	43.8 %
A_{sol}	33.6 %	92.1%	24.6 %
T_{vis}	66.7 %	0.21%	64.6 %
R_{vis}	11.2 %	6.17%	8.93 %
A_{vis}	22.1 %	93.6%	26.5 %
U-value	1.42 W/m^2K	1.42 W/m^2K	1.27 W/m^2K
g-value (SHGC)	0.66	0.065	0.34

When simulating the influence of a smart window with a low-e pane as the inner pane and an electrochromic foil laminated on the outer pane, the electrochromic foil decreases the g value without changing the U-value of the window noticeably.

The cooling balance per square meter window area for a building located in Stockholm, Sweden, can be seen in figure 3. It can be decreased by 10-40 kWh annually depending on the bearing direction, by limiting the daylight optimization to office hours, 7am-6pm. The most dramatic decrease would installation of presence detectors have. If assuming that the office is occupied 50 % of the time, the decrease would be between 50 and 100 kWh per square meter window area, compared to the daylighting optimization case.

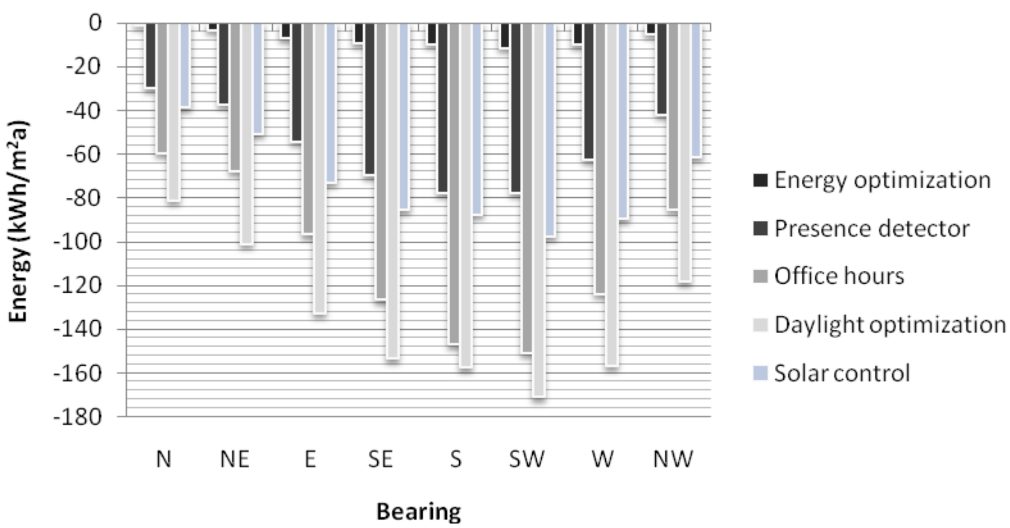

Figure 3 Cooling balance of a window in Stockholm for different bearing directions.

For the same simulation but with the building located in Miami, USA, the results are similar but because of the larger cooling need the figures change correspondingly. By limiting the daylight optimization to office hours, 7am-6pm the cooling balance for Miami can be decreased by 15-45 kWh depending on the bearing direction. Also here the most dramatic decrease the installation of presence detectors would have. The decrease would be between 150 and 300 kWh per square meter window area, compared to the daylighting optimization case.

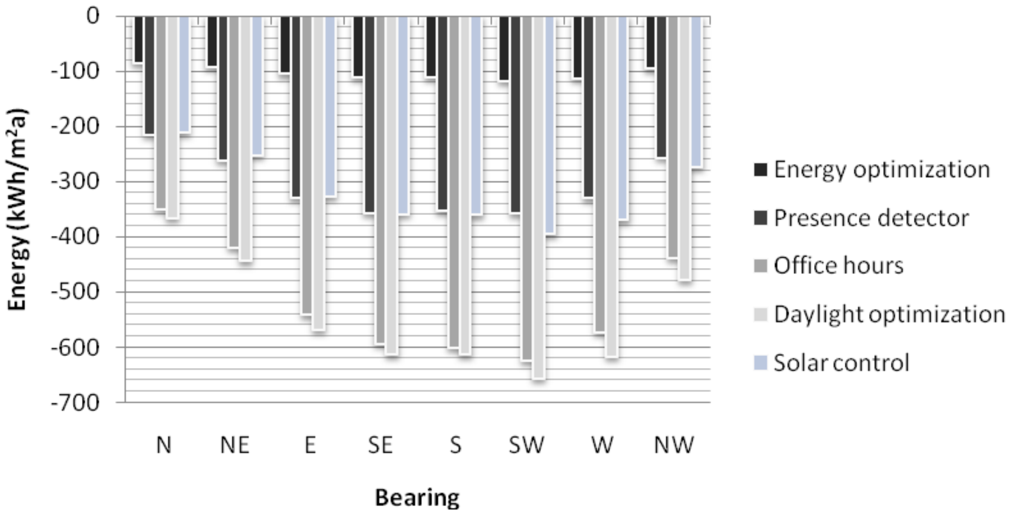

Figure 4 Cooling balance of a window in Miami for different bearing directions.

The use of electrochromic windows can lower the heating need of the building compared to solar control windows due to the larger solar heat gain with the electrochromic windows in the clear state. For heating the gain of using the "energy optimization" in favor of the "daylight optimization" is limited. If there is a heating need, there is also most often a need for daylight. The results for Stockholm can be seen in figure 5. For Miami there would be no heating need for the simulated building.

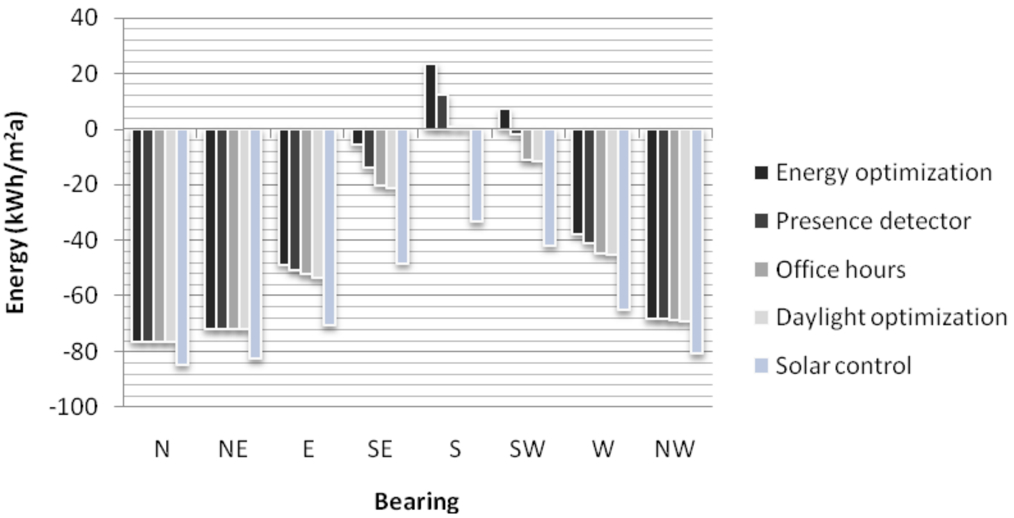

Figure 5 Heating balance of a window in Stockholm for different bearing directions.

4. Discussions and conclusions

The energy simulations in this study were made for buildings in Stockholm and Miami and for buildings located elsewhere the results can be quite different but with the same trend. The simulations in this study were based on windows in office buildings. For real estate buildings the need for cooling is usually lower and the decreased energy need using the electrochromic layers would not be as drastic.

The occupancy pattern would in a real estate case be totally different than what has been assumed here. Also the internal loads for the building would look drastically different with a longer heating season, so it is not possible to generalize these results to a real estate case.

Smart windows are usually considered to have a large potential for the future to give a decreased energy usage in buildings, due to a reduced need for cooling by air conditioning. Earlier studies often investigate the windows only from an energy perspective. The results in this study indicate that by having thoroughly worked out control strategy and system, the windows can in an energy perspective become almost as good as when sub optimizing them only from an energy perspective.

With a control strategy based on user presence the window can be set in a clear state whenever someone is in the room, letting in daylight and thereby decreasing the need for other lighting. The amount of reduced energy need due to this has not been included here but is an interesting aspect for future studies.

To get the products from the labs out in reality, user acceptance is a key issue. For high user acceptance it is important not to focus too much on the energy perspective. Windows are there to let in light and to create visual contact with the surroundings. The control system is the link between good energy and visual performance. The results show that the need for an occupancy based control system is clearly beneficial.

Summary

This paper describes the results of my Masters studies at The Bartlett, University College London, a year-long exercise in experimental urban design. It begins from a philosophical basis which is rooted in an understanding of the natural systems and phenomena which surround us, and an awareness of our place within them. The investigation then seeks parallels in contemporary scientific thought, to ground the philosophy in real-world knowledge. The principles are then applied to urban planning and development through a rigorous design proposal for a large urban area in the Thames Gateway region, a vast, flood-prone urban growth area between London's Docklands and the English Channel, earmarked for extensive urban growth.

This study investigates the very basis of our approach to urban planning and development. It is based on the notion that a truly sustainable approach to urban growth requires a fundamental shift in the way we approach urban planning, and the way we perceive our place in the world. The nature of this shift is drawn from the emerging, ancient philosophies of the East, which are gaining increasing understanding in the Western world.

The resulting design proposition for a large, new urban area is based on this theoretical, philosophical and scientific framework for integrating urban development with natural systems, towards a balanced, adaptive, holistic, sustainable urban form.

Presentation of this paper shall be accompanied by an extensive sequence of images illustrating the design context, process and outputs, a small selection of which is displayed below.

1. Modern urban space and the *unhomely*

Modern urban environments often convey harsh, aggressive, unwelcoming qualities, through hard-edged and ageing built form, 'dead' spaces, and vast scale and intensity, making them feel confronting, unnatural and uncomfortable. They are perhaps most prevalent in post-industrial areas and in more urban environments, which are products of early-mid 20th century planning, with little consideration of 'human' qualities or 'liveability'. The spatial environment in London's Thames Gateway reflects its industrial heritage, with little consideration of the human impacts of these spaces, which are now unattractive, decayed and inhumane.

These environments are immediately perceived as ugly, messy, damaged or decayed, but there is a deeper human reaction which creates the discomfort or unease we feel in these spaces. These perceptions have been theorised and psychologised through the notion of the *unhomely*, or *uncanny.*

This philosophy is closely linked to, or even rooted in, notions of modernity and the city, through the writings of Vidler, Freud, Constant and others (Vidler, 1992). The industrial-era transformation of the city, from intimate and communal, to strange and unfamiliar, caused feelings of unease, isolation, and estrangement of citizens. The modern urban qualities of vast scale, heterogeneity and imposition over nature were perceived as an alien presence, strange and unfamiliar, isolating individuals from nature and from the past (Vidler, 1992).

2. Alienation from nature

Our environment is a self-balancing ecological system, in which organic and inorganic species are interacting with each other in highly complex ways. The human species is an integral part of this system, but the modern condition has led us to think we have escaped from it. Dominant forms of Western thinking suggest that nature is an inert, readily exploitable mass, and that humans are masters of the system of which they are an integral part. This is seen as originating from our adoption of environmentally unsound ideas (Dickens, 1991).

The modern city is held in sharp contrast to the natural environment - visually, aesthetically, organisationally and qualitatively. Modern ideals are characterised by a fear of emotion and spirituality, and a craving for control through the rigid doctrines of science and technology, resulting in severely reduced consciousness, and cities which are aggressive, impoverished and depressingly banal. Our times call for a greater consciousness and awareness, and a more meaningful approach to caring for our cities (Fingerhuth 2004).

Our inherent tendency towards connection with nature is evident in our yearning for a return to natural space, to seek 'reintegration' with nature, by 'escaping' the city. The current study seeks a new approach to urbanism, which reflects and responds to the emerging consciousness of our place in nature, our dependence on the fragile natural systems around us, and the need to re-think our attitude and relationships with these systems, through our most significant physical intervention in nature – our cities.

3. Finding an alternative environmental/spatial philosophy

"The world will not evolve past its current state of crisis by using the same thinking that created the situation" Albert Einstein (cited in McDonough and Braungart, 2002)

"If we want the city to remain the driving force behind human development, we must reinvent it now; otherwise there is the risk that it will become the final stage of human civilisation in the twenty-first century" (Burdett and Sudjic, 2007)

The significant recent shift in our communal consciousness towards sustainable practices is paralleled by an increasing awareness of the urgent need to drastically re-think and change our approach to urban planning, design and development.

The rapid growth of cities, particularly in developing countries, through massive urbanisation of rural populations, is the subject of much discussion and concern. Currently this growth largely reflects outdated western planning models predicated on separation rather than inclusion, which have been dumped on the fragile urban conditions of the exploding cities of the global South (Burdett and Sudjic, 2007).

The task, therefore, is to develop a new philosophy and methodology for city building, which promotes integration of urban and natural environments and systems, sustainable relationships between cities and hinterlands, and physical/spatial urban environments which are humanistic, responsive, adaptive and comfortable, as opposed to the *unhomely* environments of the modern era.

Traditional and/or indigenous cultures are seen as a potential source of knowledge and understanding, towards a more integral, balanced and sustainable approach to human action in natural systems. The cultures, cosmologies and ways of life of most indigenous societies incorporate a respect for the natural world, which results in a harmonious, non-exploitative relationship with ecological systems (Dickens, 1991).

The Eastern traditions of *Taoism* and *Zen Buddhism* provide a philosophical and methodological route towards a holistic, integral approach to living with nature, through guiding principles which are themselves derived from observations of nature, and an understanding of our place within it. These principles, which are explained below, when applied to the design of urban development, may allow built form and urban space to reflect and respond to our integral relationship with nature.

The *Tao* describes the course, flow or drift of nature. Followers of this paradigm seek to spontaneously co-operate with the dynamic process of the universe, to 'go with the grain'. This provides the potential for escape from the modern, rationalist imposition of rules and laws on nature.

Current thinking on sustainability principles also focuses on how our living patterns might integrate with natural systems in a balanced, harmonious relationship. Although designers operate within a closed system of materials and energy, our established processes contaminate the Earth's biological mass to create materials and products which quickly become waste. Nature, however, exhibits a highly effective system of metabolism and nutrient flow, in which the concept of waste does not exist. We must seek to emulate this 'cradle-to-cradle' system, rather than the 'cradle-to-grave' one we currently inhabit, if we are to develop a truly sustainable, balanced relationship with the natural systems and materials upon which we depend (McDonough and Braungart, 2002). Philosophically, the Eastern traditions adopt a view of life which reflects this eternal, cyclical principle.

4. Ancient Eastern Philosophy and Contemporary Science: Principles and Parallels

The striking resonance between ancient Eastern philosophies and contemporary scientific theories and discoveries in the Western world serve to align the mystical with the physical, and the traditional with our contemporary view of the universe and our place within it.

This Section looks in more detail at these principles and parallels, while the following Section considers the implications for urban planning and development.

4.1 Time/Space

A key aspect of Eastern mysticism, which has been confirmed by modern physics, concerns the ways in which we describe and measure nature, in that our notions of geometry are not part of reality, but parts of our maps of reality. They are constructs of the mind, not part of nature itself, and are relative, limited and illusory.

Classical physics was based on the notion of space as an absolute, three-dimensional construct, structured according to Euclidean geometry which was seen as inherently part of nature. The notion of time was also seen as fixed, and the temporal order of two events was assumed to be independent of any observer.

Einstein's Relativity Theory has forced the abandonment of classical concepts of absolute space and time, replaced by the notion that space and time coordinates are merely elements of a language used to describe an observer's environment. This opened up a range of possibilities for redefining space and time, by realising that geometry is not inherent in nature, but is imposed on it by the mind (Capra, 1991).

4.2 Unity and Interconnection

"Without leaving my house, I know the whole universe." (Lao-tzu, c. 226-259, cited in Watts, 1975)

"Ten-thousand formations, one suchness" (Watts, 2000)

The most important and essential characteristic of the Eastern philosophical worldview is the awareness of the unity and mutual interrelation of all things and events in the universe, as manifestations of a basic 'oneness'. All things are seen as interdependent and inseparable parts of the cosmic whole (Capra, 1991).

This understanding of unity and interconnection has also become a central aspect of modern physics. The classical physicists saw the universe as a collection of separate entities, isolated in space and time by definite boundaries, and capable of being precisely measured and counted, to derive scientific laws and principles. They began to believe that all of nature was governed by these Newtonian principles, and assumed they would also apply to subatomic physics. They developed laws governing separate things, only to discover that separate things don't exist (Wilber, 1979).

The revolution of quantum physics around 1925 shattered this world of classical physics, revealing that the constituents of matter and the basic phenomena involving them are all interconnected, interrelated and interdependent, and cannot be understood as independent entities, but only as integrated parts of the whole, forcing the reinterpretation of time, space, matter and structure (Capra, 1991). The fundamental building blocks of matter, seen as the last objective reality, were found to defy all forms of objective location in space and time.

The ultimate metaphysical secret is that there are no boundaries in the universe. Boundaries are illusions, products not of reality, but of the way we map and edit reality, reflecting an infinite system of relationships, of interconnections between all things and events. Buddhists describe the universe as "all in one and one in all", and modern physics as "each particle consists of all the other particles, each of which is, in the same way and at the same time, all other particles together" (Wilber, 1979).

4.3 Polarity

The principle of polarity lies at the very roots of Chinese thinking and feeling, and is symbolised in the concept of *yin and yang*, polar opposites whose dynamic interplay is manifest in the constant flow and change observed in nature. The *yin-yang* principle is not a dualism, but an explicit duality expressing an implicit unity. Any pair of opposites constitutes a polar relationship where the two poles are dynamically linked, forming different but vital aspects of the same system. The removal of one would mean the disappearance of the system (Watts, 1975).

We see opposites as being at war with each other (life with death, good with evil, positive with negative), and so we attempt to cultivate the positive and remove the negative. Our social and aesthetic values are always put in terms of opposites – success/failure, beautiful/ugly, intelligent/stupid, but nature does not know these differences, and does not concern itself with fighting one condition over its opposite, but rather calmly accepts life and death, large and small, pleasure and pain (Wilber, 1979).

4.4 Emptiness/Form, Observer/Object

"Form is emptiness; emptiness is form" (Buddhist Mahayana philosophy, cited in Watts, 2000)

In science, the classical, mechanistic worldview was based on the notion of solid, separate, indestructible particles moving in the void. Modern physics has not only radically revised this view of particles as discrete entities, but also profoundly transformed the concept of the void. In the 'quantum field theories', the distinction between particles and the space surrounding them loses its sharpness, and the void is recognised as a dynamic quantity of great importance.

This unity and interrelation between a material object and its environment is made manifest at the macroscopic scale in relativity theory, and even more strongly at the subatomic level. Here, the contrast between solid particles and the space surrounding them is overcome, and the quantum field is seen as the fundamental physical entity; a continuous medium which is present everywhere in space (Capra, 1991).

This view is closely paralleled in the Buddhists' or Taoists' conception of a single, unified essence or energy, from which springs all phenomena. In Eastern philosophy, the relationship of form and emptiness cannot be conceived as a state of two mutually exclusive opposites, but only as two aspects of the same reality, which co-exist and are in continual co-operation (Capra, 1991).

The relationship between an observer and the object of observation, traditionally considered as separate entities with no direct interconnection, is also called into question both by Eastern philosophy and Western physics. Perhaps the most important aspect of quantum physics is that it destroys the concept of the observer as separate from the world he observes, replaced by the scientist becoming involved in the world he observes (Capra, 1991).

This idea is well known to the mystical traditions, where knowledge can never be gained by observation alone. Subject and object are not only inseparable, but become indistinguishable. In these traditions, the external world and one's inner world are two sides of the same fabric, in which the threads of all forces and events are woven into an inseparable net of endless, mutual relations (Capra, 1991).

4.5 Change and Transformation, Adaptation

Central to the understanding of all things and events as manifestations of an ultimate unifying reality is that the universe, or all things, is intrinsically dynamic. The Eastern mystics see the universe as an inseparable web of dynamic interrelations, which moves, grows and changes continually (Capra, 1991).

Modern physics has also come to recognise the universe as a dynamic web of relations, within quantum theory and in relativity theory, in which matter cannot be separated from its activity, and the properties of subatomic particles can only be understood in terms of movement, interaction and transformation. Quantum theory implies a fundamental 'restlessness' of matter, which is always in motion. Seemingly passive, 'dead' objects around us are actually alive with activity, and this is also the way the Eastern mystics see the material world (Capra, 1991).

5. Applying the Principles: A new approach to urbanism

This Section describes the application of the above Principles to a design proposal for urban development in the Thames Gateway. The accompanying design proposal seeks to reflect the principles of its philosophical foundations, through urban form and spatial character. This theoretical source is based on a holistic, balanced, harmonious relationship with the natural environment, which is the core objective of sustainable development, and so is seen as a powerful, effective and resonant basis for a new approach to the way we build cities.

Therefore the proposal provides limited detail on technological devices or systems, which would of course be incorporated, but instead focuses on the formal, spatial and experiential qualities of the urban environment, and its integration with and adaptation to the natural context, as well as the opportunities for sustainability presented by this new formal approach.

The principles provide a vehicle towards a new approach to urban design and development, which reflects and encompasses our contemporary view of the world and our place within it, as well as a balanced, integral relationship with the natural systems on which our cities depend. The design explores how one perceives the city, and one's place within it, and seeks to reflect an elevated level of consciousness of our place within the

Earth's dynamic, ecological system (rather than separation from it), and a balanced, integrated, homely urban environment for people.

5.1 Time/Space

The new high-speed railway between London and continental Europe runs through the Thames Gateway, and is causing significant change in the region. Faster connections between places can effectively alter their apparent separation, bringing them closer together, and distorting our perception of geographic distance. We commonly associate places and distance by travel time, rather than physical distance, and new infrastructure can radically reduce the travel time, and therefore the perceived spatial separation. As understood by Eastern philosophy and modern physics, our understanding of time and space becomes relative, based on the travel modes available.

These connections, however, typically link major nodes, while other locations are excluded from the network, and may effectively be pulled further apart in terms of travel time. This polarity of conditions raises the potential of 'fast space' and 'slow space', where the nodes of the high speed networks are characterised by speed, intensity, activity and density, while the 'slow spaces' are more spacious, dispersed and engaged with the natural environment. Transitions between these opposing conditions are made explicit, visible and legible in the urban form.

5.1.1 Time / Space: Opportunities for Sustainability

The development of 'fast space' and 'slow space' within urban areas provides numerous opportunities for implementing sustainable design. 'Fast' spaces are appropriate locations as activity centres and transit nodes, with population intensity and high-density development to support high-quality transport and services provision, with 24-hour activity and mixed uses, focussed on work, education and entertainment. By contrast, the urban form in 'Slow' spaces is closely engaged with the landscape, forming locations suited to recreation, leisure, meandering, and landscape-oriented activities, such as urban agriculture and water treatment.

In spatial terms, the urban area escapes the rigidity and permanence of modern planning, adopting a dynamic, fluid form and resultant spatial qualities, presenting opportunities for a flexible, adaptable development which is responsive to changes in external and internal conditions (climate, occupancy patterns).

5.2 Unity and Interconnection

Urban development and planning procedures are based on defined boundaries and edges. Space is precisely measured, demarcated, fixed, and allocated to specific activities. This strict rational approach is focused on separation, constriction, and imposition of a rational order upon an apparently unordered, irrational natural landscape. As discussed above, the city effectively severs links between its inhabitants and the natural world.

This design proposal reflects a more integrated, interconnected pattern of urban development, reflecting a greater consciousness of the natural systems and relationships on which our cities depend. Rather than strict, fixed boundaries and separations between land parcels and individual infrastructure connections, the plan provides for incremental, informal growth from key infrastructure locations, with each development providing onward service connections for future 'layers' of development. These layers are defined and integrated by 'interface zones' which provide for natural light and ventilation, movement and circulation between buildings. The incorporation of cybernetic, adaptive features in the interfaces between buildings facilitates this blurring of boundaries and flexible modulation of space, as discussed below in 5.5.

The project seeks an urbanism where boundaries and barriers between buildings and spaces are blurred, broken down, and constantly changing in a dynamic balance. The boundary between urban and rural is made indistinct through engagement of built form with the land, and the penetration of landscape into urban areas.

5.2.1 Unity and Interconnection: Opportunities for Sustainability

Rather than fixed, rational boundaries, this proposal incorporates 'interface zones' or 'zones of change', within which the dynamic, cybernetic functions of built form modulate the internal and external spaces between buildings, supporting microclimates, indoor amenity, weather protection, energy efficiency and water management.

The potential of *smart material* technologies may allow the built form 'skin' to evolve from a fixed, thin, planar element, to a flexible *zone in which change occurs*, which is fully integrated and responsive to the external environment and internal use patterns. Through exploring the limits of this technology, the built form may become a dynamic, ever-changing construct of internal and external spaces.

The proposed incremental urban growth will facilitate reduced disturbance of the landscape and smaller infrastructure costs, as each development provides onward connections to subsequent 'layers' of development.

5.3 Polarity

The project seeks to encompass a range of polar opposites in urban form, programme and spatial character, expressing the transitions between them, at a range of scales, to enhance awareness of the enduring presence of opposing conditions, including: Fast/Slow, Intense/Quiet, Dynamic/Stable, Large/Small, Open/Closed, High/Low density, Deep/Shallow space and Landscape-engaged/separate. These contrasting conditions are distributed and balanced on the site according to site conditions, infrastructure and programme, with each condition offset and balanced by its juxtaposed other. This approach supports an elevated consciousness among occupants of the dynamic, sustainable balance our cities must maintain with the natural environment.

5.3.1 Polarity: Opportunities for Sustainability

The development of a diverse range of spatial qualities within close proximity, located according to natural site features and existing infrastructure elements, allows occupants to perceive these variations and transitions, while providing optimal choice for citizens. An important aspect of social and environmental sustainability is the provision of a diverse range of accommodation options, within an overall structure which supports the viable provision of services and protects surrounding areas for agriculture, recreation and conservation.

This proposal reflects an overall development density to facilitate sustainable transport, community services and walkable urban structure, while providing a diverse choice of urban qualities, for permanent residential occupation or temporary activities.

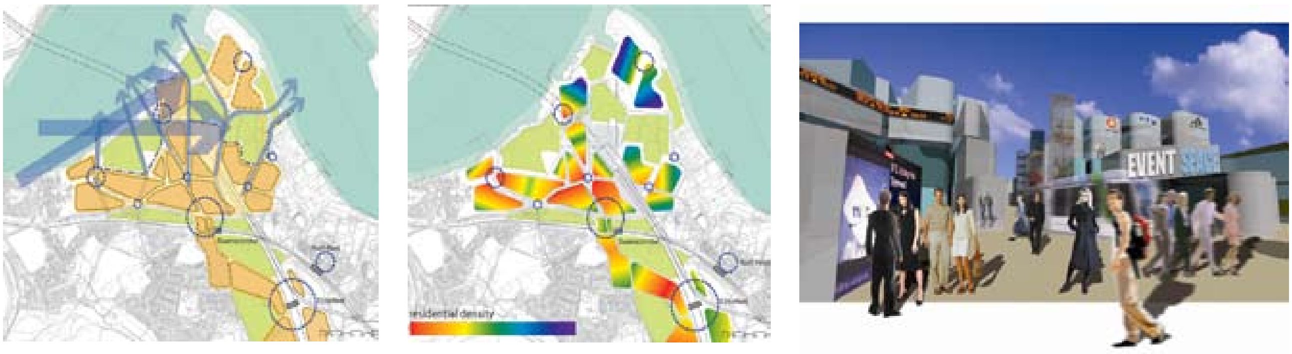

Figure 1 Site plans indicating hydrology and prevailing winds and residential density distribution, and perspective view of nodal space

5.4 Emptiness/Form, Observer/Object

In cities, we traditionally view built form as solid, closed, *figure*, against a backdrop of void, space, or *ground*. In this proposal, the spatial merging of built form with open/circulation space, serves to blur the boundaries between solid and void in the city, in that form (buildings, for occupation) is also emptiness (space between buildings, for circulation and recreation).

From the viewpoint of the pedestrian moving through the public realm of the city, the sensation of being *in* the dynamic flow of built form, rather than outside, between buildings, in left over space, reflects the merging of subject and object, observer and observed. Through merging built form with circulation and outdoor space into a dynamic continuum, the pedestrian is placed in the dynamic interplay of built form and landscape.

5.4.1 Emptiness/Form, Observer/Object: Opportunities for Sustainability

The integration of built form and open/circulation space facilitates highly compact, efficient urban development, which in turn supports sustainable services and sense of community and vibrancy through walkability (facilities within walking distance of dwellings). This is achieved through the interconnection and merging of buildings, and the use of roof spaces as public open space and 'street' space. This approach to built form also provides opportunities for enhanced thermal insulation and weather protection, water management and small-scale agricultural activities in urban areas. The integration of built form with the landscape creates opportunities for access to open space, urban agriculture, energy exchange, and increased awareness of the dependent relationship between urban and rural areas.

The principle of reduced distinction or separation between private and public realms, building and 'street', roof-space and open space requires each development to contribute directly to the public realm, depending on its location, creating a communal, cooperative approach to planning and development.

Figure 2 Images of design models, demonstrating formal and spatial manifestation of design principles

5.5 Change and Transformation, Adaptation

Notions of change and adaptation are reflected in the design proposal on a number of levels, both experiential and physically dynamic. The proposed city dynamically engages with the ever-changing natural environment, reflecting an integral, responsive relationship. The experience of transitions between opposing urban conditions reflect change and transformation, perceived as one moves through the urban area. The urban character, encompassing built mass and height, footprint size and proportion, development density and proportions of open space, is constantly changing between one location and another, as perceived by the observer.

The potential applications of smart material technology in architecture and urbanism are vast, and this project merely posits some ideas, including how these potentials might apply to the interfaces between buildings and adjoining internal and external spaces. The 'interface zones' between individual units or buildings incorporate cybernetic, adaptive capabilities, to allow the dynamic, negotiative modulation of space in response to changing conditions, such as climate or living patterns. These zones effectively blur the boundary between adjacent units, replacing a fixed line with a constantly changing adaptive space. The incorporation of adaptive capabilities also allows the establishment of various microclimate zones throughout the urban area, as well as the expansion or contraction of space demarcated as public or private, open or enclosed.

5.5.1 Change and Transformation, Adaptation: Opportunities for Sustainability

Perhaps the most critical factor of sustainable building performance is the capacity for adaptation in response to changing external conditions. As we adjust our clothing to suit the conditions, our buildings can become our 'third skin', and should also be changeable as conditions change. These conditions may include external factors such as the seasons, weather and ambient light levels, as well as internal factors such as activity type, intensity and occupation levels.

Active, dynamic systems are well established in sustainable architecture, but a more far-reaching investigation of the potential of adaptable buildings explores the very nature of the building envelope or external skin, and posits the potential for a flexible, dynamic, 'organic' urban form which changes its shape and enclosure in response to internal needs and to changing natural conditions.

5.5.2 Smart Materials

An emerging scientific field with direct application to adaptability and responsiveness in built form is that of Smart Materials. These are materials which change their form or state temporarily, in response to signals or impulses, then return to their original state or form.

In the built environment, our accepted belief that the spatial envelope acts like a boundary serves to limit our current thinking about materials. Our current design methodologies privilege the surface, and we essentially think of materials as planar. While conventional materials are applied to meet a specific need, smart materials have changeable properties, and can respond to transient needs. This allows the privileging of the static planar surface to be challenged, whereby the 'boundary' is no longer delimited by the material surface, but may be reconfigured as the *zone in which change occurs*, thereby blurring the defined boundaries of built form (Addington and Schodek, 2005).

Figure 3 Details of interconnected, incremental development, and adaptation for climatic responsiveness

6.0 Conclusion

This research and design proposal encompasses my search for an intuitive, balanced and natural approach to urbanism, based on a framework of principles which derive from ancient observations and teachings about nature and our place within it.

The work presented reflects an intensive, experimental design and exploratory research process. The outputs are not complete, final or fixed, but could be developed, tested and enhanced as we move forward towards sustainable urban development. The principles, approach and understanding, however, may be applied immediately, in place of our ingrained modern, rational, forceful approach to urban planning.

The need for change in our cities and how we design them is clear, but this work calls for a more fundamental shift, in our understanding of cities and our position within the Earth's dynamic, diverse, unified ecology.

PUBLIC SQUARES AS A MEANS OF INTEGRATING ECONOMY, ENVIRONMENT AND SOCIETY IN BRITISH CITY CENTRES

Bob GIDDINGS DPhil[1]

[1] School of the Built Environment, Northumbria University, Newcastle upon Tyne, UK, bob.giddings@unn.ac.uk

Keywords: public space, economic activity, society, privatisation, sustainable development

Summary

Sustainable Development is invariably epitomised by economy, environment and society represented as three equal sized rings in symmetrical interconnection. This assumes a separation, even autonomy, and detracts from the fundamental connections. Much debate is now centred on how to integrate these sectors, rather than seeking trade-offs between them. Up to the 20th Century, public squares, offered clear examples of this integration as they are representative of the values of the society that created them. There are numerous examples from different time periods in a variety of cultures. In the second half of the 20th Century, British cities experienced increasing competition for space, which partly led to domination by market economies. As city centres became commodities, more devices were employed to attract consumers. One of the most significant was the indoor shopping centre. As malls were constructed over city streets, increasingly public space became privatised. The public sector is now experiencing substantial decline and the balanced model of economy, environment and society has been grossly distorted. Social capital may be a means of regaining equilibrium. This paper will demonstrate the significance of squares in sustaining vibrant communities; and consider mechanisms for their re-introduction as a means of contributing to the integration of economy, environment and society.

1. Economy, Environment and Society

Sustainable Development is generally represented by the following diagram:

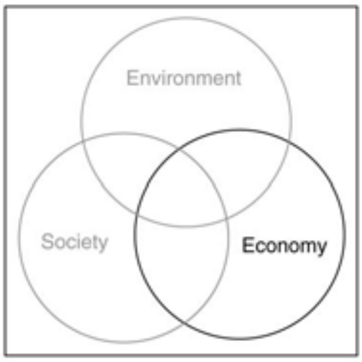

Figure 1 Common three-ring view of sustainable development

The model has a conceptual simplicity. By encouraging the classification of impacts into three convenient categories, it makes analysis more straightforward. Often sustainable development is presented as aiming to bring the three together in a balanced way, reconciling conflicts. If they are seen as separate, as the model implies, different perspectives can give priority to one of them. This view risks approaching and tackling issues of sustainable development in a compartmentalised manner. The separation detracts from the fundamental connections between economy, environment and society. It leads to assumptions that trade-offs can be made between the three sectors, such as the notion that poor environmental quality does not matter if the economy is strong (Neumayer, 1999). In most debates either the environment or the economy is given priority, and one of the effects of the three sector separation is to encourage a technical solutions. With environmental issues, this approach suggests that provided pollution control, lower resource use, greenhouse gas trading etc. are resolved, then environmental sustainability is on track. Technical solutions in the economy, such as changing interest rates, benefits or taxation are seen as ways to move the economy towards sustainable development. They are attractive to some as they can be introduced quickly; but neither these measures nor the technical environmental solutions involve a fundamental examination of the relationship between economy, environment and society. A sectoral approach can divert attention from asking questions that are important to analysing the essence of sustainable development, such as those about the nature of society. The wider social matters often disappear from the sustainable development agenda. It is partly a quantitative versus qualitative debate. Economy and environment have sufficient quantitative factors as shown by the technical solutions, that neglecting the qualitative issues may not appear to be particularly harmful. Whereas society is predominantly about qualitative issues. It is the same dilemma that has plagued numerous research agendas – quantitative factors are just easier to identify and measure. It is hardly surprising that Prime Minister Thatcher infamously stated that 'There is no such thing as society'. Political reality always gives primacy to the economy, and treats environment and society as resources to be exploited. By contrast, it could be argued that in material reality, the economy is dependent on society and the environment (Daly, 1992; Rees, 1995; Wackernagel and Rees, 1996). Society embraces a multitude of actions and interactions that encompass human life. Without society, humans would not survive as their very existence, in both evolutionary terms and in the present, is based on social interaction. In addition, human activity takes place within the environment, which provides the source of much culture and leisure. Art and spiritual beliefs, and most of science and technology, draw from the environment. Although some human needs are met through the production of commodities, many are met by other activities that take place partly or wholly outside what is described as the economy (Langley and Mellor, 2002). A more accurate representation of the relationship between economy, environment and society could be a pattern in which economy is nested within society, which in turn is nested within the environment.

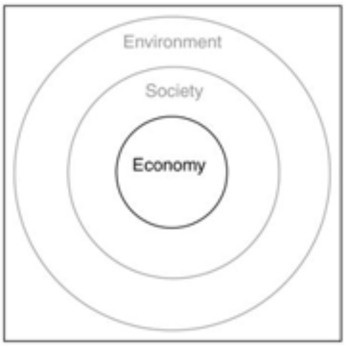

Figure 2 Nested view of sustainable development

Placing economy in the centre does not mean that it should be seen as the hub around which the other sectors and activities revolve. Rather it is a subset of the others and is dependent upon them. Human society depends on the environment, while the economy depends on society and the environment. A key issue for sustainable development is the integration of different actions and sectors, taking a holistic view and overcoming barriers between disciplines. The nested model, rather than the three-ring model, encourages a conceptual outlook sympathetic to integration. Both models are simple representations that imply one economy, one environment and one society; assuming that each sector is a unified entity. This is, of course, a further abstraction. There are a multitude of economies, environments and societies at different spatial scales. The simplified approach risks ignoring the richness and multi-layeredness of reality.

2. Dominance of Economy

As the Labour Government (1997 to date) has followed the Conservative Government (1979-1997) in abandoning Keynesian and social democratic policies in favour of neo-liberalism in social and economic policies, there has been an identifiable shift in priorities from meeting social needs to responding to the needs of capital. Thus, there is a clear discontinuity between environmental and social policies on the one hand, and economic policies on the other. The private sector is tightening its grip on city development, directing the character and priorities for development, and basing its decisions on maximising profitability. Ironically, the public sector gatekeepers, who are supposed to be protecting cities by applying environmental policy, are reduced to supporting the private sector. They are striving to attract investors, support property development and increasingly encourage the private provision of services.

Modern landmarks in British cities often reflect the values of the private sector and market forces. Traditionally, the symbols of society, such as town hall and library, stood out from the surrounding built fabric. However, the public sector is now experiencing substantial decline and the balanced model of economy, environment and society has been grossly distorted by the domination of market economics. Thus, there is now competition between commercial buildings, as to which can dominate the city. They are invariably large and anonymous, connecting neither with the community nor with the traditional built fabric, as they lack identity with place. Bookchin (1995) has argued that where there is a loss of city-ness in favour global commercialism, there is a parallel loss of citizenship. Active citizenship is discouraged and replaced by the role of consumer. Power is concentrated in the hands of large companies, and government largely acts in their favour. Smith's (2002) case that the speed and scope of development is mainly driven by property developers with no interests within a specific city, so that the urban scale and appearance is actually defined by the needs of capital, remains valid.

Throughout the 20th century, people lost much of their community perspective and became individual and nuclear family orientated. The growth of technology, such as home entertainment and cars as the primary means of transport, generated much fragmentation and retreat into the private domain. This was reflected at city scale by the decline of the public realm and privatisation of public space. As city centres have become commodities, more devices have been employed to attract consumers. One of the most significant is the indoor shopping centre - advertised to provide all the necessary retail outlets in one location and offering protection from the elements. Malls are frequently constructed over city streets to preserve the illusion of the public domain, whereas in fact the whole development is privately controlled. Arguably even more insidious, has been the colonisation of squares and pavements. While public space should allow citizens to sit and socialise, increasingly this can only be done as a consumer as all the seats are owned by cafes, bars and restaurants.

Figure 3 Cafes colonise public squares

In the second half of the 20th Century, British cities experienced increasing competition for space, which partly led to domination by market economies. Public space was reduced to the most direct means of accessing commercial and retail premises; while national and global capital generated buildings that did not respond to the special characteristics of each city. The pattern of urban form in cities changed dramatically. Appleyard (1981) notes that the greatest transformation in cities of the 20th century was from the city containing largely walkable spaces, to the onslaught of spaces designated for the sole use of the automobile. Both Appleyard (1981) and Tibbalds (1992) highlight that cities have become scarred by major road networks, invariably leaving wounds or gashes through the urban fabric. The insertion of new roads occupy large areas of land, fragment and blight neighbourhoods, destroying local social interchange and often leaving an excess of uncared-for, left-over space, vacant sites, temporary car parks and buildings facing the wrong way. Tibbalds (1992) states that such spaces are ugly and unpleasant and have lost the human scale, which is vital to successful urban areas. The Urban Task Force (1999) highlights that British cities have tolerated a lazy over-use of off-the-peg designs and layouts, allowing highway and traffic requirements to dominate urban layouts, as well as allowing developments that undermine the coherence and viability of cities, without giving careful thought to the effects on the logical hierarchy and balance of the whole urban structure. Traditionally cities were composed of blocks of buildings that defined squares and streets. The so-called comprehensive redevelopment schemes of the late 20th century tended to destroy this familiar and successful urban form. Paradoxically, the configuration of developments and space for motor vehicles that replaced it, actually reduced ground level building density - while ever larger areas of external space became neglected, left-over and unusable by society.

3. Compact Cities

It has been asserted for many years that the growth of the internet, telecommunications and global economics, has meant that people can live and work anywhere; and therefore the city does not have the significance that it occupied in the past. Some would even say that place no longer matters. This notion is counter-intuitive, but more importantly the evidence does not support it. It is true that there has been an outward migration from many cities, as people have been seeking their rural idyll away from noise and the fear of crime. Yet, at the same time, there has been unprecedented residential development in the centres of numerous cities. Moreover, although some people live miles from the city, they do not lose their connection with it. The city is still the heart of culture and society for them, as they return in the evenings and weekends for entertainment and social interaction. Gillen (2005) is one of a new breed of consultant researchers, who have concluded that the city has significance as a necessary physical hub for people whose work patterns are becoming increasingly orientated around technology-based networks. It is clear from this work that human beings need interaction that cannot be satisfied with email and video links. Meeting people, even casually for discussion, is essential to maintain a good psychological balance. It may be for these reasons that there has been a recent increase in the number of policy documents proposing improvements in the design of cities (eg. CABE, 2004; CABE, 2006; CABE, 2007; English Partnerships, 2007) However, these documents do not tackle the deep-rooted trends that undermine socio-economic quality and the environmental sustainability of urban life.

Thomas and Cousins (1996) state that the initial impression of walkable city is its concentration of activities. Lozano (1990) states that the urban form of traditional cities is rooted in pervasive factors that shape physical organizations and spaces. It has a tightly clustered pattern, with marketplace and trade streets. Often two centres of power (political and religious), and countless social and cultural institutions, such as town hall, theatre, museum and university. Cities that fall into this category tend to have a compact core and an organic system of streets and squares.

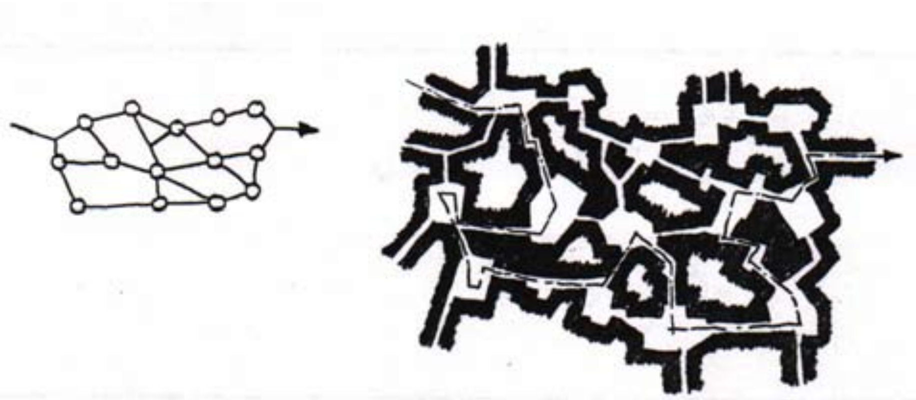

Figure 4 Organic System of Streets and Squares

Generally, as Alberti (1475) recognized, the organic layout tends to be most applicable to cities of variable terrain. The curving pattern of the organic street system is appreciated for the aesthetic advantages the curved vistas provide, by reducing the chance of monotony, and increasing the opportunity of surprise as suddenly a particular square appears. Norberg-Schulz (1971) holds much the same viewpoint, stating that in traditional cities, oblique angles and curved lines created closed perspective that enliven the experience of being there.

According to Lozano (1990), traditional cities are responses to the various factors that govern and influence form. He states that traditional cities have been consistently shaped by their location and morphology. They originate from places where human beings meet and trade, live and find recreation. There is substantial support among urban scholars for the traditional compact city. Jacobs (1961), Elkin et al. (1991), McLaren (1992), Hillman (1996), Thomas and Cousins (1996), Frey (1999), Girardet (2004) and Marshall (2005) all believe that the compact city has environmental advantages, and social benefits. A number of scholars have been calling for a return to the compact city, which is seen as ideal place to live and work. Such places have high population densities that can encourage social mix and interaction. This is emphasised by the Urban Task Force (1999), which states that the traditional compact city with its well designed and integrated framework plays a fundamental role in linking people and places together. The compact urban form highlights the value placed upon proximity and ease of contact between people. It gives priority to the provision of public space for people to meet and interact, to learn from one another and to join in the diversity of urban life. At its best, the compact city therefore operates as a series of interconnected networks of places and spaces devoted to making the most of human interaction. According to the Urban Task Force (1999) most compact and well-ordered cities are designed around a well-connected pattern of streets and public squares. Where the framework is fragmented and unstructured, as in so many modern urban developments, it contributes to social segregation and alienation. Gosling and Maitland (1984) note that the vision of the traditional compact city is more inspirational than factual in its message, less a model than a mirror of the community that created it. These kinds of cities can be seen as expressing themselves through thousands of small decisions taken over a long period of time. Tibbalds (1992) states that this is because they have certain essential qualities, like recognizable patterns and complexity within order. The question needs to be posed, then, as to why new development should not have the same richness, individuality, intricacy and user-friendly qualities of existing patterns? Valuable urban patterns recall their citizens' history, collective memory, values, beliefs and pride.

4. Public Squares

Urban space has always been the place for the community rather than the individual and is therefore public rather than private in nature. Historically, activities that took place in urban spaces have been representative of that settlement. They were the places where the framework of society was debated and formulated, and where economic activity took place. Of all types of urban space, squares are the most representative of the values of the society that created them - the agora, forum, cloister, mosque courtyard, are all examples. Squares have deeper significance than merely functional attributes. They engender a range of human responses which start with the comfort of a protected space right up to a spiritual experience. Moreover, the continued success of a city can in part, be derived from the quality of its public spaces. If the physical, psychological and spiritual well-being of a community and visitors is partially in response to these places, then sociological factors such as crime as well as economic aspects like trade and the number of visitors, must also be affected.

The argument is that the sustainability of city centres has suffered as the number of squares has declined. The neglect of squares as a part of late twentieth century city structure was based on functional justification and associated economic viability. The trend has been the transposition of outdoor activities to indoor arenas, but has this really been in response to community demands? The case for transposition is usually made in terms of increased comfort and convenience for the public, especially in relation to protection from the climate. There are however, economic and social arguments which suggest that such transposition could equally well find its source in the privatisation of public space and increased social control by the private sector. These kinds of developments are invariably large-scale single function enterprises which are consumer led. Some are out of town, which militates against the focus of the city centre. Moreover, through a subtle selection of goods and/or services on offer coupled to a particular pricing policy, in practice such developments can segregate the community through a form of social exclusion. All of this is highly undesirable and runs contrary to almost every principle of sustainable development. At the same time collective and sustainable outdoor activity is as much under threat from the reduction of suitable spaces, as the converse notion. Activities like outdoor markets, concerts, political meetings, charitable collections, theatre, religious gatherings, sporting events such as road races and cycling, spectacles like firework celebrations or laser shows, and many more functions - all have valid roles in the 21st Century. They are only hampered by the lack of suitable spaces and the unwillingness of Authority to encourage them. Secondly, does the creation of public space necessarily have to follow the rules of function and economic viability especially when the latter may be short term? The social argument is that if it acts as possibly a place for chance meetings, a focal point in the city, a recognisable landmark which offers orientation, the junction between various established routes, an entry position - especially when arriving in the centre by underground railway - a square is justified merely on those criteria, for which value cannot be measured in monetary terms. Unwin (1909) suggests that to help the positive image of a city, its principal buildings should be offered dignity by setting out a clear open space in front of them (see Figure 5). Sitte (1889) recalls the familiar feeling of the cosy old squares. He notes that only in our memory do they loom gigantic, because in our imagination the magnitude of the psychological effect takes the place of actual size.

Figure 5 Cathedral Square

Yet, the interaction between these spaces and buildings, suggests an even more significant role. As each of these buildings also displays a distinct attribute of the society it represents, then each square marks the arrival at that symbol of society. Individually, every pairing of symbolic building and square can have quite a dramatic effect on the psyche of the citizens (see Figure 5). Thus, if the most prominent squares in a city contain the symbols of society, then citizens and visitors may feel re-invigorated as they move from one symbol to the next. Thus the urban spaces are defined and there is scope for external community activities; and the symbols of society are visible and accessible, with each acting as a landmark and orientation signpost. Squares celebrate the entrance to the symbolic buildings and the whole composition offers linkages and variety within a framework.

5. Social Capital

In Britain, local authorities are under the most sustained attack in their history. This has yet to be researched and documented but there is ample evidence that the Government is removing them from so many public services that have been fundamental to their existence, and reducing their budgets accordingly. It has already been stated in this paper that local authorities increasingly occupy a support role for the private sector. Although, there is a disturbing trend in the privatization of public space, councils are still the largest owners of land in city centres. Therefore, they have the potential to re-introduce squares as a means of integrating economy, environment and society for their communities, but their influence is diminishing. Crucial to the development of this form of sustainability is the commitment and will of the community. This may need to be found in other ways than the traditional voting for councilors. Social capital may be a means of regaining equilibrium, and developing city centre spatial structures in which all members of society can fully interact. It is a way of reclaiming public life to enable societies to prosper and for development to be sustainable. Based on collective action by different groups in the community, social capital can differ in operation. It can work with elected representatives by giving a voice to the community through a network of existing organizations. Alternatively, the community can actually undertake the work themselves. (The World Bank, 1999). For example, the proposed redevelopment of the Bullring shopping centre in Birmingham, produced an alternative scheme by the community. Although the final design still demonstrated a consumer city in terms of malls, shops, cafes and restaurants, nevertheless civic society is represented by the incorporation of several public squares. It is surely not coincidence that while many cities are reporting low public esteem due to the dominance of private sector economics and declining local authorities, Birmingham has seen a significant increase in civic involvement (Field, 2003).

Figure 6 A two tier public square in the Bullring Birmingham

6. Conclusion

This paper has reviewed the theoretical relationship between economy, environment and society in sustainable development. The conclusion is that the common presentation as three rings, compartmentalises the three aspects and detracts from their connections. More damaging is the assumption that there can be trade-offs; and that poor conditions can be accepted in one sector if compensated in another sector. This can lead to a significant imbalance. In addition, quantitative issues can be given prominence over qualitative matters, because they are easier to identify, assign targets, measure and so on. Of the three sectors, society seems to suffer most in this situation. It is suggested that a nested model may be preferable, as it encourages integration.

In practice, especially since the latter part of the 20th Century, the economy has dominated city development. There has been an identifiable shift from meeting social needs to responding to the needs of capital, and the private sector has tightened its grip. The landmarks in British cities are now often a competition between commercial buildings. Power is concentrated in the hands of large companies and active citizenship replaced by the role of consumer. Nevertheless, people still have strong connections with cities. Even those who use the electronic revolution as a means of living and working in a rural idyll, still regard the city as the heart of culture and society. At the same time, unprecedented residential development is taking place in city centres.

There is substantial support among urban scholars for the traditional compact city. Many of them point to the environmental advantages and social benefits. The walkable city also appears to be synonymous with a high concentration of activities. This kind of city is epitomised by a tightly clustered pattern of streets and squares. These city centres have a high proportion of public space in which economy, environment and society can be brought together. Of all urban space, squares are the most representative of the values of the society that created them. Moreover, if symbolic buildings are located in the most prominent squares, citizens and visitors may feel re-invigorated as they move from one symbol to the next.

The re-introduction of these values and the re-construction of squares in particular is a public sector activity. However, local authorities are currently being subjugated by the private sector and national government. It would be excellent if they could restore public city structures but there is little sign that it is likely to happen. An alternative is social capital, as a means of reclaiming public life. It requires collective action by different groups in the community. Although difficult to organise, there are modest signs of its success in the city of Birmingham and others.

[2] Department of Civil Engineering, University of Minho, Guimarães, Portugal, ricardomateus@civil.uminho.pt

Keywords: sustainability, building, refurbishment, assessment

Summary

A sustainable built environment results from the best trade-off between each three dimension of the sustainable development (environment, society and economy). In Western Europe it is usually considered than more than 60% of the buildings to be used in 2050 are already built today and it is expected that the rehabilitation becomes a leading sector in the building industry. To ensure the sustainable rehabilitation of the built environment it is necessary to consider tens of parameters related to the overall impact of the project on the local and global environment as well as preservation of heritage, social trends, economic development, or health and safety of the users. The integration of a huge number of evaluation criteria, some quantitative, other purely qualitative, makes the assessment of such strategy very hard to carry out without a real methodological work. The aim of this paper is to present a multi-criteria decision based methodology that allows the integrated assessment of all different sustainability parameters. The proposed methodology is applied to a case study, which aim is to select the most sustainable solution between different refurbishment scenarios for a building façade.

1. Introduction

The building sector plays a major role in the perspective of a sustainable built environment. Buildings accounts for the greatest amount of the total residues production and energy consumption. Besides that, buildings are the population's center of life: an adult in a developed country spends almost 90% of its life inside buildings. Globally, buildings construction is responsible for about 40% of raw materials (stone, gravel, sand, etc), 25% of wood, 40% of energy and 16% of water annually spent all over the world (Roodman, 1995). In Portugal, in spite of existing important differences between the reality and the statistical figures, according to national energy directorate (DGGE) and national statistics institute (INE), during operation phase, buildings (houses and offices) accounts for about 25% of the national primary energy consumption, 6.7% of the total water end-use and are responsible for the annual production of 420 millions of cubic meters of residual water. According to INE, construction industry is also responsible for the annual production of about 7.5 millions tons of solid residues. These figures show that buildings are related with strong environmental, social and economical impacts that have great potentialities to be to some extent overcome.

Most of the buildings related impacts are linked to the "cradle-to-gate" stage of their materials and products and to the operation phase of the buildings. Rehabilitation allows to increases the life span of a building and therefore the embodied impacts related to the materials and products used in its construction are amortized in a larger time span. Nevertheless, rehabilitation allows updating the comfort of the building users and, on the other hand, the thermal refurbishing is on the basis of higher energy efficiency and therefore it contributes to the reduction of the environmental impacts during the operation phase.

For the reasons stated above, rehabilitation in opposition to demolition and new construction is an important step towards sustainability. Correcting the actual policy of "use and throwaway" it is possible to overcome some economic problems; to increase the occupants and users comfort; to reduce the environmental impacts through the energy consumption, raw materials and residues reduction; and to preserve the city's cultural legacy.

Many efforts have been done regarding environmental protection and urban quality, and in recent times, a greater attention has been given to pollution control, energy efficiency, proper waste disposal, landscape preservation, heritage preservation, social integration, etc.. Therefore, more and more, building operation have to consider rehabilitation, partial or complete of a building or a group of buildings, and they have to fit into numerous criteria, sometimes contradictory, concerning quality of materials used, economic pressure, improvement of quality of life and environment.

Although, there still is an important question that must be solved: the definition of the sustainable building rehabilitation concept and actions through tangible goals. Sustainability assessment is a holistic approach that doesn't consider all aspects related to the environmental, economic and social performances of a solution, but only those parameters that better compromises the objectives of the assessment, the type of solution, the available data, among others (Bragança, 2007). The application of the "Sustainable Development" concept is based on the definition of objectives and criteria to be used in the sustainability assessment and comparison of different building solutions. This way it is possible to choose the most sustainable solution, according the considered aspects.

This paper presents the first steps of a sustainability assessment methodology that is being developed to support the sustainable rehabilitation of buildings, which is based in the three dimensions of the "Sustainable Development". At the end of the paper, the methodology is applied to a case study, whose aims are the selection of the most sustainable refurnishing solution for a building façade, according to the assessment objectives.

2. Sustainability Assessment Methodology

The methodology presented in this document is a derivation and adaptation of the Methodology for the Relative Assessment of Building Solutions (MARS-SC) that was developed in order to evaluate new construction solutions (Mateus, 2004). This methodology follows these steps: definition of parameters, quantifications of parameters, normalization of parameters, aggregation of parameters, representation and assessment of the solution.

In the next paragraphs a short description of the methodology MARS-SC adapted to refurnishing operations is made.

2.1 Definition of Parameters

The sustainability assessment is holistically made, because it is impossible to consider all parameters that express the performance of a solution at the level of the three dimensions of the sustainable development. Thus, in this phase the number and type of parameters to be assessed inside each dimension are defined. The definition depends on one hand in the objectives of the assessment, type of solution to be refurnished, local conditions, functional requirements that are necessary to be fulfilled, available data, and in the other hand in the assessment boundaries: the sustainability assessment of a project to refurbish a single construction element is not based in the same parameters used for a whole building or district. Table 1 presents some parameters that could be considered in a sustainability assessment of a refurbishment technology for a façade.

Table 1 Parameters that could be used in the sustainability assessment of refurbishing solutions for building façades

Environmental	Social	Economic
Global warming potential	Airborne sound insulation	Construction cost
Destruction of the stratospheric ozone layer	Thermal insulation	Operational cost
Potential acid deposition onto the soil and in water	Structural safety	Maintenance cost
Local tropospheric ozone formation (smog)	Fire safety	Dismantling cost
Addition of mineral nutrients to the soil or water.	Water permeability	Residual value
Abiotic depletion	Maintenance aptitude	
Non-renewable primary energy consumption	Preservation of the city's heritage	
	Aesthetics	

2.2 Quantification of Parameters

After selecting the parameters it is necessary to proceed with their quantification. Quantification is essential to compare different solutions, aggregate parameters and to accurate assess the solution. The quantification method should be anticipated. There are several quantification methods: previous studies results, simulation tools, expert's opinions, databases processing, etc. (Cherqui, 2004). In some cases the parameters to evaluate are quantitative. When assessing qualitative parameters like for instance, aesthetics and preservation of the city's cultural heritage, the qualitative performance level is transformed in a quantitative scale, using the equivalences presented in Table 2.This transformation is based in the comparison of the performance with the best and conventional/minimal normalized performance.

Table 2 Equivalences between the qualitative and quantitative performances

Qualitative performance	Score
Best solution	1,00
Good solution	0,75
Slightly better than the conventional solution	0,25
Conventional solution/minimum standard	0,00

It is not easy to evaluate the environmental parameters mentioned above. Although there are some life-cycle inventory (LCI) databases about the environmental pressure related to several construction materials that could be used to support life-cycle analysis (LCA). It is also possible to use LCA tools to evaluate the parameters mentioned above.

To assess the social parameters related to the indoor environment comfort, it is possible to use one of the several normalized methodologies available. Another way is to use and process some available databases that collect common functional performance data related to some conventional refurbishing solutions. Whenever possible, experimental results should be used, because those are the ones that best draw up the real performance of the solution.

Life-cycle cost assessment (LCCA) is more straightforward than the environmental performance assessment, since there are different standardized methodologies and published construction costs databases. LCCA is a method that allows the quantification of the global cost of a product for a certain period of service life. In this method all costs are included: construction cost (capital cost), operation cost, maintenance cost and the residual value of the building or of some part of it. LCCA is an important approach whenever it is necessary to compare two solutions that have the same functional requirements but that differ at the level of their initial and operational costs.

2.3 Normalization of Parameters

The objective of the normalization of parameters is to avoid the scale effects in the aggregation of parameters and to solve the problem that some indicators are of the type “higher is better” and others “lower is better”. Normalization is done using the Diaz-Balteiro *et al.* (2004) equation (Equation 1).

$$\overline{P_i} = \frac{P_i - P_{*i}}{P_i^{*} - P_{*i}} \forall_i \qquad (1)$$

In this equation, P_i is the value of i^{th} parameter. P^*_i and P^*_i are the best and worst value of the i^{th} sustainable parameter.

The normalization in addition to turning dimensionless the value of the parameters considered in the assessment, converts the values into a scale bounded between 0 (worst value) and 1 (best value). This equation is valid for both situations: “higher is better” and “lower is better”.

2.4 Aggregation

Sustainability assessment across different fields and involves hundreds of parameters. Each sustainable dimension is characterized by several parameters or indicators. A long list of parameters with their associated values will not be useful to assess a project. The best solution to overcome this situation is to combine parameters with each other to obtain “global indicators”, allowing assessing the sustainability of each solution at the level of each sustainability dimension.

The complete aggregation method that is used in this methodology is presented in Equation 2.

$$I_j = \sum_{i=1}^{n} w_i . \overline{P_i} \qquad (2)$$

The global indicator I_j is the result of the weighting average of all the normalized indicators $\overline{P_i}$.

w_i is the weight of the i^{th} parameter. The sum of all weights must be equal to 1.

Equations 3 to 5 present how to aggregate the parameters inside each indicator in order to assess the performance of a solution within each sustainable dimension.

$$I_{Env} = \sum_{i=1}^{n} w_{Env\,i} . \overline{P_{Env\ i}} \text{ , environmental dimension} \qquad (3)$$

$$I_{Soc} = \sum_{i=1}^{n} w_{Soc\,i} \,.\, \overline{P_{Soc\ i}}$$, social dimension (4)

$$I_{Eco} = \overline{P_{Eco\ i}}$$, economic dimension (5)

In the economic dimension, the global indicator as the same value of the normalized economic parameter because the normalized parameter results from the sum of every cost found in the life-cycle costing analysis.

Weights are strongly linked to the objectives of the project: higher weights must be adopted for parameters of major importance in the project. Although the weight of each parameter in the assessment of each dimension is not consensual, as it is possible to verify when analysing the several different available methodologies to support and assess the sustainable design. This is the major inconvenient of this method, when compared to performance based methodologies, since it is possible the compensation between parameters.

In what concerns to the weights of the environmental parameters, actually there are not Portuguese impact scores for each environmental parameter, according to their relative importance in the overall environmental performance. Additionally, this issue was not dealt so far by the European Environmental Agency. However there are some international accepted studies that allow an almost clear definition of it. One of the most accepted studies is the one performed by the United States Environmental Agency's Science Advisory Board (SAB) that developed two lists of the relative importance of various environmental impacts to help EPA to best allocate its recourses (EPA, 2000). MARS-SC allocates the environmental parameters in the EPA's impact categories and therefore it considers the same relative importance. Table 4, presents the relative importance of the environmental parameter considered in MARS-SC.

In spite of being easy to quantify the functional parameters, the way as each parameter influences the functional performance and therefore the sustainability is not consensual. This assessment involves subjective rating and depends, above all, on the type of solution and on the valuator's social-cultural and economic status. This way, in a first approach the methodology considers the same relative importance for all functional and societal parameters. MARS-SC is being developed in order to accommodate a more consensual distribution of weights.

2.5 Global Assessment

It is understood that the majority of stakeholders would like to see a single score representing the overall building performance. Therefore, after assessing the performance of a solution within all dimensions (environmental, societal and economics), the next step is to combine the performance at the level of each dimension with each other in order to obtain the sustainable score. Sustainable score (SS) is a single index that resumes the global performance of a solution. As nearest to 1 is the sustainable score, more sustainable is the solution. The aggregation method used to calculate the sustainable score is presented in Equation 6.

$$SS = I_{Env}.w_{Env} + I_{Soc}.w_{Soc} + I_{Eco}.w_{Eco} \qquad (6)$$

Sustainable score, *SS*, is the result of the weighting average of each global indicator I_j. w_i represents the weight of the i^{th} parameter.

The weight of each dimension in the global sustainability is still not consensual. It depends, among other, in the objectives of the project and local priorities. In MARS-SC it is proposed to use the weights presented in Table 3.

Table 3 Weight of each sustainable dimension in the sustainable score assessment

Dimension	Weight (w_i)
Environmental (I_{Env})	0,3
Societal (I_{Soc})	0,5
Economic (I_{Eco})	0,3

The sustainable score is useful to communicate and compare results but it should not be used alone to characterize the sustainability of a solution, since the possible compensation between dimensions could cause some distortions in the results. Moreover the solution has to be the best compromise between all the different aspects: every aspect has to be considered.

3. Case Study

The scope of the case study is the assessment of a refurbishment project related to a multi-storey building with three floors, located in the city centre of Guimarães, Portugal. This building was built at the end of the 60's and most of its envelope, mainly the façade, is at a considerable degradation state, as it is possible to verify in Figure 1. This building doesn't have any kind of heritage value and in the façade it is possible to identify some cracks that endanger the water permeability of this construction element. The aim of this project is not only to improve the building aesthetics, but also to improve other functional characteristics, mainly the thermal comfort, in order to turn it compatible to the updated comfort standards and user demands. Another requirement to fulfil is that the refurnishing solution should be the best compromise between the three dimensions of sustainable development.

After examining the façade it was possible to conclude that the cracks are stable and that the original solution used in the façade is a hollow brick cavity wall without any insulation material, as presented in Figure 2.

The refurbishment solution to adopt should disturb as less as possible the indoor living conditions of the occupants. This way, the design team selected three refurbishing scenarios for this project, as presented in Table 4. Table 4 also presents the predicted energy consumption for heating and cooling according to the actual Portuguese Thermal Regulation (Decree-Law 80/2006). The time boundary considered for the project is 25 years.

Table 4 Refurbishing scenarios in assessment

Refurbishing Scenarios	Description	Expected maintenance in the time boundary	Energy consumption during operation (MJ/m^2.year)
Scenario 1	To paint the façade and replace the windows	3x painting	640,8
Scenario 2	To place a ventilated façade and to replace the windows	No maintenance	439,2
Scenario 3	To place an external thermal composite systems (ETICS) replace the windows	3x painting	439,2

Figures 3 and 4 represent the cross section of the refurnishing solution adopted in scenarios 2 and 3, respectively.

Figure 1 Elevation of the façade.

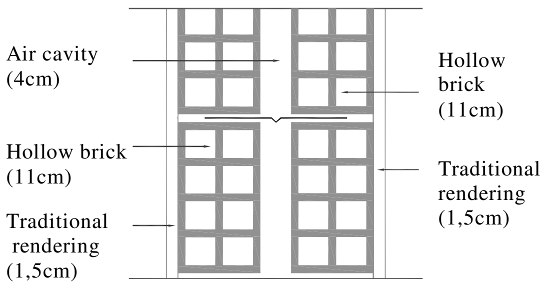

Figure 2 Cross-section of the existing solution.

3.1 Accessed Parameters and Related Weight

At the level of the environmental performance, the project team decided that the solution to adopt should have the lowest possible embodied environmental impact. The design team selected seven mid point impact categories to assess the environmental performance: abiotic depletion (AP), global warming potential (GWP), destruction of the stratospheric ozone layer (OD), local tropospheric ozone formation-smog (PO), potential acid deposition onto the soil and in water (AP), addition of mineral nutrients to the soil or water (EP) and the non-renewable primary energy consumption (PEC). The environmental performance is analysed in the following life cycle stages: construction, maintenance and operation. During the construction and maintenance stages, the study considers the construction material's embodied environmental impacts, from cradle to factory's gate, according to the material inputs. For the operation phase it considers the impacts related to the energy consumption for heating and cooling, according to the Portuguese energy mix and associated environmental impacts.

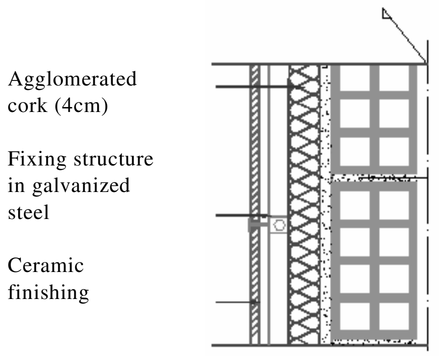

Figure 3 Refurnished façade's cross section after (solution 2).

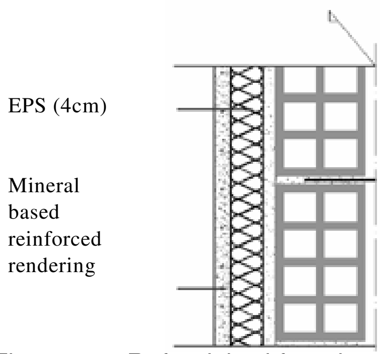

Figure 4 Refurnished façade's cross section after (solution 3).

In what regards to societal performance, the aim was to find the best compromise between two parameters related to the comfort of the building: airborne sound insulation (Dn,w), and U-value (U), related to the acoustic comfort and thermal comfort, respectively.

For the economic performance the aim was to choose the solution with lower life-cycle costs. The considered indicator is the life-cycle costs (LCC) and it considers the costs related to the construction and maintenance of the refurbishing technology as well the predicted energy costs for heating and cooling, according to actual energy costs. Table 4 resumes the considered parameters and related weights.

Table 4 Assessed parameters and related weight

Dimensions	Parameter	Weight of parameters (%)	Weight of dimension (%)
Environment	Abiotic depletion (AD)	13	
	Global warming potential (GWP_{100})	33	
	Destruction of the stratospheric ozone layer (OD)	11	
	Local tropospheric ozone formation-smog (PO)	13	30
	Potential acid deposition onto the soil and in water (AP)	11	
	Addition of mineral nutrients to the soil or water (EP)	11	
	Non-renewable primary energy consumption (PEC)	8	
Social	Airborne sound insulation (Dn,w)	50	50
	Thermal insulation (U-value)	50	
Economic	Life-cycle cost (LCC)	100	20

3.2 Quantification of Parameters

In Portugal it is not yet available the environmental inventory data related to the major part of the building materials, therefore the quantification of the environmental performance was carried out using the SimaPro software. The CML 2 baseline 2000 method was used to assess the first six mid point environmental categories and the "Cumulative Energy Demand" method was used to assess the embodied non-renewable primary energy. Table 5 lists the results of the environmental performance assessment for each refurbishing scenario.

Table 6 presents the results found in the functional performance assessment of the three scenarios and Table 7 presents the Net Present Values of the life-cycle costs. The construction and maintenance costs are based in a cost estimation drawn up by three construction companies which head-office is situated in the North of Portugal and they include all direct and indirect costs and profits related to construction works. The operation costs are base in the actual energy costs fixed by the Portuguese electricity provider - EDP – 0,1131 €/kWh.

3.3 Global Assessment of the Different Refurbishing Scenarios

Table 8 summarizes the results found in the sustainability assessment of both refurnishing scenarios, using the methodology MARS-SC. Analysing the results it is possible to see that refurnishing scenario 1 is the worst and scenario 2 is the best one, since it has the higher sustainable score. Although refurbishing scenario 2 has higher embodied environmental impacts and higher construction costs, those impacts are compensated with the lower environmental impacts and higher comfort during the operation phase. Scenario 3 is almost equivalent to scenario 2 and also a possible refurbishing solution. In fact, scenario 3 compared to scenario 2 has lower life-cycle costs and environmental impacts, but it has the disadvantage of having a lower social/functional performance. Therefore, in the analysed example and according to the considered dimensions, parameters and related weights, the most sustainable refurfishing solution is the ventilated façade (scenario 2).

Table 5 Life-cycle environmental impacts

Refurbishing Scenarios	AD[1] ($kgx10^3$)	GWP_{100}[2] ($Kgx10^3$)	OD[3] (kg)	PO[4] (kg)	AP[5] (kg)	EP[6] (kg)	PEC[7] (GJ)
Scenario 1							
Construction	6,70E-04	70,97E-03	1,03E-05	0,02	0,45	0,10	1,33
Operation	16,73	2214,60	1,31E-01	754,25	20185,25	966,50	11534,40
Maintenance	2,00E-03	2,12E-01	3,09E-05	0,06	1,35	0,30	3,99
Total	16,73	2214,89	1,31E-01	754,33	20187,05	966,90	11539,70
Scenario 2							
Construction	16,73E-03	1,24	1,55E-04	0,80	9,68	0,95	37,68
Operation	11,46	1517,88	0,09	516,96	13834,84	662,43	7905,60
Maintenance	-	-	-	-	-	-	-
Total	11,48	1519,12	0,09	517,76	13844,52	663,38	7942,88
Scenario 3							
Construction	4,87E-03	8,94E-01	3,24E-05	0,51	2,04	0,22	11,65
Operation	11,46	1517,88	0,09	516,96	13834,84	662,43	7905,60
Maintenance	2,01E-03	2,12E-01	3,09E-05	0,06	1,35	0,30	3,99
Total	11,47	1518,99	0,09	517,53	13838,23	662,95	7921,24

(1) Abiotic depletion in Sb equivalents.
(2) Global warming potential in CO_2 equivalents.
(3) Ozone depletion in CFC-11 equivalents.
(4) Smog creation in C_2H_4 equivalents.
(5) Acidification in SO_2 equivalents.
(6) Eutrophication in PO_4 equivalents.
(7) Primary energy consumption in GJ equivalents.

Table 6 Results obtained in the quantification of the functional parameters

Refurnishing Scenario	$D_{n,w}$ (dB)	U ($W/m^2.ºC$)
Scenario 1	29	1,40
Scenario 2	30	0,60
Scenario 3	29	0,60

Table 7 Life-cycle costs of each refurbishing scenario

Cost	Scenario 1	Scenario 2	Scenario 3
Construction	9300€	15075€	10350€
Operation	362372€	248367€	248367€
Maintenance	4500€	0€	4500€
Total life-cycle cost (LCC)	376173€	263442€	263217€

Table 8 Results from MARS-SC

Refurbishing Scenarios	Performance			
	Environmental I_{Env}	Societal I_{Soc}	Economical I_{Eco}	Sustainable Score (SS)
Scenario 1	0,00	0,00	0,00	0,00
Scenario 2	1,00	1,00	1,00	1,00
Scenario 3	1,00	0,50	1,00	0,75

The results also show that it is very important to consider in this kind of assessment all life-cycle stages of a building instead of considering only the initial stage (construction). The initial costs and the embodied environmental impacts are normally insignificant when compared to the same parameters in the operation phase. Therefore a solution with higher capital costs and embodied environmental impacts could be justified if it has higher performance during the operation phase that results on savings.

4. Conclusions

Sustainable building design, construction, operation and refurbishment are based in the assessment of the environmental pressure, societal performance (related to the construction standards, regulations and psycho-social characteristics of building's users, among others) and life-cycle costs. Sustainable construction seeks a better compatibility between natural and artificial environments, nevertheless without forgetting the functional quality of a building and the cost-effectiveness of a project.

The rehabilitation of the building stock is a very important aspect in order to increase the sustainability of the construction market: refurbishment increases the durability of the construction elements, which allows the amortization of the initial environmental impacts in an extended life span and, on the other hand, it allows to update the buildings' functional performance, with all societal and cultural advantages, along with the exploitation of the existing structures, with all related economical advantages.

Despite of several studies about sustainable construction indicators, up till now there is not an accepted methodology that could assist the project team in the sustainable refurbishment projects. In this paper it was presented a methodology to assess the sustainability of the building refurbishment projects. There are still some important limitations to overcome, like for instance the development of a more consensual list of parameters and weights. Although at this step, the methodology could give an important input to project teams in order to turn the refurbishment operations much more compatible to the sustainable development aims and allow that the future generations could have at least the some conditions as the actual ones.

ABSTRACT: This paper presents the transfer and adaptation of the former Lisbon EXPO 98 Macao Pavilion from its original location to a town park in Loures as a case study in building deconstruction. An essential aspect for promoting Building Deconstruction is the demonstration of its multiple advantages, mainly to those directly involved in the designing and building processes, proving the compatibility of deconstruction friendly principles with architectural expression, functional efficiency and economical profitability. A description of the disassembly and reassembly operations of the former Macao Pavilion is made, identifying the main difficulties found. An analysis of the overall profitability of the operation is also made, estimating the amount of material diverted from landfill and the amount of embodied energy saved through material reuse. An economical profitability study compares the costs of disassembling and reassembling the pavilion with those of a new building.

1 INTRODUCTION

Portugal is currently facing serious challenges to its production and consumption habits. The country is very dependent on imports for its energy needs, with 87,2 % of the national yearly consumption deriving from external sources (DGEG – Geology and Energy General Directorate, in Portuguese, 2005), and energy efficiency is 25% above European Union's average with 240 kgoe/1000 Euros in 2004 (EUROSTAT, 2004).

The building construction industry, one of the largest employers in the country, is also considered a major responsible for several negative environmental impacts: energy consumption, associated emissions and waste production. Although the exact amount of construction and demolition waste (CDW) produced each year is not known, estimates point to a value of 4,4 Million tons (Farinha, 2007), the vast majority of which is land filled or illegally dumped. This value of CDW production may be attributed to lack of awareness, lack of other processing options and prevalence of construction habits that do not allow material separation or reuse. In this context, it is urgent to adapt design and construction paradigms to achieve greater resource use efficiency, reducing the amount of embodied and operational energy and also increasing the diversion of CDW from landfills.

Building Deconstruction emphasizes promotion of "reuse" of building materials and components (and even whole buildings) as a way to "close the loop" of materials, and avoid the loss of matter and energy through construction and demolition waste. Whole building reuse is an example of Deconstruction, by disassembling a building and transferring part or the whole of its components to a new site for reassembly. Such operations are quite rare in Portugal and the opportunity to follow and fully document the transfer of the former Lisbon EXPO 98 Macao Pavilion was considered a good subject for a case study in Deconstruction, as it would allow evaluating its environmental and economical profitability.

2 BACKGROUND

The Lisbon Expo 98 Macao Pavilion was designed by RISCO architectural design office in 1997 and was built in the northern central part of the EXPO 98 exhibition grounds, alongside the main pedestrian avenue, on a rectangular eastern facing sloping plot surrounded on three sides by streets while the north side opened to a another building plot (Figure 1).

Figure 1: The former EXPO 98 Macao Pavilion (Southeast view) in its original location in May 2005.

The Pavilion was a two-story building, with an doubly symmetric 55 x 30 meters rectangular shaped plan, comprising two "blocks" with two floors each. The eastern block housed exhibition spaces and was open at the street level, while the western block also housed exhibition spaces and administration / reception areas in the enclosed lower floor. Both upper levels were linked by two partially enclosed elevated walkways, which defined a patio between both blocks. The whole building had a structure of bolted metallic elements ranging in cross-section from HEA 600 to IPE 200, with enclosing walls made of 22 mm thick wood-cement viroc panels supported by metallic frames bolted to the main structure, except for the lower western block which had a brick encased metallic structure and brick partitioning walls. The floor of the upper level was made of 3 cm thick Medium Density Fiberboards and solid pinewood boards, while the roof was integrally made of corrugated metal panels, with metal rain gutters and eaves. Interior finishes (ceiling and walls) were gypsum board drywalls, including 60 mm rock wool insulation. The upper volumes had no windows, the only glass being present on the doors and panels that enclosed the street side of the elevated walkways. Windows and doors on the lower volume were double-glazed and aluminum framed. After the exhibition's end in October 1998, the pavilion was vacated and closed. In late 2004 it was bought by the Loures municipality to be reassembled in the new town park of Loures and used as a teahouse / art gallery.

3 DISASSEMBLY

Disassembly started in May 2005, taking place in three main stages over a period of approximately 14 weeks up to mid-August 2005. During the first stage, interior finishing materials were stripped, sorted by type and piled on the elevated walkways since the patio was unavailable as a sorting and stocking point. Building systems were also disassembled at this time. Doors, hardware, fixtures, cabling and piping were removed for reuse or recycling. Metals (soft steel, copper wiring) were sold to scrap metal dealers; wooden materials were removed to be used as fuel; other materials (rock wool, gypsum) were land filled.

The second stage of the disassembly took about four weeks and consisted on the dismantling of the building's external envelope, made possible since the removal of the interior finishes had exposed all of the internal connecting points for the external façade support frames as well as the roof panel's fixings. At this point, unfamiliarity with disassembly operations led to time losses as some elements were "over disassembled" rather than kept as whole components, while there was no properly established identification system for the parts.

The third stage of the process consisted on the disassembly of the steel structure. All of the elements of the steel structure were bolted, which allowed and facilitated disassembly, and were of a manageable size, which allowed manipulation and transport with commonly available means. The external access ramp, composed of two 24 meter long trusses, had to be cut in two for transport, while the main pillars bolting plates were found to be encased in concrete, and had to be cut making. A final step of the disassembly process consisted on the demolition of all reinforced concrete (foundations, ground slab and retaining wall) and brickwork walls.

In conclusion, the configuration and constructive solutions, such as assembly sequence, geometry of product edges and connection methods (Durmisevic, 2003) allowed for a systematic separation of building materials. A more thorough audit prior to disassembly would have identified materials, components and sub-assemblies worthy of disassembly and transport, an action that might have increased the profitability of the operation, as the value of harvested materials is usually inversely proportional to the number of disassembly steps necessary to acquire them (Durmisevic, 2006). A more effective labeling system for identifying components and their connections would also have benefited the whole operation, as it was later estimated that a more effective labeling of parts would have reduced reassembly time as much as 25%.

4 REASSEMBLY

The contract for reassembling the metal structure and build a new exterior enclosure was won by the Somague company, with reassembly started in the spring of 2006 and still ongoing in May 2007 (Figure 2). The reassembly was slowed down by a variety of factors namely because the materials transported had been piled up exactly on the building's future location alongside a general lack of information on the building design (original plans were not found on the architect's archives) and deficient or inexistent labeling of parts .

During rebuilding it was discovered that a few medium sized elements from the main structure were missing, and it was necessary to produce similar ones. New structural elements also had to be produced to replace those that had been encased in brickwork, while the original (and shortened) main pillars received new bolting plates.Other changes to the original project included the introduction of an intermediate steel deck.

Other than the structural steel elements, little was reused from the originally transported parts, either because materials had already been reused ("viroc" wood-cement panels were applied in the back facade of the St. Paul church scale reproduction), because they were unnecessary (façade substructures were not needed, as infill walls were now to be made of ceramic brickwork) or because they were unusable (asphalt contaminated roof panels).

Figure 2: General view of the pavilion being rebuilt in Loures as of April 2007.

5 ENVIRONMENTAL PROFITABILITY

Although it is fairly obvious that an operation of disassemble / reassemble should be environmentally preferable to a straightforward demolition, it is essential to determine exactly the benefits of such operations in order to promote design for disassembly and material reuse. There is no voluntary building environmental rating scheme in use in Portugal (such as BREEAM, LEED or Green Building Tool), and therefore there is no immediate methodological framework to evaluate the benefits associated with reuse of building components or materials.

Guy (2003) has proposed a Green Demolition Certification Draft, consisting of a credit system, rating actions at Building, Planning and Environmental Health and Safety levels of the demolition process. The system proposes the attribution of a green certificate on attaining 25 of the 52 possible credits, while setting minimum pre-requisites such as a mandatory 20% material diversion from landfill independently of building size. The literal application of this certification draft was deemed inadequate in this particular case, nevertheless the environmental profitability of this operation was evaluated on two of the most "valuable" rating aspects of the rating scheme: diversion of materials from landfill and embodied energy saved.

5.1 *Materials diverted from landfill*

The original complete bill of materials of the pavilion having been lost, a new bill of materials was calculated from EXPO archive project drawings and partial RISCO files. This allowed an estimation of the quantities of materials present in terms of weight, with composite elements (window units, facade panels) being broken into their main materials. Smaller components (bolts, door handles, etc.) were ignored for these calculations. Materials associated with building systems such as HVAC, rainwater drainage, water supply and residual waters were not considered given their low relative weight or impossibility to decompose into basic materials (as in the case of air treatment units).

In calculating the mass and weight of the materials, several references were used (Farinha, 1997), as well as catalogues and technical information reference material. Weights of structural elements (steel and concrete) were taken from the original structural bill of materials. The pavilion weighted a total of 1.820 tons, with 75% of that value being reinforced concrete present in foundations, ground slab and retaining walls (Figure 3).

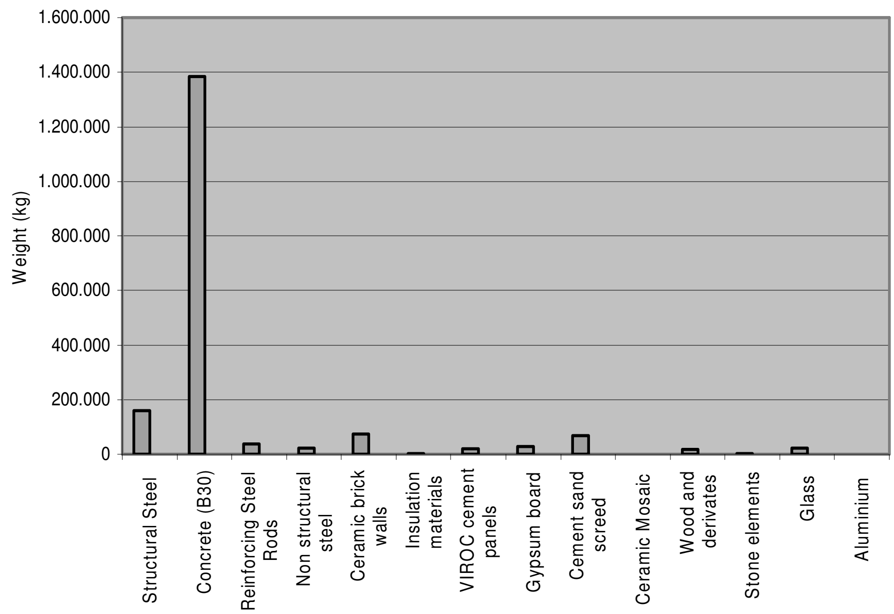

Figure 3: Volume of material per type.

Allocating the different materials per waste processing option (Figure 4), it becomes apparent that only 10% of the materials were reused (the steel structure and viroc panels), while a total of 14% were diverted from landfill (through a mix of reuse, recycling and energy recovery). While these percentages would not meet the minimum requirements of the Green Demolition Certification draft mentioned, it should be noted that almost all of the main constituting materials were adequately separated and thus the lack of a higher diversion rate from landfill could be attributed to lack of processing options and not to project or process characteristics.

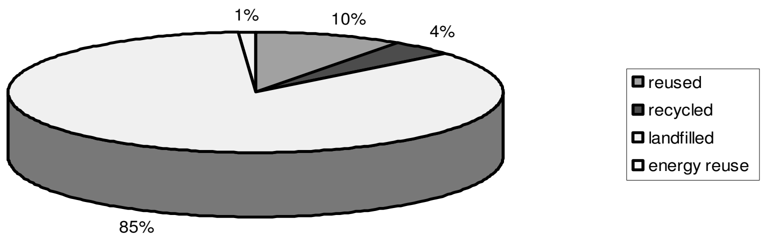

Figure 4: Volume of material per waste processing option.

5.2 *Embodied energy savings*

Another complementary assessment of environmental profitability of the transfer / rebuild operation is to quantify the amount of embodied energy saved. Treloar (1998) defines embodied energy as "the quantity of energy required by all the activities associated with a production process, including the relative proportions consumed in all activities upstream to the acquisition of natural resources and the share of energy used in making equipment and other supporting functions, i.e. direct plus indirect energy".

In the context of this study, embodied energy was understood as "process embodied energy" and not "gross embodied energy", thus excluding energy used to transport the materials and workers to the building site, upstream energy input in making the materials (such as factory / office lighting, energy used in making and maintaining the machines that make the materials, etc.) or embodied energy of urban infrastructure (roads, drains, water and energy supply). Process embodied energy values for construction materials can vary greatly since there are many different combinations of possible input / output paths to attain a certain embodied energy value per unit of material. Studies (CSIRO, 2003) have identified the following variables affecting embodied energy calculations: efficiency of manufacturing process; fuels in manufacture of materials; distances of transport and amount of recycled product used.

Embodied energy values are considered useful as an additional decision factor when comparing different building materials for a specific design problem, ideally complemented by environmental impact reference materials, since a low embodied energy material may be less favorable than another with higher energy content for a variety of reasons (lower technical service life, reciclability, etc.). Nevertheless, given the demonstrational character of this study, it was considered useful to demonstrate potential energy savings in this building transfer operation by calculating the amount of embodied energy preserved in reused building materials.

The previously calculated material volumes were converted into MegaJoules using several reference tables for embodied energy values per unit of mass. Since there are no specific embodied energy tables for construction materials in Portugal, the closest comparable source was used, namely the tables of the Spanish Instituto para la Diversificación y Ahorro de la Energía (IDAE), as cited by Gonzalez (2006). These reference values were considered to be very reliable as Spain and Portugal have similar geographic conditions, construction habits and construction material usage. In the only instance where a value for a material used in the Macao

Pavilion was not available in these tables, data from the New Zealand Institute of Architects "Comparison of building elements - Life cycle analysis" database (1995) was used. In calculating the embodied energy of steel elements a value of 14,25 MJ/kg was used, as a mean average between the values of 35 MJ/kg for virgin material and 10 MJ/kg for recycled source material considering that 83% of current steel is recycled or of recycled content (Steel Construction Institute, 2002). The original pavilion materials thus corresponded to a total of approximately 5.630.000 MJ of embodied energy, distributed according to Table 1.

Table 1: Embodied energy present in the original building, including waste processing options (RU - reused; RE - Recycled; LF - Land filled; ER - Energy recovery)

	Weight (kg)	MJ/kg	Energy (MJ)	Option
Structural elements				
Steel structural elements	159.900	14,25	2.278.575	RU
Reinforcing steel rods	38.360	10,00	383.600	RE
Concrete (B30)	1.383.120	1,20	1.659.744	LF
Exterior walls				
Perforated ceramic brick wall, 30 x 20 x 20 cm, with cement / sand mortar render	5.384	2,50	13.460	LF
Perforated ceramic brick cavity wall, 30 x 20 x 15 + 30 x 20 x 11, with cement / sand mortar render	35.148	2,50	87.871	LF
Cavity wall insulation rigid PU board (30 mm)	71	72,20	5.147	LF
VIROC wood-cement facade panels (22 mm)	18.701	9,50	177.657	RU
50 x 50 x 4 RSH facade panels metal frames	7.075	14,25	100.813	RE
Interior walls				
Perforated ceramic brick wall, 30 x 20 x 11 cm, with cement / sand mortar render	33.587	2,50	83.966	LF
Interior single 12,5 mm plasterboard wall (inc. substructure)	7.612	6,10	46.431	LF
Rock-wool insulation (60 mm thick)	1.305	14,60	19.051	LF
Floor finishings				
Cement sand screed, smooth finish (100 mm)	67.859	1,20	81.430	LF
Ceramic mosaic 10 x 10 cm	170	2,50	425	LF
Pinewood floor baseboard (20 x 70 mm section)	122	2,00	244	ER
Solid pinewood floor (30 mm)	3.936	2,00	7.873	ER
Moist resistant MDF boards (30 mm)	14.388	11,90	171.214	LF
Ceiling finishings				
Interior suspended plasterboard	9.709	6,10	59.223	LF
Exterior moist resistant suspended plasterboard	10.237	6,10	62.444	LF
Rock-wool insulation (60 mm thick)	2.459	14,60	35.905	LF
Stonework				
Door sills (average thickness 4 cm)	1.801	6,00	10.805	LF
Doors and windows				
Glass	4.720	15,90	75.041	RE
Aluminum frames	280	191,00	53.461	RE
Steel frames and doors	4.261	14,25	60.715	RE
Various steelwork				
Exterior hand-railings	1.235	14,25	17.592	RE
Roof panels, corrugated sheet metal "Alaço" type	7.809	14,25	111.271	LF
HVAC protection perforated panels, inc. substructure	1.230	14,25	17.524	RE
1 mm zinced water-drains and eaves profiles	251	14,25	3.583	RE
TOTAL	1.821.482		5.630.036	

According to the various disposal options for the different materials present in the Pavilion, it can be observed that 43% of the total EE value, corresponding to 2.450.000 MJ, was preserved due to the steel structure being reused. Considering the loss of 10-15% of the original steel components of the building, nevertheless approximately 2.200.000 MJ of embodied energy may have been saved. The production of this energy from fossil fuel would correspond to approximately 52,5 tons of oil equivalent (1 toe = 42 GigaJoules), whose combustion would release (on average) approximately 45.000 kg CO_2 to the atmosphere. The amount of energy saved corresponds to 680.000 KW/h, which would cost 75.000 Euros (at current national rates).

A comparison made using values from Portugal's General Directorate for Energy "Energy Consumption Management Regulation" (1995), which stipulate maximum tons of oil equivalent to be spent in the production of certain construction materials, yielded steel embodied energy values almost 20% higher than those obtained through the Spanish IDAE values.

As mentioned earlier the embodied energy values considered do not account for energy from transport, and so the added energy from the trips necessary to transport the pavilion steel components was not considered. However, it is important to refer that if this transport energy were accounted for, the option to reuse would be even more favorable than new building since there is no source of steel elements closer to Loures than the Expo site (the sites are just 18 km apart). CO_2 emissions and embodied energy due to transport corresponded respectively to 550 kg CO_2 and 56 MJ, from the 200 l of diesel estimated to have been used in the 20 two-way journeys to transport the structure (consumption and distance obtained in www.mappy2.com).

In conclusion, although only a low percentage of the total material volume of the existing building was reused, it did correspond to over 40% of the total estimated embodied energy present, which constituted a considerable environmental and financial saving.

6 ECONOMICAL PROFITABILITY

Parallel to the environmental benefits estimation, an equally important assessment (some would argue, the most important one) is that of the economical profitability of this operation. The Loures municipality paid a total of € 260.000 (excluding taxes) for disassembly, reassembly and construction of a new enclosure. The pavilion itself was donated, an obvious choice for the owner as the property becomes available for redevelopment at zero cost.

An economical profitability study must compare the values paid for actually (re)used elements to the value of supplying and assembling new comparable products. As seen before, material reuse was limited practically to steel structure elements, of which the original pavilion possessed 160.000 kg. Considering a 10% replacement rate for lost parts and 24.000 kg to replace the elements that were originally encased in brickwork (estimated from the original bill of materials) a total of 200.000 kg present in the new pavilion is obtained.

Considering that the value of the new foundations, enclosure walls and roof (which should be discounted) is equal to the price paid for the road transport of the elements (which should be added), an average value of 1,30 Euro paid per kg of steel is obtained.

If a fully similar building were to be built anew, the budget of supplying and assembling 160.000 kg of steel structure (the original amount needed) would be € 528.000 using 2006 average tender prices of € 3, 30 per kg of steel. If the original 198.000 kg of steel (160,000 kg from the structure plus 38.000 kg of reinforced concrete bars) had been sold for recycling, it is reasonable that a price of 0.5 Euro/kg would have been paid, resulting in a net total of 429.000 Euro to be paid for a new pavilion.

Considering both the least and most advantageous relationships between the aforementioned values, the disassemble / reassemble option is always more profitable (for the owner), with prices 65 to 100% lower than the price of an all new structure. It is interesting to consider that if a reinforced concrete structure had been used in a new similar building, the estimated cost (from average prices per sqm of construction) would have been approximately 295,000 Euro, a value still higher than the 260.000 Euro paid by the municipality.

7 CONCLUSION

Although the disassembly and reassembly of the former Lisbon Expo 98 Macao Pavilion was affected and slowed down due to the novelty of the process, the balance was nevertheless positive on both economical and environmental aspects. A low 14% diversion rate from landfill was achieved, but the materials reused amounted to almost 40% of the total embodied energy present. Economically the operation was profitable on all levels, and a more efficient planning on disassembly would have raised the profitability of the operation even further.

Studies (Boyle, 2005) have shown that transport and degree of waste processing infrastructures are the main conditioning factors to salvaged material reuse overall profitability. In the Macao Pavilion case, the very short distance between disassembly and reassembly sites reduced the negative impacts of transport, but the lack of appropriate disposal options greatly hindered the degree of diversion from landfill. This was made more evident since the original design was very favorable to deconstruction, permitting an effective reversal of the building sequence and allowing a high degree of material separation.

This operation was greatly facilitated by the fact that it was promoted by a public body which eased bureaucratic procedures, as no project and building permits were required, while the "whole rebuilding" option allowed bypassing structural calculations and verifications. A mention must also be made to the overall architectural strategy as it allowed functional adaptation with little effort, benefiting from the typology of the building (an isolated building).

This study shows that in more urbanized areas of Portugal, where building habits are more developed, more sophisticated building techniques are available and transport networks are more dense, it may prove profitable on all dimensions to design all steel structure buildings that allow disassembly and transfer, thus obtaining a higher construction material usage efficiency, and ultimately a more sustainable construction.

In order to achieve this ultimate objective, further efforts are necessary in many areas, including raising awareness of stakeholders, laying down appropriate legal framework, creating adequate processing infrastructures and raising the consciousness of designers and builders.

School of Environment and Technology, University of Brighton, Cockcroft Building, Lewes Road, Brighton, BN1 6HL, United Kingdom. k.ip@brighton.ac.uk, aa1@brighton.ac.uk, a.miller@brighton.ac.uk

Keywords: Ground-air heat exchanger, TRNSYS simulation, soil temperature, LZC technology, Earthtube

SUMMARY

The use of ground-air heat exchangers (GAHX) in a ventilation system is gaining recognition as a low or zero carbon ventilation strategy. However, there is very limited research and published data on the thermal performance of GAHX under UK climate. This research project currently undertaken at the University of Brighton aims to fill this gap in knowledge. The research evaluates the thermal performance of the GAHX - so called Earth tube - under different configurations, climatic and operating conditions in the UK. Thermal simulations have been carried out, using validated thermal models developed by others and the ground temperature and climatic variables established from this research, to predict the daily air supply conditions from GAHX and to evaluate the annual energy gain/saving potential. A low rise office building located in Brighton, Southeast of UK, is used as a case study to demonstrate the potential and effectiveness of the GAHX. The issues related to the application of GAHX and the further research are discussed.

1.0 INTRODUCTION

The Ground-Air Heat Exchanger (GAHX) is a subterranean cooling system that consists of a network of pipes buried below the ground surface, through which ventilation air supply is circulated. Difference in temperature between the pipe surface and the air drives the pre-cooling/pre-heating of the ventilation air. The magnitude of the heat exchange between air and pipe surface is dependent on factors such as, soil temperature, air temperature and pipe dimensions, air flow rate, pipe burial depth, soil and pipe thermal properties (density, heat capacity and thermal conductivity) (Pfafferott, 2003). There is significant evidence of summer temperature rise in the UK, with the average temperatures expected to rise by 4-6ºC over the next 50-80 years, creating risk of building overheating (CIBSE, 2005). There is also evidence of the rise in the use of mechanical cooling in buildings with about 20% of total floor area in UK offices now air-conditioned (CarbonTrust, 2007). The concept of cooling using GAHX is well established, but the behaviour of such systems depends on climatic and soil conditions (Piechowski, 1999). The dynamic thermal performance of GAHX is therefore not universal and needs to be studied within the context of climatic, soil and building load conditions. Potential of the system for improving comfort conditions in buildings and sensible energy reduction/gain by ventilation air has been established for the climate of Southeast UK.

2.0 METHODOLOGY IN THE RESEARCH

The thermal simulation study has been carried out using the Transient System Simulation Programme (TRNSYS) which is a modular simulation environment for the study of dynamic energy systems. (TRNSYS16.0, 2005). The open modular structure within TRNSYS allows for the use of inter-connection of existing components and user written components to develop thermal simulation projects. The simulation study of the GAHX has been based on a numerical model developed by Hollmuller and Lachal (2001). TRNSED applications have been developed and used to run parametric studies for different configurations of GAHX. TRNSED application in TRNSYS is used for the development of standalone windows based applications that can be used to carry out parametric study of energy systems. Building description files have been generated for a typical low rise office building in Southeast UK using the TRNSYS building interface TRNBLD. The building description file has been coupled with the GAHX model to study the impact of GAHX on building indoor operative temperatures. Climatic and soil variables have been established for Southeast UK by collecting and analysing soil temperature records held by the UK Meteorological Agency (UKMO) and validating soil temperature prediction model. Figure 1 shows a description of the thermal simulation process and the input and output parameters.

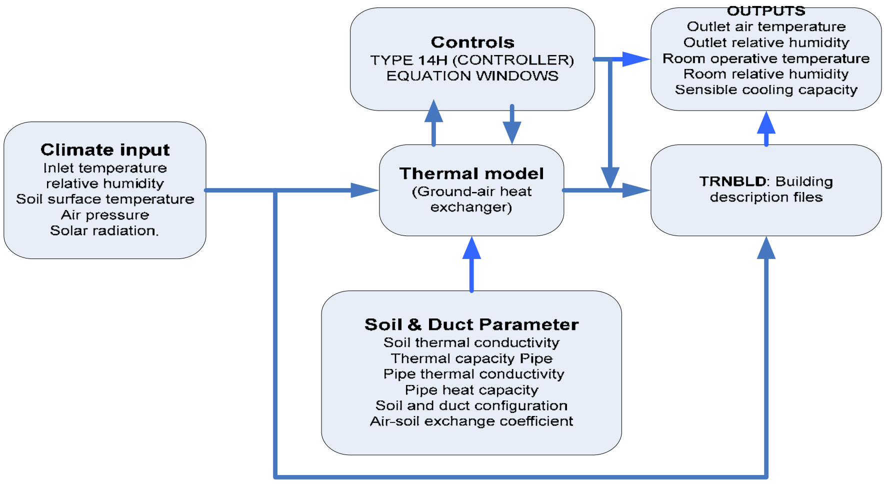

Figure 1 Thermal simulations and input parameters

3.0 THERMAL MODELLING

There are a number of attempts by researchers to develop thermal models for predicting the outlet air condition from GAHX. These models have been developed with different levels of accuracy, complexity and assumptions. A rigorous review of existing thermal models and their underlying assumptions have been carried out to establish current state of the art and to find a base model for this research. The models are grouped into:

1. Steady state models (Sodha et al., 1985, Bojic et al., 1997): solves the problem as a one-dimensional heat transfer problem, solving only the convective heat transfer between the tube and air. These models assume constant soil temperature around the GAHX. This is not an appropriate solution for a transient system in which heat loss/gain from air to the ground gradually raises/lowers the soil temperature around pipe.

2. Single pipe transient models (Mihalakakou et al., 1994a, Kumar et al., 2003, Al-Ajmi et al., 2006): solves convective heat transfer from tube to air and the heat diffusion from external tube surface to the surrounding soil. In this category there are those models that solve both heat transfers in soil and heat exchange between air/soil, the models therefore assume negligible mass transfer as a result of temperature gradient in the soil. More detailed models however, solve heat and mass transfer as well as sensible and latent heat exchange between soil and air. These models are limited to modelling single pipe configurations.

3. Multiple pipe transient models (DePaepe, 2002, Gauthier et al., 1997): these are numerical and analytical models that solve both sensible and latent heat exchange between tube and air and three-dimensional heat and mass transfer in soil and also allow for the dimensioning of multiple pipe problems. Mihalakakou et al. (1994b) used principle of superposition of the solution of a single pipe to account for thermal interference of neighbouring pipes. These models even though they account for the thermal solution to the multiple pipe configuration of GAHX, the solutions assume homogenous soil conditions and uniform surface condition, which limits their application to simple geometries.

4. Detailed numerical solutions developed by Hollmuller and Lachal (2001) has been found to be the most comprehensive solution for the thermal analysis of GAHX. The model solves both sensible and latent heat exchange between air and soil and the fully three-dimensional heat transfer in soil. It also allows for dimensioning multiple layers of pipes with non-homogenous soil profile, multiple soil surfaces and variation in air flow rate and directions. The model has been validated against analytical solution and long term monitored data from real scale installation by Holmuller and Lachal (2005). This model has been adopted for the purpose of this study.

4.0 SOIL TEMPERATURE IN THE UK

Soil temperature is the main parameter that determines the potential of GAHX. In order to study the behaviour of this system there is a need for understanding temperature changes with time and soil conditions. Soil temperature records for 10 locations in Southeast England have been collected and analysed to understand the potential of ground cooling or heating systems and the variation of soil temperature with locations within the region. Soil temperature records have been kept for most metrological stations across the country by UK Metrological Office (UKMO). The data held by the UKMO range from 10cm-100cm depth. Data indicated there is a variation of less than 1ºK between the nine locations studied within the Southeast region of United Kingdom.

4.1 SOIL TEMPERATURE PREDICTION

Soil temperature records held by UKMO is available for 10cm-100cm depths, however, there is less variation in soil temperature with increasing depth below ground surface. Because of the lack of records below 1m depth, soil temperature prediction models have been utilised to simulate soil temperature below 1m depth. Soil temperature prediction models have been developed as Fourier series based on the solution of one-dimensional heat transfer in semi-infinite solid medium with surface temperature as a harmonic function of time (Carslaw and Jaeger, 1959). The validated mathematical model developed by Labs (1989) shown in equation 1, has been used to predict the soil temperature profile for Brighton. The model uses information on soil thermal properties and surface temperature derived from soil properties and air temperature records.

$$T_{z,t} = T_m - A_s \times \exp\left[-z\left(\frac{\Pi}{8760\alpha}\right)^{1/2}\right] Cos\left\{\frac{2\Pi}{8760}\left[t - t_o - \frac{z}{2}\left(\frac{8760}{\Pi\alpha}\right)^{1/2}\right]\right\} \qquad (1)$$

T_{zt} = Soil temperature at time t and depth z (ºC).

A_s = Mean annual ground surface temperature (ºC).

α = Thermal diffusivity of soils (m^2/hr)

Z = Depth below ground surface (m)

t = Time elapsed from the beginning of the year (hours)

t_o = Phase constant (day of year coinciding with minimum surface temperature (hours).

T_m= Mean annual soil surface temperature.

Π = PI (3.1416)

Table 1 Parameters used to predict soil temperature for Brighton

Parameters	**Values**
Mean annual surface temperature (T_{mean})	12 ºC
Surface temperature amplitude (T_{amp})	11 ºC
Depth	1m
Time Shift (T_{shift})	15 days
Soil type	Chalk
Specific heat capacity	900 J/(kg.K)
Density	2290 kg/m³
Thermal conductivity	0.83 W/mK

The parameters in table 1 have been derived from 10 years air temperature records for Brighton. Ten years monthly average air temperature has been used to determine the mean annual soil surface temperature (T_m), and annual surface temperature amplitude (A_s) which is the difference between maximum and minimum surface temperature. Soil type and thermal properties have been determined from the records of British Geological Survey borehole records (Survey, 2006).

The simulation results have been validated with ten years records of soil temperature, as shown in figure 2, which shows variation of less than 1°K between simulation and measured records of soil temperature. Figure 3, shows soil temperature for 1-10m depths, the amplitude of soil temperature is damped significantly with depth. At about 10m depth the variation is almost completely damped showing almost constant temperature throughout the year. The cost of excavation may however limit depth of the GAHX, especially is areas with hard/rocky soils.

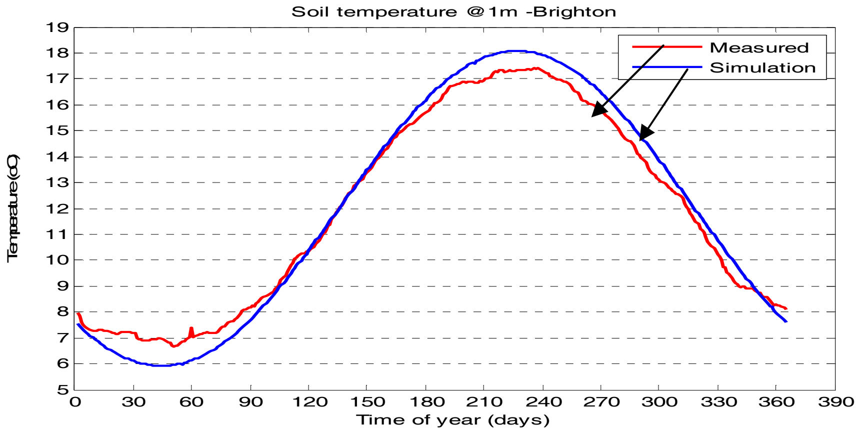

Figure 2 Comparison of simulated and measured soil temperature (1m - Brighton)

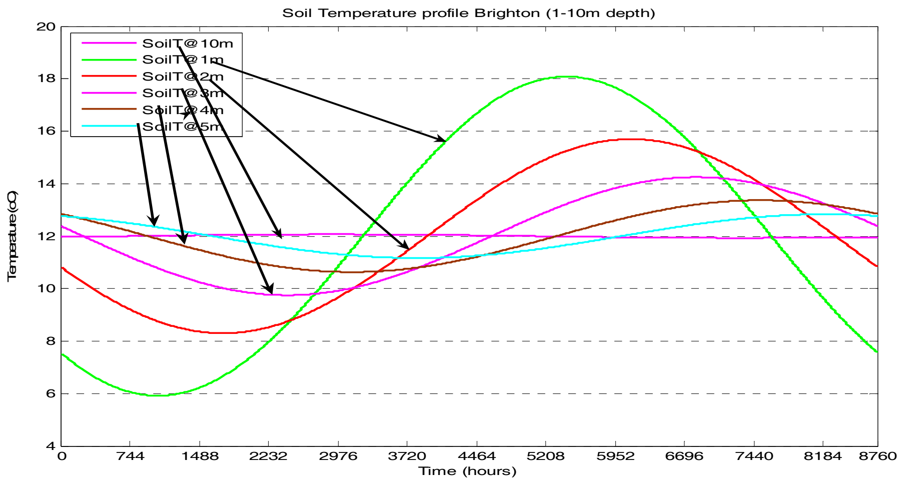

Figure 3 Soil temperature profile for Brighton, Southeast England (1-10 m depth)

5.0 SIMULATION STUDIES OF GAHX

The thermal performance of GAHX is affected by the pipe configurations and air velocity, burial depth and inlet air condition. Thermal simulations have been run using the TRNSED application developed in this research for various combinations of input parameters and pipe configurations. The outlet air temperature and sensible energy gain have been determined and presented for some pipe configurations and air velocities. Ambient air conditions for Gatwick airport have been generated and used as input to the simulations. Hourly simulation for a year has been carried out and the results presented in the following section.

6.0 Discussion of results

6.1 OUTLET AIR TEMPERATURE

The air passed through GAHX has been found lost/gained heat from the soil. The soil temperature is lower than ambient air temperature in summer and higher than ambient temperature in winter. Figure 4 shows the plot of ambient and pipe outlet air temperatures. Ambient air temperature has been damped from 29ºC to just over 20ºC during peak summer conditions. Similar benefit have been achieved in the winter, ambient air temperature of about -4ºC has been raised to around 3ºC. The outlet air temperature follows the soil temperature around pipe burial depth, there is less variation of soil temperature with increase depth below the surface. Figure 5 shows the cumulative temperature frequency distribution for GAHX buried at a depth of 1-4 m. This compares the outlet air temperature for GAHX at different depths and shows that at 4m depth the maximum outlet air temperature is 20ºC compared to 22.5ºC at 1m depth.

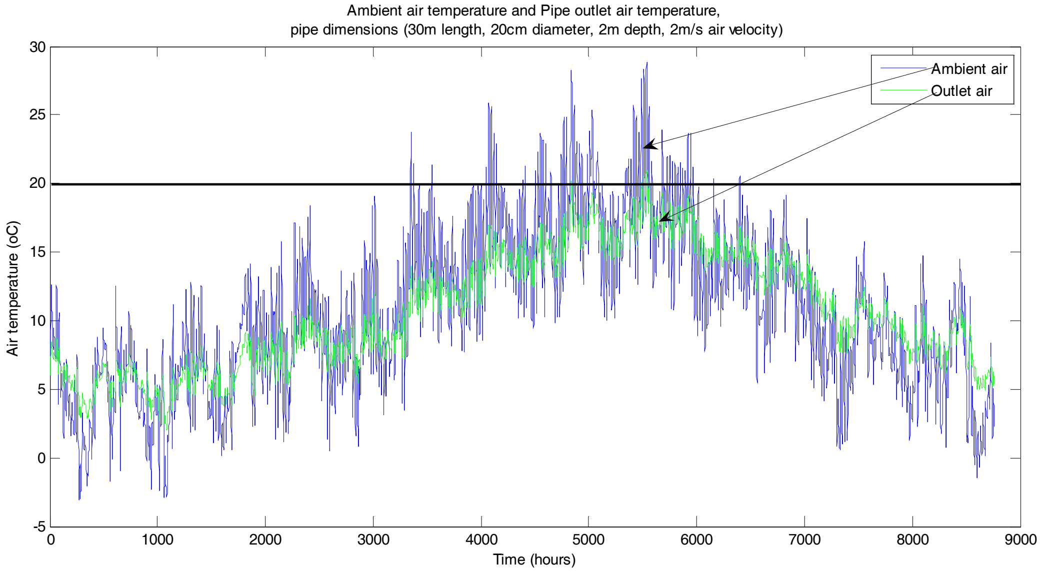

Figure 4 Ambient air and pipe outlet air temperature

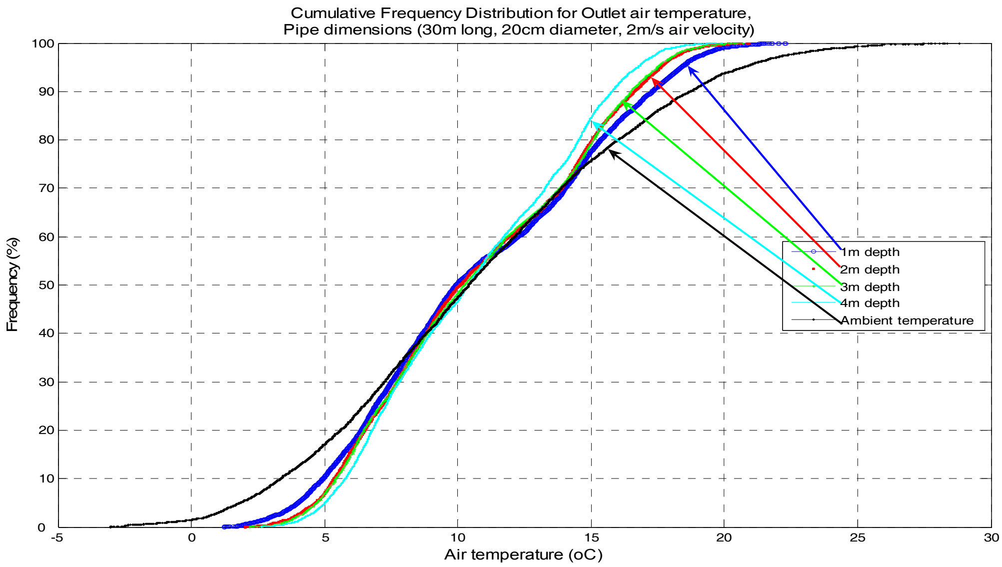

Figure 5 Cumulative frequency distribution of pipe outlet temperature (1-4 m depth)

6.2 SENSIBLE COOLING CAPACITY

Existing work on the sensitivity of pipe configuration on the performance of GAHX system focused more on the outlet air condition; in this work total sensible energy gain by the air has been used as a yardstick for comparison. The energy gain as a result of pre-cooling or pre-heating of ventilation air is a good indicator of the thermal performance of GAHX, this have been studied for different configurations of pipe, air velocity and depth, Figure 6 shows monthly sensible cooling capacity of GAHX of 20cm diameter, 30m long and 2m depth. The results reveal the need for effective control to avoid air cooling during heating season and heating during cooling season. The control will be best achieved by using outside temperature through a by-pass when the outlet air is within acceptable conditions or when the ambient temperature is lower than air temperature in summer. There is clear increase in energy gain with increase in air velocity as a result higher volumetric flow rate; this however comes with a penalty of higher fan dissipation energy.

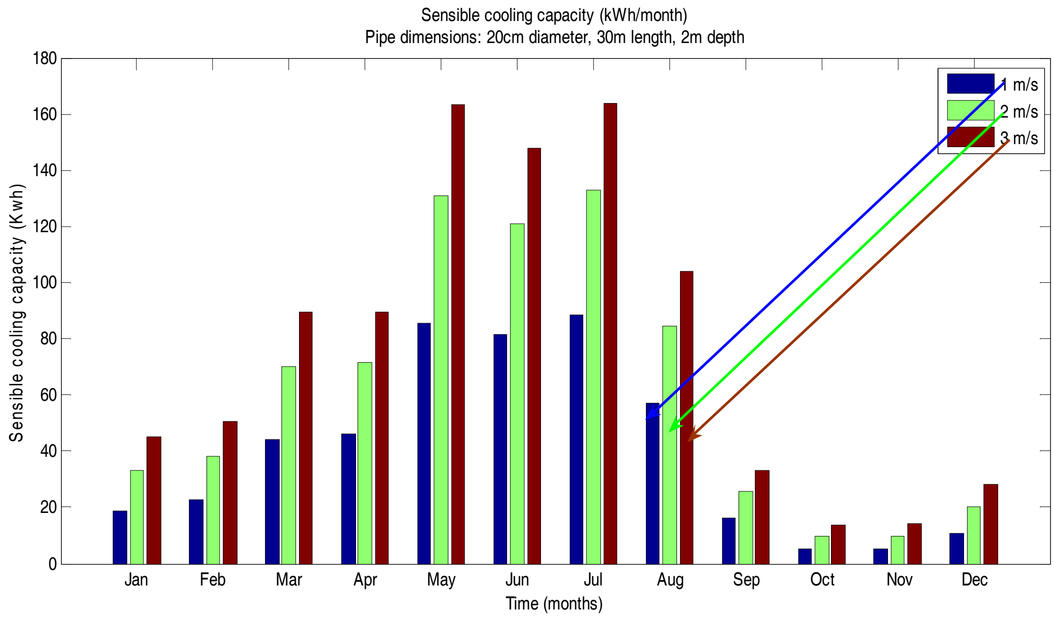

Figure 6 Sensible cooling capacities (kWh/month)

6.3 PIPE CONFIGURATION

Tube length is of significant influence on the outlet air condition and heat exchange with GAHX. Longer pipes provide more heat exchange area in contact with the soil mass. Figure 7 shows the cooling energy for pipe lengths 30-80m. The results shows that at smaller pipe diameter, however there is no significant gain in cooling capacity between 30m-80m pipe length, however as the pipe diameter increases, pipe length becomes a much more sensitive parameter. The pressure drop in the duct also increases with pipe length, therefore some of the cooling capacity may be offset by higher fan dissipation energy. Figure 7 also shows the effect of pipe diameter on the cooling capacity, which increases with increase in diameter. The diameter of pipe is an important parameter when sizing GAHX for both cooling capacity and the pressure drop, with larger diameters having lower pressure drop and hence lower fan dissipation energy. The choice of tube diameter is related to the expected air flow rate, which is dependent on the chosen mode of operation, comfort cooling, room cooling or auxiliary cooling (Zimmermann, 1998). In order to achieve complete amplitude dampening or phase shifting of ambient temperature the GAHX should exploit the more stable temperature of the soil at 2-5 m, in terms of overall cooling capacity. Figure 8 shows that there is no significant difference in cooling capacity by the EAHX from 2-4m deep, this is true because, the change in temperature beyond 1m depth not significant, as shown in figure 3.

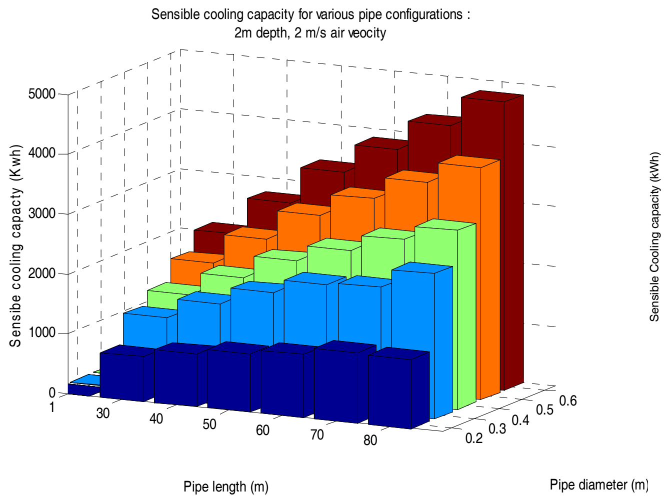

Figure 7 Sensible cooling capacity (kWh/annum)

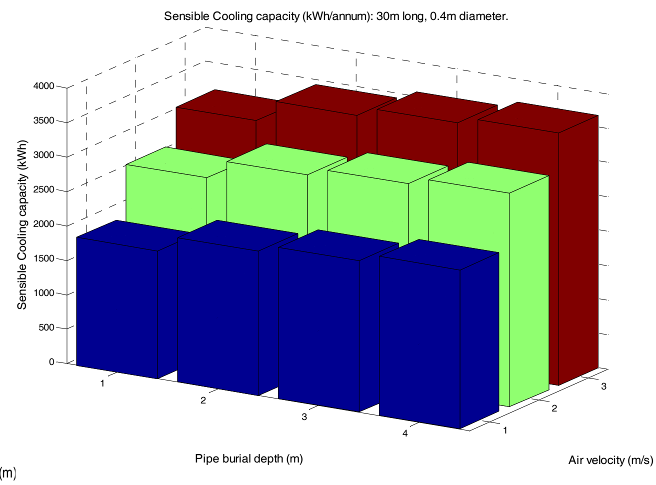

Figure 8 Sensible cooling capacity (kWh/annum) for pipe depth 1-4m

7.0 INDOOR TEMPERATURE AND COOLING LOAD

Building simulations have been carried out to compare the indoor temperatures for a ventilation system utilising ambient air and a similar ventilation system utilising outlet air from GAHX. This comparison is made assuming the building does not have any auxiliary cooling. The office building located in London near Gatwick Airport and occupied from 8am to 6 pm during weekdays has the dimensions of 5m (L) x10m (W) x 3m (H). The simulation period is from May to September. Cooling load for similar buildings has been calculated to maintain indoor temperature range of 19-24°C. Figure 9 shows comparison of indoor operative temperature of these ventilation strategies. It shows clearly that using GAHX have significant benefit in lowering summer indoor temperature. The indoor temperature has been maintained at below 25°C by the GAHX, on the other hand the building indoor temperature is around 27-30°C without the ground cooling.

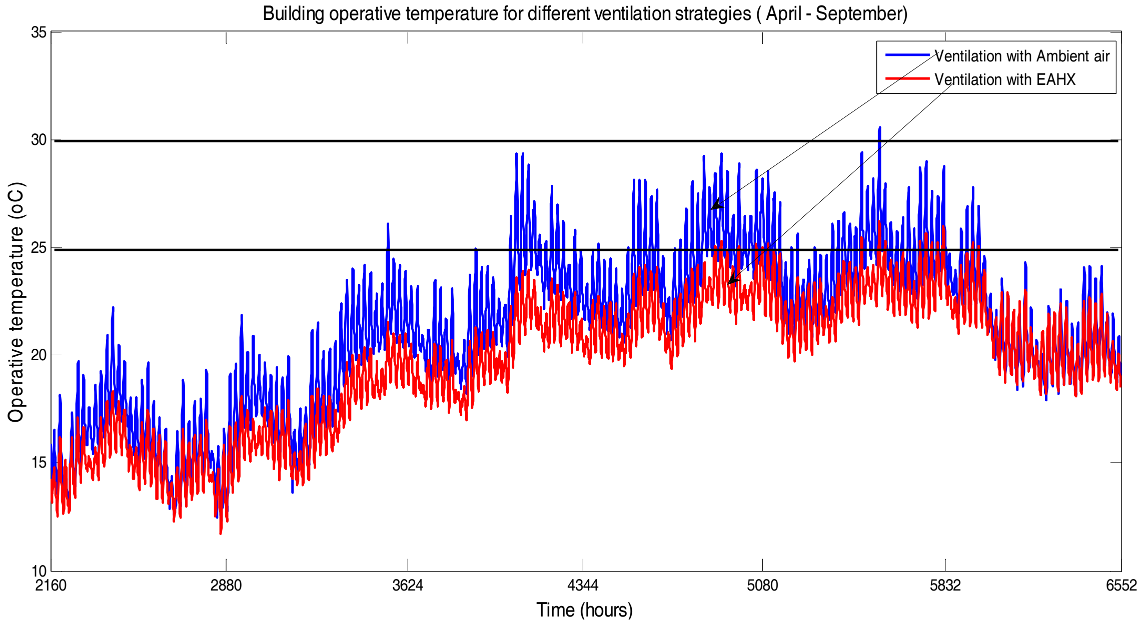

Figure 9 Building indoor operative temperatures with and without GAHX

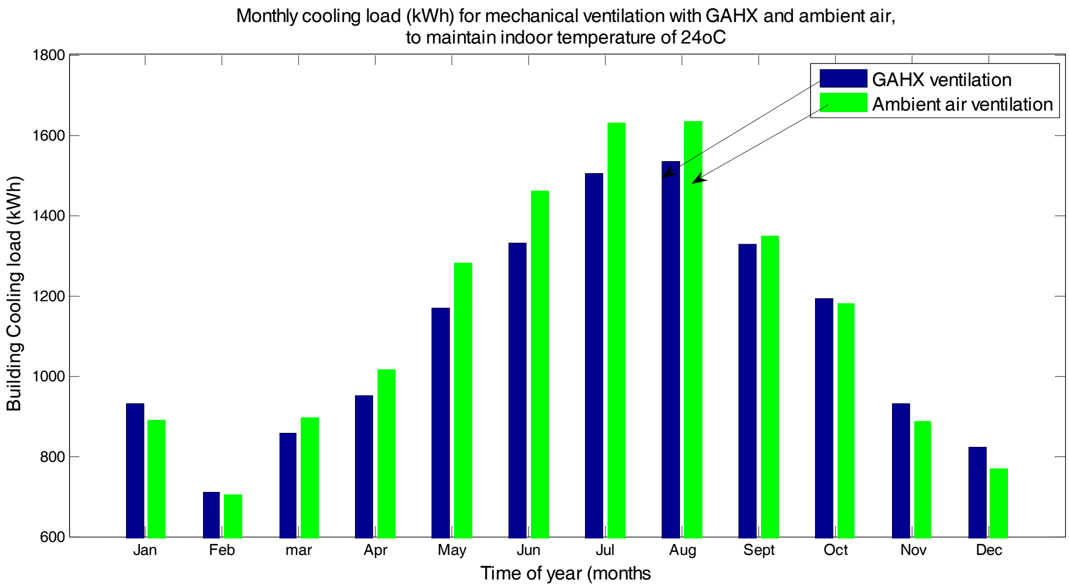

Figure 10 Monthly building cooling loads with and without GAHX

The other strategy is to use GAHX with an auxiliary cooling, where ventilation air supply to the air-handling unit is through the GAHX. Two set of simulations have been run to compare the cooling load of the building for a ventilation system utilising ambient and one with air supplied through the GAHX. Figure 10 shows the comparison of cooling load for the 2 strategies. Overall it reflects a significant reduction in cooling load when the GAHX is used.

8.0 CONCLUSION AND FUTURE WORK

This research investigates the potential of ground-air heat exchanger under the climate of the Southeast of UK. It has identified and demonstrated the impact of the key parameters on the thermal behaviour of the earth tube system. Soil temperature profile and thermal models for predicting the outlet air conditions of the earth-air heat exchanger have been determined and applied in the thermal simulation software TRNSYS. Simulation of the sensible energy gains for various configurations of the GAHX system and the cooling demand of an office building showed significant benefits in improving indoor thermal conditions and reduction of cooling load if air-conditioning is used. The on-going research will study the performance of the system in other locations around the UK and assess the cooling capacities of various system configurations and boundary conditions.

ACKNOWLEDGEMENT

Many thanks to British Atmospheric Data Centre for giving access to the MET Office climate database, this is the source of soil and air temperature used for this study.

A NEW PARADIGM FOR SUSTAINABLE RESIDENTIAL BUILDINGS

M.B. LUTHER, Arch D.[1]

[1]Built Environment Research Group School of Architecture and Building, Deakin University, Australia, luther@deakin.edu.au

Keywords: sustainable building, modular housing, pre-fabrication

Summary

The development of mass-produced environmentally-benign housing is one of the critical factors in the transition to global sustainability. Such housing will need to be constructed from renewable and/or recycled materials, be conditioned using minimal or no conventional energy, and affordable. The need for such housing is urgent. In developing countries, their requirement is to house both growing squatter settlements, as well as those who have benefited from recent economic booms. In industrialised countries, there is a need for an alternative to the current resource- and energy-intensive housing.

Traditionally, mass housing construction can be characterised as skilled-labour intensive, and by on-site construction using non-recyclable materials with minimal prefabrication. This process is costly, can result in variable quality and is time-consuming. These houses are often constructed from a variety of materials including concrete, aluminium, steel and brick, which are energy-intensive to produce, resulting in a structure with high embodied energy content. A new design and building construct introduces Relocatable, Adaptive, Recyclable, and Environmental (R.A.R.E.) architectural concepts as a solution (Luther, Altomonte, Coulson, 2006) .

This paper explores a new paradigm in housing, where dwellings will be pre-fabricated, modular, energy efficient, transportable and use renewable and/or recyclable resources. The paper reviews previous attempts to produce housing, which meets some of the criteria for this new paradigm. Their advantages and disadvantages are discussed. An approach towards a new type of modular prefabricated unit is proposed. A preliminary energy analysis, comparing a present relocatable classroom construction with one upgraded, is provided as an example towards low energy building operation. Finally, conclusions are drawn about the requirements of future housing if we are to progress towards sustainability.

1. Introduction

Globally there is a critical need for an environmentally sustainable mass-produced housing typology, which is both thermally comfortable and affordable. In some developing countries, squatter settlements range from 40-50%. In other developing countries, recent economic growth has fuelled a housing boom. Continued reliance on traditional housing solutions is environmentally unsustainable. Tiwari and Parikh (2000) analysed the impact on resources and carbon emissions of housing in India, if housing was provided to the estimated 15% of their population that currently has inadequate shelter. The present construction trend was found to be unsustainable from both a resource and environmental perspective if conventional materials (concrete, steel, aggregate and bricks) were used.

In Australia, current housing construction practice is unsustainable in terms of materials, energy for production as well as operation. The ecological footprint of the average Australian is approximately four times the level that is globally supportable (Simpson et al., 2000). Housing has become less affordable for the next generation of homebuyers (Age, 2006) and household sizes have been steadily declining for decades (Haberkorn et al., 2004). Scenarios of constrained choice, inappropriate housing options and continued heavy environmental impact are envisaged (AHURI, 2006). This study identified a set of values for policy development. These included: diversity i.e. housing forms that are flexible and accommodate the different needs and uses of society; affordability i.e. provision of dwellings that are appropriate for all incomes; and sustainability i.e. provision of housing that has a minimal impact on the environment. There is thus a convergence of the housing needs in developing and industrialised countries.

Previous mass housing construction in industrialised countries like Australia can be characterised by on-site construction, use of traditional materials and limited design variation. While some pre-fabrication (e.g. trusses) has been adopted by the traditional mass housing market, construction mainly takes place on site by various skilled tradespeople (bricklayers, carpenters, plumbers etc). This process is costly, requires skilled labour, results in variable quality and is time consuming. The houses are constructed almost exclusively from the traditional building materials, namely concrete, aluminium, steel, brick and timber, which are energy-intensive to produce. Australia's completed houses have high embodied energy content (Newton, 2001).

2. Towards a New Paradigm

A new paradigm in housing design, materials, construction, and its services is urgently required for environmental sustainability. A direction towards this architecture is outlined through eight Sustainable Building Categories (S.B.C.'s) presented in a Renewable, Adaptive, Recyclable and Environmental (R.A.R.E.) architecture (Altomonte and Luther, 2006). The purpose is for a project to strive towards success in all eight Sustainable Building Categories, in as much as possible.

- Biodiversity, Sustainable Site & Climate Analysis;
- Flexible & Adaptive Structural Systems;
- Renewable & Environmental Building Materials;
- Modular Building Systems;
- Innovative Building Envelope Systems;
- Renewable & Non-conventional Energy Systems;
- Innovative Heating, Ventilation & Air Conditioning;
- Water Collection & Storage Systems.

Other SBC's are continuously being incorporated into the above list as they become acknowledged, for instance, daylight autonomy and optimised building control. When producing an effective design, the above SBC's set a framework for 'items' to be seriously considered.

2.1 Modular and Prefabricated Design

Sustainable construction is in search of building system that can offer R.A.R.E. building principles. It is believed here that the revisitation of an older paradigm – modular building – holds the answer to future construction. Such processes have tremendous potential over conventional systems regarding material use and waste minimisation. Today, robotic and pre-programmed building processes can offer 'one-offs' and unique diversity in pre-fabricated construction (Bock, 2007). One of the greatest intentions is to introduce modular renewable and sustainable building services into R.A.R.E. building principles.

Modular design is not new. The 1920's to the early 60's were full of inventors and innovations for modular construction and its on-site delivery. The 'Turning Point of Building' (Wachsmann, 1961) was an indication that such constructs would be the predecessor over conventional building processes, as we know them today. Relocatable school buildings represent one of the most popular forms of 'modular' construction today. Yet, the processes by which such buildings are manufactured, is a far cry from applying present technological advancements. There are significant opportunities to advance the entire modular design, its structure, building materials and most importantly services technology.

Figure 1 offers a diagrammatic analogy for the range of construction types and suggested flexibility offered by pre-fabricated building. This diagram is an attempt to organise the vast undefined chaos of modular building systems into some sort of categories. It is however, not intended to cast a specific modular system into a particular category, but rather to acknowledge various methods of construction. Most pre-fabricated buildings will in fact be a combination of several design construction systems.

2.2 Pre-fabrication, Materials and Recyclability

The mixed nature of building materials makes recycling of demolished buildings difficult and usually financially unprofitable. Hence large amounts of building waste are buried as landfill. It is estimated that 30-40% of all Australia's solid waste disposed of at landfill sites comes from the construction and demolition of buildings (Newton, 2001). Mass-market housing developers have accommodated the differences in consumer choice by offering multiple design options e.g. 2, 3 or 4 bedrooms or superficial design variations e.g. facade. While offering some degree of flexibility, this approach is limited. Ultimate flexibility, and therefore choice, can be accommodated only if buildings are constructed in a modular component or kit-of-parts basis.

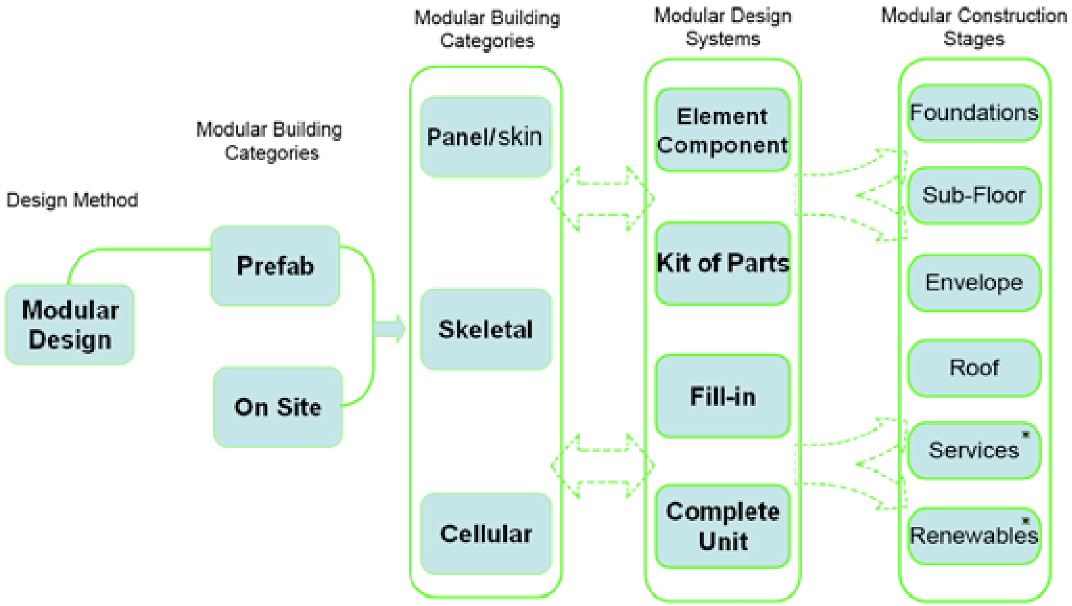

Figure 1: A Categorisation of Modular Pre-fabrication Systems and Construction Methods (Luther et.al., 2007)

Prefabrication of building envelopes has taken off in North America through the use of Super Insulated Panels (SIP's). The developments of such have advanced into the provision of the structural system within the panel itself. SIP buildings apply about 60% less timber than conventional frame construction. Their insulation properties are outstanding and the construction technique has substantially reduced unwanted infiltration in buildings.

One of the criticisms of SIP panels rests with its insulation material, applying polycyanurinate and polyurethane materials that involve oil-based products, potential CFC emissions, and out-gassing. Several of these problems have been resolved and the post baking of the material has almost eliminated out-gassing. Yet, the recyclability of the material is debated. In lieu of this, one manufacture (in the U.S.A.) has produced a SIP with compressed straw and wheat fibres claiming an 80% recyclable produce with high insulation properties. Other home manufacturers, such as SALA homes (QLD) have been applying rice and straw based products (Durra board®) as the insulated wall material.

Another construction material with growing interest is paper. Cardboard structures have been applied to many packaging applications. One of the major drawbacks is their vulnerability to moisture and water damage. Recently, an Australian manufacturer has investigated cardboard door materials that consist of a corrugated 4mm layer to either side of a 25+mm thick paper honeycomb core structure. Both corrugated sides are filed with polyurethane in their flutes, yielding an incredible structural strength, moisture proofing and a higher insulation value. The company manufacturer, Ureflute claims environmental recyclability of the product. Such products as this, hold the key to future building, yet, require extended research input.

There is room for improvement in the search of benign products that provide our palette of construction materials. According to McDonugh and Braungart (2002) our waste should equal food, and the building materials which are 'edible' will not be toxic. We need to also consider our application of materials and avoid mixing of manmade ones with those that are natural, in order to improve the capability of recyclability.

2.3 Relocatable and Adaptive

New design concepts, materials and construction techniques are essential for a new paradigm in housing. This paper explores progressive construction techniques, modularising and pre-fabricating building services and the application of benign (recyclable) materials. It follows a recently developed outline, a roadmap, towards developing a R.A.R.E. (renewable, adaptive, recyclable and environmental) responsive architecture. Several examples of previous research in this area are discussed with the idea of a particular concept – a renewable relocatable – introduced in greater detail. Design and material options, as well as the integration of services (water and energy) into the design. The results of some simulations are then presented. Some conclusions about further research directions for this building typology are finally suggested.

It is realised here that most of our buildings, unlike indigenous architecture, are static and permanent. Alternative structures consider structural systems that are flexible and removable like screw pile foundation systems. Too often our foundation methods resort to high embodied energy slab on grade concrete floors.

There are several raised insulated timber floor construction methods being explored by the University of Tasmaina School of Architecture through their test cell buildings.

In regards to relocatable and adaptive construction, it is believed that modular prefabricated design can deliver such. One of the most critical concerns is the connection points of vertical and horizontal building surfaces where potentially the most leakage can occur. The concept of building in elements that can be assembled and replaced is an important one and has been addressed by many of the pioneers of building, like John Prouve (Figure 2). Here the wall panels can be ‘switched’ or replaced with a selection of alternative making the building ‘adptive’ to various climatic conditions.

Figure 2 The Tropical House by John Prouve

2.4 Services

One of the most neglected areas of present design is the haphazard approach to which building services are integrated into the construction process. The services are one of the most labour intensive and costly items on a building project. It is therefore essential that these systems become integral components of design. In other words, they are a part of a designed system. Our present on-site installation of services, and specialised fabrication of connections is outdated and costly.

An example of such service integration is offered through an organization in Germany called Digitales Bauen, where all the services of a building are planned and divided into their ‘least common denominator’ (see Figure 3). This provides for actual pre-fabrication of entire service modules to be produced off-site and installed with minimal effort and interference of trades on-site. The approach guarantees performance and reduces operational failures and assures ‘interference free’ services.

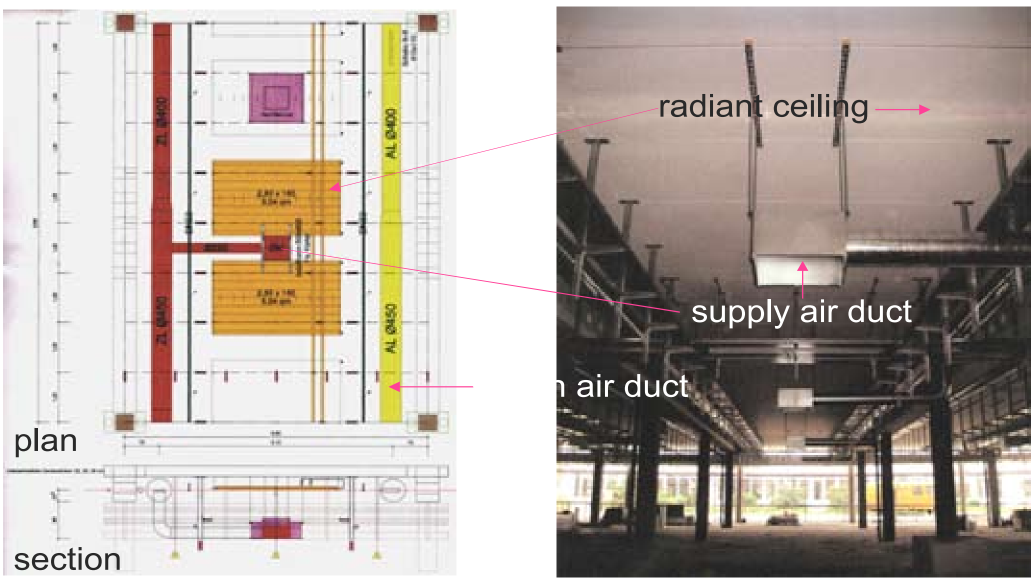

Figure 3 Total Integrated Building Services Planning (Digitales Bauen)

An example of integrating services is provided by a student project of a pre-fabricated modular house design by H. Pallot (Deakin University). This project, although not completely resolved, considered the services as complete 'snap-in' components. In this case the aim was for renewable services to be integrated into the housing design. Figure 4 shows the roof system as an energy (photovoltaic) generator, a hot water heater and a water collector. These systems are considered with an interior wall (service) component and storage into the floor foundation system.

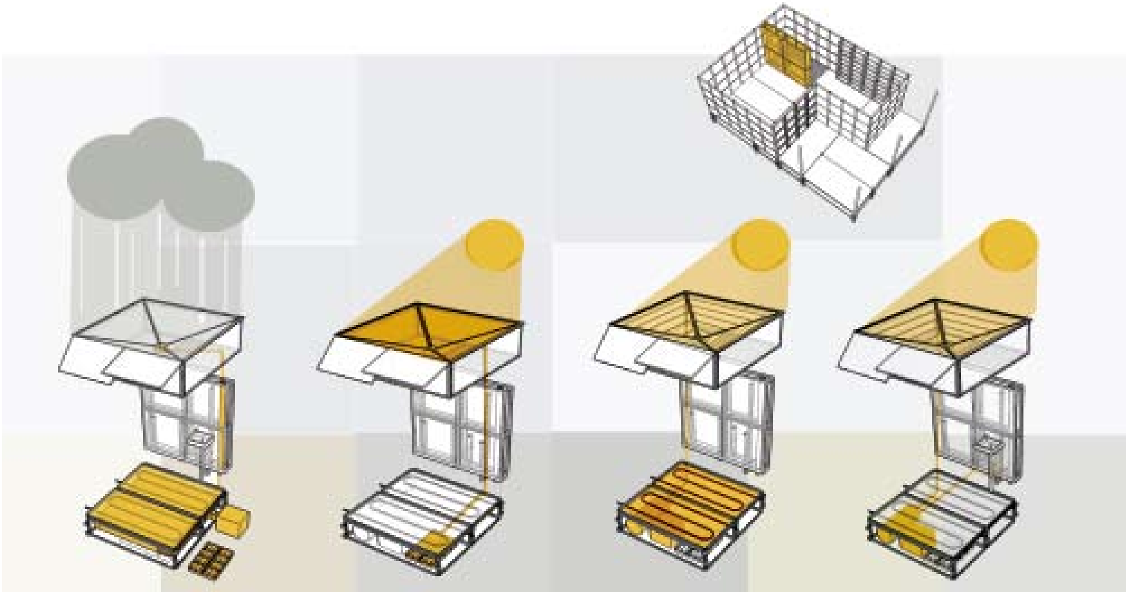

Figure 4 Service Modules Integrated into a Building System (student project: H. Pallot, 2007)

3.0 Energy Consumption and Operational Concepts

The move towards renewable energy systems for our building systems is inevitable. We need to move forward on the concepts of Reduce, Reuse and Renewables. A study on energy and comfort measurements in relocatable school buildings (Fuller and Luther, 2003) prompted further research studies into energy conservation. An energy simulation conducted for a two-classroom relocatable school building, indicated that up to a 50% improvement in the consumption of fossil fuels is reasonably achievable (Figure 5). Once this energy reduction has been realised, two aspects need to be considered: solar thermal processes and renewable energy generating systems.

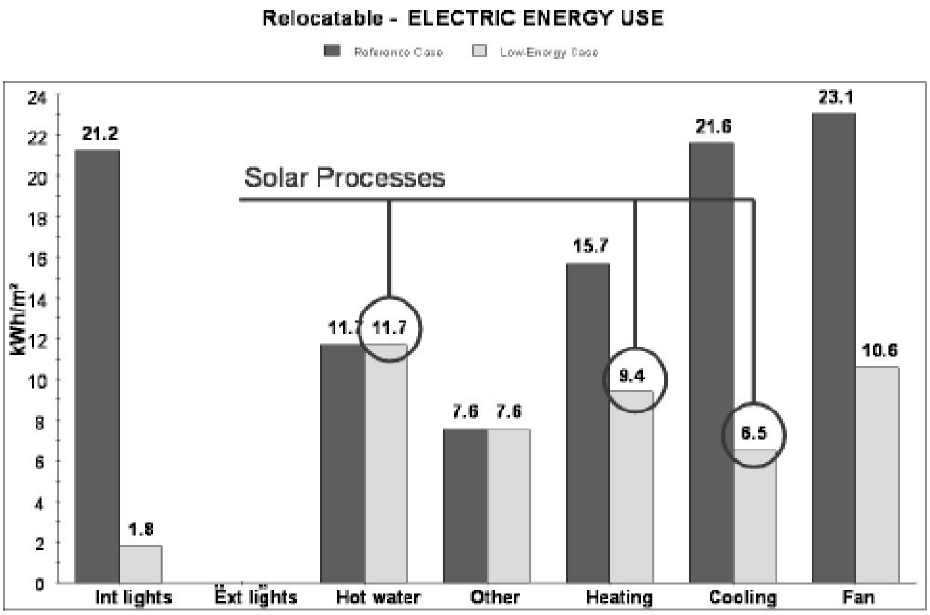

Figure 5 Annual energy consumption comparison for a reference and an energy efficient relocatable school building (ENERGY-10 simulation).

Figure 5 highlights (circled) the items that could be accommodated to a large extent through solar thermal processes. These would require minimal electric energy input. Finally, the application of photoelectric panels that cover the remaining required needs of electricity is considered. Furthermore, it is interesting to note that if only 98% of the peak hourly demand electricity load was acceptable, the original peak demand load would be reduced by 50% (Figure 6).

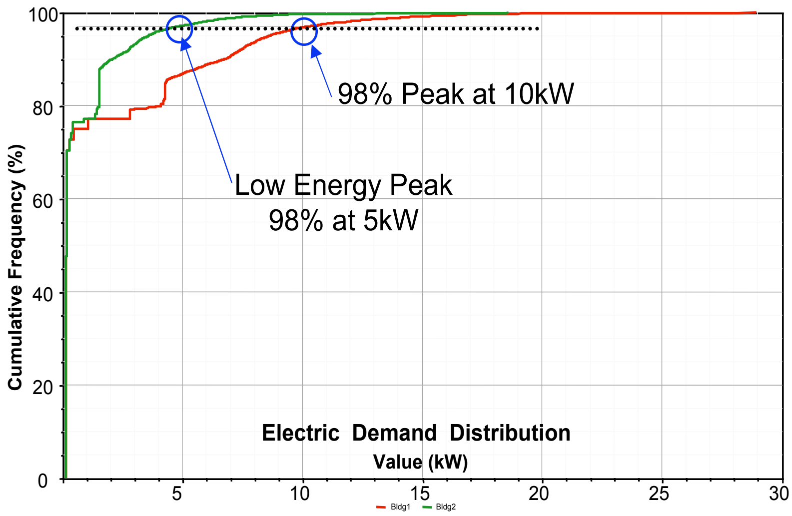

Figure 6 Peak energy demand frequency of the reference vs. the low energy building (ENERGY-10)

Another important and often overlooked aspect of energy consumption is due to leaky and unpredictable construction techniques. This issue has being researched in Australia by Air Barrier Technologies and the Mobile Architecture and Building Laboratory (MABEL). Buildings in Australia are often 2-4 times leakier than European countries (Luther, 2007). The simulation results provided by the ENERGY-10 program (Balcomb, 1998) indicate infiltration as one of the top three energy saving strategies (see Figure 7).

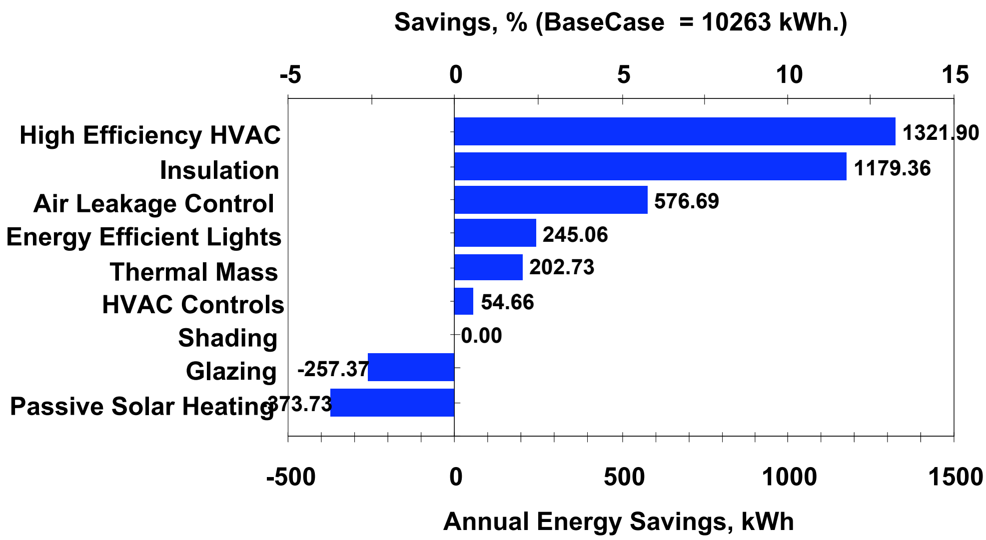

Figure 7 An energy saving strategy ranking as provided by simulation (ENERGY-10)

4. Conclusions

The development of mass-produced environmentally-benign housing is one of the critical factors in the transition to global sustainability. This new housing will have to be made from renewable and/or recycled materials, be naturally conditioned and affordable. The need for such housing is urgent. In developing countries, their requirement is to house both growing squatter settlements, as well as those who have benefited from recent economic booms. In industrialised countries, there is a need for an alternative to the current resource and energy-intensive housing.

A new approach towards sustainable housing, suggesting methods of prefabricated modular construction, recyclable materials, reducing energy consumption and introducing renewable energy has been outlined. The criterion for designing sustainable, renewable and adaptive buildings has also been introduced. The entire construction industry merits a re-visit in its methods and processes if we are to assure affordable and sustainable buildings for our future. Several of these methods have been presented in this paper.

Keywords: Demand Response, HVAC Supervisory Control, Machine Learning, Sustainable Buildings

Summary

Taking advanced concepts from the artificial intelligence domain, CSIRO is developing intelligent HVAC management techniques for minimising energy consumption and operating costs whilst considering the impact on human comfort. Along with optimised space energy performance, these techniques enable automated participation in demand response initiatives, alleviating the rapidly growing pressures of peak electrical demand. Encompassing machine learning techniques, the CSIRO's Intelligent HVAC Controller technology comprises of autonomous controllers that automatically form models of the surrounding built environment, using these models to determine optimal set-point values and operating schedules. This technology is designed to be low-cost and easily retrofitted to existing infrastructure. This article details our latest work on intelligent HVAC management, with results presented from recent technology trials on two commercial office buildings (combined conditioned space totaling 13,466m^2), with a mix of under-floor and conventional overhead HVAC systems.

1. Introduction

In Australia, Heating Ventilation and Air-Conditioning (HVAC) typically accounts for over 60% of energy use in commercial buildings (Australian Greenhouse Office, 1999), is a substantial contributor to greenhouse gas emissions and is driving peak demand in the electricity network. Motivated by this, Commonwealth Scientific and Industrial Research Organisation (CSIRO) is developing Intelligent HVAC Controller technology, encompassing advanced HVAC management techniques for increased end-use efficiency and peak demand reduction, with wider application in the intelligent control of distributed energy resources (Platt *et al.* 2006).

Specific to the air-conditioning and HVAC systems domain, CSIRO is developing advanced control methodologies to provide optimised HVAC operation depending on a building operator's preferences for (in no particular order):

1. Reducing operating costs, exposure to peak electricity prices and alleviating peak demand;
2. Reducing environmental impact, particularly CO_2 emissions and;
3. Achieving acceptable thermal comfort for building occupants.

Clearly these have competing goals, and the balance between them is determined according to the combination of the desired preferences.

CSIRO's Intelligent HVAC Controller technology utilises machine learning techniques to automatically form models of the surrounding built environment, using these models to evaluate different control strategies for determining optimal HVAC operating schedules. This philosophy has been used to develop a more intelligent HVAC supervisory control system that is readily retrofitted to existing building management systems (BMS) through industry standard control interfaces such as OPC and BACnet[1]. As this technology is targeted towards both new and existing building stock with relatively minimal capital expenditure, significant inroads can be made towards reducing operating costs with relatively short payback periods. Further, improvements in building energy efficiency and performance ratings are facilitated through reduced energy consumption and associated CO_2 emission reductions.

The remainder of this article is structured as follows: Section 2 introduces advanced HVAC management techniques as utilised by CSIRO's Intelligent HVAC Controller technology. Section 3 presents "black box" modelling approaches for predicting thermal response, with a framework for determining optimal HVAC

[1] OPC (OLE for Process Control) and BACnet (Building Automation & Control Networking) as maintained by the OPC Foundation and ASHRAE respectively, are standards specifications designed to facilitate interoperability in process control and building automation.

operating schedules then introduced. Finally, results of a recent technology trial are presented in Section 4, with a conclusion drawn in Section 5.

2. Intelligent HVAC Control

Conventional HVAC control strategies involve changing set-points for chilled-water temperature, supply-air temperature, and space temperature. This is not always easy to achieve, as many installed control systems do not permit direct access to room thermostats or may not allow an operator to globally change them. Consequently, the operator may look at changing other indirect set-points, though this can have undesired second order effects. For example, for a typical variable-air-volume (VAV) system, raising supply-air temperature set-point causes the air handling unit (AHU) fan to supply a larger quantity of warmer air, resulting in increased fan power. For this strategy to achieve a net energy saving, chiller power must drop by more than the increase in fan power. What should be a straightforward HVAC set-point adjustment is found to depend on building load, building thermal mass, and part load performance of the fan and chiller.

Simulation studies to date have identified such issues and have shown the potential benefit of appropriate controls actions (Reddy and Norford 2002, Gu and Haves 2001, Xing 2004). These studies considered changes in space temperature, supply-air and chilled-water temperatures, and fan speed set-points. However, they did not consider optimal combinations of set-point adjustments and noted that the simulations were not capable of reliably modelling the impact of the control strategies on the thermal comfort of building occupants.

Motivated by these shortfalls, CSIRO's approach involves utilising a multi-objective optimisation framework for identifying optimal combinations of set-point adjustments and operating schedules. This makes it possible for building operators to set preferences for fully automated HVAC operation based on a combination of cost, CO_2, and comfort metrics.

2.1. Advanced HVAC Control Strategies

In addition to conventional HVAC control strategies, CSIRO's Intelligent HVAC Controller considers a number of more advanced control strategies when determining optimal operating schedules. These include the following:

2.1.1. Thermal Energy Storage using Pre-Cooling

The concept of pre-cooling involves cooling the space the lower bound of what is considered to be comfortable prior to a forecast peak demand period (either when electricity prices are low or when ambient conditions are most favourable), storing energy in the thermal mass of the building fabric (Braun, 2000). When a demand response (DR) is initiated, HVAC system load can be reduced during the peak demand period, with the energy stored in the building's thermal mass used to slow the rise in temperature towards ambient conditions. A wider range of acceptable internal temperatures can be used during both the pre-cooling and DR phases so as to maximise the amount of energy stored during pre-cooling, in addition to prolonging the DR duration.

2.1.2. Intelligent Load Limiting

Intelligent load limiting strategies involve the reduction of HVAC system electrical load in a manner that achieves load reduction targets whilst minimising human discomfort. An advanced optimisation algorithm can be used for the optimal control of a combination of HVAC system set-points, e.g. chilled/hot water temperature, supply-air temperature, space temperature, cooling/heating valve position, fan speed and duct pressure, based on building operator preferences for operating cost, end-use efficiency and comfort requirements.

2.1.3. Optimised HVAC System Startup and Shutdown Times

HVAC systems are typically turned on in the morning well before the building is occupied, and then off in the afternoon well after the building is vacated. This can often result in unnecessary HVAC operation and energy consumption. An optimised startup/shutdown strategy involves the utilisation of a sophisticated control algorithm that utilises machine learning based models for calculating the latest possible start time and earliest possible shutdown time, thus saving unnecessary operation and energy.

2.2. Enabling Technologies

To support the aforementioned control strategies, CSIRO has developed a number of enabling technologies to assist the Intelligent HVAC Controller in data acquisition, control of HVAC plant, and assessment of human comfort. These technologies, as detailed below, have been designed to be low in cost and to enable ease of deployment, particularly for retrofit style installations on existing buildings.

2.2.1. Informative Alerting & Comfort Feedback Software

One of the factors that affect our satisfaction with our surroundings is the ability of an individual to control his or her environment. Equipping an occupant with a mechanism to provide some level of control over their individual space whilst providing fair and timely distribution of system capacity can be used to promote thermal acceptability, comfort and increased energy savings. To facilitate this, virtual human comfort sensors consisting of a human comfort level feedback mechanism (e.g. electronic comfort survey or comfort push buttons) integrated with sophisticated comfort models are being trialed for their effectiveness in increasing comfort and reducing energy consumption.

The use of an advanced alerting system via an occupant's personal computer increases occupant awareness of a change in HVAC operating mode, thus maximising the potential for promoting thermal acceptability and encouraging energy saving behaviours. CSIRO has developed HVAC Alert software that resides on an occupant's personal computer, informing them of a change in HVAC mode of operation (e.g. Air Conditioning, Natural Ventilation, Peak Demand) via a small colour coded icon and informative "pop-up" message alert. This software also has the capability to provide historical performance data, as well as comfort feedback functionality via an electronic survey for collecting an occupant's perceived comfort level. Fig. 1 shows a screen shot of the HVAC Alert software indicating the current HVAC mode of operation via a small icon and pop-up alert, with the user submitting comfort feedback information via an electronic survey.

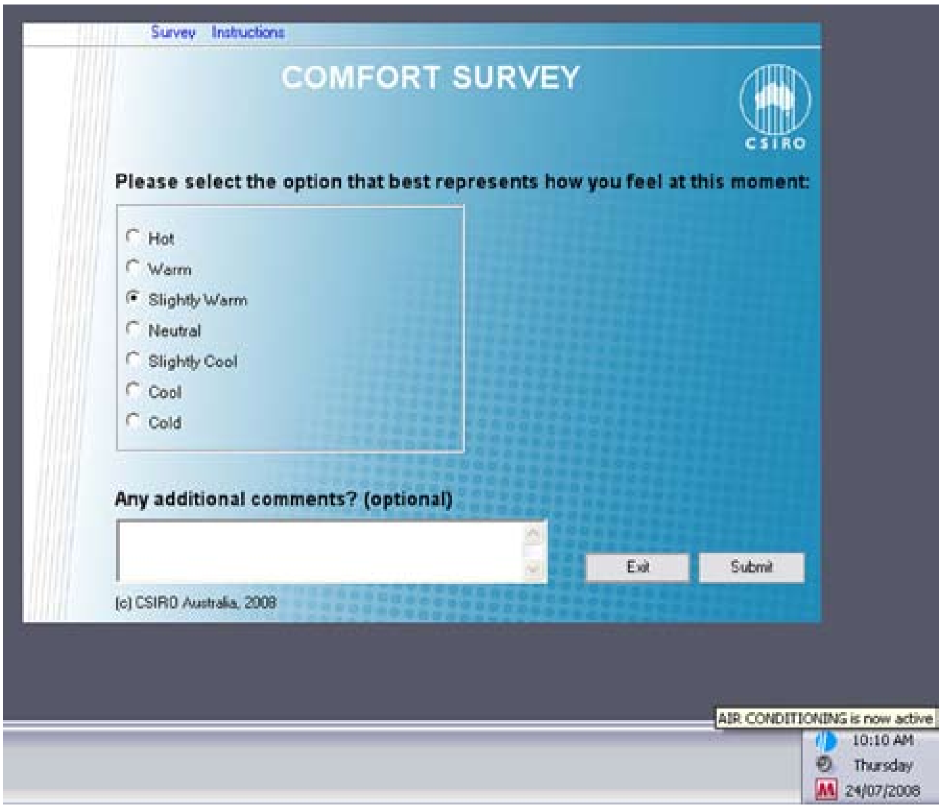

Fig. 1. HVAC Alert software with electronic comfort survey.

2.2.2. Wireless Sensor Networks

It is common in commercial buildings to condition the temperature of multiple spaces or rooms with a single HVAC system and controller. Whilst typical HVAC systems use wired sensors for transmitting information such as room temperature and humidity back to the central controller, such installations can be expensive. As such, typical HVAC installations often have a limited number of sensors located in a subset of the rooms being controlled. This method of deployment erroneously assumes every room is the same temperature as the room containing the temperature sensor. The resulting energy inefficient control decisions often cause unnecessary heating or cooling and occupant discomfort. WSN technology alleviates the deployment costs associated with conventional wired sensors and controller hardware; facilitating high spatial resolution sensor data (temperature, humidity, occupancy) for retrofit applications, with advanced capabilities including ad hoc installation, robust self-healing communications, control and actuation of HVAC plant, and up to 5 years battery operating life.

3. HVAC System Modelling and Control Optimisation

To enable intelligent scheduling of HVAC systems, a model is required that can evaluate the system response to the range of possible control actions. To allow such a supervisory control system to be easily installed and commissioned in both new and existing buildings, the "black box" models presented here are able to learn the response of the system by observing the control signals, external conditions and the resultant outputs. Once a model has been fitted to the system under control, it is able to be used as part of an optimisation loop which evaluates a range of possible control actions to identify a control strategy that minimises a number of parameters that affect operation.

As illustrated in the Fig. 2, the model is able to observe outside air temperature and zone power consumption, and learn their relationship to zone humidity and temperature. The optimisation process then identifies a range of desirable power profiles, obtains detailed ambient air temperature forecasts, and uses them simulates the zone temperature and humidity throughout the day.

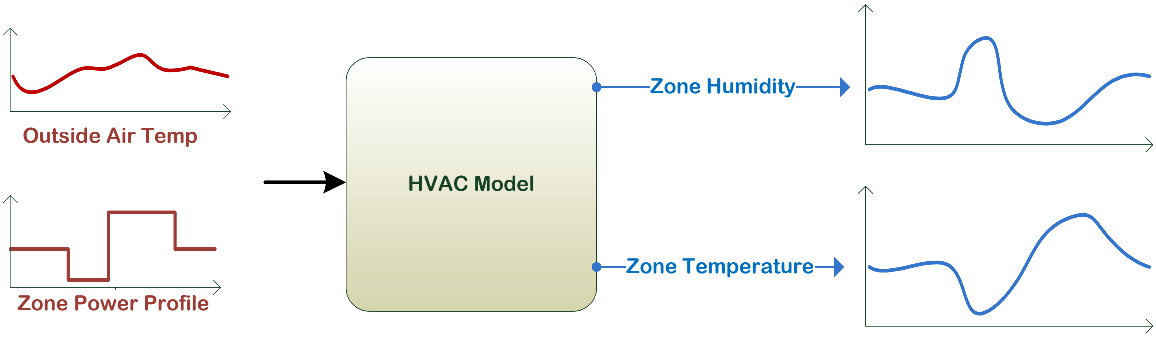

Fig. 2. Functionality of the zone power model.

This system is designed to be useful for the large range of existing HVAC installations, and the wide variety of different operational priorities they require. Some building managers may value the comfort of their occupants above the cost of operating their plant, while others may wish to reduce CO_2 emissions and claim carbon credits in a carbon trading scheme. Energy retailers absorbing the financial risk of fluctuating market spot prices may give incentives to large HVAC operators for demand response capabilities, and installations on time-of-use electricity pricing schemes may wish to pre-cool to avoid high running costs during peak price periods. This optimisation process is designed with all these priorities in mind and will allow operators to specify their preferences based on three criteria – their desire to minimise occupant discomfort, running cost and carbon emissions. This is done by specifying a cost function of the form:

$$\text{Cost}(t) = \alpha.\text{PPD}(t) + \beta.\text{energy}(t).\text{price}(t) + \gamma.\text{energy}.\text{CO}_2\text{Factor} \quad (1)$$

where α, β and γ are user-assigned values which specify how to weigh the three parameters during the optimisation, PPD is the Predicted Percentage Dissatisfied (%) comfort metric (ISO, 2005), energy is the power (kW) consumed by the HVAC system, price is the current energy price ($/kWh), and $CO_2Factor$ is the full fuel cycle emissions factor (kg CO_2/kWh) as reported in (Department of Energy & Climate Change, 2008).

The basic optimisation process is as follows:

1. The optimiser identifies a desirable power profile for the zone throughout the day.
2. *Power profile*, *weather forecasts* → **Zone Model** → *zone temperature profile*, *humidity profile.*
3. *Zone temperature profile*, *humidity profile*, *comfort parameters* → **Comfort Model** → *comfort profile.*
4. *Comfort profile, power profile, energy price forecast profile* → **Cost Unit** → *cost*.
5. Repeat with a range of potential power profiles and select lowest cost profile to follow.

The cost unit is a module that knows how to aggregate the three profiles over the course of the day and give a single number that represents their combined sum. This sum is the number that the optimisation is designed to minimise. The best power profile identified by the optimisation run is provided to a simple feedback control loop which manipulates the zone's set-point to match the power consumption. In this way, we are able to guarantee a given power consumption level at any given time, thus meeting the performance limits imposed during the optimisation run.

The advantage of this approach is the ability to evaluate the utility of control actions performed now, based on the impact they have on the system later in the day. Evaluation of many different strategies, such as optimised startup and shutdown times, load shifting and pre-cooling can all be assessed, and optimisations based on user comfort can prevent uncomfortable conditions on a zone-by-zone basis, potentially achieving significant efficiency gains. Another benefit is that the flexibility of the approach and the self-learning models eliminate the need for detailed measurements of the building and plant (such as zone volume, wall thickness, insulation losses, etc.) to be taken prior to installation, and that it can cater to a large range of preferences on how to optimise the HVAC system operation.

3.1. Thermal Modelling and Energy Prediction

To capture the zone's response to set-point changes and external conditions, several modelling approaches have been taken. Our main approach utilises "black box" models, where the models are derived solely from observation of the input/output characteristics of the system without explicit knowledge of the actual process being modelled. Such models are particularly useful for complex and nonlinear multivariable systems, and the approach avoids the need for any manual configuration of system parameters.

3.1.1. Supervised Learning Model

A widely used black box modelling technique from computer science domains known as a Support Vector Machine (SVM), as first developed by Vapnik (Vapnik, 1995), was employed to learn the relationship between the power consumed by a zone's HVAC plant, and the changes in temperature and humidity inside that zone.

SVMs are a general supervised learning modelling method which performs well on complex problems with high dimensionality, and noisy data. They have been applied in a wide range of real-world applications from stock-market prediction to satellite imagery analysis, and are well suited to learning the complex thermal model presented here. Advantages of this approach are that the model doesn't need to know specifics of the type of data it is dealing with, specific measurements such as floor areas, or the explicit effects of certain parameters on the model output, as it will learn these from patterns in the data provided. This greatly simplifies installation and retrofitting to existing systems, and will allow the model to be applied to a wide range of buildings.

3.1.2. Other Modelling Techniques

Although our research is based heavily on the SVM approach, we are utilising other system identification methods for result validation and to identify any improvements that could be made to our modelling approach. There are two additional modelling techniques we use:

1. Physical principles based modelling – where we have used detailed physical models of chiller characteristics, heat exchanges, fans, pumps, temperature flows and building envelope models. In this case, the systems characteristics are parameterised in a number of variables which we have used a Genetic Algorithm to learn. This is a "grey box" model, being based on a reasonably detailed physical model of the underlying process.
2. Polynomial approach – utilising a "black box" linear time invariant model to approximate the underlying system. The benefit of this model is that it is linear in the fitted parameters, substantially simplifying the model fitting process. Some additional detail of the polynomial approach follows.

The polynomial model utilises HVAC power, ambient temperature and an identified thermal baseload profile for the building to estimate the average zone temperature for the building. This model is of the form:

$$T_{Av} = \frac{k_1 s^2 + k_2 s + k_3}{(\tau_1 s + 1)(\tau_2 s + 1)} T_{Ambient} + \frac{k_4 s + k_5}{(\tau_1 s + 1)(\tau_2 s + 1)} P_{HVAC} + \begin{Bmatrix} Initial \\ Conditions \end{Bmatrix} + \begin{Bmatrix} Thermal \\ Baseload \end{Bmatrix} \quad (2)$$

where:

T_{Av}	is the average zone temperature throughout the building
$T_{Ambient}$	is the ambient (outside) temperature
P_{HVAC}	is the total power consumed by the HVAC system
k_1, k_2, k_3, k_4, k_5	adjustable parameters obtained by best fit to measured data
τ_1, τ_2	are the dominant thermal time constants for the building and HVAC system
S	is the complex Laplace variable
Initial Conditions	accounts for uncertainty in the internal thermal states of the building fabric and HVAC system at the start of the measurement period. These initial conditions result in a transient that is a combination of the natural modes of the system and hence is of the form: $k_6 e^{-t/\tau_1} + k_7 e^{-t/\tau_2}$. These modes are explicitly identified so as to not bias the system identification.

Thermal baseload — is an identified baseload profile that accounts for different thermal loads throughout the day. This will be dependant on factors such as solar gain and the activities of the building occupants. The thermal baseload is parameterised as a piecewise linear function.

This baseload function is assumed to be the same for every day in the data set, so is found by determining the function that when subtracted from each day of the recorded building data yields the best fit to the measured data.

Utilising data from a trial building with a conventional VAV system, five minute interval data for 16 of the hottest days was fitted to the polynomial model using regression analysis to determine the various parameters. The coefficient of determination of the fit over this data set is r^2=0.956, suggesting that the model provides a good fit. Additional second order terms were evaluated (i.e. power squared) but they did not significantly alter the quality of the fit so are not included in the model. The fit is shown in Fig. 3.

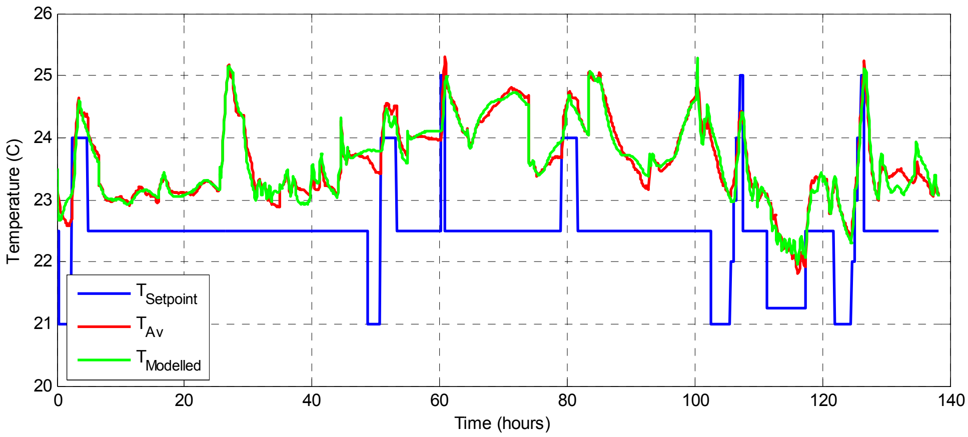

Fig. 3. Comparison of modelled and measured average zone conditions.

3.2. Optimisation Framework

Implementation of the optimisation system is derived from the Model Predictive Control (MPC) technique which is well suited to optimal control of complex processes with nonlinearities, state constraints and actuator saturations. At each sample time (every 5 minutes), the following actions are performed:

1. Current system state is measured and the system model is updated based on the new data;
2. A forecast is obtained for exogenous inputs to the system – specifically energy price data & weather forecasts for the next 24 hour period;
3. Utilising the cost function described in equation (1)– that is, a multi-objective function describing our desire to minimise PPD, CO_2 emissions & dollar cost– the optimal HVAC power profile for the next 24 hours is determined. This required running the model multiple times with different power scenarios. Depending on the model and constraint complexity, different optimisation techniques have been used, the fastest being the case of a simplified polynomial (LTI) model, for which the optimisation reduces to the well known quadratic programming (QP) problem.
4. The Building Management System runs the HVAC power at the level of the first 5 minute interval in the optimised HVAC power profile.
5. The system state is again measured and then we return to step 1.

By only every applying the first control interval of the optimised HVAC power profile, the system is able to quickly re-optimise and correct for any disturbances from the predicted strategy.

3.3. Trial Deployment Sites

To evaluate our models and techniques, two commercial buildings have been used. The first building is located at the CSIRO Energy Centre in Newcastle, Australia, and consists of around 2,911m^2 of conditioned office space serviced by an under-floor air distribution (UFAD) system. The second building located in Melbourne, Australia, consists of a VAV system servicing 10,555m2 of commercial office space.

In the following section, we show some typical optimisation results for full day ahead forecast under different optimisation criteria.

4. Results and Performance Analysis

In this section, we utilise the polynomial model described in section 3.1.2 and applied one HVAC zone of the CSIRO Energy Centre building, to demonstrate the results obtainable from our multi-objective optimisation approach. The polynomial model was trained using data from early January 2008, and the results are shown for the day of 31st Jan 2008.

Fig. 4 shows both zone temperatures and HVAC power consumption for 3 scenarios. These are (i) the actual measured zone data (solid line), (ii) a maximum thermal comfort control strategy (dashed line), and (iii) a CO_2 minimisation strategy that provides the same average thermal comfort as (i), but with minimum CO_2 emissions (dash-dot line). The plot also shows ambient temperature for reference (dotted line).

The most obvious feature of the optimised scenarios, is the apparent startup time optimisation– this is not an explicit feature of the system, but rather emerges from the optimisation process since our metric for PPD is only evaluated over business hours (8:30am to 5:00pm), so the optimised system does not run any longer than absolutely necessary to provide thermal comfort over this time interval. The comfort and CO_2 emissions improvements for the two scenarios are somewhat harder to see, though are clear from the metrics presented in Table 1.

Scenario	Average PPD	Daily CO_2 emissions	Daily Energy Costs
Baseline – as measured from existing BMS	5.2	44 kg	$6.23
PPD minimisation	5.06	40 kg	$6.74
CO_2 minimisation	5.2	31.4 kg	$5.38

Table 1: Comfort, CO_2 emissions and energy costs corresponding to Figure 4.

Of most interest here is that while maintaining identical thermal comfort to the existing BMS, we see that substantial savings on both energy costs & CO_2 emissions are feasible. (Note that although per zone savings seem small, there are around 100 zones throughout the building)

By allowing the building manager or user to determine the relative weightings given to the competing performance objectives, they are empowered with explicit knowledge of tradeoff being made when selecting a particular control strategy. This tradeoff is further explored in Fig. 4, where we show two scenarios of different energy cost structures and their effect on the optimisation process.

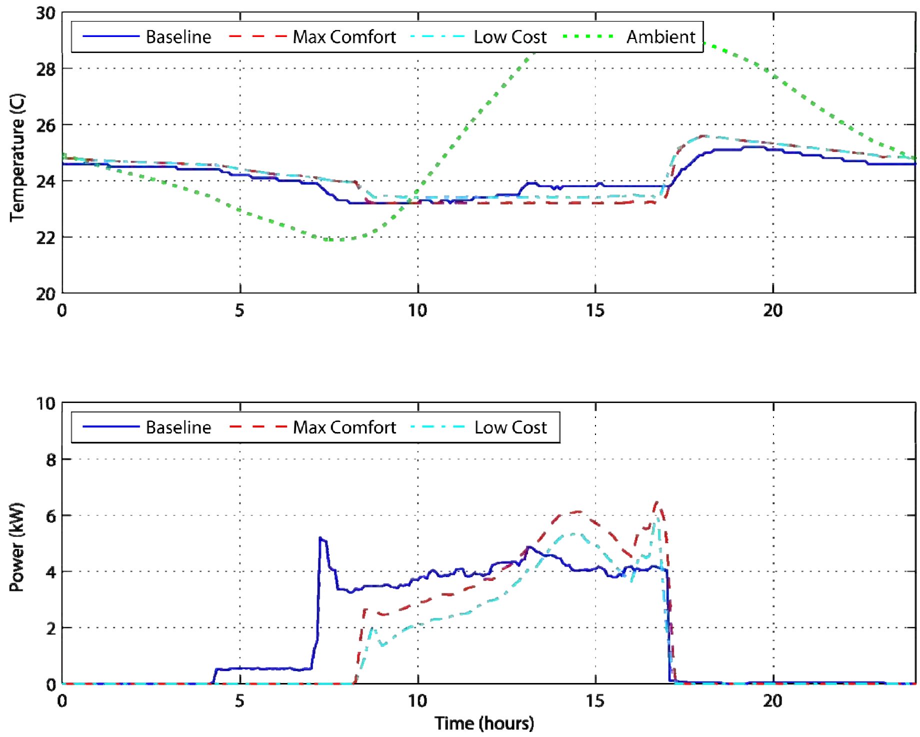

Fig. 4. Comparison of actual HVAC performance, and simulated performance under PPD & CO_2 minimisation strategies.

In Fig. 5, the baseline existing BMS strategy is shown (solid line) along with optimised scenarios for Time-Of-Use (TOU) energy pricing (dashed line), and the more novel Real-Time-Pricing (RTP) option where consumer prices are directly based on wholesale prices on the Australian National Energy Market. For these scenarios, the same optimisation objective function was utilised, though with the price spike on the energy market, significantly different behaviour is observed. As with the apparent start-up time optimisation previously noted, an electricity network demand response *emerges* from the optimisation rather than having to be explicitly programmed. Performance of these energy cost minimisation strategies are given in Table 2.

Scenario	Average PPD	Daily CO_2 emissions	Daily Energy Costs
Baseline – as measured from existing BMS	5.2	44 kg	$6.23
TOU cost minimisation	5.2	32.9 kg	$5.16
RTP cost minimisation	5.94	21.32 kg	$4.90

Table 2: Comfort, CO_2 emissions and energy costs corresponding to Figure 5.

As with the earlier comfort and CO_2 emissions, the multi-objective optimisation framework here allows direct evaluation and control of the tradeoffs being made, and so empowers the user with the knowledge to optimise their system according to their objectives.

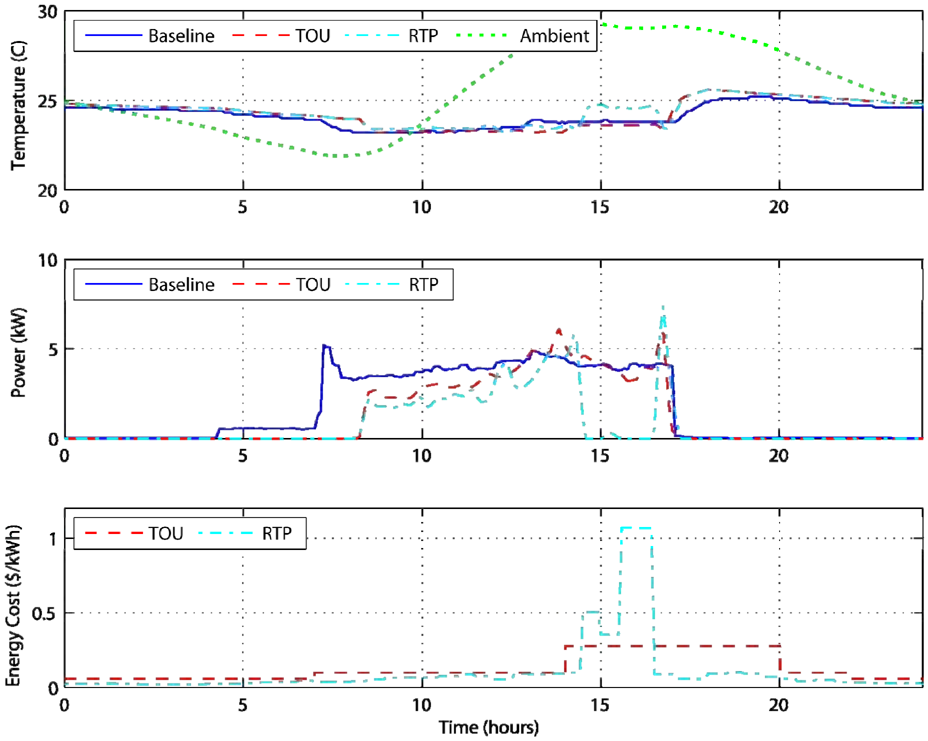

Fig. 5. Comparison of actual HVAC performance, and simulated performance under TOU & RTP cost minimisation strategies.

5. Conclusion

Using machine learning techniques and integrated enabling technologies, CSIRO is developing optimised HVAC supervisory control techniques applicable to both new and existing building stock for achieving increased end-use efficiency and peak demand reductions. Results from initial technology trials on two commercial office buildings show that reductions in HVAC energy and CO_2 in the order of 10-15% are achieved for a simple adaptive scheme without loss of thermal comfort. Theoretical performance analysis has shown potential energy and CO_2 reductions of up to 30% without loss of thermal comfort. Further savings are expected to follow current trials with full implementation of CSIRO's technology.

Keywords: Airflow Window, U-factor, Solar Heat Gain Coefficient, energy recovery, Thermal Image

Summary

This paper presents a system description and results of field measurements for two new energy recovery systems installed in a high-rise office building in Tokyo. The first is the new airflow window system in which air exhausted from a rotary heat exchanger is channeled between panes of a double-glazed window to improve fenestration performance. In this study, the U-factor and Solar Heat Gain Coefficient of this system were developed from measurements. The second is an “under floor cooling water i.e. a condensing water circulation system” for heating, in which cooling water is circulated through tubes laid in cinder concrete on the slab to reduce heating load of a public passage on the ground level of this building. Thermal comfort in the passage is improved by this system. This building requires cooling through the year, so heat can be provided by cooling water of a centrifugal refrigerator even during winter nights. This paper describes thermal images and heating load reduction achieved by this system. The U-factor and Solar Heat Gain Coefficient of this new airflow window system and heating load reduction by “the under floor cooling water circulation system” obtained through these measurements can be used for more accurate calculation of cooling and heating load for future projects.

1. INTRODUCTION

A high-rise headquarters building has been designed and constructed for “FUJI SOFT inc.” in Akihabara Tokyo. It incorporates various kinds of green engineering technologies in accordance with the owner’s requirements. This paper describes two systems developed using these technologies, called "EXAFW" and "UCCS."

When an airflow window and a rotary heat exchanger are used together, the rotary heat exchanger is usually installed downstream of the airflow window. However, EXAFW is a new system in which the rotary heat exchanger is installed upstream of the airflow window. This building has a refresh area at the south-west corner of the office floors. The exterior appearance of the corner facing the Akihabara station plaza was the most important point of the design. The architects required "transparency" using full-height, clear glazing. At the same time we needed to cut down the large air-conditioning load coming through the full height fenestration facing south-west and save energy. EXAFW was developed to resolve these two conflicting requirements. The air flow window is known as high energy performance fenestration. However, when a rotary heat exchanger is also used, the overall energy performance could drop. In a conventional airflow window system, room air is drawn between double panes, heated or cooled within them, led to a rotary heat exchanger, and discharged to the outside. The temperature of the air entering the rotary heat exchanger is higher in summer and lower in winter than room air temperature. It is inefficient to recover the exhaust air energy. Additionally in winter, when the dew point temperature of room air drawn between the double panes remains above the inner surface temperature of the outside pane, condensation will occur. Thus, the new airflow window system "EXAFW" was developed, in which exhaust air from the rotary heat exchanger flows between the double panes and is then exhausted. The U-Factor and SHGC of EXAFW were necessary to calculate the air-conditioning load. In the literature, Ishino et al. (1995) described the U-Factor and SC of conventional airflow windows. However, the U-Factor and SHGC of EXAFW were not available. The authors then carried out a full-size mockup experiment and estimated these values based on calorimetric measurement, as shown in the article by Numata et al. (2006). In 2007, the high-rise office building equipped with EXAFW’s was completed. In August 2007 summer peak field measurement, and in January 2008 winter peak field measurement were carried out. This paper provides calculated U-Factor and SHGC of EXAFW based on these field measurements.

“UCCS” is “the under floor cooling water circulation system”. In this building, there is a public passage leading through to the station. As this passage has frequent pedestrian traffic, infiltration through the entrance doors increased heating load. Energy and cost efficient equipment is required for this public space. Meanwhile the building is the head office of a software house, and the building has cooling demand through the year. The chillers are running through the year and condensing heat is discharged from the cooling tower even on winter nights. Since it is difficult to utilize such low potential condensing heat, we tried to use this cooling water directly to warm the floor structure of this passage. In this system, cooling water is circulated through tubes laid in the cinder concrete on the slab to reduce the heating capacity of the air-handling unit and to maintain thermal comfort for passengers. This paper provides thermal images comparing a UCCS equipped floor with a conventional floor, and estimates heating load reduction.

2. System Description

2.1 EXAFW

The full-height EXAFW is installed at the southwest corner of the office building, which has 31 floors and a gross floor area of 58,500m^2. Exterior and interior views of EXAFW are shown in Figure 1.

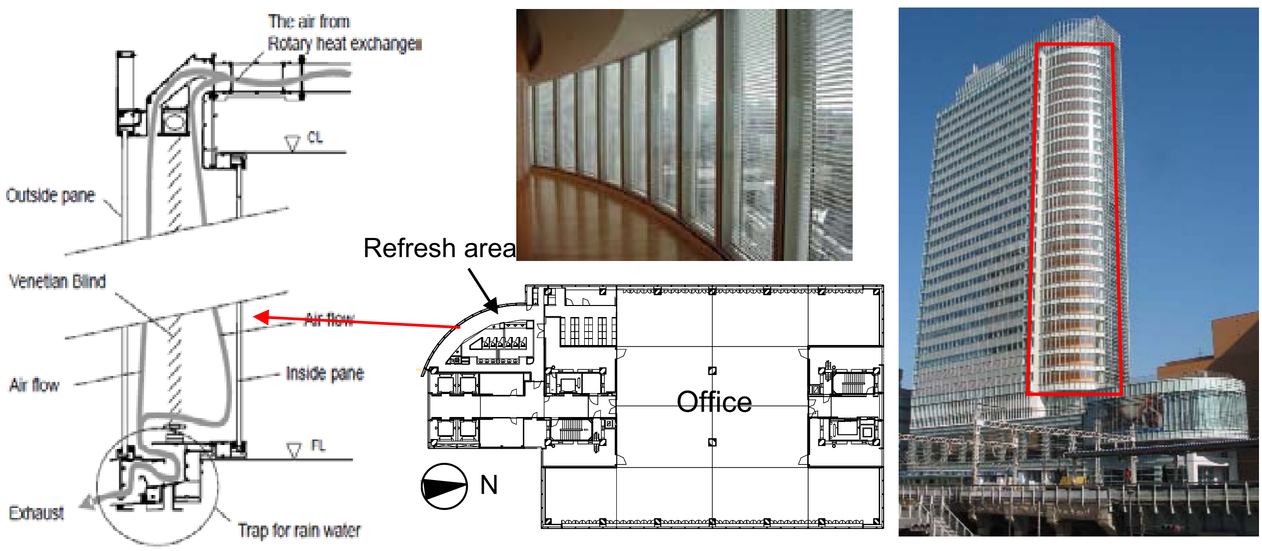

Figure 1. Exterior / interior view of EXAFW and typical floor plan

A schematic diagram of the EXAFW is shown in Figure 2. The return air from the room enters the rotary heat exchanger and passes heat to fresh outside air. The air leaving the rotary heat exchanger enters the double-glazed cavity and is then exhausted from the building. The flow rate of exhaust air is 290m^3/h per unit bay window (1100mm×2600mm). This flow rate is higher than that of a conventional airflow window. To obtain enough exhaust air for the EXAFW, the air exhausted from the office is used for the refresh area, as shown in Figure 1. The new system has the following features: (1) Since the exhaust air from the rotary heat exchanger is used, fresh air loads are reduced. (2) There is no condensation on widow panes in winter.

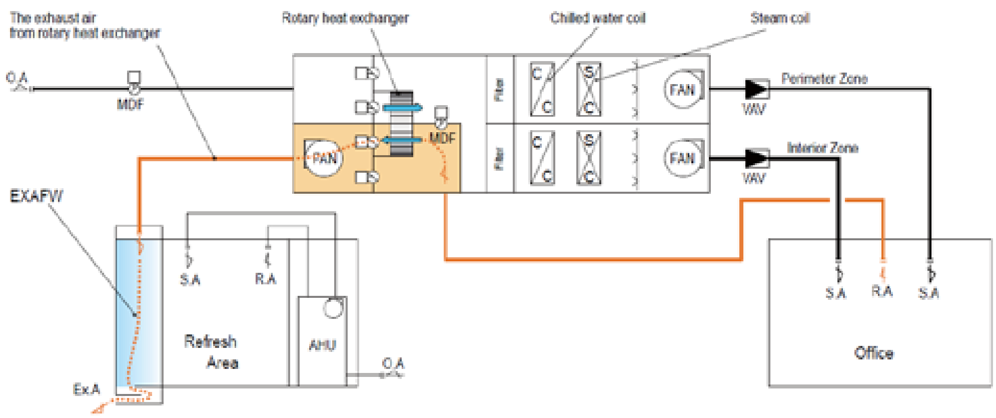

Figure 2. Schematic diagram of EXAFW

2.2 UCCS

The public passage on the ground level of the building has a large heating load due to intruding outside air. A moderate room temperature condition was adopted for a single-duct air-conditioning system. The UCCS was developed as the auxiliary system of this moderate air-conditioning system. Since the building has cooling demand through the year, cooling towers run even on winter nights. By channeling the cooling water returning to the cooling tower to the passage floor, the heat of cooling water, which is usually discharged to outside air, is utilized and the following benefits are achieved in winter. (1) Reduction of heating load of the moderate air-conditioning system. (2) Improvement of thermal condition by reducing cold radiation from the floor. A schematic diagram of the UCCS is shown in Figure 3 and the area of the UCCS is shown in Figure 4.

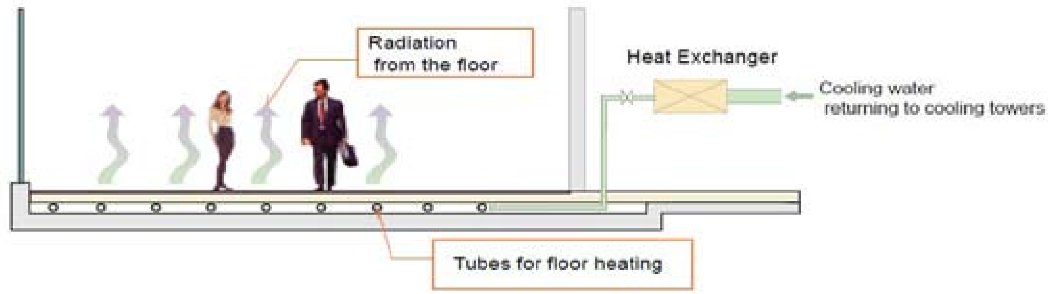

Figure 3. Schematic diagram of UCCS

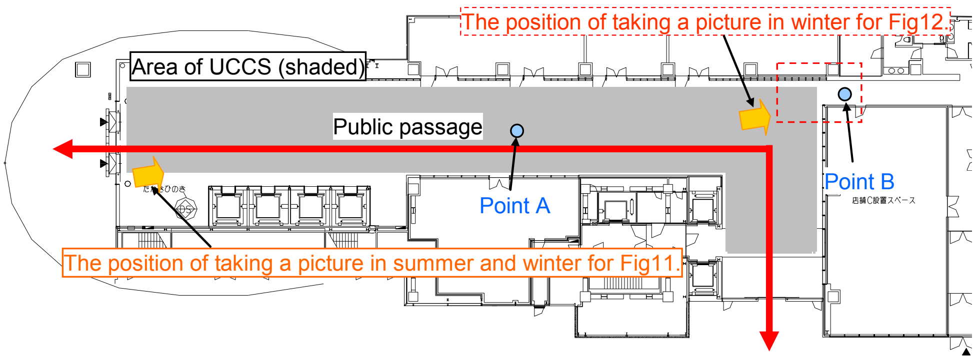

Figure 4. Area of UCCS (Shaded)

3. Measurements

3.1 Measurement of thermal performance for EXAFW

U-factor and Solar Heat Gain Coefficient of EXAFW are provided based on measurements as follows.

3.1.1 Night-time measurement

To avoid the influence of solar radiation, measurements for estimating U-factor were performed at night. The inner surface heat flux q_t (W/m^2) of EXAFW is calculated as:

$$q_t = q_c + q_r \qquad (1)$$

where q_r is measured inner surface heat flux caused by radiation (W/m^2) by a radiant temperature asymmetry transducer, as shown in Figure 5. Heat flux q_c caused by convection (W/m^2) is calculated as:

$$q_c = h_c(\theta s - \theta r) \qquad (2)$$

where hc is convection heat transfer coefficient (W/(m^2·K)), and θs, θr are surface and room air temperature(°C).

Henmi (2003) indicated hc as:

$$h_c = 1.98(\theta s - \theta r)^{1/4} \tag{3}$$

U-factor U (W/(m^2·K)) is calculated as:

$$U = \frac{q_t}{\theta o - \theta r} \tag{4}$$

We measured inner surface air temperature θs, room air temperature θr and ambient outside air temperature θo; calculated heat flux q_c caused by convection using equation (2); and also measured heat flux q_r caused by radiation. Inner surface heat flux q_t and U-factor are calculated by equations (1) and (4).

3.1.2 Multiple linear regression analysis

At night, the inner surface heat flux of EXAFW varies according to 4 parameters: (1) temperature of air entering EXAFW, (2) ambient outside air temperature, (3) room air temperature, and (4) air flow rate. The air flow rate is fixed. By night-time measurements we observed various sets of these values under real conditions. Using multiple linear regression analysis, the night-time (without solar radiation) heat flux $q_{t,night}$ (W/m^2) caused by three air temperatures θ_i, θ_r, θ_o (°C) can be expressed as:

$$q_{t,night} = f(\theta i, \theta r, \theta o) \tag{5}$$

$$f(\theta i, \theta r, \theta o) = a\theta i + b\theta r + c\theta o + d \tag{6}$$

where θ_i is the temperature of air entering EXAFW, $f(\theta_i, \theta_r, \theta_o)$ is a function for estimating the heat flux $q_{t,night}$ caused by three air temperatures θ_i, θ_r, θ_o, and a, b, c, d are coefficients of the multiple regression equation. We note that these values are not influenced by solar radiation.

3.1.3 Daytime measurement

During daytime, the inner surface heat flux is considered to consist of heat flux caused by solar radiation and heat flux caused by three air temperatures θ_i, θ_r, θ_o (without solar radiation). Solar heat gain coefficient (-) is given by:

$$SHGC = \frac{I_1 + q_C + q_r - f(\theta i, \theta r, \theta o)}{I_0} \tag{7}$$

where I_0 and I_1 are incident and transmitted vertical solar intensity(W/m^2). We measured the incident and transmitted vertical solar intensity at the outside and inside of EXAFW, and measured the inner surface heat flux q_r caused by long wave radiation as shown in Figure 5. We calculated the inner surface heat flux q_c caused by convection using equations (2) and (3). SHGC is calculated by equation (7). We note that the heat flux q_r caused by long wave radiation includes absorbed solar radiation, and transmitted solar radiation is expressed by I_1.

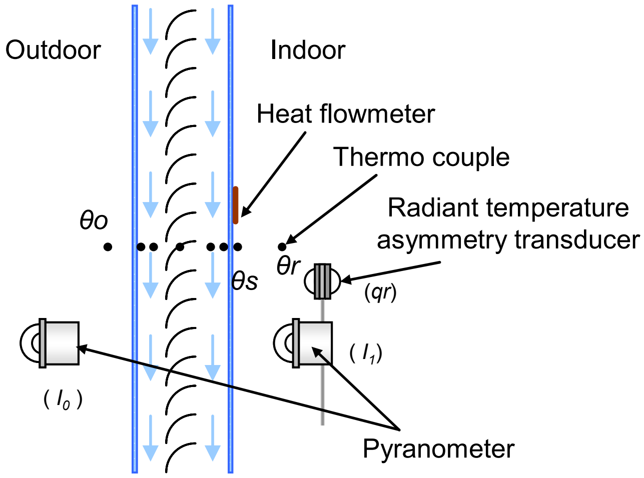

Figure 5. Measurement apparatus on EXAFW

3.2 Thermal imaging and temperature measurement of UCCS

Thermal images, floor surface temperature, air temperature and globe temperature in the public passage were measured as shown in Figure 6. Under floor sand temperature, flow rate and temperature of circulating cooling water were measured by BEMS of the building.

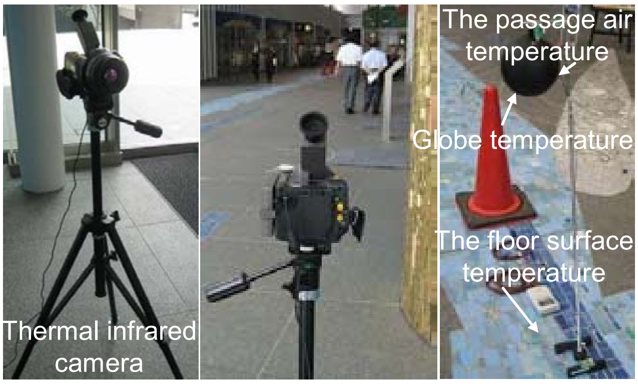

Figure 6. Measurement on UCCS

4. Results

4.1 Night-time inner-surface heat flux and U-factor of EXAFW

As the results of night-time measurement, U-factor, ambient outside air and room air temperature are shown in Figure 7. U-factor varied from 1.1 to 1.8 and averaged 1.6.

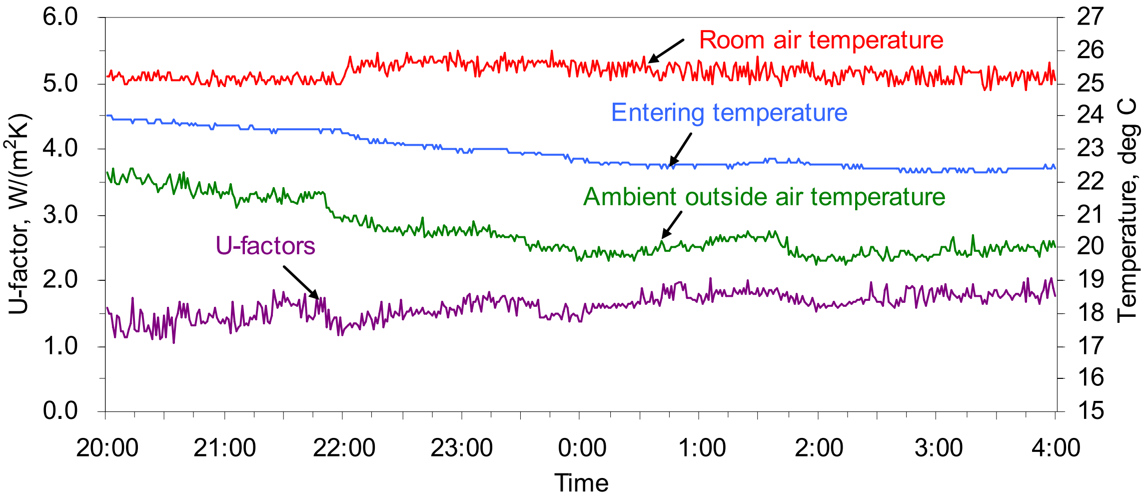

Figure 7. U-factor of EXAFW (July 30th and 31st, 2007)

We carried out a regression analysis using those measured data and the obtained model of "the heat flux caused by three air temperatures θ_i, θ_r, θ_o (without solar radiation)". $f(\theta_i,\theta_r,\theta_o)$ (W/m^2) is written as:

$$f(\theta i,\theta r,\theta o) = -2.86\times\theta i + 2.78\times\theta r - 0.11\times\theta o + 5.24 \quad (8)$$

4.2 Daytime inner surface heat gain and SHGC of EXAFW

Incoming vertical solar radiation and ambient outside temperature measured in a peak summer day are shown in Figure 8. The blind slat angle was kept vertical. Figure 9 shows daytime heat gain through EXAFW. Figure10 gives the SHGC of EXAFW. SHGC is approx. 0.05~0.10 and the mean value is 0.7 (blind at 90°). Long wave radiation, convection and solar radiation transmitted through EXAFW make up 58%, 30% and

12%, respectively. We can find an extremely large value of SHGC. This is because the response speed of the pyranometer is quicker than that of the thermocouple on the inner surface of EXAFW. When solar radiation sharply decreased, the change of the inner surface temperature was delayed by the thermal capacity of the window pane.

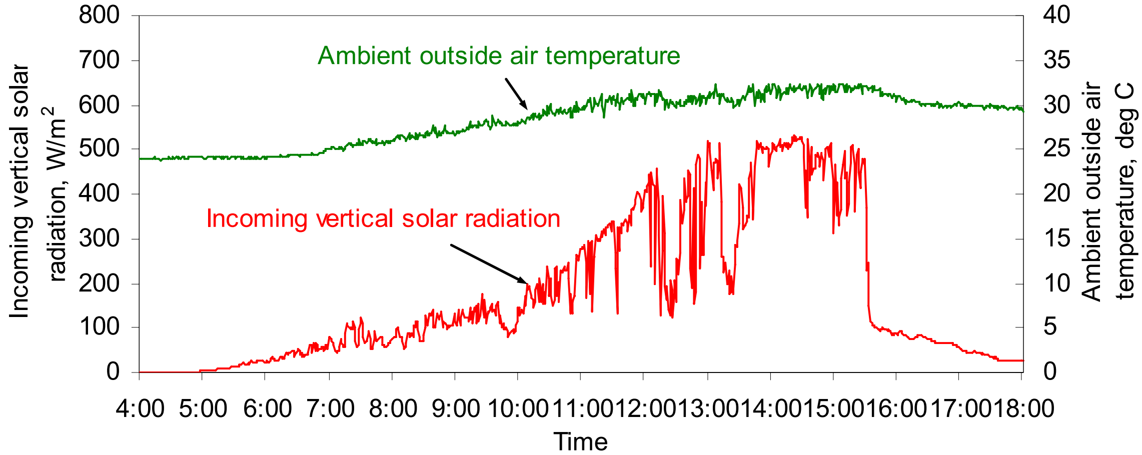

Figure 8. Incident vertical solar intensity and ambient outside temperature (August 1st, 2007)

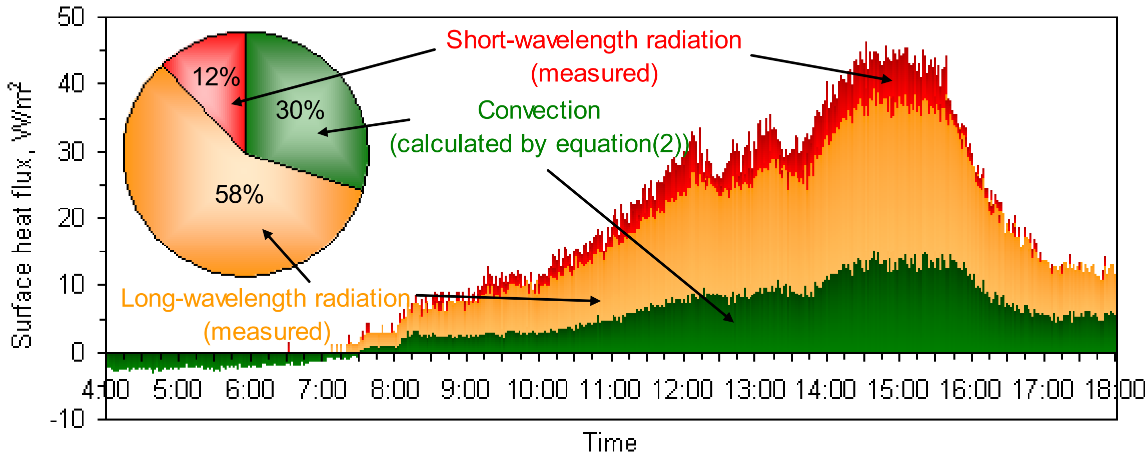

Figure 9. Daytime inner surface heat gain of EXAFW (August 1st, 2007)

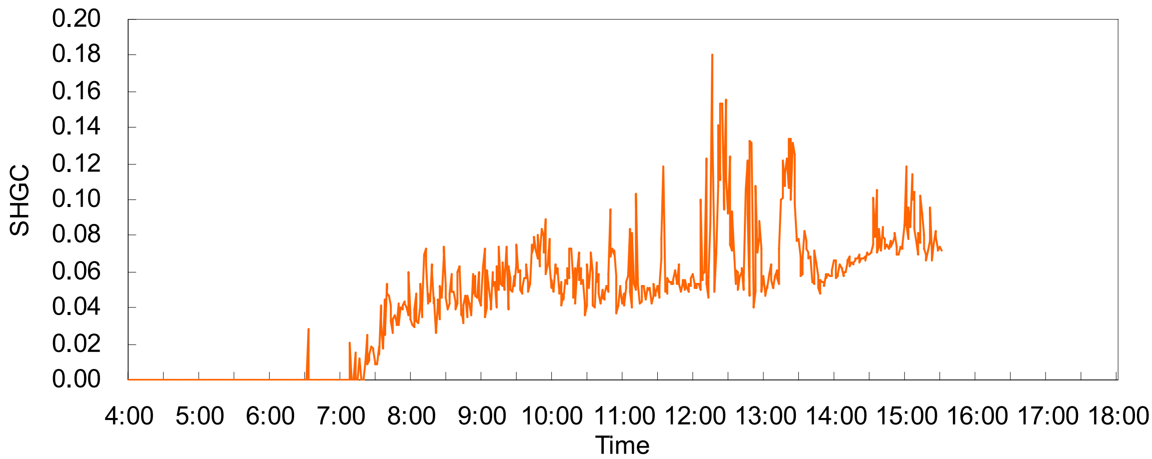

Figure 10. SHGC of EXAFW (August 1st, 2007)

4.3 Thermal images of UCCS

Figure 11 shows a thermal image of the UCCS, and Figure 12 and Figure13 compare the UCCS-equipped floor with the normal floor. The surface temperature difference between the UCCS-equipped floor and the normal floor is approx. 3K. When the heat transfer coefficient is assumed to be 8 W/(m^2.K), the heating load reduction of the air-handling unit for the passage is estimated to be 24 W/m^2.

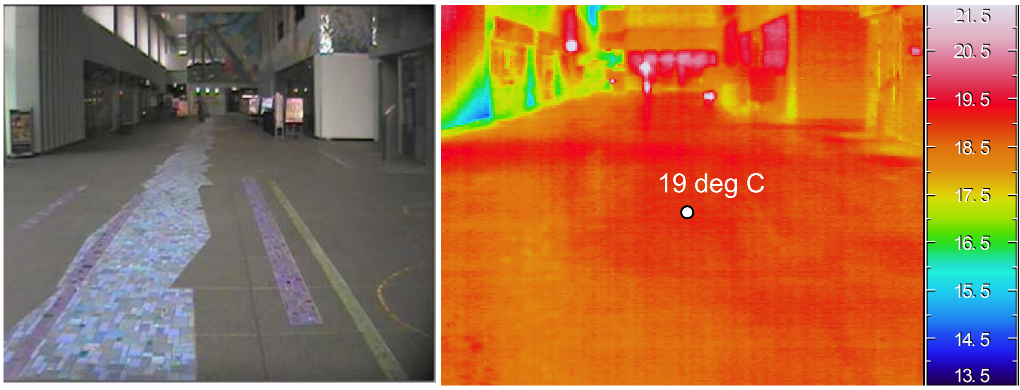

Figure 11. Thermal image of UCCS (10:40 February 2nd, 2008)

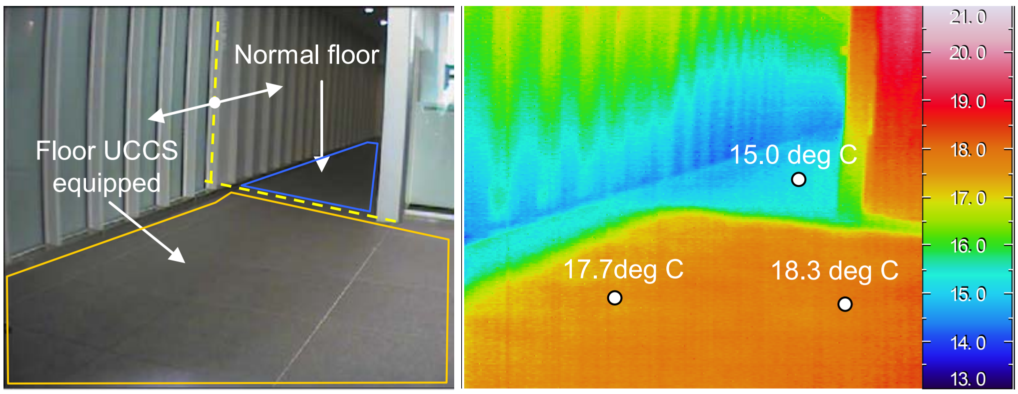

Figure 12. Comparison of UCCS-equipped floor with normal floor (10:40 February 2nd, 2008)

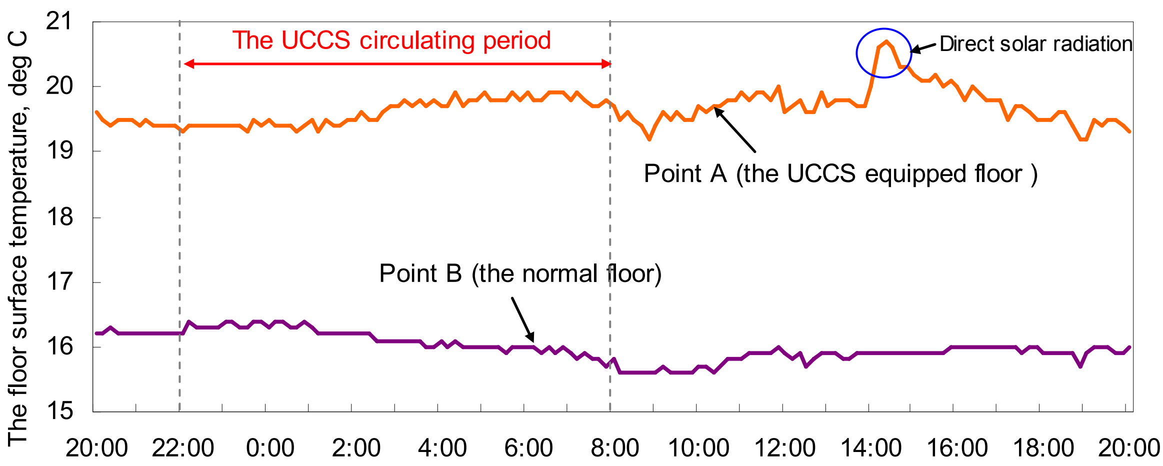

Figure 13. Comparison of floor surface temperature (February 14th and 15th, 2008)

5. Discussion

We estimated the U-factor and SHGC of EXAFW to be 1.6 and 0.07 (blind at 90°) based on field measurements. These performances are similar to those of conventional AFW (U=1.3, SHGF=0.17, 80m^3/h, blind at 45°). We note that the ventilating flow rate of EXAFW (290m^3/h) is 3.6 times that of the conventional AFW (80m^3/h). We tried to calculate and compare the cooling load of EXAFW against that of the conventional AFW using the above values. The load difference between these two systems comes up in heat gain through fenestration and in fresh air load. The EXAFW has 143% heat gain through fenestration and 93% of fresh air load compared with conventional AFW. Total cooling load of EXAFW is 5% less than that of conventional AFW (Figure 14)

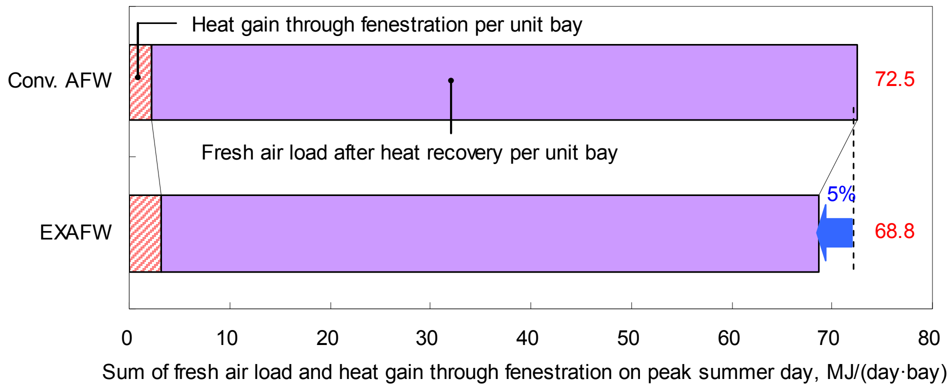

Figure 14. Comparison between EXAFW and conv.AFW

We measured the surface temperature difference between the UCCS-equipped floor and the normal floor. It is approx. 3K averaged over the peak winter day, as shown in Figure 13. The heating load (supplied by the air-handling unit) reduction is estimated to be 24 W/m^2. According to BEMS measurement data, averaged heating load over winter is 184 W/m^2. Thus, it is estimated that UCCS reduces the winter season heating load by13%.

6. Conclusion

We applied two new green technologies and produced the new airflow window system (EXAFW) and "the under floor cooling water circulation system"(UCCS), and applied them to a high rise office building. We measured the thermal performance of these systems, and determined the U-factor and SHGC of EXAFW and the heating load reduction by UCCS. We compared the cooling load of EXAFW including fresh air load against that of conventional AFW, and obtained a 5% reduction. The UCCS reduces heating load of the public passage by 13% and saves gas consumption of boilers. This information can be used for more accurate calculation of air conditioning load and for design of these new systems.

Acknowledgements

We thank Reiji YAMADA, Hitoshi TABEI, and Ichiro ISHII for permission to take measurements in the FUJISOFT Akihabara Building.

HOLISTIC LIFE-CYCLE GHG EMISSIONS ASSOCIATED WITH BUILDINGS

Keywords: Greenhouse gases, life-cycle, holistic, sustainable, building, accounting, planning tool

Summary

In this study we have developed a model to calculate greenhouse gas (GHG) emissions associated with buildings and development projects. The purpose of the study is to give property owners and managers a *GHG emission accounting tool* for existing buildings, which also can function as a planning tool for urban planners, architects and advisors in construction.

The model consists of four modules: 1. Embodied emissions from building materials, 2. Emissions from construction and earthwork, 3. Emissions from annual operational energy, 4. Emissions from use-phase transport.

The model has been tested on six Norwegian building projects, and the results have been compared with the results from two housing examples in Canada (Norman et al. 2006). The results from the Norwegian examples are in the same range as the Canadian findings, i.e. between approx. 40 and 90 kg CO_2 equiv. per m^2 per year.

The results demonstrate the importance of moving towards a more holistic life-cycle based understanding of GHG emissions associated with buildings. If we compare the buildings and the main sources, the results show that factors such as location, use of the building (function) and choice of energy solutions have the greatest impact on emissions. As emissions from operation-phase stationary energy use and transport are reduced, emissions from materials will become relatively more important.

The results show that the choices that give the lowest emissions of greenhouse gases are:

- Choice of energy-efficient design and renewable sources of energy and carriers can reduce emissions by more than 50 %.
- Central location and/or proximity to a good public transport system – emissions from transport linked to use of the building can be reduced by more than 50 %.
- Renovation and reuse of buildings – emissions can be reduced by 60–70 % compared with a new building.

It must be stressed that we need more examples and research to provide information about different types of building projects, architecture, location, public transport, etc., as well as further refinement of methods for comparing projects. As more examples become available calculated using the same method, it will be possible to set benchmarks for different types of buildings.

IPCC (2007) recommended global reductions by around 85 % against 2050. If we compare the preliminary results with this recommendation, the emissions from building projects ought to be lower than approx.10 – 15 kg CO_2 per m^2 per year (all sources of emissions).

1. Introduction

Climate change as a result of human emissions is probably the greatest challenge the global community has ever faced. All options must be explored to try to reduce emissions by as much as possible as quickly as possible.

Construction projects contribute to greenhouse gas emissions through the materials produced and transported, energy use during construction, energy consumption when the building is in use, energy use for maintenance, energy use for transport during operation of the building and emissions in connection with demolition and removal. According to the IEA (2005), construction and operation of buildings account for between 30 and 40 % of the world’s energy use. Transport during the operation phase of the building is in addition to this. Overall buildings are responsible for more than 40 – 50 % of the global emissions of greenhouse gases.

The EU and Norway have set themselves the goal that the global mean temperature will not rise by more than 2 °C. The IPCC has calculated that we can achieve this goal with a reasonable degree of certainty if global emissions in 2050 are 50 to 85 % lower than in 2000 (IPCC, 2007, Summary for Policy Makers, table SP.5.). This means an average emission of less than 0.5 tonnes of CO_2 per person per year, taking into account population growth. Today the global average is approx. 4 tonnes of CO_2 per person, and in Norway it is approx. 12 tonnes of CO_2 per person. All avenues for reducing emissions must be explored, and new solutions must be found, if we are going to get down to an individual emission rate of less than 0.5 tonnes of CO_2 per year.

Evaluating greenhouse gas emissions from a life-cycle perspective for building projects will indicate which aspects of the project are responsible for the most emissions; production of the materials used in the building, the construction phase, energy use for heating, cooling, etc. or transport to and from the building during daily operation.

Research from recent years generally only covers emissions from operation and the materials included in the building. The findings suggest that energy use for heating and cooling dominates (Junnila and Horvath 2003, Thormark 2002). It has been shown that the more energy-efficient buildings are, the greater the significance of emissions linked to choice of materials (e.g. Chen et al. 2001; Adalberth 1998).

At the same time, others have stressed that location and urban development are an integral part of a building project's total greenhouse gas emissions, and in many cases this factor can be the dominant one (Næss 2006; Anderson et al. 1996; Newman and Kenworthy 1999; Gurin 2003).

A study from Toronto compared two different types of housing developments: blocks of flats in the centre of town and detached houses in a suburb. The results underline the importance of location in reducing emissions from transport, but also that emission from stationary energy use is lowest in blocks of flats/urban developments. Emissions from use of materials were less significant (Norman et. al 2006).

Statsbygg is Norway's largest government property agency in the civil sector with a property portfolio of approx. 2.3 mills. square metres over 1500 properties in Norway and overseas. In 2007, Statsbygg completed 28 building projects. Statsbygg's main clients are central government agencies such as ministries, directorates, universities and colleges. Core activities are planning, providing advice on construction matters, property management and management of building projects. Statsbygg is a government corporation with 720 employees. Statsbygg wishes to lead the way in developing environmentally sustainable solutions.

Planning and developing from an environmental perspective, i.e. long-term ecologically sustainable development, is one of Statsbygg's priority areas. Low emissions of greenhouse gases has been a premise in connection with the transformation of Fornebu, the old main airport area, to a large housing and commercial area on the outskirts of Oslo, the capital of Norway. As part of the work the analysis model www.klimagassregnskap.no has been developed to calculate greenhouse gas emissions for building projects to ensure that greenhouse gas emissions from all phases of the projects can be documented.

The development and testing of the model has provided new knowledge about the importance of different sources of emissions in building projects. Greenhouse gas emissions have been calculated for six Norwegian building projects. These projects are planned and carried out by Statsbygg (4) and Bærum Municipality (2).

2. Calculation model www.klimagassutslipp.no

2.1 The main features of the model

The model for calculating greenhouse gas emissions www.klimagassregnskap.no consists of four modules and covers emissions from (1) production of materials used in the building, (2) transport of materials to the building site and energy use in the construction phase, (3) energy for use heating and cooling in connection with operation / use of the building and (4) energy use for transport in connection with operation / use of the building.

The calculation model has been designed in such a way that the emissions from the various different parts are calculated separately. The results are also summed up across the modules.

The basic principle for the calculations is:

Input factor/activity x emissions factor (CO_2, CH_4, N_2O) = greenhouse gas emission (CO_2 equiv.) (1)

The input factor / activity is a litre of fuel, a litre of heating oil, a kilogram of steel, a square metre of timber outside wall, the number of vehicle kilometres driven by lorry, energy need / use per square metre, etc.

Emissions factors for stationary energy consumption and transport are taken from national emissions accounts based on international sources (Statistics Norway, 2007). Emissions factors for materials have been calculated from a number of different references and are mean figures for European production, given as CO_2 equiv. per tonne of basic material. Emissions factors have been defined for 43 different building materials.

The building's lifetime has been set at 60 years.

2.2 The four modules

2.2.1 Materials, module 1.

The figures for greenhouse gas emissions from materials include extraction and transport of raw materials as well as the production process for the basic material. For some building materials, emissions have been calculated up until the final processed building product, for example plasterboard. Transport from the manufacturer to the building site is calculated in module 2 "Construction phase".

The material module contains emissions factors for 43 basic/building materials, and we estimate that this covers approx 80 % (weight) of the materials used in a building. The factors are taken from national and international studies and are given as emission per tonne or kg of a basic material. European average figures have been used.

Two sets of emissions factors have been established. One set includes emissions from electricity used in production; the other set does not. The emissions factor for electricity can be selected by the user of the model, but we recommend using the average value for the European OECD nations. In 2004 this was 357 g per kWh. This value has stayed relatively stable over time and corresponds roughly to a modern gas-powered power station that does not have CO_2 capture and storage.

Binding of CO_2 in the materials has not been included in the calculations. We are working on including a set of net emissions factors that take into account CO_2 binding and capture.

Different materials have very different life expectancies. So far, we have not included this in the calculations, but have assumed that all the parts of the building will last for the building's lifetime (60 years). This results in underestimation of the emissions from certain parts of the building. The error is probably not larger than the uncertainty in the overall calculations. We are working on including lifetime functions in the calculation model.

The material module is organised according to building components, Norwegian standard NS 3451. This makes it easier to gather input data from existing building documentation, as well as making the system recognisable.

The material quantities are entered using the units used in the industry i.e. m^2, m, per item, m^3, etc. The model includes an automatic conversion from commonly used units for material quantities (m^2, m^3, etc.) and for composite products (doors, windows, etc.) to kg of the individual basic materials.

In order to make conversion automatic, we have had to introduce some simplifications in terms of the density of the materials, a limited choice of dimensions, representative average values for composite products regardless of manufacturer, etc. This leads to and underlines the generic nature of the model.

We have only included values for construction work; i.e. the model does not yet include technical installations. It thus produces a rather simplified version of an emissions account; however, there is ample opportunity to further develop the model to include technical installations, to expand the number of basic materials and to include composite products directly. The module is going to be expanded to also include these parts.

We are currently working on integrating the module with building information models – BIM. Statsbygg is aiming to ensure that BIM also include a greenhouse gas module, so that greenhouse gases will become a premise when choosing materials.

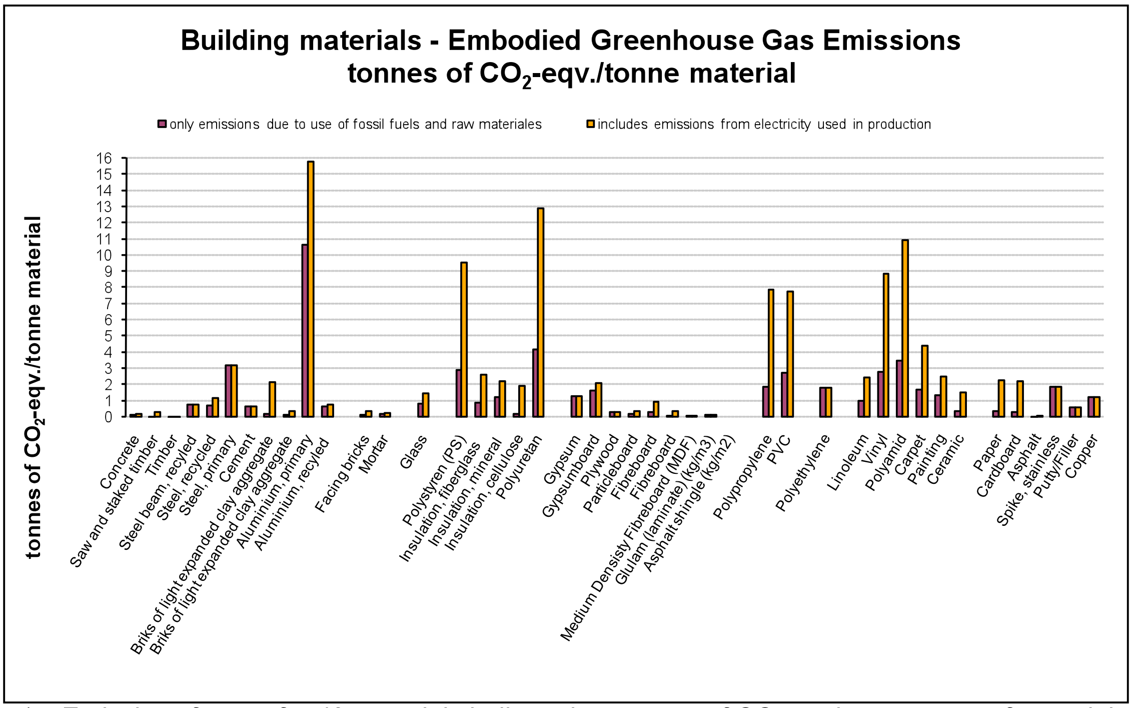

Figure 1 Emissions factors for 43 materials indicated as tonnes of CO_2 equiv. per tonne of material.

2.2.2 Transport of materials, site and construction, module 2

This module calculate GHG emissions from transport to and from the building site using light and heavy vehicles, use of construction machinery such as diggers, bulldozers, drills, cranes, etc. and stationary energy use such as diesel generators, building dryers, lighting, etc.

This requires reporting of data throughout the entire construction phase. Empirical data from similar projects can be used. Emissions factors are linked to the various sources of energy involved: auto-diesel, petrol, gas (LPG) and electricity.

2.2.3 Energy use in the operation phase, module 3

Emissions of GHG from stationary energy use depend on net energy need, the type of energy system and sources used in energy supply. A number of factors affect net energy need, including the design of the building, the thickness of the insulation in the walls, roof and floor, lighting and sun screening, the position of the building in relation to local topographical and climatic conditions, the function of the building, e.g. private home, hospital, etc.

The calculation model cannot assess the impact of these kinds of factors. The purpose of the model is to calculate emissions of greenhouse gases from stationary energy use based on input data on energy needs or measured energy use and chosen source of energy. The percentage of the energy need for electricity-specific purposes must be indicated. The remaining energy needs are hot water, heating and cooling.

The model allows you to specify energy solutions: electricity, district heating, oil boiler (light or heavy heating oil), natural-gas-fired boiler, LPG boiler, bio-boiler and wood-burning stove / open fire. Emissions factors for the different energy systems are given as defined in the Norwegian emissions accounts (Statistics Norway, 2007).

District heating is dealt with separately. The factors must be calculated individually for each project on the basis of information provided by the supplier of district heating to the building, i.e. information about the energy mix involved in production.

It is assumed that emissions factors and energy solutions remain stable throughout the building's lifetime of 60 years. In the event of remodelling or changes in the energy system, new calculations must be performed to find the greenhouse gas emissions from stationary energy use for the building project.

2.2.4 Transport, module 4

Emissions of greenhouse gases from transport come from combustion of fossil fuels such as petrol, diesel, natural gas, LPG, etc. In the event of a subsequent switch to another fuel based on renewable raw materials such as biodiesel, bioethanol, hydrogen, etc., emissions per vehicle kilometre will be reduced. The analysis model allows you to indicate share of carbon-neutral fuel.

The location of the building in relation to city-centre functions and collective transport is an important parameter that affects trip production rates and choice of means of transport. The functions within the building also affect the amount of transport.

The basis for establishing a calculation of the amount of transport from a building in use is empirical data collected in connection with Norwegian National Travel Survey (RVU). This survey has been undertaken several times and provides a good, broad picture of trip production rates, choice of means of transport, purpose of travel and distance travelled in different parts of the country, in different types of location and in different land-use categories.

Default data are used, but can be corrected in terms of the location of the building project in relation to urban centres and any concrete local travel surveys, choice of vehicle fleet policy, etc. Only daily travel is included, not long recreational trips.

Since a trip always has a starting point and a destination, only half of the travel activities are ascribed to the project. There are no grounds for choosing any other distribution of the length of the trip than ascribing equal parts to the point of departure and the destination.

The results are given as emissions distribution between private car, public transport and goods transport.

3. Results

3.1 Six Norwegian building projects

Six building projects that are in the design phase, under construction or recently completed and in use have been chosen; two day-care centres, two university extensions, renovation of a university building and construction of a block of flats.

The functions in the six buildings are so different that we expected to find large variations in construction and choice of materials, energy use, trip production / transport and in the calculated greenhouse gas emissions. The range in the examples provides new insight into the significance of the various different sources of emissions and the scope of the variation between different buildings.

With the exception of Bodø University College, all the projects use district heating, and emissions factors have been calculated for the individual district heating systems. We have calculated emissions from the electricity used for operation of the buildings and in production of the materials used in the construction. Table 1 indicates a number of details for the individual projects.

3.2 Greenhouse gas emissions in a holistic life-cycle based perspective

The model www.klimagassregnskap.no has been used to calculate emission of CO_2 equivalent for the life cycle of the six buildings. The emissions are annualised over 60 years and calculated per m^2 to allow comparison of the buildings. The emissions have been calculated for the three main sources: materials, operational energy use and transport during the operation phase. The results have been further broken down into different building components and personal transport – either public transport or private car.

Emissions from the construction phase and demolition (end-of-life) are not included in the GHG emissions calculations, because of insufficient data. Studies that have documented this have found that they have little impact in a life-cycle perspective. It probably constitutes less than 5 % of the total emissions (see for example Junnila and Horvath, 2003).

Traffic congestion as a result of new development projects, maintenance of infrastructure, changes in land-use (cutting down woodland), etc. are sources which have not been included in the model because of a lack of data and methods.

In the six Norwegian examples in figure 2, the annual emissions of greenhouse gases vary between approx. 40 kg CO_2 / m^2 / year and approx. 90 kg CO_2 / m^2 / year. Greenhouse gas emissions from the two examples from Canada in figure 2 have been re-calculated to approx. 65 and approx. 90 kg CO_2 equiv. / m^2 / year (Norman et al., 2006). All the examples have been calculated over a lifetime of 60 years. The calculated emissions from the projects are all within the same range. However, there are considerable variations; for example in terms of which of the main sources (materials, transport and energy use) dominate the emissions spectrum.

Table 1: Details of six building projects

Name	Year built (compl.)	Gross floor area m^2	Heated area m^2	Net energy needs kWh/m^2	No. of people (inhabitants, teachers / students)	Location
Fornebu Hage, Bærum Municipality	Under constr.[1)]	15,000	15,000	130	167 dw., average of 90 m^2, 2.1 p/dw.	12 km from central Oslo. Local service facilities, average public transport. Good access to parking
Storøya day-care centre, Bærum Municipality	Under constr.	1,000	1,000	65	110 p., approx. 9 m^2/p. (children,staff)	12 km from central Oslo. Local service facilities, average public transport. Good access to parking
Hundsund day-care centre, Bærum Municipality	Under constr.	1,100	1,100	120	134 people, approx. 8 m^2 / pers. (children,staff)	12 km from central Oslo. Local service facilities, average public transport. Good access to parking
The Norwegian Academy of Music (Oslo), Statsbygg	2007	8,000	5,700	222	198 p., approx. 29 m^2 /p. (student,staff)	Central Oslo / Majorstua, good public transport, poor access to parking
Bodø University College, Statsbygg	2004	12,150	11,000	166	1,183 p., approx 10 m^2/p. (student, staff)	5 km from central Bodø, local services, poor public transport, good access to parking
Sørhellinga, the Norwegian University of Life Sciences (UMB), Ås, Statsbygg	2007	11,000	10,000	132	406 p, approx. 25 m^2/p (student, staff)	3 km from Ås town centre, no local services, poor public transport, good access to parking

[1)] Under constr. = Under construction

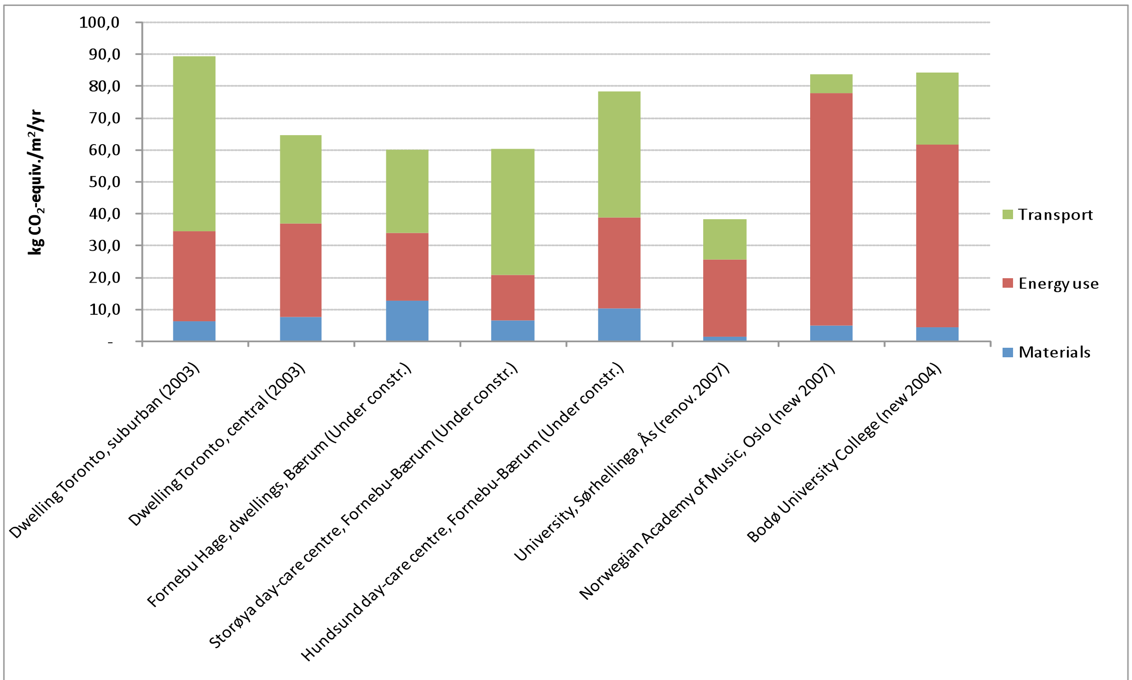

Figure 2: Greenhouse gas emissions from building projects calculated as CO_2 equiv. per m^2 per year. The examples from Norway have been calculated using the model www.klimagassregnskap.no. The examples from Canada (Toronto) re-calculated from Norman et al., 2006, 60 year life cycle.

3.3 Greenhouse gas emissions from transport

Variations in Transport volume can be explained by the function of the building; housing, day-care centre, office block, university or something else. Another important factor is its location in relation to urban functions and public transport. GHG emissions from transportation varies from approx. 6 to approx. 40 kg CO_2-eqv./m^2/year.

The two examples of housing projects in Toronto illustrate this clearly in that emissions from transport are much lower for the central location compared with the peripheral location. In this case, the difference is 40 %. The three Norwegian colleges demonstrate the same ratio: the emissions from transport are four times higher at the peripheral location (Bodø University College) than at a central location close to a major public transport hub (metro, trams and buses) (the Norwegian Academy of Music in Oslo).

The difference in emissions as a result of the different functions is demonstrated clearly if we compare the day-care centres with the housing development at Fornebu. All these three buildings are located in the same area, eliminating the impact of the location factor. The day-care centres appear to generate approx. 1.5 times as much greenhouse gas from transport as the dwellings, calculated per m^2 (see figure 2). The reason for this may be that there are more people (children and employees) per m^2 in the day-care centres, compared with a residential building.

3.4 Greenhouse gas emissions from stationary energy use

Emissions from stationary energy use are determined by the energy needs, energy system and choice of energy source / carrier. GHG emissions from stationary energy use in the Norwegian examples varies from approx. 14 to approx. 75 kg CO_2-eqv./m^2/year (figure 2).

The examples illustrate the importance of a good building envelope with little heat loss and low energy needs, and the significance of choosing a central heating system supplied by a district heating system based on water pumps or bio-energy (choice of primary energy).

The two day-care centres at Fornebu in Bærum Municipality have made different choices regarding energy efficiency. Storøya day-care centre is built according to the Passive House standard, whose requirements considerably lower than those in the Norwegian 2007 Technical Regulations (TEK07). The result is that emissions from energy use in Storøya day-care centre are half the emissions from Hundsund.

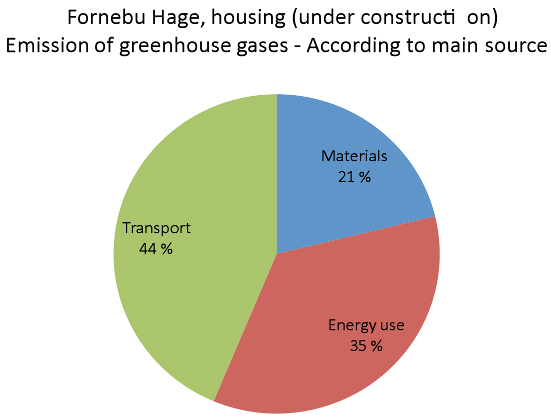
The two colleges, in Oslo and Bodø, have considerably higher emissions from stationary energy use than the other buildings. There are two reasons for this. The first is that they have been designed and built pursuant to old technical energy requirements (TEK97). This means a high specific energy use of 166 and 222 kWh/m^2. The second reason is that heating and hot water are based on electricity and not district heating. The other Norwegian projects use district-heating systems with bio-energy or heat pumps based on geothermal or seawater heat.

3.5 Embodied greenhouse gas emissions of building materials

Emissions linked to use of materials do not occur at the building site, but during production and transport of the materials. The results show that embodied emissions of materials range from approx. 1.5 – 13 kg CO_2-eqv./m^2/year, a share of approx. 5 – 20 % of the total emissions in a life-cycle perspective (figure 3)

The relative significance depends on the energy efficiency of the building and how transport-intensive the activities in the building are. As buildings are being designed to be more energy efficient, renewable energy supply and central location with good relation to service functions and public transport systems, emissions from materials will constitute a larger share of the overall emissions.

For some groups of materials, emissions from transport of the materials from the production place to the building site can be quite significant. These emissions are not yet included due to a lack of data for several of the groups of materials.



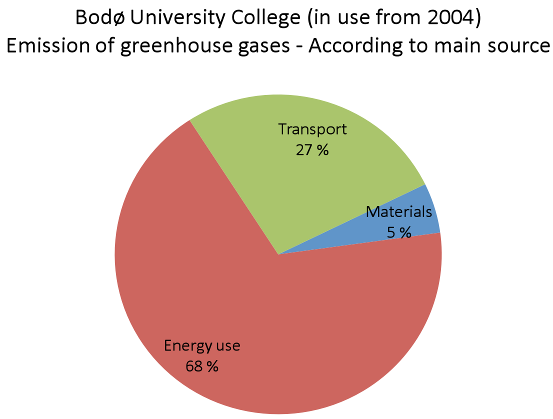


Figure 3: The emissions shares show the relative contribution from materials in a building project where energy efficiency has been given priority (Fornebu Hage) and one where it has not (Bodø University College).

The emissions calculations are based on European averages (generic data) for 43 groups of materials (see figure 1). Two sets of emissions factors have been established: one including emissions from electricity; the other only including emissions from fossil fuel consumption and process emissions. The user can decide which of these two sets of emissions factors to use. In the calculations presented in this paper, we have used the European OECD nations' average of 357 g CO_2/kWh (EEA, 2007). We recommend using this figure, as this factor has remained stable over time and reflects emissions in an integrated European energy market.

The emissions factors are gross factors, i.e. they do not take into account any binding of CO_2 in the materials in the building's lifetime. If binding is included, wood in particular will score better than the other groups of materials.

If we compare the buildings in more detail, we notice large differences in total emissions from materials and in which building components are responsible for the greatest emissions. Overall emissions from materials in the Norwegian examples vary from approx. 1.5 to 13 kg CO_2 eqv./m^2/year (see figure 4). The two Canadian examples are also in the same range, with approx. 6 and 8 kg CO_2/m^2/year (see figure 1).

The renovation of a university building at Sørhellinga (10,000 m^2) has the lowest emissions from materials. In this project, all the heavy, large materials are being reused, i.e. the load-bearing systems, ground and foundations, floors and ceilings, and large parts of the outside walls and roof. As a result, the overall emissions are only approx. 1.5 kg CO_2 eqv./m^2/year.

The three colleges have low emissions per m^2 compared with the housing projects and the smaller day-care buildings (see figures 1 and 4). And this is despite the fact that both the Norwegian Academy of Music in Oslo and Bodø University College have chosen to use concrete and steel in the load-bearing structures and a lot of glass in aluminium frames and bricks on the facades. The explanation for this is that these are huge buildings where the heavy structural elements constitute a relatively small part compared with the indoor area (surface area to volume ratio). Many of the rooms inside the buildings are also large (auditoria, classrooms, reading rooms, libraries, etc.), meaning there are fewer inside walls and surfaces than in a block of flats or a small day-care centre.

At present, we do not have a basis for setting a general score for greenhouse gas emissions from materials per m^2 pr year. The ratio between building volume and volume of materials in the ground and foundations and in outside walls and roofs has a major impact on emission level. However, there are clear tendencies concerning which options seem to yield the lowest emissions regardless of building volume. Renovation and reuse are best, followed by using timber instead of concrete, steel and glass.

Nevertheless, we must emphasise that these calculations are uncertain, and that there are other parameters and factors that need further investigation before we can start planning benchmarking of emissions from materials in buildings.

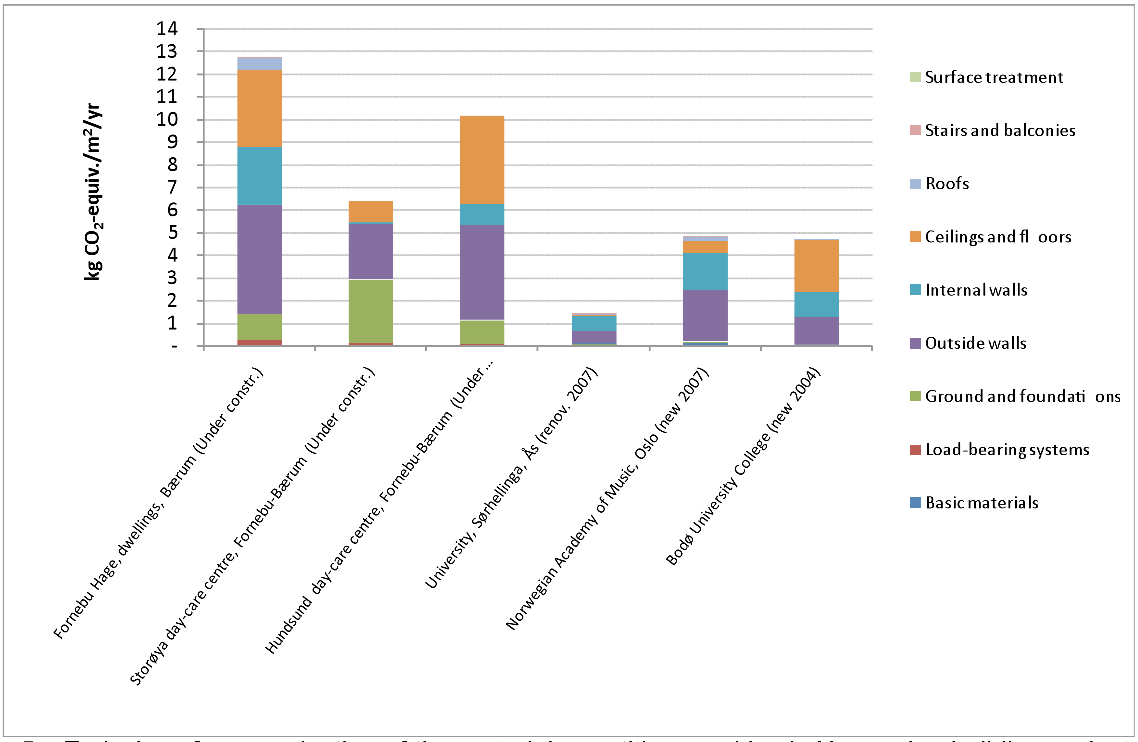

Figure 5: Emissions from production of the material quantities used in six Norwegian building projects.

4 Conclusions

The calculation model www.klimagassregnskap.no has been developed to enable systematic calculation of greenhouse gas emissions for building projects in a holistic, life-cycle perspective. The main sources included in the model are materials used in the structure of the building, operational energy use and operation-phase transport.

The calculation model has been tested on six Norwegian building projects, and the results have been compared with the results from two housing examples in Canada. The results from the Norwegian examples are in the same range as the Canadian findings, i.e. between approx. 40 and 90 kg CO_2 eqv./m^2 /year.

If we compare the buildings and the main sources, the results show that factors such as location, use of the building and choice of energy solutions have the greatest impact on emissions. As emissions from energy use and transport are reduced, emissions from materials will become relatively more important.

The results show that the choices that give the lowest emissions of greenhouse gases are:

- Choice of energy-efficient design and renewable sources of energy and carriers can reduce emissions by more than 50 %.
- Central location and/or proximity to a good public transport system – emissions from transport linked to use of the building can be reduced by more than 50 %.
- Renovation and reuse of buildings – emissions can be reduced by 60–70 % compared with a new building.

The calculation model is easy to use and represents a systematic calculation method that provides new insight into the significance of sources of emissions and measures that help reduce emissions. Integrated with building information models – BIM could the model also be a planning tool.

As more examples become available calculated using the same method, it will be possible to establish benchmarks for different types of building.

LIFE CYCLE ENERGY PERFORMANCE: EXPLORING THE LIMITS OF PASSIVE "LOW ENERGY" BUILDINGS

Keywords: life cycle, energy performance, embodied energy, passive, low energy

Summary

There is an increasing trend in reducing energy demand of buildings by improving building envelope thermal characteristics. Proven construction examples as used with the German PassivHaus standard achieve substantial reductions on the heating demand compared to mainstream construction, generally by using high levels of insulation together with ensuring excellent air tightness and minimizing of thermal bridges. However, the limits to which levels of insulation in a building can be increased and still represent overall life cycle energy savings are not clear. Particularly for temperate climates, adopting very-high insulation standards can lead to a danger of over specifying construction elements: once we reach certain levels of insulation, any extra material used can have larger energy costs or "embodied energy" than the energy it saves in the life cycle of the building. This paper presents the heating energy use of sample houses in the Irish maritime climate, and analyses the life cycle energy use including the embodied energy of the materials used. A 50-year perspective is presented, and conclusions about the limits to which the heating energy consumption can be lowered by "passive" means on a particular climate are drawn. This paper demonstrates the life-cycle benefits of optimizing the building design ensuring a correct orientation and sizing of the openings, but respecting certain limits when using energy intensive insulation materials.

1. Introduction

Reducing heating energy demand in buildings by means of insulation is recognized as one of the most cost-effective methods for saving energy and reducing CO2 emissions (COMMISSION OF THE EUROPEAN COMMUNITIES 2006). Building regulations around the world are changing to include more strict limitations of heat transfer on construction elements. Voluntary standards such as the PassiveHaus (Passive House Institute) introduced a more radical approach defining strict limits for the heating demand (15kWh/m2 per year), which are normally achieved by ensuring high levels of insulation, together with ensuring excellent air tightness and minimizing of thermal bridges. The potential savings of the application of these type of standards are very high, not only in colder countries but also in maritime climates such as in Ireland (Kondratenko, Brophy et al. 2006). However, as the building envelope performance improves, a higher amount of materials are generally needed, and some of the most commonly used materials like polystyrene have gone through a very energy intensive manufacturing process before they are installed in a buildings, which reduces the net energy savings achieved thorough its life cycle.

Some voluntary assessment methods such as LEED (US Green Building Council) or BREEAM (Building Research Establishment) do account for embodied energy issues, together with a wide range of other environmental impact issues. More detailed LCA tools as SIMAPRO (PRé Consultants) or ATHENA (ATHENA Institute) also offer the possibility of analyzing in detail a wide range of environmental aspects of materials including embodied energy. This paper focuses on a simplified assessment of heating energy demand including embodied energy of materials. While this is not as exhaustive an analysis as the above mentioned environmental assessment methodologies and LCA tools, the authors believe it provides a useful insight when applied with official calculation tools as part of building regulations or national rating systems. In this paper, the methodology is used to explore how far can the energy demand in a building be decreased by "passive" means, including the increase on the levels of insulation, to a level which is no longer a benefit from a life-cycle energy performance perspective, because the additional energy savings of any further improvements are counteracted by the embodied energy of the materials used.

2. Case Study

This case study analyzes the heating demand of a sample house in Ireland. The Irish climate could be classified as a mild climate, which under classifications such as the Köppen-Geiger system would correspond to a maritime temperate climate without a dry season and with reasonably warm climates (Peel, Finlayson et al. 2007). Figure 1 shows the annual solar radiation in Europe, where we can observe that levels in Ireland would have similar levels to those in Central and Northern Europe. This fact together with the mild temperatures means that in Ireland it should be possible to reduce the heating demand by passive strategies, and also might indicate that certain design strategies could be more useful than the mere increase of building envelope insulation levels.

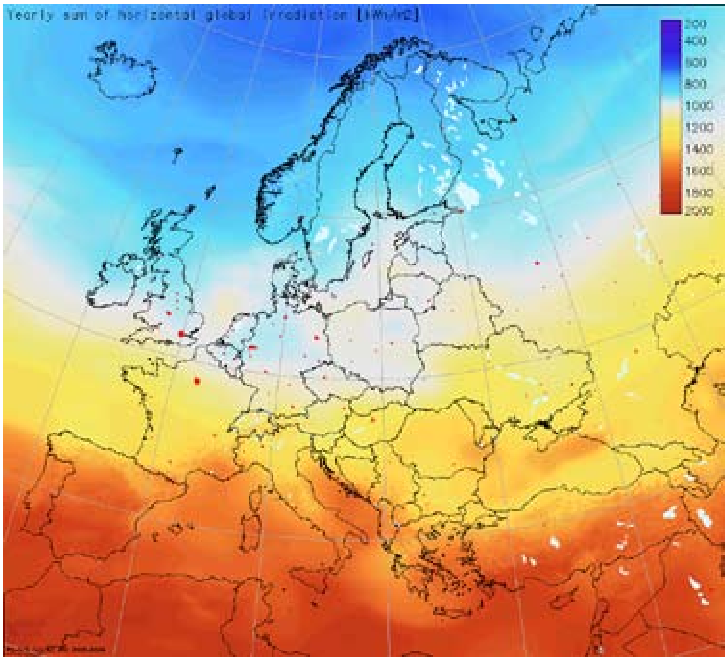

Figure 1. Yearly global irradiation on horizontal surface [kWh.m^{-2}] (Suri, Huld et al. 2007)

For this study the house size and type was selected from examples in the Irish Building Regulations Technical Guidance Document L (Minister for the Environment Heritage and Local Government 2006; Minister for the Environment Heritage and Local Government 2007).

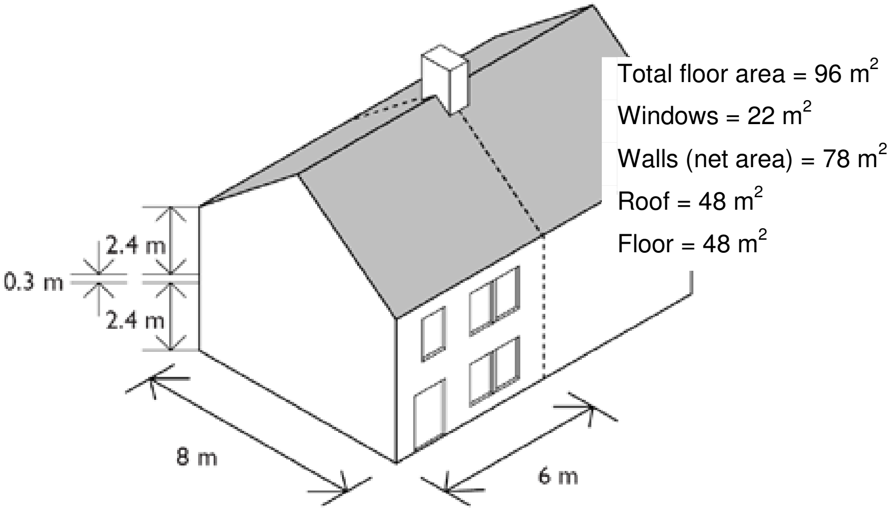

Figure 2. Case study semi-detached dwelling characteristics

These details of the house correspond to a semi semi-detached two storey house, which is the most common type in Ireland. Total area of the windows is set to 22 m^2 with an east-west orientation, which could also represent a typical situation

Our BASE CASE scenario for the case study corresponds to a house complying with the insulation levels from the 2006 Building Regulations, but including some additional energy efficient features such as the reduction of thermal bridging to a value of 87 W/K for the whole house, the limitation of infiltration and ventilation heat losses by air tightening the house (up to 0.60 ach at 50 Pa) and including mechanical heat recovery ventilation with an efficiency of 85% and an specific fan power of 1.0 W/ l *s.

A range of improved U values from the BASE CASE have been considered, the maximum upgrade achieving levels of 0.1 W/m2 K, which is a value already reached in some Irish Passive House constructions. Table 1 shows the different upgrades and U values considered:

Table 1. U values of construction elements for the five building envelope insulation options studied [W/m2 K]

	BASE CASE	UPGRADE 1	UPGRADE 2	UPGRADE 3	UPGRADE 4
Walls	0.27	0.21	0.15	0.12	0.1
Floor	0.25	0.2	0.15	0.12	0.1
Roof	0.16	0.14	0.12	0.11	0.1

Table 2 shows the thickness of the insulation layer needed to achieve the U values for each construction element. Calculations were carried according to the EN ISO 6946 (CEN 1997). The additional insulation material selected to lower U values was polystyrene, which is still one of the most widely used insulation materials in Irish construction. Physical properties of the polystyrene used in this case study are 20 kg/m3 density and 0.034 W/mK thermal conductivity.

Table 2. Thickness of insulation layer [mm]

	BASE CASE	UPGRADE 1	UPGRADE 2	UPGRADE 3	UPGRADE 4
Walls	115	150	210	265	315
Floor	85	120	170	215	270
Roof	255	285	325	365	425

Two options for windows are also considered, a first option is a double glazing unit with an U value of 2.2 W/ m^2 K, which would correspond to a typical window installed to comply with building regulations, and a second option of a triple glazed argon filled window with a U value of 1.0 W/m^2 K, which corresponds to current practice of Passive House designs in Ireland.

To account for the differences between typical and passive solar design strategies, different window sizes and orientation are also considered. The original option of 22 square meters of East / West oriented windows is compared with North/South orientations, and with an increase in windows areas on the south façade. This approach will serve to check benefits of window sizing and orientation on reduction of heating demand, while ruling out daylight issues, although it is understood that the use of daylight will improve with increasing window sizes. The following three additional sets of options are considered:

- A first set considers a change just on the orientation of the windows, maintaining the same house design and window area, but with an equal distribution of windows between south and north, instead of an East/West orientation.
- A second set of options considers an increase of 25% on the total window area, placing the additional area on the south façade.
- A third set of options considers an increase of 50% on the total window area, placing the additional area on the south façade.

As a result of the explained variations of building envelope, window type, and windows size and orientation, a total of 40 possible combinations of options are studied. Each option has been assigned an ID, with the following codes:

- Envelope insulation levels: BASE, UP1, UP2, UP3, UP4 for the 5 envelope insulation options.
- Glazing type : 2G for Double glazing, 3G for Triple glazing
- Glazing orientation: OR represents a North/South orientation
- Glazing area: +25%, +50% represents an increase to the total window area, added to the south façade

As an example, the option UP2_3G_OR_25% would correspond to the case study with the envelope UPGRADE 2, triple glazing, a north south orientation and with an additional 25% glazing area on the south façade.

3. Calculation Methodology for Heating Demand and Embodied Energy

3.1 Heating Demand

The heating demand for the different options was calculated with the DEAP Irish calculation methodology (Sustainable Energy Ireland 2007). Space heating demand in DEAP is calculated for an 8-hour daily heating schedule, between 7-9am and 5-11pm, which is considered a typical schedule. The setpoint temperature is considered 20 degrees Celsius for the living room area (which represents 30% of the total space) and 18 degrees for the rest of the occupied space. DEAP calculation of the heating demand is based on the European standard EN ISO 13790 (CEN 2004), and considering, on a monthly basis, only sensible heat and the following components of the energy balance:

- Transmission losses between heated space and external environment (including thermal bridging).
- Infiltration and Ventilation losses (accounting for air tightness of the house and the effect of heat recovery mechanical ventilation.)
- Internal heat gains
- Solar gains

The results for the monthly heating demand of three of the options, and of annual heating demand of the 40 options considered are displayed on Figures 3 and 4:

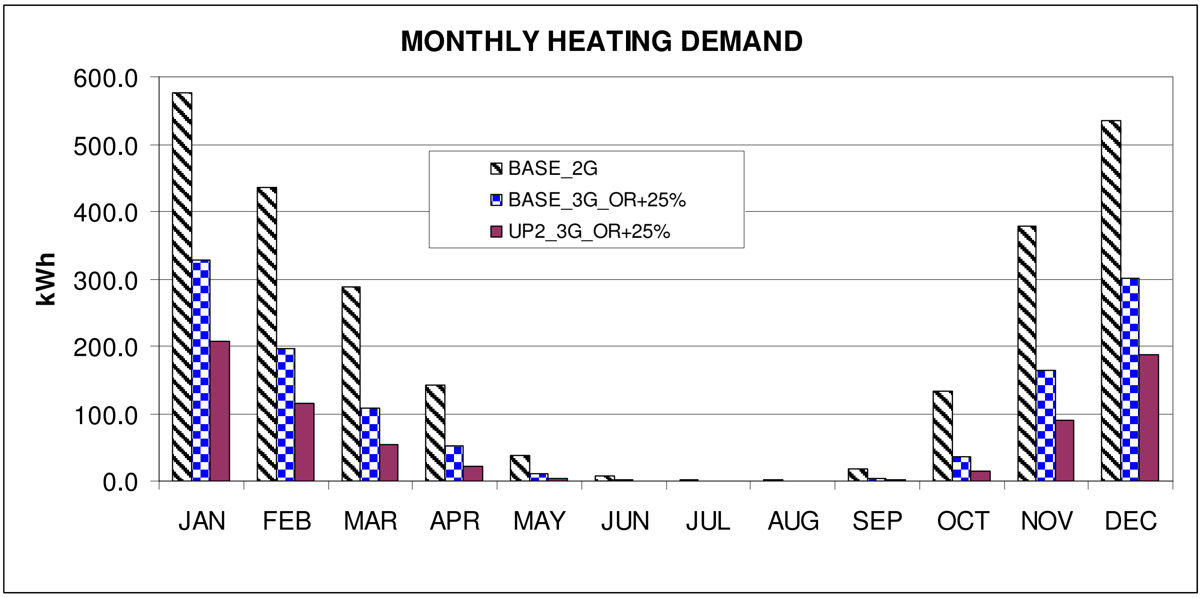

Figure 3. Comparison of monthly heating demand for three of the options

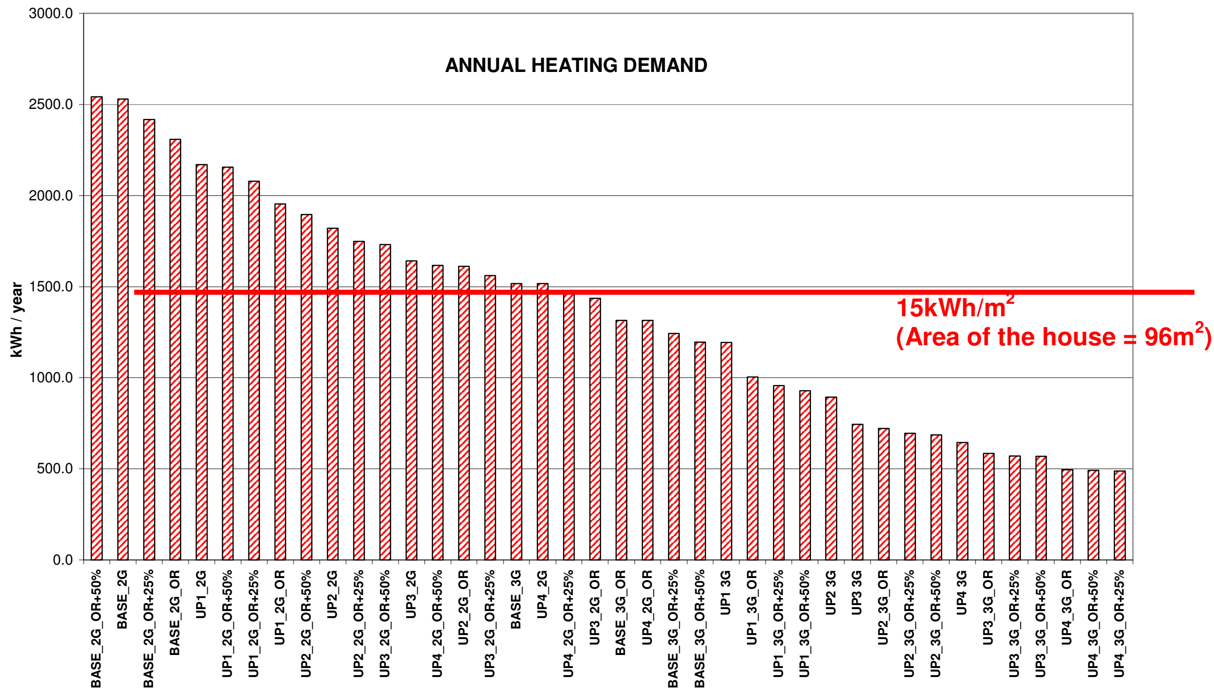

Figure 4. Comparison of heating demand for the 40 different options

From these se figures we can observe that the upgrade of insulation levels from the base case to UP1, UP2, UP3, UP4 has a progressive impact on the reduction of heating demand. It is also very noticeable the impact of the change in the glazing type, where the inclusion of the triple glazing windows has, in most cases, as much impact in terms of heating demand as it has the maximum upgrade of insulation levels. The options with a south/north orientation have a consistently lower heating demand as expected due to the higher solar gains. The increase in the areas of glazing on the south façade, when using the double glazing windows, in most cases increases the heating demand. For triple glazed windows, the annual heating demand slightly decreases when increasing window areas on the south facades, in all cases except for the most insulated option (UP4) where due to the super-insulation solar gains usage would not be enough to offset heat losses through the window.

These first results are what we would expect from an annual heating demand analysis. We can observe that more than half of the options considered will be for example below the threshold of 15 kWh/m^2 per annum which is one of the pre-requisites for PassivHaus standard, the progressive energy savings as we increase the insulation levels.

3.2 Consideration of embodied energy

To simplify the consideration of embodied energy, without the need of a full inventory of all building materials, we propose to use a differential comparison of the proposed building options from the initial base case (BASE_2G). The differential embodied energy referred to the BASE_2G is considered only for the construction elements most directly related to the energy performance, which for this study on heating demand will be the insulation of the building envelope and the windows. All other elements that are not directly related to the energy performance in use of the building or that can be considered the same as the reference base case are then neutralized.

The consideration of embodied energy of materials will be in all cases from “cradle to site”, which will consider all the energy used on from the extraction of raw materials, to manufacturing and transport to the building site.

To calculate the differential embodied energy of each of the options, information was sourced from the following references:

- The embodied energy of building envelope upgrade materials from the Inventory of Carbon and Energy ICE v1.5 (Geoff Hammond and Craig Jones 2006). For polystyrene insulation, a value of 88 MJ/kg was used.
- Embodied energy of upgrading windows was approximated from Weir and Muneer (1998) and Asif, Davidson et al. (2001). The upgrade of windows from double glazing with U value of 2.2 W/m2 K to triple glazed windows with a U value of 1.0 W/m2 K was considered as 500 MJ per m2.

The total differential embodied energy for each of the options, with relation to the basic case, was calculated. The values were annualized for a 50-year period which is a value widely used in literature as shown in a review of case studies by Sartori and Hestnes (2007), and representative for the life of the materials of a building before undergoing major renovations.

Figure 5 shows the comparison of energy options in the same way as Figure 4, but adding the annualized embodied energy for each of the options as calculated for the upgrade of insulation levels or of the windows as a differential from the option BASE_2G. This analysis will give an additional life-cycle perspective of the total energy use and another view on the limits of reduction of energy use by improving building envelope characteristics.

As a first observation, we can note that the differences in the overall energy use (space heating plus annualized embodied energy) between the options with the lower space heating demand is very small. The best option from this life cycle perspective would be the UP3_3G_OR, which is the second best insulation upgrade. That means that upgrading the insulation beyond the limits set on UP3 using polystyrene as the insulation material, would have a negative effect from a life cycle perspective for this case study dwelling in a temperate climate.

The high relative importance of orientation is also clear to observe, as insulating options UP4 with an East/West orientation will have a higher overall energy use (including embodied) than options with insulation two levels below (UP2) and a North/South orientation.

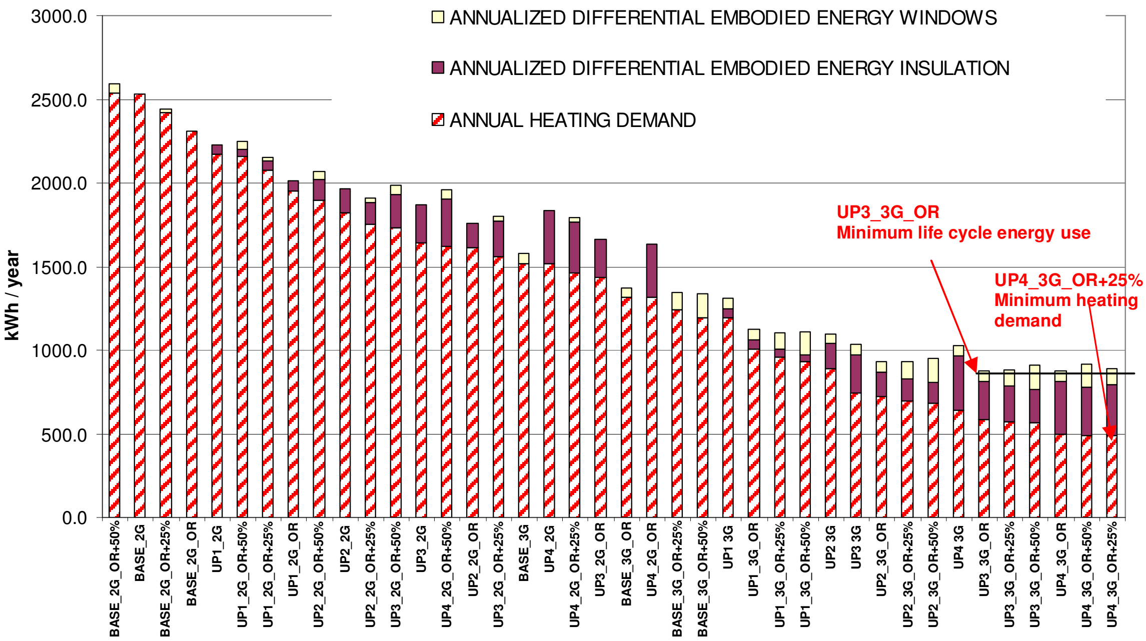

Figure 5. Comparison of heating demand and annualized differential embodied energy (related to the BASE_2G option) for the 40 different options

4. Conclusions

This paper has presented a very simplified approach to study the limits of reduction of heating demand from a life cycle perspective. The analysis added an annualized differential embodied energy factor to the space heating demand of different building design options. The heating demand was calculated according to the current official Irish calculation methodology for energy assessment of dwellings, while the embodied energy of materials was sourced from various references, annualized to a lifetime of 50 year and presented as a differential value related to the option BASE_2G.

The results show how high insulation levels using energy intensive materials such as polystyrene could lead to a higher overall life cycle energy use (over 50 years) than less insulating options. This aspect highlights the importance of choosing low energy intensive materials when pursuing extremely low energy demands, and also the need to carefully study the design alternatives for very low energy buildings, as aspects as orientation and opening sizing would have more beneficial effects from a life-cycle perspective than the mere upgrading of construction materials and elements.

As a final conclusion, this paper with its simplified inclusion of embodied energy adds a life-cycle perspective to the heating energy demand calculation, giving a hint to the dangers of over-specifying insulation levels, which is particularly relevant for mild climates such as that of Ireland and many parts of Western Europe.

The paper also exposes the need for methodologies to allow for this type of calculations in a simplified manner that could be readily available to architects, designers and engineers, perhaps together with official energy assessment tools, to avoid potential situations where no overall life-cycle energy benefits are being achieved by upgrading building envelopes with energy intensive materials.

SUSTAINABILITY INDICATORS FOR THE BUILT ENVIRONMENT – THE CHALLENGES AHEAD

Prof. Holger Wallbaum

Department of Civil, Environmental and Geomatic Engineering, Chair of Sustainable Construction, ETH Zürich, Zürich, Switzerland, holger.wallbaum@ibb.baug.ethz.ch

Keywords: Sustainable development indicators, tools, stakeholder, construction, materials, buildings

Summary

Methods and tools including sustainable development indicators (SDIs) are important aids to the implementation of sustainable development in the construction industry. Through a qualitative analysis, a variety of methods which are widely used internationally can be assessed to establish their compliance with the general requirements of sustainable development. This paper looks at five fundamental criteria: holism, lifecycle assessment, directional certainty, traceability/transparency and local suitability. Most methods more or less meet these requirements, in which users play a central role in compliance. This paper identifies a number of remaining knowledge deficits: the recording and analysis of sociocultural indicators, additional environmental indicators such as land use, resource intensity, interior quality and usability, and a more detailed understanding of building usage and decommissioning costs. In addition to these knowledge deficits, and for a variety of reasons, there is also an implementation deficit: the practice of sustainable construction is lagging far behind the theory.

1. Introduction

Since its beginnings in the 1980s, the principle of sustainable development has become widespread in almost every section of society and area of the world (United Nations Commission for Environment and Development (UNCED) 1992 and (WSSD) 2002). Many governments, cities and companies have endorsed this principle and engaged in national and international dialogue concerning its implementation (Schweizerischer Bundesrat 2002, World Business Council for Sustainable Development). This follows a process of institutionalisation, for example incorporating the principle into federal law (Bundesverfassung der Schweizerischen Eidgenossenschaft vom 18. April 1999) and allocating responsibilities within and between ministries (Wachter 2006). It is usually then implemented within individual states or sectors such as business, transport and private households.

One example is the European Union's objective of reducing greenhouse gas emissions by 20% between 1990 and 2020 (EC 2008[1]) and the "burden sharing" of national targets between the twenty-seven EU member states. The latter has yet to be completed, and individual states are responsible for taking action to ensure that the national targets are met on time. The construction sector has an important part to play in meeting these targets, since it is responsible for some 40 percent of national greenhouse gas emissions in most industrialised countries (United Nations Environment Programme 2007.) However, the sector is very heterogeneous, with very different structures, standards (see Figure 1) and stakeholders such as private and institutional contractors, tenants and facility management companies.

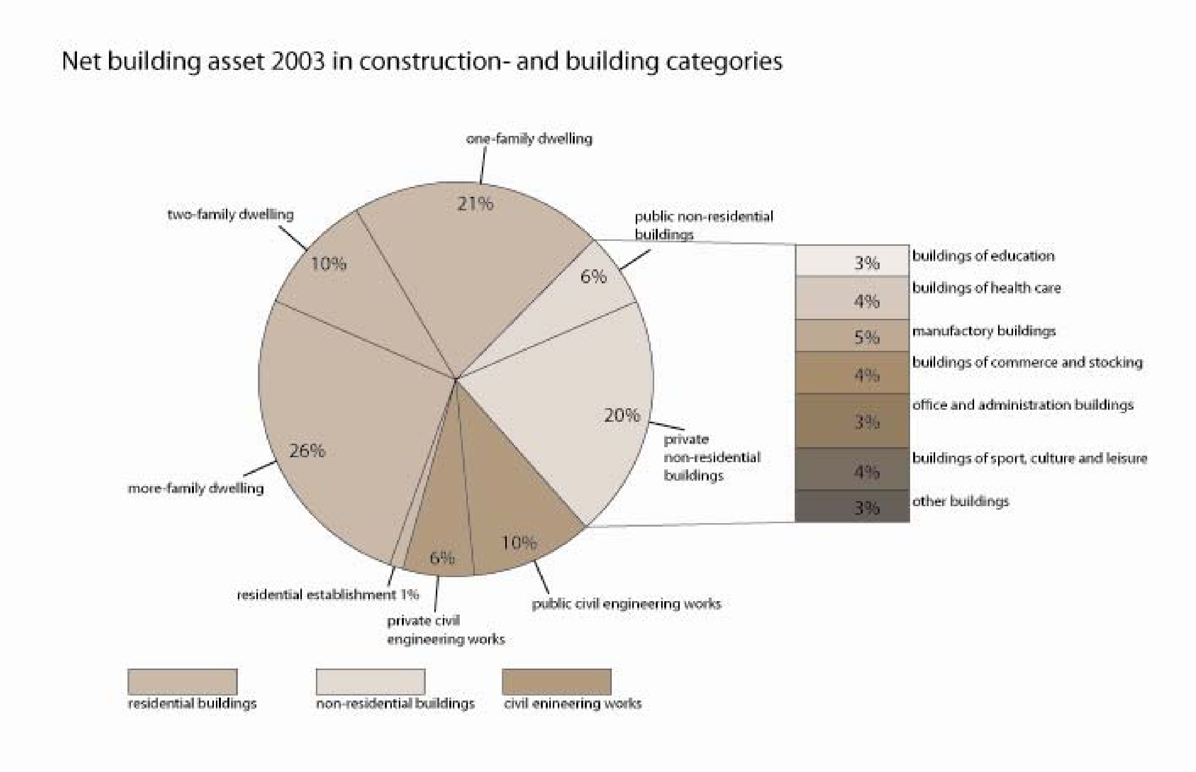

Figure 1 *Structural categories by net building assets in Germany, 2003 (Source: Zeitschrift für Immobilienökonomie, Sonderausgabe 2005; Data: Federal office for Statistic Germany (2004 - VGR); Euroconstruct 1999; Assumption by the ifo institute).*

Any strategies developed, for example to make new and existing buildings more energy efficient, must therefore reflect this diversity while focusing on national greenhouse gas emissions targets. Clearly, specific units of measurement are needed in order to aggregate the effects of what are sometimes localised measures and show these as a national contribution to the overall objective, in this case EU emissions targets. These units are also known as indicators (CO_2 or CO_2 equivalents in this example), and are the focus of this paper, which attempts to

- Formulate requirements for indicators used to assess and measure the construction industry's contribution to sustainable development
- Assess current progress in developing such indicators
- Assess the quality of the data on which the indicators are based, and how widely they are used
- Highlight further research needs

2. Sustainability Indicators

2.1 Definition and History

Indicators are a part of everyday life, often without our being aware of them. Units of measurement such as time, weight, temperature and price are used to describe the condition of anything from a simple object to a complex system. In terms of sustainable development, they allow the key components of the three-pillar approach – environment, business and society – to be converted into usable and relevant information. They can also be used to derive indices, which represent data in its most compressed form (see Figure 2).

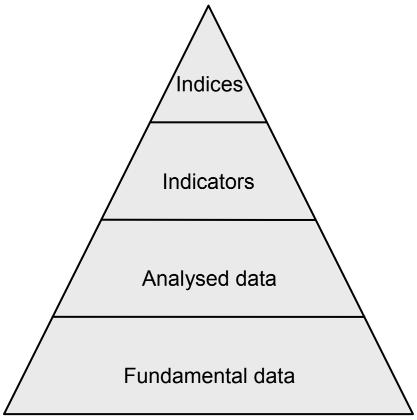

Figure 2 The stage model of information compression (Wallbaum 2002: 59)

In environmental terms, indicators can be defined as “measured, calculated, observable and quantifiable key figures forming part of a targeted system used to make statements about the state and development of the environment. The OECD pressure-state-response approach, for example, distinguishes between pressure, state and response indicators.

The historical background to the rise of sustainable development indicators (SDIs), which cover not only environmental but also economic and social development, is detailed in chapter 40 of Agenda 21 (United Nations, 1992). The first session of the United Nations Commission on Sustainable Development (UNCSD, 1993) expressed the need for a set of SDIs to measure progress in this direction. The first such set was introduced in 1995 and accepted by the UNCSD as a basis for evaluation, and the mandate was further confirmed by the Johannesburg Plan of Implementation, which called for

> …further work on indicators of sustainable development by countries at the national level, including integration of gender aspects, on a voluntary basis, in line with national conditions and priorities (World Summit on Sustainable Development 2002).

The report of the 13th session of the UNCSD on 11-12 April 2005 also pointed to the need for continuing work on SDIs at an international level (UNSCD 2005).

Alongside the more general efforts to develop SDIs, the construction industry has a long tradition of developing and using indicators. Table 1 below, which makes no claim to comprehensiveness, gives an idea of the many other tools and approaches used in an international context. These mainly differentiate between indicator-based analysis of materials, components, buildings and settlements. Towns and cities are not mentioned at this point since, to the best of the author's knowledge, the only comprehensive and specifically construction-related studies focus on individual aspects such as material flows and energy consumption rather than on the interaction between them.

Table 1 Use of SDIs in construction-related methods and tools, differentiated by level (in alphabetical order)

Materials	Components	Buildings	Settlements
Ecoinvent* (e), GaBi* (e, f, s), ixbau (e, s), OGIP (e, f), Simapro (e), Umberto* (e, f)	Bauteilkatalog (e, f), BEES (e, f), ecosoft (e), Ecoinvent* (e), GaBi* (e, f, s), Minergie-ECO (e), OGIP (e, f), Simapro* (e), Umberto* (e, f)	CASBEE (e), LEGEP (e, f), LEnSE (e, f. s), EPIQR (e, f), HQE (e, s), LEED (e, s), OGIP (e, f), SBTool07 (e, f, s), SNARC (e), Vitruvius (e, f)	COMPASS (e, f, s)

The letters in brackets refer to the main emphasis of the indicators used in the method or tool, as follows: (e) ecological, (f) financial, (s) societal.
*Not specifically developed for the construction sector

Table 1 is noticeably dominated by environmental indicators, which are used in all the methods cited. The second most common are financial indicators, and societal indicators appear only in a small number of methods.

Another noticeable feature is the large number of methods at the component and building levels, since these are used by planners and architects. The traditional environmental balancing tools at the component level require a very comprehensive knowledge of such areas as process technology and materials science, and are therefore not primarily aimed at these two professions.

Very few methods use SDIs at the settlement level. One current sustainability research programme being carried out by Novatlantis at the Swiss Federal Institute of Technology[2] deals with the development of sustainability criteria at district level. During the first stakeholder consultations, it became clear that settlements contain a more varied pattern of interests and stakeholders than other levels such as materials, components and buildings; stakeholders on the demand side, such as banks, contractors, tenants and local councils, do not yet have clearly localised interests and sometimes have to be served by target-group-specific SDI sets. Any meaningful set must also meet other requirements in terms of practicality and scientific rigour, and these are described below.

2.2 Fundamental Requirements

If SDIs are to serve their purpose, they must cover all dimensions of sustainable development; in other words, they must be **holistic**. These dimensions vary depending on the theoretical, social, political or cultural approach adopted, though most use the three-pillar model, comprising financial, environmental and social dimensions. Cultural and institutional dimensions may also be included, and individual dimensions may be further subdivided; the five-level model, for example, combines the environmental dimension with the chemical-physical and biological levels (Rauch-Schwegler 2005). Here, the challenge lies in implementing the selected dimensions for the construction industry. A view focusing primarily on ecological criteria does not meet the requirements for sustainable development, though the limited perspective in which ecology equals sustainability is still very widespread.

Secondly, SDIs must **cover the whole life cycle**, including all the various activities involved, such as raw materials extraction and processing, transport costs, and the construction, use and decommissioning of the building. Here, the challenge lies in selecting appropriate system boundaries so that the SDI set can still be used. Depending on the level at which the system is being examined, this also includes infrastructure such as water and sewage disposal.

System boundaries must be chosen in such a way that the significance of the elements being analysed is not consciously or unconsciously limited. The observed parameters or boundaries will need to be restricted on the grounds of practicality, but this should not be at the expense of **directional certainty**. SDIs should, if possible, be designed and used to ensure bottom-up and top-down compatibility, which can make the use of statistical data easier or more difficult.

Another requirement is **traceability and transparency** in terms of the dataset used, the assumptions made and the accounting and evaluation processes employed. This is important in ensuring scientific precision and as the basis for the intended communication to the target group.

In order to ensure transparency, SDI sets must be **adapted to local conditions**, at least in terms of the evaluation process used. For example, adequate supplies of fresh water are available in most north European countries, whereas in most southern European towns and cities it is a scarce commodity requiring particular attention.

3. Discussion

Most of the methods shown in table 1 are designed to meet pre-formulated requirements. Responsibility for the accurate use of SDIs lies primarily with users, so the conformity of these methods and tools has not been assessed here. However, in order to ensure that the analysis is holistic, it is possible to carry out an initial assessment based on the focus of each method

[2] http://www.novatlantis.ch/index.php?id=50&L=1, last checked April 8, 2008

shown in table 1. This clearly shows, for example, that societal indicators and evaluation processes must often be supplemented by others if the developer/seller intends to carry out any type of holistic sustainability assessment.

Although many methods deliberately do not assess holism, the dimensions depicted show room for improvement in terms of knowledge and implementation deficits. Table 1 shows that more research is undoubtedly required into the development and testing of social and cultural indicators. Some efforts have been made in this direction, such as SEEBalance, BASF AG's socio-efficiency assessment of products and processes,[3] or Sabento software for the biotechnology sector,[4] which make a valuable contribution when these dimensions have only just begun further development.

Even the environmental dimension, which has received a very great deal of international attention, requires further research. The knowledge deficits in this area include quantitative land use indicators, and qualitative indicators for construction sector activities. While some work has been carried out in this area,[5] there is still no conclusive analysis of the indicators' suitability and directional certainty. Most methods do not give sufficient attention to resource consumption throughout the life cycle in terms of energy sources and sustainable and non-sustainable raw materials (Wallbaum 2007), although the first tools are being developed.[6] More research is needed into the measurement and evaluation of sick building syndrome and other aspects of interior comfort, and in this respect there is considerable overlap with heating, ventilation and air conditioning. Here again, it is important to select appropriate system boundaries, since many contaminants are introduced into building interiors not from construction materials but from floor coverings and/or furniture.

More research is also needed into lifecycle costs, which are still often simplified to cover only capital costs. Some studies have been carried out into building usage costs (Stoy 2005), though these still have some gaps in terms of sample size and coverage of different types of building. They also highlight the fact that usage costs have traditionally been defined as operating costs (such as repairs, maintenance, electricity, water, and waste removal), and need to be extended to include capital costs and depreciation. This is the only way of monitoring and influencing construction-related decision-making by institutional investors and others; if costs are monitored throughout the lifecycle, it will undoubtedly be possible to develop financial indicators for decommissioning costs.

A specific challenge must be seen in the sustainable development of the building stock. Most of the listed tools in table 1 are not limited to new constructions but they are not specialized in the assessment of the building stock. First tools in this regard have been developed and approved in practice. One tool is "idi-al"[7], a tool developed by the Working Group on the renovation of the building stock (Bundesarbeitskreis Altbauerneuerung - BAKA) in Germany. idi-al assesses the physical situation of existing buildings and derives from this status quo study building appropriated refurbishment measurements. The proposed measurements include prices and the ecological optimisation potential, e.g. in terms of achievable energy savings. However this tool does not answer all the questions the issues of longevity and survival rates and their impact over the whole life cycle. But these issues are crucial to enable us to make a statement about the mix of new constructions, replacement buildings and the refurbishment of the building stock for a city to achieve the optimum in terms of economic, ecological and societal performance of the city building portfolio.

4. Conclusions

Although this paper has highlighted various knowledge deficits, the existing data and the large number of methods available can be described as very good. In most cases, if the methods were used accurately on this basis, they could make a substantial contribution to sustainable development in the construction industry. In practice this is very rarely the case, for a variety of reasons:

- limited awareness of sustainable construction (industry, politics and building owner/tenants),
- limited government enforcement and incentives,
- a lack of training within the sector,
- and the finance sector's lack of commitment to sustainable construction.

If the industry is to start becoming sustainable, the knowledge gaps must be filled and the existing knowledge implemented.

Creating a framework to make this possible is one of the key social challenges facing decision makers in the construction sector. This framework could be created by properly addressing the issues raised above. However, the most promising point, in terms of effectiveness of fostering sustainability in the construction sector, seems to be the stimulation through standards and regulations (UNEP SBCI 2007: 53) to overcome the most important barriers in this sector, i.e. hidden costs (transaction costs) and market failures.

Another promising approach could be the (additional) implementation of certain market driven incentives, like the implementation of a national rating and labelling system for sustainable buildings. To achieve a high degree of acceptance for such a rating and labelling system, it has to be developed in a participatory process that includes a broad variety of stakeholders. Furthermore this rating and labelling system should make use of existing data and information, e.g. to apply for a planning and building permission. Redundancy of data input from the side of the planer, architect or construction company has to be minimized as far as possible. At the best a planer will get with the rating certificate other supporting documents as "by-product" that are related to governmental requirements. Finally, this rating and labelling system should replace as much of the permissions and certificates that are needed at present.

The ongoing activities of the German chapter of the Green Building Council are currently running such a process[8]. The results and a first national rating and labelling system should be available at the end of the year 2008. To ensure the scientific accuracy of this sustainability rating and labelling system for buildings in terms of conformance with its goals it will be crucial to monitor the process, especially in the very beginning. Ecological and Economic Life Cycle Assessment that are conducted in parallel from case to case could contribute with results that indicate gaps or recommendations of adjustment within the rating system. Using a full Life Cycle Assessment it has been shown in the case of LEED that a better labelling grades does not necessarily correspond with a better ecological performance (Humbert et al. 2007).

Both filling knowledge gaps and implementing this knowledge need to go hand-in-hand if sustainable development in the construction industry is to be transformed from a utopia into a reality.

BUILDINGS DESIGNED WITH AN ENERGY-EFFICIENT BUILDING ENVELOPE

Torben Valdbjørn Rasmussen MSc. CivEng, PhD

Danish Building Research Institute, Aalborg University, Department of Building Design and Technology, Dr. Neergaards Vej 15, DK-2970 Hørsholm, Denmark, tvr@sbi.dk, http://www.sbi.dk

Keywords: air tightness, thermal bridge, leakage, sustainable, building envelope, heat loss, joints

Summary

In buildings the largest and most cost-effective potential for energy savings lies in reducing energy consumption. Reducing energy consumption in buildings for heating and comfort will lead to more sustainable buildings. Methods for reducing the energy consumption in buildings by reducing heat loss through the thermal envelope were discussed. In particular air tightening of the building envelope and superinsulated building components. Principles for air tightening of the building envelope were discussed and new principles for making superinsulated strip foundation of prefabricated lightweight elements were introduced and demonstrated as an alternative to strip foundation of concrete as traditionally used. The prefabricated elements, made of expanded polystyrene, were designed to be handled on site by one man. An area of non-freezing ground was established by using outer insulation located at the outer plinth. The element was integrated into the insulation located underneath the concrete floor slab, constructing a foundation system that allows very little energy to be lost through the joint that connects the concrete floor slab with the outer wall. The strip foundation allows for a full and continuous insulation cover against the heated part of the building.

1. Focus (2008)

The new Danish Building Regulations (Danish Enterprise and Construction Authority 2008) will have an impact on energy consumption in buildings, in that the regulations focus on the thermal envelope as well as individual building components. The aim is to reduce energy consumption for heating and comfort and that this will lead to more sustainable buildings. The new Danish Building Regulations entered into force on 1 February 2008.

One focus area was heat loss through the thermal envelope, in particular methods that ensure air tightening of the building envelope, eliminating thermal bridges and innovation of individual building components.

The new Building Regulations are part of a major action plan presented in 2005 by the Danish Government. The action plan aimed to promote significant results in the energy field. This action plan will have an impact on Danish energy-saving initiatives in years to come (Ministry of Transport 2005). The action plan includes a description of the Danish energy sector in the years leading up to 2025. One strategy of the action plan is the climate policy related to the Kyoto Protocol, United Nations (1998), which entered into force on 16 February 2005. As part of the internal distribution of obligations within the EU, Denmark must reduce its emissions of greenhouse gases by 21% compared with 1990 (Olesen, et al. 2004).

The action plan focuses on energy consumption in buildings, where the largest and most cost-effective potential for energy savings lies. The most important initiative is the tightening of the energy provisions in the new Danish Building Regulations.

The tightening of the energy provisions paves the way for further strengthening in 2010 and in 2015. The tightened energy provisions will result in an energy reduction of 25% for new buildings compared with buildings built in accordance with the former Building Regulations (Danish Enterprise and Construction Authority 1995).

2. Heat Loss through Leakages in the Building Envelope

Air tightness is an important property of building envelopes. It is a key factor for determining infiltration and related wall performance properties such as heat loss, indoor air quality, maintainability and moisture balance. Air leakage through the building envelope contributes to ventilation, heating and cooling costs and moisture migration. Air tightness is the property of building envelopes that is most important for understanding ventilation. It is quantified in a variety of ways, all of which typically go under the heading of “air leakage”. Air tightness is important from a variety of perspectives, but most of them relate to the fact that air tightness is the fundamental building property that impacts infiltration. There are a variety of definitions of infiltration, but fundamentally infiltration is the movement of air through leaks, cracks, or other unforeseen openings in the building envelope.

There is a direct connection between an airtight building envelope and a low consumption of energy in the building. In the North European countries, where outdoor air that seeps in through unforeseen leakages in the building envelope, infiltration increases the energy consumption for heating. It is estimated that infiltration increases the energy consumption by 20 to 30% compared with an airtight building envelope (Valdbjørn Rasmussen and Nicolajsen 2007). With regard to a better heat–insulated thermal envelope, the importance of an airtight building envelope becomes more pronounced in relation to the total energy consumption of the building. Furthermore, infiltration in the building envelope will result in both a less efficient heat exchanger if used for the ventilation system of the building and an increased risk of mould growth within the building envelope. However, a building must be ventilated. Fresh air should be provided to the building in an energy-efficient way that satisfies human needs for hygiene and comfort.

2.1 Air tightening of the building envelope

An airtight shell defined as that shell which encases the heated interior of a building and prevents infiltration in the thermal envelope is introduced, see figure 1.

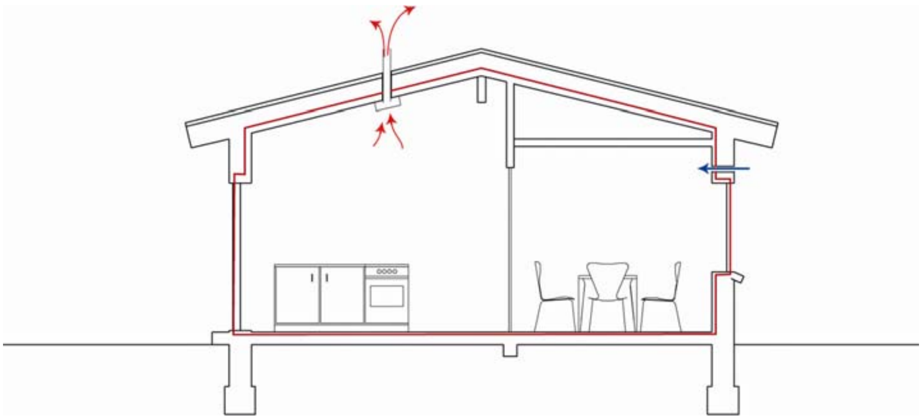

Figure 1 Location of the airtight shell in a building. The shell follows the building envelope, which consists of lightweight or heavy weight building components like wood-stud walls and concrete wall elements, respectively, combined with windows, doors, ceiling, roof and floor-slab constructions.

Typically the airtight shell follows the building envelope that consists of lightweight or heavy weight building components like wood-stud walls and concrete wall elements, respectively, combined with windows, doors, ceiling, roof and floor-slab constructions. Critical locations in the shell are located where building components are located in staggered levels, in joints between building components and at ductways, where installations are brought into the building. For lightweight building components such as wood-stud walls and ceilings, the airtight shell can be established by a 0.15 to 0.2 mm polyethylene foil additionally serving as the vapor barrier located within the insulation layer, e.g. placed between the wood trusses and the laths, see Figure 2. When the foil is used as a vapor barrier as well as an airtight shell, it is crucial that the foil is located at the warm side of the dew point and that the joints between the sheets of foils and joints facing other building components are securely fixed and airtight. Furthermore it is crucial that the joints keep their airtight properties during the lifetime of the construction, and are not damaged or decomposed during their service life. This entails a great deal of focus on how to establish the airtight shell on site during the design phase.

When preventing infiltration of the building envelope, a more efficient heat exchanger can be established, if used for the ventilation system of the building. A building should be ventilated to provide the building with fresh air to satisfy human needs for an indoor climate with a good hygiene and good comfort. When designing the ventilation system of a building, indoor air is primarily removed from rooms producing moisture and pollution from indoor activities, including rooms such as kitchens, utility rooms, bathrooms etc. Outdoor air supply is provided to living rooms and residential areas. The ventilation should not cause air velocities that locally exceed 0.15 m/s, which is normally considered to be the limit when humans feel a draft from airflow. Figure 2 shows a vent for ventilation mounted in the ceiling. The airtight shell was located in the ceiling and the vent was built into the shell. The vent was fixed to a wood support attached to the wooden trusses. The vent itself should be airtight and attached airtight to the airtight shell of the entire ceiling. The airtight shell of the ceiling was established by a polyethylene foil that also served as a vapor barrier. The polyethylene foil was placed between the wood trusses and the laths. The polyethylene foil was mounted on the frame of the vent and joint. The joint was secured and fixed in a way that ensured that it would perform and stay airtight during its service life.

Figure 3 shows a hatch for passage to the loft through the ceiling. Where the airtight shell was located within the ceiling, a hatch was mounted in the ceiling so it was built into the airtight shell. The hatch itself was airtight and the airtight shell of the hatch was extended to the airtight shell of the entire ceiling. By using a polyethylene foil as the airtight shell in the ceiling, the foil had to be securely attached to the frame of the hatch. A packing between the opening part of the hatch and the frame of the hatch ensured that the hatch was airtight when it was closed.

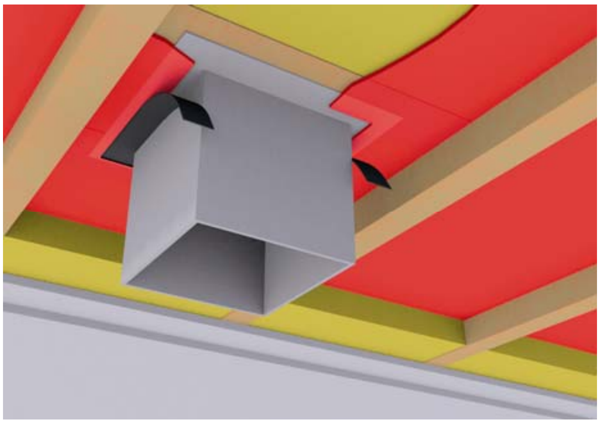

Figure 2 Ceiling-mounted vent for ventilation. The figure shows in detail how the airtight shell of the entire ceiling was attached to the vent. The airtight shell in the ceiling was established by a polyethylene foil, additionally serving as the vapor barrier. The polyethylene foil was placed between the wood trusses and the laths. The polyethylene foil was joined to the frame of the vent. The joint was secured and fixed in a way that ensured that it would perform and stay airtight during its service life.

Infiltration in the airtight shell was located by creating a pressure difference between the interior and the exterior of the building. By maintaining a pressure difference, infiltration would be revealed when designed openings in the building envelope were closed. Having lower outside temperatures compared with the temperature inside the building, infiltration was easily revealed by maintaining a low pressure inside and using thermograph equipment.

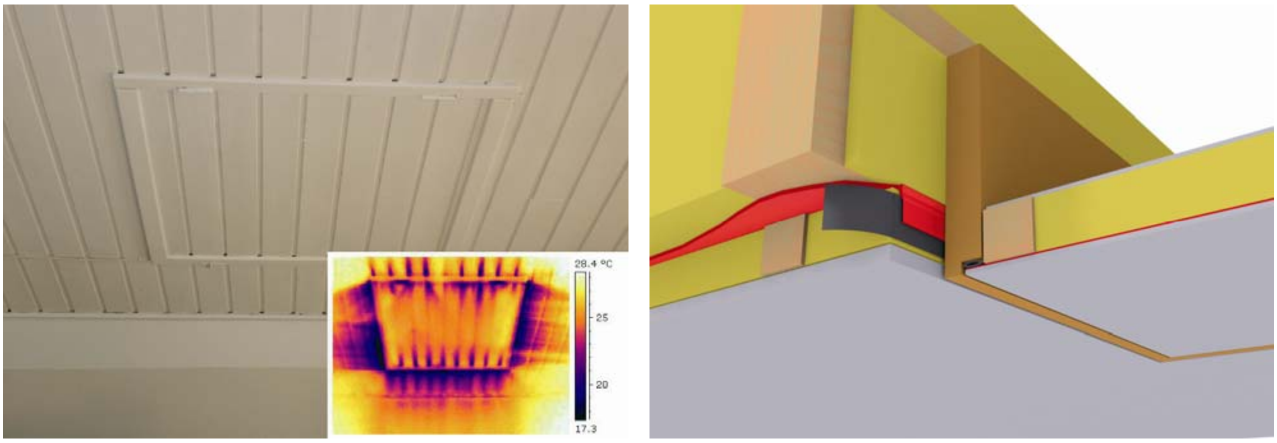

Figure 3 Ceiling with a hatch. The picture to the left shows an ordinary photo of a ceiling with a thermographich picture inserted at the lower right corner. The thermographic picture shows the infrared thermographic observation of a ceiling with a hatch. The colors on the infrared thermographic picture visualize the temperature of the ceiling. To the right, the figure shows in detailed how the airtight shell of the hatch was extended correctly to the airtight shell of the entire ceiling. The airtight shell in the ceiling was established by a polyethylene foil that also served as a vapor barrier. The polyethylene foil was placed between the wood trusses and the laths. The polyethylene foil was joined to the frame of the hatch. The joint was secured and fixed in a way that would ensure that it stayed airtight during its service life.

Thermograph equipment was used to show surface temperatures. Low temperatures inside a building reveal thermal bridges or locations of infiltration where cold air was sucked in when a low pressure was created inside. An infrared thermographic observation of a ceiling with a hatch is shown in Figure 3. The colors on the infrared thermographic picture visualize the temperature of the ceiling. The pictures to the left show an ordinary photo of the ceiling with the thermographic picture inserted at the lower right corner. To the right, the figure shows in detail how the airtight shell of the hatch was extended correctly to the airtight shell of the entire ceiling when fixed. The airtight shell in the ceiling was established by a polyethylene foil, additionally serving as the vapor barrier. The polyethylene foil was placed between the wood trusses and the laths. The polyethylene foil was mounted on the frame of the hatch and joint. The joint in particular was secured and fixed in a way that would ensure that it stayed airtight during its service life.

Heavy-weight building components such as concrete wall elements should themselves be airtight as well as being able to joint airtight for use in and as the airtight shell. Guidelines for establishing an airtight shell are given in Valdbjørn Rasmussen and Nicolajsen (2007).

2.2 Heat Loss through Thermal Bridges in the Building Envelope

A thermal bridge is defined as that a part of the building envelope where otherwise uniform thermal resistance is significantly changed. Typically by a full or partial penetration of the building envelope by materials with a different thermal conductivity, or by a change in thickness, discontinuation of the insulation material e.g. at wall, floor and ceiling joints. Typically such thermal bridges occur at the joints of different building components where it is difficult to achieve continuity in the thermal insulation layer. Thermal bridges give rise to two- or three-dimensional heat flows and have a major effect on the thermal performance of the building envelope. Thermal bridges decrease the internal surface temperature locally, thereby increasing the risk of mould growth at high humidity levels (Valdbjørn Rasmussen et al. 2006). The better the insulation of the building envelope, the larger the relative contributions of thermal bridges to the overall transmission heat loss of the building, and the more important it is to develop improved constructional details as well as improved buildings components. The effect of thermal bridges in the building envelope is significant, either due to the long length of joints per unit of the heat loss surface or due to joints with large thermal transmittance. It is estimated that thermal bridges in the building envelope increase the energy consumption by 13 to 17% compared with a continued homogenously insulated building. When attention is paid to avoiding thermal bridges in construction detailing, the contribution of building joints to the thermal transmittance may be minimized to less than 5% of the heat loss (Janssens et al. 2007). In low energy building design, this quality of detailing is certainly necessary to obtain a sufficiently low average thermal transmittance of the overall building envelope.

One focus area has been heat loss through the strip foundation of a building. In order to improve the joint between the exterior wall and the floor slab, a new solution was introduced as an alternative to the traditional Danish strip foundation of concrete. The new solution was a prefabricated lightweight element intended to meet the same performance requirements as the ones traditionally used.

2.2.1 Superinsulated strip foundation elements

The prefabricated elements were made of expanded polystyrene to form an element that could be used as the strip foundation of a house up to two storeys high. Elements were produced as one coherently shaped element through a production including an injection-molding process. The expanded polystyrene is produced from a mixture of about 5-10% gaseous blowing agent (most often pentane or carbon dioxide) and 90-95% polystyrene by weight. The solid plastic is expanded into a foam through the use of heat, usually from steam. The voids filled with trapped air give the element a low thermal conductivity. This makes it ideal as a construction material used as insulation in building systems. In the following the expanded polystyrene will be referred to as EPS. The calculated thermal conductance is 0.034 W/mK. The prefabricated element was specially designed to form the base for a house with an exterior wall of either a traditional double-brick wall, a traditional wood-stud wall, or combinations of lightweight concrete, brick and wood-stud walls with insulation. However, only when the strip foundation was fully integrated into the insulation located underneath the house, a foundation system was created that allowed very little energy to be lost through the foundation element that connected the concrete floor slab and the outer wall. In this case the strip foundation was to form the base for a house with an exterior wall made as a traditional wood-stud wall within insulation. The prefabricated EPS element was produced as units of 1.2 m in length and 0.6 m in width. The prefabricated element is 98% air by volume and has a density of 33.0 kg/m^3. The EPS has a characteristic short-term compressive strength equal to 250.0 kPa and long-term compressive strength equal to 75.0 kPa with a 2% strain, see Figure 4 a).

Figure 4 b) shows the prefabricated element made of EPS used as the strip foundation of a traditional wood-stud wall within mineral fiber insulation. When supporting a wood-stud wall, the insulation underneath the concrete floor slab can be of the same thickness throughout the concrete floor slab. The exterior wood-stud wall is supported by the concrete beam behind the outer plinth.

The prefabricated element of EPS was designed to form part of a foundation system that allows very little heat to be lost through the strip foundation, the joint between the ground deck and the exterior wall. The heat loss through the strip foundation will be referred to as the surplus heat loss, [W/mK] in the following. The surplus heat loss is defined as that heat loss which cannot be attributed to the one-dimensional heat loss through the ground deck and the exterior wall, individually. Surplus heat loss through the joint between the ground deck and the exterior wall is closely related to the design of the strip foundation.

Stainless steel rods of 5 mm in diameter were put through the EPS, every 0.6 m, forming the mechanical fastening point of the concrete for the outer plinth and the concrete floor slab. The mechanical fastening between the concrete for the outer plinth and the concrete floor slab contributes to the surplus heat loss through the strip foundation element. By using stainless steel rods, the contribution to the surplus heat loss is 0.002 W/mK (Danish Standards 2002, Table A.3.2). However, the contribution to the surplus heat loss decreases by using carbon fiber or other types of materials with a low coefficient of heat transmission to establish the mechanical fastening of the concrete for the outer plinth and the concrete floor slab.

The method calculating the surplus heat loss through the prefabricated strip foundation element is shown in Valdbjørn Rasmussen (2007 and 2008); a PC is used and the finite difference program HEAT2 version 5.0 in accordance with the method described in Danish Standards 2002. Calculations are dynamic with the outdoor temperature changing throughout the year.

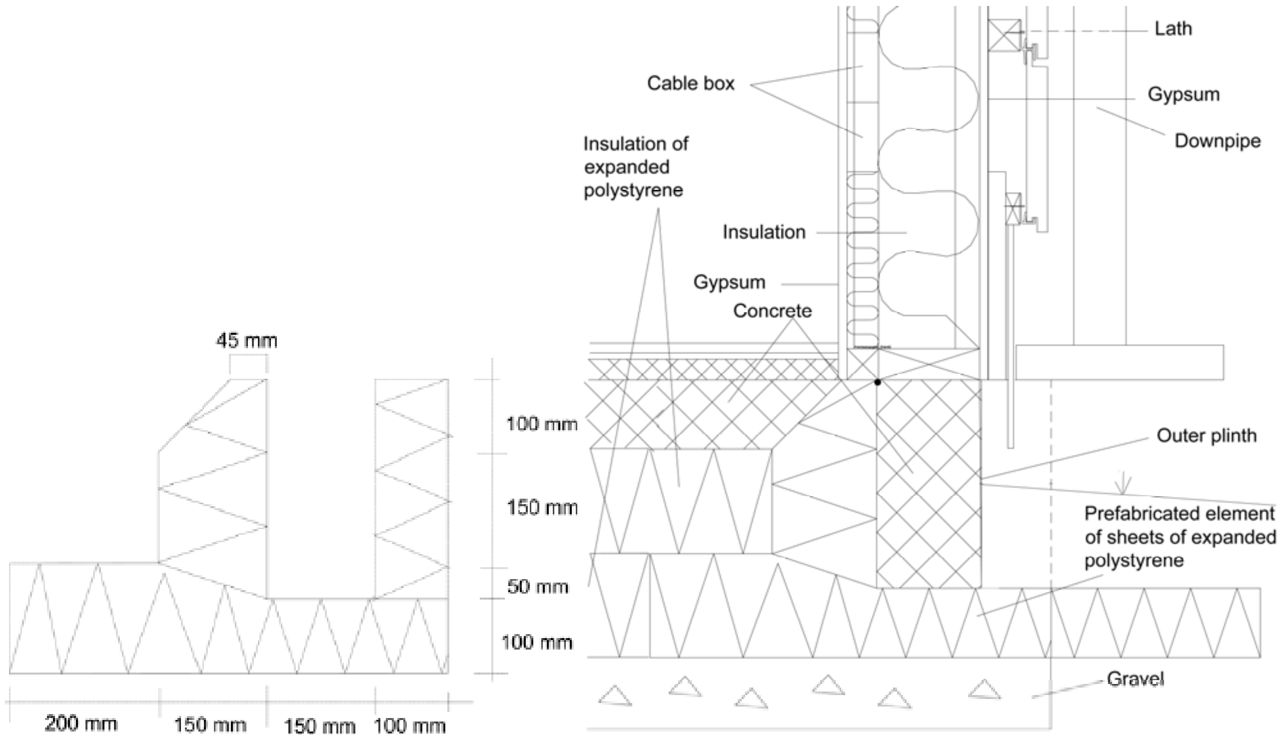

Figure 4 a): left, the prefabricated element made of EPS, b): right, the EPS element used as the strip foundation of a traditional wood-stud wall within mineral-based insulation.

2.2.2 Heat flow and temperatures in the strip-foundation system

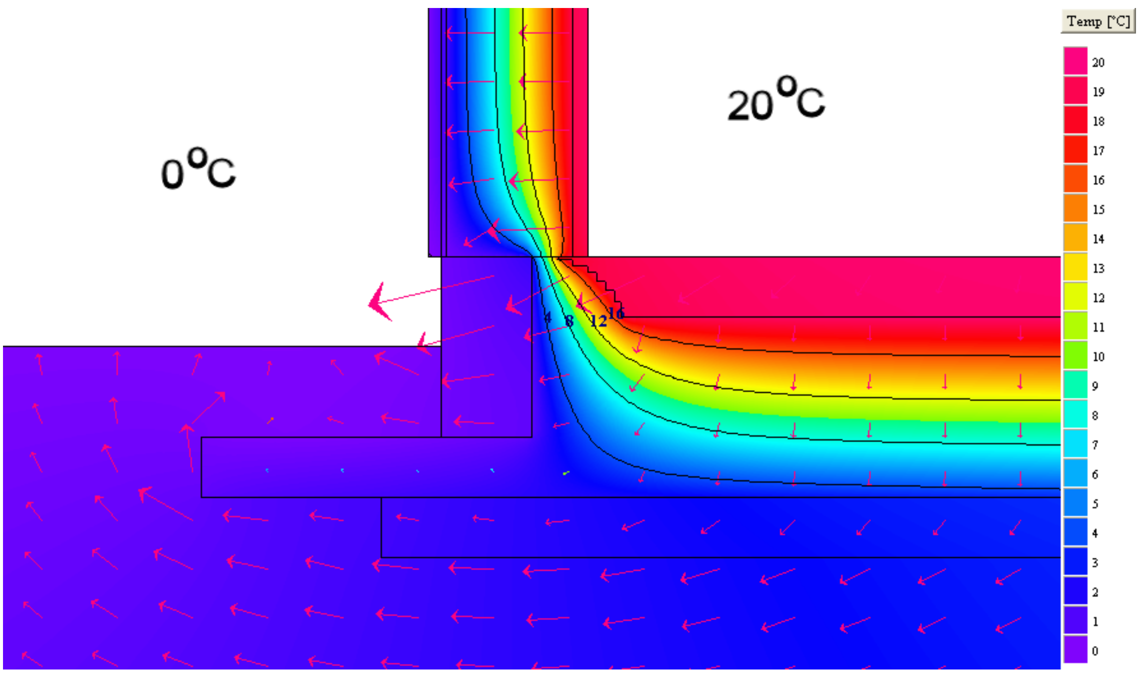

Figure 5. Temperature, isotherm curves and the heat flow through the prefabricated lightweight element used as strip foundation and the base for a traditional wood-stud exterior wall.

Ensuring stable non-freezing ground underneath the building was necessary for maintaining the stability of the structure and for avoiding settling cracks. To ensure stability of the strip foundation, it is important that temperatures lower than -1 °C do not occur in any frost-susceptible layer underneath the building during a cold winter (Danish Standards 2001). Temperatures below -1 °C underneath the capillary breaking layer could cause frost deformations of the soil underneath, which would in turn increase the risk of the strip foundation settling. Boards of EPS from the outer plinth of the strip foundation were used to form the element called the outer insulation. Design of the outer insulation was based on the descriptions given in the Danish Standards 2001, e.g. by using temperature characteristics for a cold winter, by using a design value of 100 years, where the lowest average outdoor temperature of a month decreases from -0.5 °C in a normal year to -7.3 °C in a cold year (Rose 2006).

Figure 5 shows the temperature, isotherm curves and the heat flow calculated for the prefabricated lightweight element, used as the strip foundation and the base for a traditional wood-stud wall within mineral fiber insulation. The average coefficient of heat transmission of the exterior wall was equal to 0.2 W/m^{2}K. For the calculations, the interim insulation to the ground deck and soil equaled 1.67 m^{2}K/W; the interim insulation to the soil itself equaled 1.5 m^{2}K/W, which allows the average coefficient of heat transmission of the ground deck to be 0.09 W/m^{2}K. Calculations were carried out with the specific heat capacity of the soil and the thermal conductivity of the soil set to 2.0 MJ/m^{3}K and 2.0 W/mK, respectively. Calculations were made for a building with conventional heating and for an outdoor temperature of 0 °C and an indoor temperature of 20 °C. The calculations were performed by using the PC program HEAT2 version 5.0 as a stationary calculation reaching thermal equilibrium between indoor and outdoor temperature. Arrows show the heat flow and the length of the arrows visualizes the relative heat flow. Isotherm curves are drawn as continuous lines with fixed indications of the temperature of the individual curve. Colors/grayscale used to visualize the temperatures are listed in the column to the right.

2.2.3 Building a strip foundation

Figure 6 a): Left, prefabricated leightweight elements, made of EPS, mounted as the strip foundation. The elemente were fixed together with large clamps of plastic, b): Right, 300 mm EPS, mounted as two layers on top of the base of stamped gravel bordered by the strip foundation that served as the insulation layer underneath the concrete floor slab. Iron was mounted as a net inside the strip foundation and as wires along the moat formed by the two vertical boards of EPS in the prefabricated elements, before concrete was cast and leveled.

At most locations in Denmark, a stable ground of glacial deposit (moraine) is present underneath a top soil layer of approximately 0.2 to 0.4 m in thickness. The top soil layer was removed in an area covering the area of the building. Material down to a depth of at least 0.35 m underneath the top soil surface had to be dug up. The excavated area was then covered with a capillary breaking layer of gravel, which was stamped in order to form the stable base for the building. The prefabricated EPS elements were mounted as the strip foundation, see Figure 6a). Fixed together with large clamps of plastic and with an outer support. 0.3 m of EPS in two layers, was mounted inside the strip foundation, served as insulation underneath the concrete floor slab. Before casting the concrete, an iron net was mounted to prevent cracks from developing due to shrinkage, inside the strip foundation and as wires along the moat formed by the two vertical boards of EPS in the prefabricated elements. Wires of stainless steel rods, 5 mm in diameter were put through the inner vertical boards of the prefabricated elements of EPS every 0.6 m, in order to connect the concrete in the moat to the concrete floor slab. Concrete was cast and leveled, see Figure 6b). After a few hours, when the concrete was dimensionally stable, the outer vertical boards of the prefabricated elements of EPS were removed, thus exposing the outer surface of the concrete moat as the outer plinth. The removed outer vertical boards of EPS were used as the outer insulation on the ground around the plinth.

3. Discussion

The tightened energy provisions included in the new Danish Building Regulations (Danish Enterprise and Construction Authority 2008) are intended to result in an energy reduction of 25% for new buildings compared with buildings built in accordance with the former Building Regulations. By focusing on the air tightening of the building envelope, the heat transmission of the thermal envelope and thermal bridges that cause heat transmission through individual building components and joints, more sustainable buildings are constructed with reduced energy consumption for heating and comfort.

This study focuses on two specifically important areas for the heat loss through the building envelope, in particular methods to ensure air tightening of the building envelope and thermal bridges. Thermal bridges are prevented by introducing a new building component for the strip foundation, ensuring continuity of the thermal insulation layer in the exterior wall and the insulation underneath the concrete floor slab. Furthermore, the on-site performance of the superinsulated strip foundation of prefabricated lightweight elements was introduced and demonstrated as an alternative to the traditionally used strip foundation of concrete.

3.1 Air Tightening

Infiltration in the building envelope causes unnecessary heat loss and a risk of mould growth. The water vapor content in the outdoor air is low in winter. When the cold air enters the heated rooms indoors, it will be heated up and the relative humidity of the indoor air will decrease as a consequence (Andersen et al. 1993). The indoor air will be altered by water vapor generated by occupants, plants and everyday activities such as cooking and washing. In this case the air in a heated occupied room will contain more water vapor than the outdoor air. In winter, air that leaks out through unforeseen leakages in the building envelope will decrease in temperature and rise in relative humidity. The air is likely to condense within the insulation, thus increasing the moisture content and the risk of mould growth and the decomposition of the building. By building airtight and ventilate well and controlled through vents, moisture and polluted air can be removed from the indoor environment. A certain amount of air change is necessary to keep the relative humidity of the indoor air at an acceptably low level.

Infiltration in the building envelope can easily be prevented. An airtight shell that encases the heated interior of a building should be introduced at the design phase. Typically the shell follows the building envelope that consists of lightweight or heavy weight building components. Often lightweight wood-stud walls or heavy weight concrete wall elements are used mounted with windows, doors, ceiling, roof and ground constructions. Critical locations in the shell are located where building components are located in staggered levels in between building components and at ductways, where installations are brought into the building.

For some building components the airtight shell can with advantage be established by a polyethylene foil that also serves as the vapor barrier placed within the building envelope. The foil serving as the vapor barrier should be placed in the insulation located at the warm side of the dew point in order to avoid condensation. For the airtight shell it is important that the joints between building components are securely fixed. Furthermore it is crucial that the joints keep their airtight properties during the lifetime of the construction, and are not damaged or decompose during their service life. This entails a great deal of focus on how to establish the airtight shell on site as well as during the design phase.

3.2 Superinsulated Strip Foundations

The prefabricated element was designed to comply with requirements of low energy consumption for buildings by lowering the heat loss through the thermal envelope. The surplus heat loss through the foundation element, the joint between the exterior wall and the floor slab, was partly secured by the geometrical continuity of the thermal insulation layer across the joint and partly by the overall design of the element. The prefabricated lightweight foundation element was designed to be integrated into the insulation layer located underneath the concrete floor slab at the ground deck and to face the insulation within the exterior wall. At the bottom of the exterior wall, the heat flow increase significantly changed thermal resistance regarding the change in the thickness of the insulation material towards the exterior wall, see Figure 5. Hence the geothermal heat is used to ensure that there is stable, ground not susceptible to frost underneath the building. Therefore it was necessary, for maintaining structural stability and to prevent settling cracks during cold winters, to establish outer insulation in front of the outer plinth.

The investigation covered a real life situation and use of a newly designed element to be used as the strip foundation of a single-family house. The house was a single-storey house with an exterior wall made as a traditional wood-stud wall within insulation. The performance of the element was observed and recorded on site. Ground conditions at the building site consisted of a stable ground of glacial deposit (moraine) covered with a capillary break layer of gravel, stamped to obtain stable base for the building. The base for the house was cast in one working operation and completed within two working days. The elements were adjusted on site and shown to be able to be handled by one man.

4. Conclusion

Air tightness of building envelopes is a key factor in determining infiltration, heat loss, indoor air quality, maintainability and moisture balance within the building envelope as indoors. Air leakages through the building envelope contribute to the cost of ventilation, heating and cooling and also to moisture migration.

Furthermore, air tightness is that property of building envelopes which is the most important for understanding ventilation. Air tightness is important from a variety of perspectives mostly from infiltration, movement of air through leaks, cracks, or other and unforeseen openings in the building envelope. There is a direct connection between an airtight building envelope and low energy consumption for heating in the building. With regard to a better heat-insulated building envelope, the importance of an airtight building envelope becomes more pronounced in relation to the total energy consumption of the building. If using a heat exchanger for the ventilation system of the building to ensure fresh air to fulfill human needs for hygiene and comfort, a less efficient system is provided decreasing in efficiency with less efficient air tightness of the building envelope.

Thermal bridges, parts of the building envelope where the otherwise uniform thermal resistance is significantly changed, and effects on heat loss has been ignored for many years. Full or partial penetration of the building envelope by materials with a different thermal conductivity, by a change in thickness or discontinuation of the insulation material is traditionally found at window, door, wall, floor, and ceiling joints. Such thermal bridges give rise to two- or three-dimensional heat flows and have a major effect on the thermal performance of the building envelope. Furthermore, thermal bridges locally decrease the surface temperature indoors, thus increasing the risk of mould growth at high humidity levels. As for a better heat-insulated building envelope the importance of avoiding thermal bridges becomes more pronounced in relation to the total energy consumption of the building. The effect of thermal bridges in the building envelope is significant, either due to the long length of joints per unit of the heat loss surface or due to joints with large thermal transmittance. When eliminating thermal bridges in the building envelope, it is important to design joints as well as new building component that ensure continuity of the thermal insulation layer of the building envelope.

Summary

Many recognize the value of sustainable construction as it reduces the negative impact on the environment and improves quality, accessibility and productivity for all of those who live and work inside buildings. However, economical advantages, which would help expand the concept in the marketplace, have not yet been established. The objective of this paper is to present a methodology to assess the cost-effectiveness of the application of sustainable measures in buildings through actions that establish a balance between environmental, economical and social factors. The methodology is based on the comparison of a case study (a building in which sustainable concepts were applied) with reference buildings making it possible to demonstrate triple bottom line added values. The aim is to achieve an optimum balance point, with an acceptable pay-back time and to provide evidence of good economic results in order to encourage the investment on sustainable construction.

1. Introduction

This paper was prepared with the objective of highlighting the concept of sustainable measures in building construction, a concept which has been commonly rejected for one main reason, its cost effectiveness. This problem is linked to some key issues:

- The lack of financial support, direct incentives and understanding of different advantages associated to sustainable buildings by governments, financial institutions and insurance companies.
- Builders and promoters in the real estate market have maintained a basic behaviour (and interest) to look for standard solutions that avoid an increase in the initial cost (investment) of new projects (construction phase). Thus they are transferring operational costs associated to the life cycle of the building to future owners.
- Finally, it is commonplace to observe the general conduct (building stakeholders) that is characterized by a restricted ability to consider the real costs generated during construction and operational phases in buildings. These costs are not considered or introduced in the market price formula, nor are they considered in the planning phase. Simply, they do not exist for building stakeholders. Some of these costs include: wastes, diseases and emissions (pollutants or CO2).

For this reason some countries have been trying to develop different tools for economical and financial feasibility as well as promote financial support, through incentives and subsidies that encourage the public and private investment onto Sustainable construction. These are recognized by their demand-efficiency in energy (25 to 30%) and water, less volume of construction residues and the use of durable materials (Kats, Gregory, 2003).

2. Tools to assess sustainable construction

Different countries have been developing studies and financial tools with the main purpose of implementing Sustainable Construction and disseminating a new mentality into the marketplace. Many of these studies are based on tools to assess sustainability which are divulged in a country and tailored to its reality, such as LEED (Leadership in Energy and Environmental Design) in the USA, Breeam (Building Research Establishment's Environmental Assessment Method) in the UK, Casbee (Comprehensive Assessment System for Building Environmental Efficiency) in Japan, among others.

Defined by a methodology and an evaluation system, these tools aim to classify and recognize a sustainable building, and at the same time, they work as a guideline for builders and project designers. A well-known example is the research carried out in the United States, where 33 buildings were compared (certified buildings or in the certification process, by LEED) with other conventional buildings. In this analysis, certain assumptions were used such as discount rates -5%; period of analysis - 20 years; annual inflation - 2%.

It was observed in " The costs and financial benefits of Green Buildings" report (Kats, Gregory 2003), that an investment of 2% (on average) over the initial cost (compared to a conventional building), produces financial benefits 10 times higher than the referred investment (for a period of 20 years), considering the analysis of some cost categories, such as consumptions, maintenance, emissions and productivity.

The same report gives us a simple example of how to evidence these benefits. Applied to a real case and assuming that the construction costs in California are about $150/ft2 to $250/ft2, increasing 2% to these values, it would be equal to $3/ft2 and $5/ft2, respectively. The cost effectiveness analyzed in 20 years would be equal to $48/ft2 and $75/ft2. If these values did not include the inherent benefits concerning CO2 emissions and productivity (just considering the reduction of energy and water demand, and less volume of waste) these would be around $6/ft2 (Kats, Gregory, 2003).

Another interesting study (also in the United States), prepared by David Langdon (2004), had the objective of analyzing costs linked to the construction phase of a "green building". This study showed that these costs (construction phase) drive the main decisions in sustainable projects (see figure 1). This report, which compared the construction cost per area in certified and non certified buildings by LEED, accounted for the cost of an information "database" of more than 600 projects (from 19 different States, typologies, locations, sizes and programs).

The referred study concluded that many projects reached the sustainability with their initial budgets or with a minimal additional increase (on average 2%).

In Europe, there are new incentives and legislation seeking to promote more aggressive policies in relation to the challenges of sustainable buildings. New studies have been carried out dedicated to cost effective buildings through sustainable construction concepts. These studies have been financed by the European Commission. Examples are the ASCOT model (Assessment of Sustainable Construction and Technologies Cost), a project carried out in 2004 by HQE2R and Cenergia. This tool helps users to implement a cost optimization of construction in which sustainability measures have been applied.

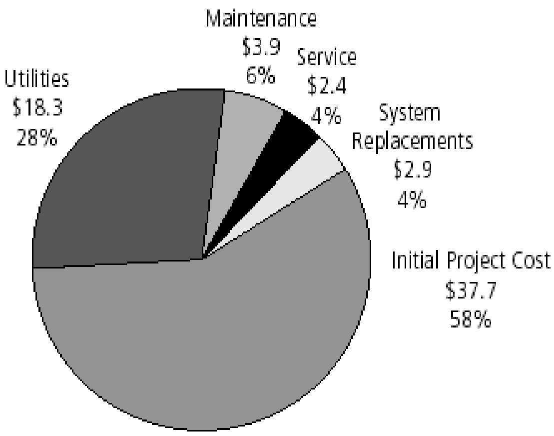

Figure 1 30 years Life Cycle Cost - Building example (Megan, Davis et. al, 2005)

There was also an increased interest in the subject of economic feasibility related to assessment tools and projects which can be applied to sustainable construction, such as SHE (Sustainable Housing in Europe): SHE has the main function of helping in the concept, cost analysis (initial cost and comparison to new buildings) and different options to obtain a higher viability of sustainable measures in projects. Another project, also co-financed by the European Commission, is the LCC-IP –"Guidebook-Integrated Planning for Building Refurbishment Taking Life- Cycle-Cost into Account". This project was constituted by several European case studies where an optimized relation between sustainable measures and cost – benefit analysis was demonstrated. Finally, it is important to make reference to the government calendar in the UK, regarding the new "Zero Carbon Emissions" program in new houses.

These studies demonstrated that a substantial amount of additional investments made in sustainable projects, are based on specific costs such as simulations, introduction of new technologies and integration of sustainable practices into the project. The studies also evidenced that it is always important to introduce these measures as soon as possible, mainly in the design phase.

3. Economic feasibility adapted to Portuguese reality

The above mentioned studies were carried out according to their national contexts. Thus, this paper intends to show a methodology that is being developed to assess the cost-effectiveness of some sustainable measures to be applied to commercial buildings, adapted to the Portuguese reality. The study will be carried out according to sustainability criteria based on two assessment tools:

- BREEAM (Building Research Establishment Environmental Assessment Method) (UK) – the first environmental assessment tool that was developed in the world;
- SBTool (Sustainable Building Tool) (Can) a tool which clearly identifies sustainable criteria (establishing environmental, social and economical criteria), and has been disseminated in several countries around the world (the Portuguese adaptation of the SBTool is in a pilot phase).

The various stages of this methodology are outlined in figure 2 and described below.

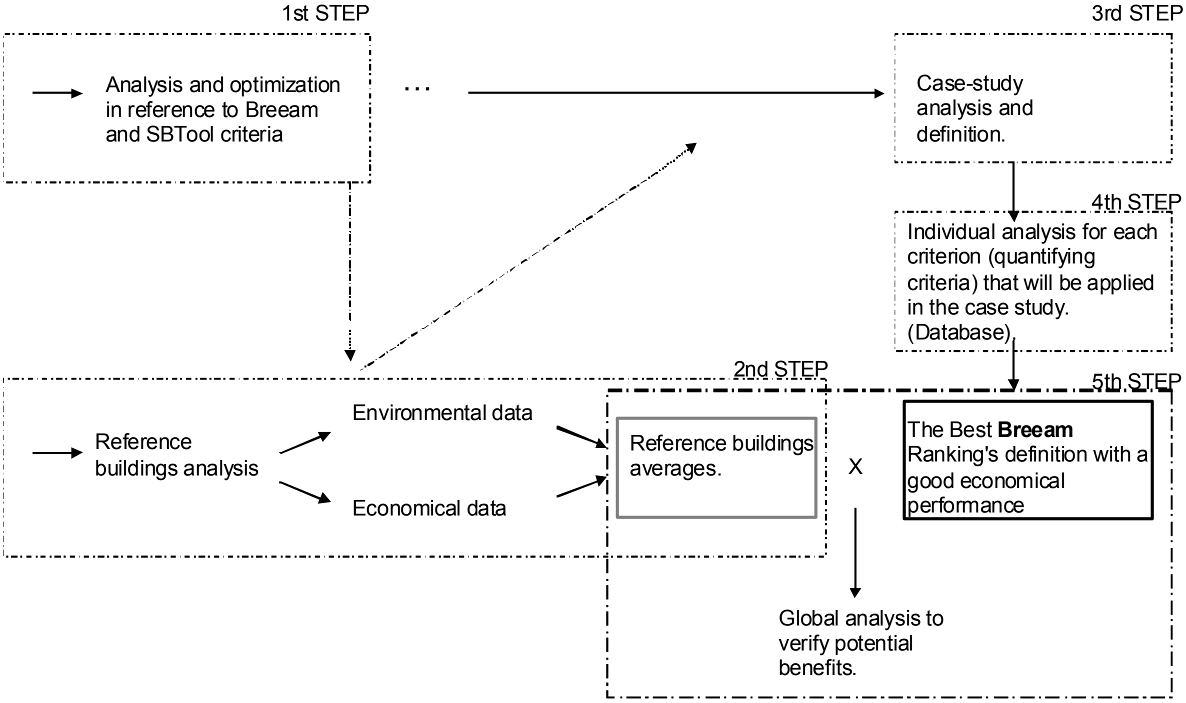

Figure 2 Structure of the proposed methodology

3.1 Guideline for sustainable construction and action analysis (1st step)

The first step of the proposed methodology is based on the criteria of analysis of a case study based on the previously mentioned tools (Breeam and SBTool), in which the criteria were identified and separated into different groups:

i) "Criteria of complex quantification", which produce indirect benefits, and are related to:

- Biodiversity;
- Measures with ethical values;
- Certain IEQ criteria (Indoor Environmental Quality);

ii) Sustainable criteria already covered by the Portuguese legislation. These are not considered in this research as they do not introduce any added value or differentiation for new challenges on Sustainable Buildings, as they are presently compulsory and related with:

- IEQ (Indoor Environmental Quality) covered by current legislation;
- Other criteria covered by current legislation.

iii) Quantified criteria through cost benefit analysis related to:

- Materials,
- Water management;
- Energy management.

These quantified criteria will be the main focus of this research. They may not be considered key elements but they can be directly quantified by cost benefit analysis, which allows for a binomial effect:

- Obtaining measurable results (direct benefits) for stakeholders - one of the main aspects for the decision-making of the project promoters and also the major contribution to the sustainable property/business value;
- Meet critical sustainable criteria based on international tools. These criteria are considered crucial to perform the best ranking proposed by these tools (See Figure 3).

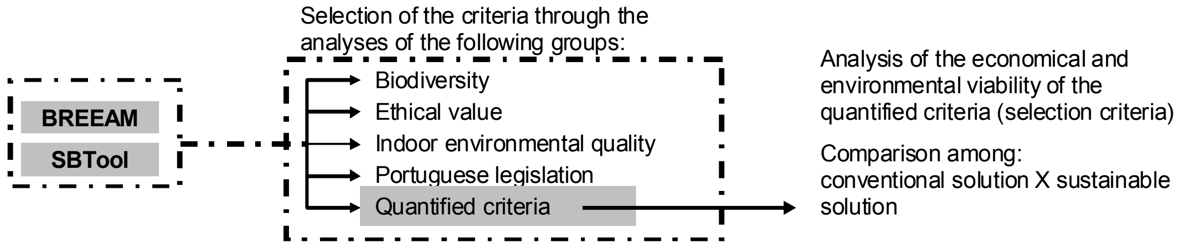

Figure 3 Selection procedures for the optimization of the criteria to be analyzed

Through this analysis it was possible to identify 116 SBTool criteria of which:

- 22% are already included in the Portuguese/ European legislation;
- 24% are related with quantified criteria.

and 72 existing criteria from the Breeam-Retail:

- 25% are already included in the Portuguese / European legislation (equivalent to the English legislation);
- 26% are quantified criteria (as above) of which a high incident is associated to profitability factors (of promoters or owners).

In spite of not being considered here, other indirect benefits may determine changes in the building performance related with economical results. An example is the IEQ (Indoor Environmental Quality) criteria which promotes excellent results in human and organizational productivity, when buildings are strongly related with services or commercial activities.

The profitability factor to owners and promoters must experience a cultural change in the interpretation of results to reflect a medium-long term perspective (positive balance between: Investment -first capital- cost, acceptable pay-back and higher cash flows during the lifecycle building or analysis period) as opposed to short term expectations (low investment cost -first capital- and comparable negative results during the building lifecycle).

The objective of this research is to recognize the evidence provided from the reduction of environmental impact when sustainable tools criteria are applied while at the same time demonstrate that these may lead to important economical advantages through direct benefits resulting from different actions on the reduction of consumption, conservation/maintenance effects and the added-value increase for Shopping Centers.

For an economical and environmental evaluation through this methodology, an individual application will be necessary. This will be demonstrated later in step 4.

3.2 Reference Building Definition (2nd step)

While actions were optimized through Breeam and SBTool criteria, environmental and economic data have been collected on three existing Shopping Centers in Portugal (which used equivalent construction methods) – Dolce Vita Porto (DVP), Dolce Vita Coimbra (DVC),Dolce Vita Douro (DVD). These commercial buildings belong to the Chamartín Real Estate Company.

Through the obtained data of those buildings, which will be referred to as “reference buildings”, it has been possible to establish efficiency indexes (consumption/m2/year and consumption /1000visitors/year) as can be seen in tables 1 and 2. In addition to these indexes (energy, water, CO2 emissions, recycled and non-recycled waste), global values will be compared with national and international "benchmarks" (see table 3). Nonetheless these can be analyzed according to the IEE (index of energy efficiency), specified for shopping centers, which is comprised by the law 79/2006 (that emerged from the transposition of the EPBD - Energy Performance Building Directive into the Portuguese law) which can be visualized in table 4.

It is important to point out that the values for the Portuguese reference building in table 3 are not directly comparable with the IEE values in table 4. To establish this comparison it would be necessary to separate the different types of consumption (heating, air conditioning and lighting) and to be identified along with the appropriate correction factors set out in the law 79/2006. The values listed in the previous tables (1, 2 and 3) represent actual and overall consumption from the different shopping centers.

Table 1 The efficiency index of the total demand (resources) and Chamartín's average per sqm (without climate correction).

DVS demand /sqm (construction area -GLA -Parking)							2006
Shopping Center	*Economical data*	*Environmental data*					
	Euros	Energy		Waste		CO_2emissions	Water
	Euros/m^2	kWh/m^2	Tep/1000m^2	Recycled /m^2	Non recycled / m^2	KgCO$_2$/ m^2	m^3/m^2
DVP	32.96	474.86	137.71	6.91	20.87	196.59	0.83
DVD	22.12	283.50	85.07	6.24	11.08	117.37	0.50
DVC	29.43	370.69	107.50	6.79	21.45	153.46	0.79
Average	28.17	376.35	110.09	6.65	17.80	155.81	0.71

Table 2 The efficiency index of the total demand (resources) and Chamartín's average per 1000 visitors.

DVS demand /1000visitors			2006
Shopping Center	*Environmental data*		
	Energy	CO_2emissions	Water
	KWh/1000visitors	KgCO$_2$/1000visitors	m^3/1000 visitors
DVP	1458.80	603.94	2.56
DVD	1265.24	523.81	2.24
DVC	1105.02	457.48	2.39
Average	1276.35	528.41	2.40

Table 3 The average efficiency index of Shopping Centers - International benchmarks. (Source: CIBEUS and other researches).

Annual Average energy Intensity (existent Shopping Centers)			
	GJ / sqm	KWh / sqm	Kgep / sqm or Tep / 1000sqm
Canadian Shopping Center average	1.30	361.40	**105**
UK Shopping Center average	1.04	290.00	**84**
Portuguese reference building	1.35	376.35	**110**

Table 4 The efficiency index, specified for the Shopping Centre in agreement with the decree-law 79/2006 (RSECE, 2006)

Existent buildings		
Activity types	Building typology	IEE (Kgep/ sqm.year)or (Tep/1000sqm.year)
Commercial	Commercial center	**190**
New buildings		
Activity types	Building typology	IEE (Kgep/ sqm.year) or (Tep/1000sqm.year)
Commercial	Commercial center	**95**

It is important to point out that the shopping centers are situated in different locations, thus different climatic factors were obtained for the "reference buildings". A basic comparison of the average values showed by the three buildings would be incoherent, as they would reflect the different climate features of the buildings performance.

With this in mind and influenced by the methodology used in the Decree-Law 79/2006 to define the IEE index (Energy Efficiency Index) for different building typologies, as referred above, climatic correction factors were applied to these shopping centers located in Coimbra (DVC), Porto (DVP) and Vila Real (DVD), when necessary.

Through these results, it will be possible to establish a comparison, on an economical and environmental level, between the “reference buildings” and a “case study”.

3.3 Case study definition (3rd step)

Following the analysis of the reference building and the verification of the selected criteria (from the sustainable tools), this methodology will be applied to a case study, the largest Iberian Shopping Center, which also belongs to “Chamartín Real Estate S.G.P.S., S.A”. The building is being constructed in Amadora, near Lisbon with a total construction area of 423.000 m2, including parking and 122.000 m2 of GLA (Gross Leasable Area). This project was designed with a new concept brand for Shopping Centers, named “Dolce Vita”, a world market reference. It will include wide reading spaces, stores, a food court, recreation areas and supermarkets.

The chosen typology is quite relevant (in relation to its dimension) since a commercial building of this size will have high environmental, social and economical impacts (Environmental impact, resulting from its construction and management, social and economical impacts, resulting from future changes in local reality, employment and road flow increases).

An evaluation of the shopping center, which is presently in the construction phase, has been carried out in order to verify if any sustainable criteria have already been applied. The measures which have already been applied will be compared (economic and environmental factors) with the reference building options, while the criteria which has not been applied will be compared with the present project options (considered less sustainable measures) of the case study.

The objective at this phase is to validate the selected criteria with an economical and environmental feasibility analysis.

3.4 Cost- effectiveness of sustainable construction indicators and database creation (4th step)

Only the Breeam tool will be used for evaluation during this stage. The final objective will be not only the analysis of the selected criteria but also to assess in which place of the ranking established by Breeam the case study results will be put on.

At this stage, the cost-benefit analysis of each sustainable measure (applied individually) will be analyzed through a simulation carried out in the selected commercial building previously mentioned.

First of all the information will be organized by categories that can be quantified (energy, water and material). This information will then be structured according to the organization schemes used in several sustainable tools.

The expected results are identified by environmental (CO2 emissions, consumption reductions and other important ecopoints) economical (investment cost, generated NPV (Net Present Value)) and payback period data. The database will be completed in the following steps:

1. Identification of BREEAM criteria that correspond to the project phase and that will be analyzed in the database. For each indicator, there are actions to reach objectives.

2. Identification of actions, which were already identified in the studied building, and which consider the Breeam criteria in the database. Analysis of actions should be accomplished through the comparison with conventional actions used in the reference buildings.

3. Identification of actions that were not found in the studied building and that should be filled out in the database. Analysis of these actions should be accomplished through the comparison with present existing measures in the studied building, regarding potential changes.

The final information will be organized in a database similar to the example shown in Table 5. Regarding outcomes from the implementation of 3 sustainable measures on the referred table, it can be demonstrated the following information.

- Energy example – Comparison between Installation of energy-efficient lifts with Regenerative system (SI –Sustainable Investment) and conventional lifts (CI - Conventional investment) – modification just applied in 30% of the lifts;
- Water example - Comparison between installation of dual flush WCs - 4,5 litres (SI- Sustainable Investment) and simple flush WCs (6 litres) (CI - Conventional investment);
- Materials example – Comparison between thermal insulation with low embodied impact (corkboard) (SI – Sustainable Investment) and thermal insulation with high embodied impact (extruded polystyrene - XPS) (CI – Conventional investment).

Presupposes considered: Inflation rate (year average) - 2, 5% Economic Cycle Analysis -20 years; Electricity price increases – Growth rate (year average) - 3%; Water price increases – Growth rate (year average) - 1%; Discount Rate for NPV (Net Present Value) – 6% (NPV - The present value of an investment's future net cash flows minus the initial investment).

For an additional Investment cost of € 72 198, 41 (SI- Sustainable Investment for the referred 3 examples), equivalent to 9,8% more than CI (Conventional Investment), It results on a total NPV of € 159 226,83 (equivalent to € 1, 31/sqm). The simple pay-back for the total investment is reached in 5 years.

Table 5 Database structure

Application example - Comparison result (conventional versus sustainable criteria)										
Case-study: DVT Shopping Center (Lisbon) Type occupancy: RETAIL Phase: Design Phase										
Breeam-Retail			Economical data			Environmental data				
Related category	Ref.	Criteria	Investment cost (€) and (%)	simple payback (years)	NPV (20yrs) (€)	KgCO2 reduction (per year)	Reduction consumption (%)(un/year)	embodied energy reduction	Breeam ranking
Energy	Ene8	Up to two credits are available where evidence provided demonstrates the installation of energy-efficient lift(s).	**29 799,00 (>14%)**	8	27407.60 (0.22€/sqm)	**< 12 709 (79.5%)**	**< 79.5%** (KWh)		2
Water	Wat1	1. All WCs have an effective flush volume of 4.5 litres or less. 2. Where dual flush toilets are specified they have guidance or symbols instructing the user on the appropriate operation of the flushing device.	**5 400,00** (13.4%)	1	168 818.64 (1.38€/sqm)		**<4 727 (m3) (<25 %)**		1
Materials	Mat6	1- Where evidence provided demonstrates that thermal insulation products used in the building have a low embodied impact relative to their thermal properties, determined by the Green Guide to Specification ratings.	**36 999,41 (>8 %)**	no payback	- 36 999,41 (-0.30€/sqm)			<7621 MWh (85%)	1
		total Investment (3 examples)	72 198,41 (0.59€/sqm)	5	159 226,83 (1.31€/sqm)				4

3.5 Defining the best Breeam ranking with a good economical performance

Following the analysis and the completion of the database with quantified criteria, the pre-assessment estimator (from the Breeam-retail) will permit the verification of rankings achieved in the case study. One of the aims of this work will be to compare and analyze the economical and environmental behaviour of three different scenarios (with different Breeam ranking) (See Figure 4). These are:

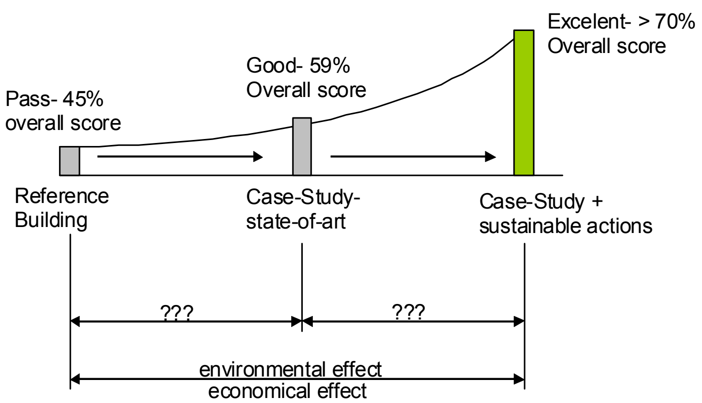

Figure 4 The comparison and analysis between different scenarios.

Scenario 1: The case study with approximately 45% overall score. (The same as Reference building)

Scenario 2: The case study with approximately 59% overall score (Actual situation of the case study with criteria already applied on the case study)

Scenario 3: The case study with >70% overall score (Breeam excellent ranking) (Case-study + criteria that were not considered in the case study at the time).

This process will be achieved by adding other Breeam criteria (referred above as “criteria of complex quantification”), which have solutions with low first capital impact.

The referred capital costs along with the new criteria will be considered as investment costs in both cases when totalizing the complete NPV and Payback effects on a global basis for the case study. Nonetheless the potential benefits of these criteria will not be considered as they provide “indirect benefits” and are difficult to quantify. This is the reason why the analysis (“Criteria of complex quantification”) will focus on solutions with a low investment cost impact. When this is not possible other solutions with a more economical impact will be used with the assurance that the expected NPV and payback results will not be negatively affected on a global basis, and at the same time capable of reaching the desirable overall ranking.

The explicitness and transparency that demonstrates efficiency benefits, and the way how to reach economic value in sustainable buildings, are a decisive incentive for stakeholders and for real estate market in general.

However, it is important to remember that this study will be defined for a specific typology in a certain area. Therefore the result will be conditional and will not allow a direct and immediate application of the best scenario methodology into other projects.

Nonetheless, through its main output information (costs definition, database output and new methodology), this study can serve as an important guideline to help different stakeholders involved in new sustainable building projects focused on economical benefits.

4. Conclusion

This paper seeks to define methodologies and objective contents to achieve newer and larger real estate projects (services /commercial), supported by sustainability concepts.

This study used the “Breeam and SBTool” tools as they are considered rigorous and are recognized among universities and academic environments and are essential resources for the study and development of Sustainable Building Evaluation.

Finally, this study seeks to define new methodologies and analysis aiming to integrate different action fields such as sustainability, functionality and economic feasibility (cost effectiveness) which more than often are used separately.

Keywords: Sustainable Urban Development, indicators, megacities, emerging countries

Summary

In the case of fast developing megacities of emerging countries, an integrated concept for the assessment of SUD, including the social and cultural dimensions comprehensively, is of particular need: Megacities are locations of polarization of people. Different cultural, social and income groups live closely together, thus opening an area of conflict. However, for the aspect of social sustainability, a theoretically stringent, systematic and comprehensive rationale which is translated into practical application does not yet exist.

The aim of the paper is to shed light on theories within the social and cultural dimensions of the sustainability assessment, on the specific socio-cultural challenges in megacities and on existing indicator systems possibly applicable in those megacities. Based on existing studies and expert interviews of local stakeholders, specific requirements for the assessment of the social and cultural dimensions are formulated for the emerging megacity Hyderabad (India). Following this analysis, both the gaps in research and practice as well as challenges and responses are pointed out.

1. Introduction

> *"There is almost complete unanimity among local and national governments and planning agencies that accurate, timely and policy-relevant data are a pre-requisite for good governance, good planning and good management."*
>
> State of the World's Cities Report 2001:114

As the citation from the State of the World's Cities Report 2001 points out, values of meaningful indicators are essential for authorities, both on urban, regional and national levels. Indicators, especially when compiled in indicator sets, help identifying the most critical issues for action. Furthermore, they provide transparency and feedback to both decision-makers and the civil society. In megacities of emerging countries indicators play a distinctive role as they increase rationality in governance[1].

Over the last years, a number of performance indicator sets[2] for the assessment of Sustainable Urban Development (SUD) have been developed. Yet, comprehensive concepts for the assessment of SUD are still lacking in most developing countries of Asia (Ooi 2007), where they would be much required: The concept of SUD poses a particular challenge to megacities[3] with their specific problems that are mainly due to their size, complexity and diversity. In the case of fast developing megacities of emerging countries, an integrated concept for the assessment of SUD, including the socio-cultural dimension comprehensively, is of particular need. Since different cultural, social and income groups live closely together, high potential for conflict is given (Laquian 2005:193-194).

The development of a megacity-specific indicator system by local bodies is typically preceded by a compilation of existing indicators. In a second step, a number of suitable indicators are chosen from this

---

[1] Dr. Jo Santoso, expert interview (03.12.2007).

[2] An indicator is, according to the definition of OECD "a parameter, or a value derived from parameters, which points to, provides information about, describes the state of a phenomenon/environment/area, with a significance extending beyond that directly associated with a parameter value" (OECD 1994:9). If indicators are used for performance evaluation (like the here discussed Urban Performance Indicators), they are "selected and/or aggregated indicators" (ibid.) of the urban economic, ecological, social and cultural environment.

[3] A megacity is an urban area or an agglomeration with more than (varying in definition) five, eight or ten million inhabitants (Kraas 2007:82).

"long list". Thus, existing indicators serve as basis for practice-oriented new indicator developments. But are the existing indicators suitable for the adaptation to megacities in emerging countries?

The goal of the paper is to analyze the suitability of existing indicator sets and indices for Sustainable Development (SD) in megacities of emerging countries in view of the socio-cultural dimension. The general requirements of socio-cultural sustainability are pointed out and an overview of the needs of megacities of emerging Asian countries in the socio-cultural sector is given. The indicator sets and indices are analyzed in view of both these requirements. Finally, the challenges for the assessment of the socio-cultural dimension of SUD in (emerging) megacities is discussed in a detailed way and illustrated by the emerging megacity Hyderabad (India).

2. Materials and Methods

2.1 Socio-cultural Dimension of Sustainable Urban Development

Concepts for the operationalization of the rather abstract concept of SD break down its complexity into several subject areas, so called *pillars* or *dimensions*. Commonly, the concepts are based on the triangle of sustainability with the corners ecology, economy and society. Besides that, a variety of other definitions exists, including different factors for the description of the relationship between people and their built environment. Among those, sustainability models including the cultural dimension are of special interest, as they enlarge the definition of *built environment*. This paper draws upon a three-dimensional model of sustainability, where the social and cultural dimensions are coalesced to a socio-cultural dimension (cf. model of UNESCO 2005).

While the ecological and economic dimensions can be described rather intuitively, the definition of the socio-cultural dimension is more difficult. Therefore, a multiplicity of varied definitions exists. The Blackwell Dictionary of Sociology defines social as "anything that is related to social systems, their characteristics, and people's participation in them" (Johnson 2000:284). A social system can, in terms of the systems theorist Parsons, „refer to a stable relationship between two actors, to societies as a whole, to systems of societies, or indeed any level between these." (Scott et al. 2005:618). Accordingly, *social sustainability* describes two layers of social aspects which are included in the majority of concepts for social sustainability: The individual level, like the fulfillment of personal needs, and the level of society, like political participation and social peace (Empacher et al. 2002:13).

According to the definition of the *Mexico City Declaration on Cultural Policies*, "in its widest sense, culture may […] be said to be the whole complex of distinctive spiritual, material, intellectual and emotional features that characterize a society or social group. It includes not only the arts and letters, but also modes of life, the fundamental rights of the human being, value systems, traditions and beliefs" (UNESCO 1982). As culture includes both material and immaterial aspects, there is a disaccord amongst researchers about what cultural sustainability should be. *Cultural sustainability* commonly occurs to one of two different, but connected notions: Firstly, the claim for consistency of changes and core values, expectations and customs (Sachs 1999:32-33) and, secondly, a culture of decisions (Krainer et al. 2007:115).

Both social and cultural sustainability are also described in literature as dimensions having strong influences on the economic and ecological pillars of sustainability. Thus, the social and cultural dimensions consist supplementary in a second layer that lies crosswise on the four pillars of sustainability.

2.2 Assessment of the Socio-cultural Dimension of Sustainable Urban Development

In the last 20 years, a number of concepts for the assessment of SD have been created. Besides a number of integrated concepts considering several dimensions of SD, focused research has been carried out, which lead to specialized indicator sets and indices like the Ecological Footprint.

In the field of social indicators, first attempts go back to the 1960s, when social accounting was introduced, but certainly not yet linked to the concept of sustainability. "Social indicators relate to some area of social concern and they may serve the purposes of curiosity, understanding or action. They may take the form of simple data series or they may be synthetic series obtained by applying a greater or lesser amount of processing to data series. […] Social indicators form a subset of the data series and constructs actually or potentially available and are thus distinguished from other statistics only by their suitability and relevance for one of the purposes mentioned." (United Nations 1975:28) In this sense, social sustainability indicators serve the purpose of monitoring SD and apply thus the concept of the earlier social indicators. The most comprehensive investigations for sustainability indicators in the social dimension have consequently been carried out by social scientists with a broad knowledge of earlier attempts to compile social indicators.

In their review of existing indicator sets for social sustainability, Empacher et al. describe the multiplicity and variety in aims of different indicator sets. However, they also observe a condensation around several items: social justice with equitable distribution of income, access to resources and chances to live and act (Empacher et al. 2002). In their proposal for an indicator set, they include both "objective" and subjective indicators "since the perception of problematic areas is an important element of the social reality and moreover can differ as a matter of principal from the objective situation." (Empacher et al. 2002:68) This broad approach and its theoretical foundation distinguish the indicator concept from others and account for its attractiveness. Table 1 shows the dimensions and "Sub-Dimensions" of the indicator set, while the country-specific (Germany) indicators are not cited here.

Table 1 Proposal Indicators for social sustainability by Empacher et al. (2002:86)

Dimension	*“Sub-Dimension”*
Fulfillment of basic needs/ quality of living	Poverty
	Education
	Employment
	Dwelling
	Health
	Individual satisfaction
Social resources	Engagement for/interest in the community
	Social integration in the familiar surroundings
	Knowledge and human resources
	Tolerance
Equal opportunities/ social inclusion	Integration
	Social mobility
	Access to education
	Gender
Participation	Ethnic and other minorities
	Degree of participation
	Chances of participation

Table 2 Proposed dimensions for cultural indicators (Fukuda-Parr 2000)

Type of indicator	*“Sub-Dimension”*
Product Indicators	Cultural viability
	Cultural diversity
	Global ethics
Process Indicators	Participation in creative expression
	Access to culture
	Conviviality/ respect for cultural identity
	Chances of participation

It was as well in the 1960s, when the development of cultural indicators set off. Cultural indicators are commonly classified in *process-indicators* and *product-indicators*. Whereas *process-indicators* describe the costs (time, financial, etc.) for the use of cultural offers, “*product-indicators* deal with the way, in which on the one hand social fundamental values are communicated and on the other hand socially relevant problems and areas of life (“issues”) are placed by symbolic meanings“ (Deetjen 1989:285). This general meaning has to be filled with specific issues describing one or several areas of reality.

Concerning cultural indicators of development or sustainable development, research in this field is still in its infancy. One of the most comprehensive indicator proposals published so far is the compilation of the development economist Fukuda-Parr (2000). She combines the product-indicators of a conjointly held workshop by UNESCO and UNRISD with the process-related indicators proposed by Lourdes Arizpe (see table 2). Generally, the development of cultural indicators still lags behind the development of social indicators, both in general terms and especially with focus on sustainability.

2.3 Needs of Socio-cultural Sustainability in Megacities of Emerging Countries

In order to investigate indicator systems and their suitability for the socio-cultural dimension of sustainability assessments in megacities of emerging countries, light has to be shed on socio-cultural preconditions in this context.

The geographer Ehlers (2006:55) compiled a list of problems, risks and disadvantages of the global trend of mega-urbanization relevant to sustainable development. The list has been extended by Kraas (2006:22) who also added aspects of the political dimension to the before existing economic, ecological and social aspects. The social challenges and risks include the following issues:

- Loss of social coherence
- Growth of socio-economic disparities and of social fragmentation
- Reduced access to health care systems, educational and security infrastructure
- Informal, partly illegal settlements, urban decay
- Social disorganization: Conflicts, crime, riots, war
- Displacement processes
- Growing vulnerability of marginalized population groups
- Social injustice, abuse of social power
- Corruption, bribery, favoritism, nepotism
- Large-scale unemployment (“surplus labor force”)[4]
- Streams of migrants and commuters[4]

[4] Listed in Kraas’ “Economic Dimension”. Due to their close relation to and great importance for the social dimension, the two aspects are included in the present list.

Also investigating the most pressing challenges of megacities, MRC McLean Hazel and GlobeScan conducted a study amongst 522 stakeholders of 25 megacities (thereof nine Asian cities) (Economist Intelligence Unit 2007). The results show similar, though less detailed results, adding the challenge *population growth* (not only due to migration) as supplementary aspect.

While social challenges of megacities have been subject to detailed investigations, their cultural issues are rarely studied in a methodically sound way. The above mentioned work of MRC McLean Hazel et al. mentions *ethnic conflicts* as serious safety and security problem in megacities which point obviously at a cultural challenge (ibid:52). Another major issue in emerging and transitional cities is generally the *speed of change* and thus the risk of neglecting core values and customs in favor of copied "solutions" in various fields of other, successful urban agglomerations. Further immaterial aspects of cultural sustainability are already included in the aspects of the social dimension compiled earlier: Social coherence and integration are both major issues of social and cultural life.

2.4 Specific Needs of the Emerging Megacity Hyderabad

Hyderabad, the capital of the Indian state Andhra Pradesh, is a city branded by the current boom of the information technology. Since the last decade, the city's growing economic prosperity has caused an enormous increase in population: Between 1975 and 2000, the United Nations Population Division calculated an annual population growth of 3.84% in the agglomeration Hyderabad (United Nations 2001:97), up to 6.2 Mio inhabitants in 2007 (GHMC 2007).

In order to identify key challenges of Hyderabad, expert interviews have been conducted amongst local stakeholders, including researchers, representatives of urban and state planning authorities as well as NGO agents. Further challenges have been identified in the context of the City Development Strategy (CDS), initiated by the Municipal Cooperation Hyderabad and prepared in 2003 (Ramachandran 2004). The preliminary synthesis of interview findings and socio-cultural challenges highlighted in the CDS include:

- Limited transparency and accountability of government
- Inadequate security of tenure, housing and basic services
- Unequal livelihood and employment opportunities
- Increase in occurring infectious diseases
- Poor retention of students
- Inadequate health and education infrastructure/services
- Loss of built heritage and inherited immaterial culture

Even though the challenges mentioned are, as expected, very similar to the general needs of megacities in emerging countries, the city faces some specific characteristics, like the *loss of built heritage and inherited immaterial culture* as well as the *poor retention of students*. The above mentioned *displacement processes* are part of the broader Hyderabadi issue *inadequate security of tenure*.

2.5 Evaluation of Suitability of existing Indicator Systems

Existing indicator systems evaluated include both an international indicator system for SD in general, four indicator systems and an index for SUD chosen from a long list of 32 indicator sets and indices. Criteria for the selection of the indicator sets/index were their broad coverage of sustainability issues and the extension of acknowledgement/use of the sets. As described earlier, indicators of indicator sets and indices are typically classified into different dimensions. A first evaluation concerns the representation of these dimensions within the indicator sets/indices selected. Questions in this context are: Do the indicator sets include both social and cultural aspects of SD? How strong is their representation in comparison to the other dimensions? How inclusive are their indicators compared to the indicator sets proposed by researchers?

In order to evaluate the suitability of existing indicator systems in the socio-cultural dimension of sustainability in megacities of emerging countries, a comparative analysis is conducted. The selected international indicator sets/index are compared with the earlier identified socio-cultural challenges in megacities of emerging countries.

The international indicator systems evaluated include the UNCSD Indicators for Sustainable Development the Global Urban Indicators, the City Development Index, Healthy Cities Indicators, the ADB Urban Indicators and Urban Audit Indicators. The different indicator systems have been developed with different foci (e.g. sustainability, quality of living, health), but all of them are related to the field of sustainability. In the following, a short characterization of each indicator set is given.

Revised in 2007, the *UNCSD Indicators for Sustainable Development* (UNCSD 2007) are newly classified into 14 dimensions. They form the basis for a large number of national and organizational indicator sets.

The *Global Urban Indicators* of the third Global Urban Indicators Database (GUID III) are a set of indicators developed by UN Habitat in order to address both the Habitat Agenda key issues and the Millennium Development Goals on the urban level. Focus of the indicator set is the improvement of slum dwellers (UN-Habitat 2004:3-4).

It is an earlier version of this Global Urban Indicators Database from which the key indicators of the *City Development Index* are taken. Developed for the Habitat II Conference, the index aims at comparative analyses of the development level of cities (UN-Habitat 2001:116-120).

The third indicator system evaluated is the *Healthy Cities Indicators* developed by the World Health Organization. Aim of the system is “to describe the determinants of health in the cities of different countries” (Webster et al. 1998:1). After setting up the Healthy Cities Project in 1986 by the Regional Office for Europe, 53 indicators were chosen and tested in a pilot phase between 1992 and 1994. Drawing on the results of the pilot study, the indicator set has been modified to a tighter set of 32 indicators which forms the basis of the present investigation.

Prepared for the application to Asian Cities, the *ADB Urban Indicators* should serve the measurement of policy outcomes. Chosen by an expert group, the indicator system is the most comprehensive one (140 indicators) within this investigation, though the individual indicators included in this survey are the 112 indicators which are part of the ADB Cities Data Book 2001 (Westfall et al. 2001).

Focusing on the European level, the *Urban Audit Indicators* are aiming at the description of the quality of living of urban areas. Drawing on a study of Eurostat, 33 indicators were identified and refined during the pilot phase of the study. Today, the *Urban Audit Indicators* consist of 21 quality of life domains and a larger number of indicators. (The Urban Audit 2000)

3. Results

3.1 Representation of different Dimensions

The index and indicator sets surveyed are divided into a number of different dimensions as displayed in figure 1. The social dimension (health, shelter, education, migration, etc.) is represented in all sets surveyed, whereas it is only in the ADB Urban Indicators and in the Urban Audit Indicators where the cultural dimension is mentioned explicitly. In the ADB Indicators, the cultural dimension is represented through merely three (out of 112) indicators: Participation in sports, attendance at public events and at galleries/museums. These indicators would be located in the earlier described sub-dimensions *Participation in creative expression* and, partly, *Cultural viability* of Fukuda-Parr’s proposal as would be the cultural indicators of the Urban Audit Indicators. Concerning her additionally suggested sub-dimensions, *Cultural diversity* is addressed partly through the indicator *Minority groups* in the ADB Urban Indicators and *Nationality* in the Urban Audit Indicators. *Chances of participation are* often included in the indicator sets in relation to elections.

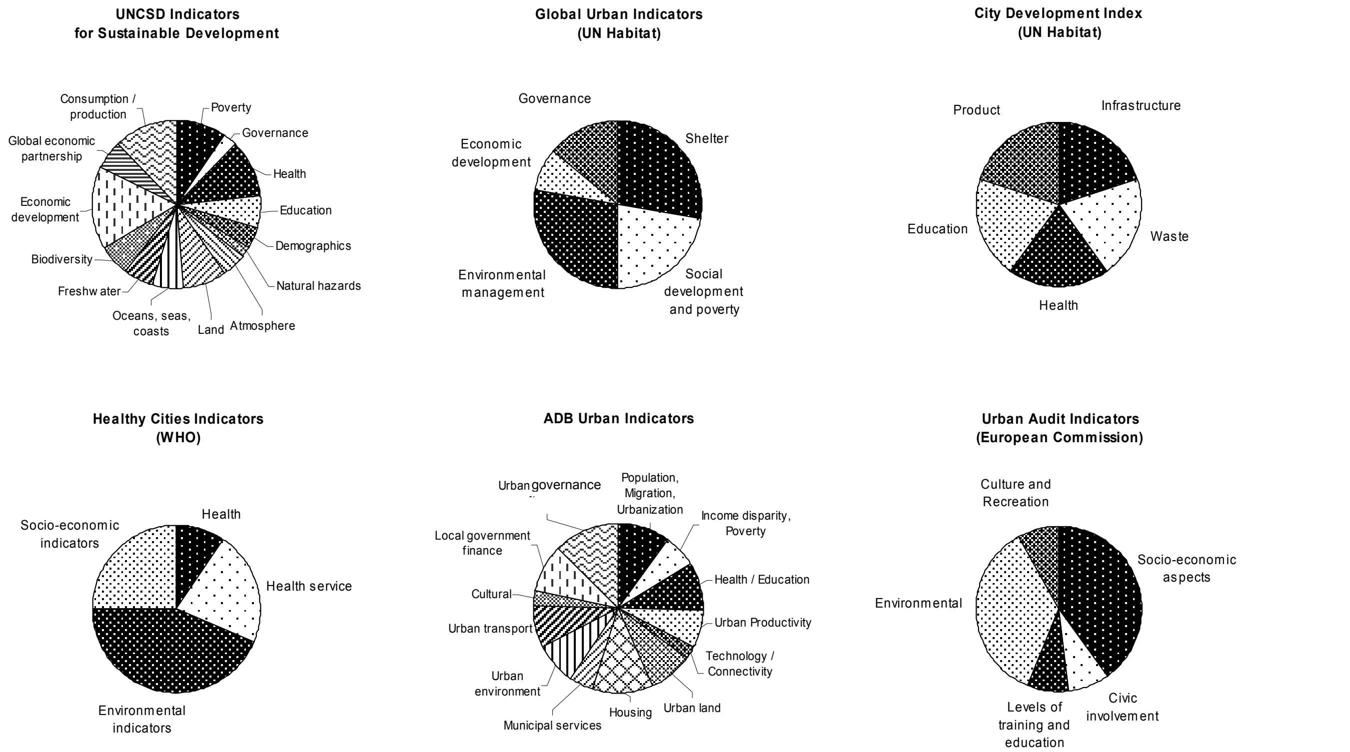

Figure 1 Quantitative representation of different dimensions within indicator sets/index surveyed

3.2. Indicator Systems by Dimensions

An overview on the results obtained from the comparative analysis is given in table 3. The listed challenges/risks are derived from the above described analysis on challenges in the socio-cultural dimension of megacity life. Solely the earlier identified aspect *Speed of change* is not included in the evaluation – if indicator systems are applied on a regularly basis, this aspect can be tracked for any indicator in use.

Table 3 Responses of existing indicator sets to the socio-cultural challenges of megacities in emerging countries

Challenges/risks of megacities	*UNCSD Indicators*	*Global Urban Indicators*	*CDI*	*Healthy Cities Indicators*	*ADB Urban Indicators*	*Urban Audit Indicators*
Loss of social coherence				(+)[5]	+	
Growth of socio-economic disparities and of social fragmentation	+	+		+	+	+
Reduced access to health care systems, educational and security infrastructure	+	+	+	+	+	+
Informal, partly illegal settlements, urban decay	+	+	+	+	+	+
Social disorganization: Conflicts, crime, riots, war	+	+			+	+
Displacement processes					+	
Growing vulnerability of marginalized population groups		+	+		+	
Social injustice, abuse of social power		+			+	+
Corruption, bribery, favoritism, nepotism	+	+				
Large-scale unemployment (“surplus labor force”)	+	+		+	+	+
Streams of migrants and commuters					+	+[6]
Population growth	+	+			+	+
Ethnic conflicts					+	

Overall, the ADB Urban Indicators seem to form the most suitable indicator set in order to address socio-cultural challenges and risks in megacities, closely followed by the Global Urban Indicators of UN Habitat. As both indicator sets have been developed for monitoring international cities of different sizes and income situations, this result has been expected.

It is only in the comprehensive indicator set of the ADB Urban Indicators, where the issue *ethnic conflicts* appears indirectly in form of an indicator (“representation of minorities” in the urban government/ management) and *displacement processes* in form of “squatter resettlement or normalization”. Waibel et al. (2007:62) describe the consequences of displacement in the case of Hanoi as follows: “Displacement processes have been common, as poorer inhabitants were out-priced, marginal settlements […] were demolished and the population was resettled to other areas […] Evidence from two inner-city upgrading programs shows that the resettlement process destroyed the inhabitants' social and economic networks in many cases and therefore often the basis of their income.” Thus, another possible future indicator for displacement processes might be the change in land prices in specific areas over time.

Another interesting aspect is *Loss of social coherence*, which also points at the integration of people. The WHO’s Healthy Cities Indicators include the “availability of primary health care services in foreign languages” which is an aspect of offering services for everybody. The only indicator set comprehending a non-specific indicator for social integration is, again, ADB’s Urban Indicators. They include “perception as a place to live” in the dimension “Urban Governance and Management”. Though, the respective descriptions of the indicator given in the ADB Cities Data Book do not clearly point out whose perspective is expressed. The *European Common Indicators* (Ambiente Italia 2003), an indicator set not included in the present review (as it has been developed as supplementary indicator set), offer a more suitable indicator in terms of inclusion of the citizens’ perspectives: Under the headline “Citizens’ satisfaction with the local community”, six different aspects are surveyed in a random sample population group: Level of social relationships, opportunities to do hobbies and enjoy leisure, level of basic services, natural and built environments, employment opportunities and opportunities to participate in local planning processes.

Streams of migrants are explicitly included in the ADB Urban Indicators (“Annual net migration”) and partially in an indirect way through the indicator “Nationality” in the Urban Audit Indicators of the European Commission. Even though the latter points at the phenomenon of migration in general, it cannot reveal the

[5] Integration of all in the healthcare systems.
[6] Indirectly and in parts measured through the Indicator “Nationality”.

time people have spent in an urban agglomeration and is thus not very helpful for the identification of possible integration difficulties. Concerning *streams of commuters*, there is a lack of indicators.

The challenge *corruption, bribery, favoritism, nepotism* is included in two sets of indicators: The UNCSD Indicators for Sustainable Development and the Global Urban Indicators. The latter includes a qualitative list on “transparency and accountability”. The check-list comprises six questions concerning the checking of municipal accounts, the publication of contracts/tenders as well as budgets/accounts, sanctions against misconduct of officials and instruments to both receive information on and investigate corruption (UN-Habitat 2004:54). The UNCSD Indicators report on the indicator “Percentage of population having paid bribes” to government officials (UNCSD 2007:50).

3.3 Challenges for the Assessment in the Indian Hyderabad

The city of Hyderabad faces, as described above, some specific challenges and risks. The comparative analysis displayed in table 4 shows the appropriateness of the surveyed indicator systems in responding to those specific challenges.

Table 4 Responses of existing indicator sets to the additional socio-cultural challenges of Hyderabad

Specific challenges/risks of Hyderabad	*UNCSD Indicators*	*Global Urban Indicators*	*CDI*	*Healthy Cities Indicators*	*ADB Urban Indicators*	*Urban Audit Indicators*
Loss of built heritage and immaterial inherited culture						
Poor retention of students						
Inadequate security of tenure	+	+			+	+

Whereas the *inadequate security of tenure* is addressed in several indicator sets, the *loss of built heritage and inherited culture* as well as *poor retention of students* are not included in any set. The specificity of the latter is suggested to provoke the absence of responding indicators. The challenge *loss of built heritage and inherited culture* would be included in Fukuda-Parr’s proposal both in form of a product indicator (*cultural diversity*) and a process indicator (*conviviality/respect for cultural identity*).

4. Discussion and Conclusions

Analyzing the suitability of existing indicator sets and indices for SD in megacities of emerging countries in view of the socio-cultural dimension, some deficiencies appear. Even relatively inclusive indicator sets like the ADB Urban Indicators lack a broad coverage of the cultural dimension of SD in comparison to the cultural indicator set proposed by Fukuda-Parr from the point of research. The social dimension is represented more comprehensively in most indicator sets even though it shows gaps in the coverage of relevant topics: The comparison of the indicator sets/index with the specific socio-cultural challenges in megacities of emerging countries showed that challenges like *displacement processes*, *loss of social coherence*, *corruption*, *streams of migrants/commuters* and *ethnic conflicts* should be addressed in a broader way. Generally, the ADB Urban Indicators and the Global Urban Indicators display a relatively good addressing of challenges. For the specific case of Hyderabad, two of the three specific challenges are not addressed.

The comparative analysis shows that the suitability of existing international indicator systems for the adaptation to megacities in emerging countries is limited in the socio-cultural dimension. Instead, proposed indicator systems from the point of research could bear an opportunity for the development of comprehensive megacity-specific indicator systems by local bodies. However, the availability of statistical data is limited, especially in developing countries. Working with relatively new indicators would imply alternative ways of data sources or collection.

Therefore, it is suggested that further research in the field of socio-cultural indicators in the assessment of SUD should not only include the development of indicators, but also try to facilitate low-cost, accurate and simple data collection.

Keywords: EnviroDevelopment, sustainability, urban development, incentives, industry.

Summary

EnviroDevelopment was developed by the Urban Development Institute of Australia – Queensland (UDIA (Qld)) to encourage more sustainable development. It is designed to reward high achieving developments and encourage others to achieve greater sustainability. It is also designed to clearly communicate to stakeholders and the public what developments have achieved in terms of sustainability.

EnviroDevelopment is performance based and applicable to a diverse range of development types and situations. It covers the broad spectrum of environmental and sustainability issues from the initial conceptual stages of a development, with elements devoted to ecosystems, water, energy, waste, materials and community. EnviroDevelopment is gathering strength and has already successfully enhanced sustainability of our future urban areas through its encouragement of industry champions.

1. The Context

Broad media coverage and credible scientific research of environmental issues has elevated community awareness in recent years. Climate change, pollution and resource scarcity (particularly water, fossil fuels, habitats and land) threaten biodiversity, human health and lifestyles. With rapid population growth in Queensland particularly, there is a need to develop our cities and towns carefully to reduce their environmental impact and conserve our resources.

The gradual recognition of the urgency of addressing these issues has seen a number of initiatives emerge. This has largely included regulation, exemplar projects, guidelines about some specific aspects of relevance to the building industry and a few rating tools. While some of these initiatives have enjoyed some success, they have had some limitations.

Environmental regulation is rapidly increasing, however regulation can generally only set minimum standards. Regulation offers no reward to high performers and its inflexibility can cause perverse outcomes. In 2002, UDIA and the Queensland Environmental Protection Agency formed a partnership to encourage and promote sustainable practices. The Sustainable Urban Development Program was able to inspire those already interested in sustainable development but had limited success in mainstreaming sustainability in on-the-ground projects as it did not sufficiently mainstream incentives.

Other tools have been limited in their scope, focussing on particular environmental elements and/or particular types of buildings and are often not applicable to the initial stages of planning or development. Many of these initiatives have been limited in their uptake and market recognition, due either to their complexity, cost, limited scope or lack of incentives for developers to implement.

UDIA recognised a need to develop a framework which would encourage and assist developers in the uptake of greater sustainability and which offered benefits to government, service providers and the community and gains for the environment.

2. EnviroDevelopment

The goal of EnviroDevelopment is to increase the uptake of sustainable urban development. To achieve this goal, implementation of the EnviroDevelopment Technical Standards must enhance sustainability i.e. it must deliver real achievements in terms of environmental and community outcomes. This must include the key concerns applicable to today's society such as reducing greenhouse gas emissions, water efficiency and protecting biodiversity. Importantly it must also motivate developers to implement sustainable development principles in their developments. The framework must be embraced by the industry, because if the program is not taken up by industry, it will have limited impact on the sustainability of the communities we live in.

The objective of EnviroDevelopment is to inspire and reward high performing developments in the field of sustainability. Designed to encourage flexibility and foster a proactive culture of innovation and environmental benevolence, it is performance-based and is adaptable to a range of development types and situations.

EnviroDevelopment is also designed to clarify the issue of sustainability in developments for local governments and consumers. It is imperative that it is clear what a particular development achieves. EnviroDevelopment also has a role in uniting sectors through partnerships based on benefits, incentives and common purpose.

To ensure the community understands what EnviroDevelopment certification represents, the message is kept simple yet meaningful through an innovative branding system. However, the system is supported by analysis using the best research available at the time and the scrutiny of professionals in the field.

3. The Journey

EnviroDevelopment has been developed in consultation with a range of stakeholders to ensure that the process of EnviroDevelopment certification is rigorous and maintains integrity. The Technical Standards Taskforce was formed at the beginning of the project to draft the technical standards of EnviroDevelopment. The Taskforce includes representatives from developers, consultants and state and local government. Careful balance was required during the formation of the concept and technical standards to ensure that EnviroDevelopment was flexible enough to encourage innovation and broad application, straightforward for consumers to understand with little interpretation and reliable enough to ensure its perennial integrity and achievement of enhanced sustainability outcomes.

The EnviroDevelopment Board of Management was established to oversee the operation of EnviroDevelopment at a strategic level and is responsible for overseeing the certification process. The Board consists of small, medium and large-scale developers, lawyers, and environmental consultants and also involves the Foundation Partners and Supporting Organisations as observers. The EnviroDevelopment concept has been supported by four Foundation Partners – St. George Bank, Boral, Brisbane City Council and GWA Caroma Dorf – with support also from the Queensland Environmental Protection Agency. Greening Australia and the Australian Green Development Forum have also provided support as Supporting Organisations.

4. EnviroDevelopment Technical Standards

EnviroDevelopment standards are structured to be substantially higher than standard practice and regulation. The standards have been set to recognise the performance of a development in achieving broad environmental goals, whilst facilitating the most appropriate or innovative method to be chosen for individual situations.

The level EnviroDevelopment is targeting is roughly such that the standards are set at a level that only the top 10-20% of developments are currently achieving. However, given sufficient encouragement and incentives, the level set by EnviroDevelopment should be within the grasp of many more developers. The Technical Standards Taskforce was mindful of not setting the standards so high that they would be perceived as too difficult or expensive to attempt compliance. Such a situation would see EnviroDevelopment become irrelevant and have little positive impact on industry performance or consumer awareness. The EnviroDevelopment Technical Standards draw together and build on the strengths of existing research and tools to provide a comprehensive system.

Table 1: Elements of EnviroDevelopment

Element	Objective	Target	Notes
ECOSYSTEMS	Healthy, sustainable ecosystems based on natural processes and rich with native biodiversity	Development that aims to protect and enhance existing native ecosystems and encourages natural systems and native biodiversity and rehabilitation of degraded sites.	Includes consideration of water quality, landform, flora and fauna.
WASTE	Reduce waste sent to landfill, more efficient use of resources	Development that includes better waste management procedures and practices and reduces the amount of waste that is disposed of to landfill.	Considers demolition and / or land clearing phases as well as construction and post-construction phases.
ENERGY	Reduce usage of polluting and non-renewable energy sources	Measures that achieve considerable reduction in greenhouse gas production from energy use across the development. As well as appropriate solar orientation and peak energy demand management.	Considers both energy efficiency measures and source substitution such as use of solar energy.
MATERIALS	Environmentally responsible material usage	Development that significantly ultilises environmentally responsible materials to lower environmental impacts in preference to other materials. There are also requirements for low toxicity material choices.	Encourages reuse of resources, materials with recycled content, materials from sustainable, renewable sources and non-toxic products.
WATER	Improve water use efficiency	Measures that achieve considerable reduction in potable water use across the development.	Considers both water efficiency mechanisms and/or source substitution such as water reuse facilities.
COMMUNITY	Vibrant, cohesive, healthy, happy, adaptable, sustainable communities	Development that encourages community spirit, sustainable local facilities, reduced use of private motor vehicles and accessible and flexible design that welcomes a diversity of people and adapts to their changing needs.	Includes consideration of consultation, transport, community design, local facilities, safe, accessible housing and indoor air quality.

The details of the standards of EnviroDevelopment and the evidence required, have been carefully set based on input from developers, a range of technical experts, local government, state government and green groups. The standards will be raised over time to set an appropriately high benchmark in light of changes in regulation, technology, expectations and industry practices. The standards will also be regularly reviewed to ensure improvements in technology and new relevant research are able to be incorporated and to ensure the EnviroDevelopment certification continues to represent a very high standard.

5. Certification Process

Developers wishing to apply to have a project certified as an EnviroDevelopment are required to demonstrate how they have met the EnviroDevelopment standards and submit the appropriate documentation as evidence of their achievement and ongoing commitment to the delivery and maintenance of the required sustainability and community attributes and features. Importantly, EnviroDevelopment is designed to minimise any additional cost burden to projects through prescriptive documentary requirements, high certification costs or additional professional fees. While protecting the integrity, to the greatest extent possible, EnviroDevelopment tries to minimise the need for reinventing or formatting existing documents and is designed to draw on existing documents prepared by experts for the purposes of development approvals or other purposes as well as appropriate additional evidence.

The EnviroDevelopment certification process has to withstand the scrutiny of the industry, government and community as well as EnviroDevelopment Foundation Partners and Supporting Organisations. The applications are initially assessed by EnviroDevelopment staff, however certification still requires the consideration and approval of the Board of Management. A site visit is also undertaken prior to certification being granted. EnviroDevelopment staff liaise with applicants during the certification process and provide feedback on strategies to improve their project's performance.

Certified EnviroDevelopments are subject to random site checks. Developers are required to advise UDIA within ten working days of any changes made or proposed to be made, to the proposed or existing EnviroDevelopment certified development which may affect eligibility for EnviroDevelopment certification.

EnviroDevelopment certification is valid for the period of twelve months from the date of approval, however it can be revoked within this timeframe for issues of non-compliance and failure to achieve commitments. Renewal of EnviroDevelopment certification is possible for a minimal fee through a review and renewal process.

6. Incentives

A key aspect of the EnviroDevelopment program is the incorporation of incentives to encourage more sustainable development. The EnviroDevelopment team can assist developers in evaluating which incentives are available and the best strategies to increase the sustainability of a particular project. The benefits and incentives offered by the EnviroDevelopment framework generally fall under two categories – the marketing benefits of EnviroDevelopment certification and the incentives facilitated by partnerships and EnviroDevelopment recognition by other organisations.

6.1 Marketing

If developers choose to have a project certified under EnviroDevelopment and are successful, they are awarded the right to use the appropriate logos for twelve months for elements for which they have been certified for. A suite of logos has been developed to facilitate this and works so that each 'leaf' represents an element of EnviroDevelopment, as detailed below in Figure 1. Developers who achieve the required performance standards in each of the elements of EnviroDevelopment are eligible to use the corresponding 'leaf'.

Figure 1: The six elements of EnviroDevelopment.

For example, Figure 2 below could be used by a development which has met the requirements for certification under each of the six EnviroDevelopment elements. Figure 3 offers the alternative logo, used to depict certification of a development that has achieved the standards for all six elements. This version may be more appropriate for other uses.

Figure 2: The certification logo for a development achieving all six EnviroDevelopment elements.

Figure 3: The alternative depiction of the certification logo for a development achieving all six EnviroDevelopment elements.

Correspondingly, Figure 4 would be able to be utilised in relation to a development that has met the standards for three of the six elements of EnviroDevelopment, namely water, materials and ecosystems. This could also be displayed in a format comparable to Figure 3 but with only the water, materials and ecosystems icons present. Figure 5 shows the generic marketing logo used only by UDIA (Qld) to promote the EnviroDevelopment concept and is primarily used for marketing and communication of the framework and for educational purposes. Foundation Partners are able to use a modified version of the generic marketing logo.

Figure 4: The certification logo for a development achieving three of the EnviroDevelopment elements (Ecosystems, Materials and Water)

Figure 5: The EnviroDevelopment marketing logo (UDIA use only)

Certified EnviroDevelopments are also featured on the EnviroDevelopment website (www.envirodevelopment.com.au) and in various related publications and media. Information about EnviroDevelopment itself and certified developments is also available at EnviroDevelopment stands at UDIA and other events. Through such mechanisms and responses to inquiries approximately 1750 hard copy EnviroDevelopment standards manuals have been disseminated to industry, in addition to those downloaded via the EnviroDevelopment website.

6.2 Partnerships and Mutual Benefit

The EnviroDevelopment concept has evolved on the basis of win-win partnerships. The uptake of EnviroDevelopment provides benefits for a range of stakeholders, given the mutual goal of enhanced sustainability of developments, although some stakeholders are particularly interested in specific components of EnviroDevelopment.

Home buyers, will be able to clearly identify which of these elements a particular development has excelled in. For instance, a development may be awarded recognition for its performance in the areas of water, energy and ecosystems or any combination of the six elements outlined above, if it meets the standards set by EnviroDevelopment for the particular elements. Purchasers of EnviroDevelopments will also have the benefit of any reduced operation costs, or enhanced liveability and lifestyle benefits resulting from the sustainable focus of the development, as well as peace of mind knowing that they have made an environmentally responsible selection. They may also have greater self-sufficiency of energy or water supply, improved access to local facilities and access to 'green loans' and rebates for example.

Similarly, local governments will be able to rapidly assess some of the likely benefits of a development application relating to an EnviroDevelopment project. There are also benefits to local authorities in terms of more efficient use of resources, more attractive and sustainable urban areas, benefits to the local environment and reduced infrastructure costs. For example, a particular development may be expected to reduce demand on potable water supplies by more than 40% or may undertaken significant efforts above and beyond the average, to protect biodiversity. Similarly, there are benefits for other levels of government, service providers and the community through the better outcomes and efficiencies inspired by EnviroDevelopment.

7. Implementation

Presently, there are nine certified developments, representing over 8,800 lots / units. At the time of writing, a number of developments were in the process of preparing applications. Interest from developers across Queensland has been significant and the EnviroDevelopment standards are being utilised by developers and consultants to guide future development plans.

Following the successful launch of EnviroDevelopment in Queensland in October 2006, and widespread industry acceptance, UDIA (Qld) has commenced a national rollout of EnviroDevelopment. At the time of writing, EnviroDevelopment was being trialled by three developments in South Australia and following significant interest from developers, a commitment has been made to also progressing EnviroDevelopment in Victoria and Western Australia where there is also a significant level of enthusiasm about EnviroDevelopment in the development industry.

Already EnviroDevelopment has achieved significant outcomes in terms of sustainability outcomes. Certified developments are saving more than 1,300ML/yr of potable water and 30,900 tonnes of greenhouse gas, compared to traditional standards.

In contrast to a weighted points-based system, EnviroDevelopment is target based, which sets required performance outcomes rather than prescribing solutions. Although this requires in-depth analysis of applications prior to certification, it has facilitated recognition of some great outcomes and minimised perverse outcomes and a ‘points chasing’ mentality. Each of the nine certified developments have achieved exemplary standards in the areas for which they have been certified. Innovative solutions employed include total water and energy self-sufficiency through the utilisation of onsite and renewable systems, extensive and cooperative community consultation programs and the delivery of extensive community facilities. Water treatment and reuse systems have also been pioneered. Despite a lack of information regarding full life cycle assessments and little market recognition, some certified EnviroDevelopments have also utilised environmentally responsible materials for a range of purposes including floor coverings, framing and to meet structural requirements. These projects have also utilised non-toxic paints, coverings and finishes. EnviroDevelopments have also delivered comprehensive waste management and minimisation programs for all stages of a development and contributed significant areas of green / conservation space for the purposes of species conservation and habitat enhancement, in addition to rehabilitation works. Certified EnviroDevelopments include detached greenfield, infill, medium density, masterplanned and mixed use developments and precincts. Applications are also be progressed for an industrial development and interest has been expressed from other sectors such as infrastructure projects and transportable homes. The application of a range of innovative sustainable development initiatives for different development types, scales and sites, promoted through EnviroDevelopment has played an important role in encouraging the industry to achieve greater sustainability.

8. Lessons Learnt

The level of interest EnviroDevelopment has received from both the industry and broader community suggests that sustainable development is becoming a key priority for a growing number of people and organisations. However, obstacles such as costs and delays still exist and impact on the industry’s ability to deliver more sustainable development. The industry is still experiencing some delays in the development approval process, particularly in instances where some local governments are nervous or unwilling to approve innovative systems such as on-site water treatment and re-use. This can result in some compromises and hindrance of sustainability achievements. The EnviroDevelopment process also highlights situations where regulation has not kept pace with science and technology and changes may be desirable.

Feedback to date indicates that developers of certified projects have found EnviroDevelopment to have merit and that the branding and independent certification has been valuable, and will of course increase further over time with growth in brand recognition so long as the integrity and meaning of EnviroDevelopment is maintained. The continued high level of interest in EnviroDevelopment and regular inquiries and website hits also indicates that there is growing interest in certifying new developments as EnviroDevelopments and in utilising the principles of EnviroDevelopment in designing new developments. This is expected to continue as the value of EnviroDevelopment certification will rise with increased brand use and recognition, and the provision of incentives from all levels of government.

EnviroDevelopment has also been recognised for its merit as an educational tool. As well as its assistance to industry and government in this regard, it has also been of interest to a number of universities and schools.

In addition to general learnings and research on the subject, the various EnviroDevelopment applications received and assessed have also highlighted instances where the lack of valid and reliable data can be problematic and further research would be of merit. This includes lifecycle assessment of materials, modelling of energy and water efficiencies in various scenarios, and understanding the benefits of various ecosystem and community attributes designed into developments. However, as further research is being conducted in many of these fields, further clarity may be achieved in future years.

9. Conclusion

EnviroDevelopment provides the effective interface between the real world and sustainability ideals. It offers a unique framework to bring together the multitude of piecemeal research, tools and general goodwill that actively promotes and rewards sustainable development. It is industry-led, revolutionary and practical.

The EnviroDevelopment system seeks to achieve meaningful outcomes which are easily recognised and understood by consumers. The integrity of a third party verification of a development's sustainability credentials, through an independent Board of Management and Technical Standards Taskforce, has been recognised by industry, government at all levels and other stakeholders.

MODELLING A SUSTAINABLE URBAN MANAGEMENT SYSTEM

Summary

After developing a methodological framework to model actions taken collectively and individually by the project group, we first established an inventory of research approaches. We then expanded our approach to professionals and future residents of an urban renewal neighbourhood in Aix-les-Bains. This methodology, while originating from the strategic analysis suggested by Crozier and Friedberg, should find new applications that complement the approach adopted for quantitative-qualitative comparative analysis.

1. Initial situation of the existing approaches

Our 'Habitat' can play a decisive role in the emergence of new forms of cooperation making it possible to reconcile in day to day life preservation of the environment, economic efficiency and social equality. The significance of these concerns falls completely within the framework of urban renewal operations to release certain areas from their decline, or even their complete exclusion from the development of our societies. 751 neighbourhoods are involved, classified as critical urban areas (zones urbaines sensibles, ZUS). The expectations of planners and the needs of public bodies have multiplied in the last few years, so a systematic methodological framework is proposed based on evaluation tools adapted to the context of each urban project.

1.1 The PASTILLE European project

Cofinanced within the 5th RDFP (Research and Development Framework Programme) by the European Commission and the Swiss government, the objective of the PASTILLE project (Promoting Action for Sustainability Through Indicators at the Local Level in Europe) was to develop an indicator base to assist public bodies to adjust their decisions, taking into account the criteria for sustainable development. The need to evaluate the policies applied involves public officials directly and leads to new forms of administration known as "New Public Management". These approaches notably reinforce the need to formulate precise objectives, evaluate the progress achieved, impose sanctions if necessary or at least corrective measures, etc.

Experiments carried out within the PASTILLE project has shown that using checklists of indicators overshadows the definition of a local policy that supports sustainable development, and therefore the priorities pointed up locally. The approach we habitually find to the indicators means they cannot be perceived as "endogenous elements of the dynamics of public action, in a particular context". On the contrary, the PASTILLE consortium[1] suggests the indicators be used as strategic tools for the governance process. Shared as the chief device for a perpetual forum between the different participants in urban governance, the indicators can create more cross-functionality, enabling better negotiation of often conflicting strategies and visions…

1.2 The European measure HQE2R

Under the coordination of the Centre Scientifique et Technique du Bâtiment (CSTB, Scientific and Technical Building Centre),the European project for research and demonstration known as " HQE2R"2 (Sustainable Renovation of Buildings for Sustainable Neighbourhoods) has between 2001 and 2004 brought together ten research organisations or centres and thirteen towns belonging to seven European countries. The HQE2R project has established as objectives the proposal of some tools, methods and guides containing recommendations or good practice for urban planning or renewal operations.

Three evaluation models have been developed by the members of the HQE2R project for evaluating urban projects: the ENVI model (Committee on the Environment, Public Health and Consumer Policy) on the environmental impact of projects or scenarios, the INDI model (INDicator based sustainability Impact assessment) for project evaluation and selection, the ASCOT simulation model (Assessment of Sustainable Construction and Technologies cost) that enables the comparison of a sustainable building with a benchmark building in terms of overall cost. These tools make it possible to meet respond to the requirements of European Directive 2001/42/CE pertaining to the environmental evaluation of programmes and plans.

1.3 The ADEQUA project

The purpose of the ADEQUA method3 is to create a tool to help in decision making during the rehabilitation of a residential quarter. The project consisted first of all of a classification of the criteria for sustainable development then secondly an inventory of the methods for their evaluation. The method was then validated using case studies chosen in partnership with the authorities.

A final quantification of the indicators associated with the objectives enables construction professionals, the planner or the authority to evaluate quantitatively and to compare different planning alternatives for an area, with the aid of spidergrams. This quantification is based on the use of simulation tools and multi-criteria aggregation.

2 A new Eco Obs approach to sustainable urban management

2.1 Concept

The research presented below clearly emphasizes the importance of developing in an often conflictive context the strategic tools to aid the public authority in their decisions or their negotiations. Here the concern is to examine, in a context of urban complexity[4], sustainable urban planning projects as a mode of organisation of the actions and the participants. Elsewhere we have observed, in the context of the ADEQUA project, the difficulties encountered in evaluating different urban project scenarios. This approach does not sufficiently respect habitual practices and the resources available to the participants. So it does not suffice on its own to favour the inclusion of sustainable development issues at this scale.

The methodology that we are currently developing aims at detecting objectively the convergences or "cooperation sets" and divergences or "conflict sets" between the participants in the urban planning operation. The project group, as a sociological system, exists because of the interdependence of the participants and actions, whose objectives may converge or diverge. Different strategies are analysed with the aim of encouraging the necessary collective actions for the success of the operation. The authority can then organise the conduct of the project in accordance with the supposed blockage points inherent to the participants. Our approach represents each participant in the environmental management of an operation. The tool which has been developed on this methodological basis makes it possible to create various sociograms representing the direct influences on the participants and the impact of each participant on the objectives of an operation. It is important to develop, in an often conflictive context, tools that assist the public authority in its decisions or its negotiations.

2.2 The use of MACTOR

In order to be able represent our results visually, we have had recourse initially to the MACTOR application. This illuminates the sets of alliances and potential conflicts between the actors and makes it possible to enquire about the possibilities of change in the relations between the different participants. So at first sight it is a suitable tool for the type of study desired, and for these reasons it has been used[5] on the Mérigotte mixed development zone (ZAC, zone d'aménagement concerté) and the Aix les Bains project today.

Analysis of the sets of participants is a crucial stage for the construction of a basis for reflection that then makes possible the construction of scenarios: without this precise analysis, the scenarios lack relevance and coherence, and very often analysis of the interplay of participants is preceded by a structural analysis to identify the key variables.

So the objective of using the MACTOR method is to provide to a participant an aid to decision making for establishing their policy on alliances and conflicts.

2.3 Creation of a new tool for observing eco-districts

The tool previously described and the use of MACTOR has made possible a real advance in the domain of sustainable urban management. However, the method of collecting data took a long time: all the participants had to be interviewed separately and the data then had to be captured to proceed with the analysis.

Now it is desired to attempt to set up an IT platform on which some questionnaires would be placed online, completed remotely and collected via the internet.

The approach adopted for the creation of the new tool breaks down into five stages. The first is the choice of IT system that best responds to our expectations. The second is the creation of 2 questionnaires aimed at users and professionals as well as a working framework to filter the data from the planning project's environmental chart. The third is collection of the responses. The fourth is the processing the data, with the establishment of sociograms (using MACTOR mathematical formulas) and statistical elements. The fifth and last stage is accumulation, interpretation and the creation of a database.

3 Application to the Sierroz / Franklin district in Aix-les-Bains

The Urban Renewal of the Sierroz / Franklin Roosevelt district in the town of Aix-les-Bains is a project with the aim of transforming the area by opening it up to the rest of the town. Specifically, this is achieved by:

- dismantling 300 dwellings (4 x 14 floor towers)
- creating environmental quality (HQE® or similar approach)
- 311 dwellings in small collective homes
- shops
- premises for services
- the rehabilitation and residentialisation of 422 residences (creating defensible and 'owned' space, and/or installing security devices)
- reorganising the road network.

This project, extending over the period 2006-2012, falls very definitely into sustainable development practice. So protection of the environment, one of the components of sustainable development along with the economic and the social, must be exemplary. Like for the follow-up in the Mérigotte mixed development zone, we started by identifying several initial participants and objectives :

- The public authority and services associated with the Town of Aix les Bains;
- The town planner at Passagers des Villes architectural office

Each participant chosen has been identified based on a non-directive interview so that they can specify their goals and objectives, their strengths, their weaknesses. A single questionnaire enables us to grasp the position of each participant on the same basis. Just as we have established with MACTOR, we have been able to esta hows how closely the participants adhere to their obje

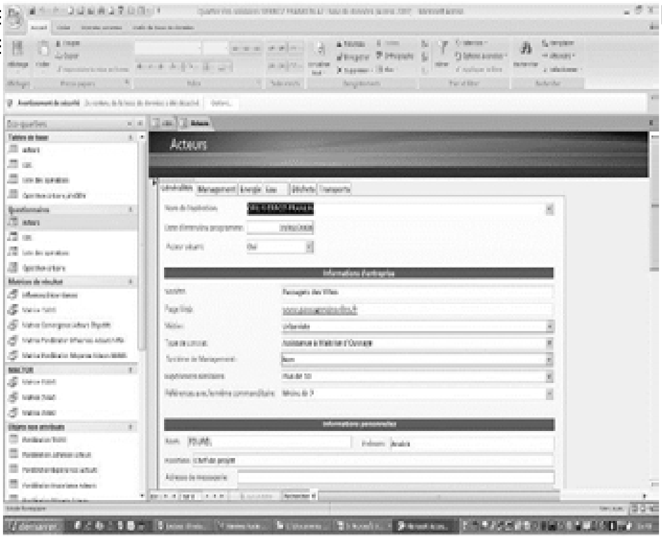

Figure 2: Eco-districts database

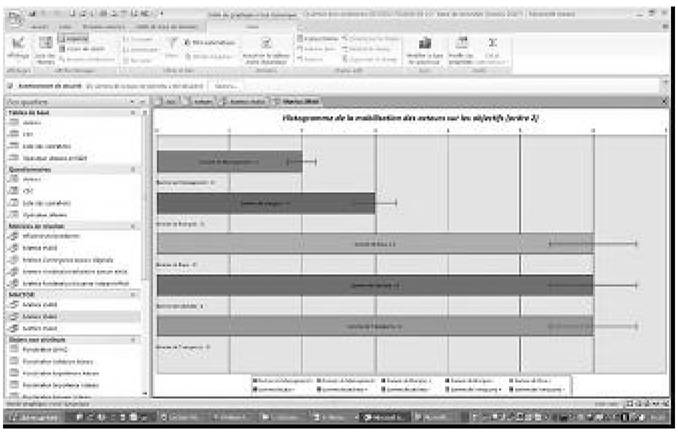

Figure 3: histogram of adherence of the participants to goals

4. Conclusions and prospects

Considering the significant number of urban rehabilitation operations sustained by ANRU (National Urban Renewal Agency), the ambitions of these programmes and the importance of the associated issue of urban sustainability, the need for evaluation and feedback is intensified and should intensify still more in the near future.

Our approach proposes to respond to this by making available, via a unit monitoring the energy efficiency integration practices in these "ANRU operations", a systematic framework based on evaluation tools adapted to the context of each urban project. So our work positions us at the intersection of these expectations in order to :

- Evaluate the practices applied to respond to the challenges of urban sustainability,
- Support exchanges between those running projects agreed by ANRU,
- Set up a monitoring centre based on the operational evaluation tools.

This monitoring centre will therefore monitor three types of indicators:

- Indicators of financial and economic incentive practices
- Indicators of performance or results
- Process or management indicators

STRUCTURAL MODEL OF WATER AND ENERGY CONSUMPTION EFFICIENCY IN RESIDENTIAL BUILDINGS

Jarosław Chudzicki, Ph.D

Faculty of Environmental Engineering, Warsaw University of Technology, Nowowiejska Str. 20, 00-653 Warsaw, Poland, e-mail: Jarek.Chudzicki@is.pw.edu.pl

Keywords: Water Saving, Buildings Component, Planning, Tools and Methods

Summary

Supply of water in appropriate quantities and at the required pressure and temperature is the key criterion for any water consumer or user.

The criterion of the possible water consumption efficiency (and the efficient use of the energy required to ensure the water supply) is estimated cold and hot water more and more discussed and taken into consideration in the context of a water supply system operation.

A structural model has been used for recording the process of water consumption in residential buildings. Simulation models of the operation processes are of a functional character. The characteristic feature of those models is their operation in the cause-and effect chain which represents the reality.

The calculations of the cold and hot water consumption levels have been based on the data about the duration of individual activities (namely: how long does water flow out of tap batteries in individual types of activities) and their frequency (how many times during a day or a week etc.). The data used in the calculations have been based on a questionnaire survey focusing on the water consumption behaviours demonstrated by residents of buildings, and measurements taken by the author.

In line with the methodology developed for the purpose of this research the water consumption levels have been calculated for two identical buildings with different types of water system fittings installed therein, and the levels of pressure at individual storeys.

The structural model of water consumption presented herein illustrates the scale of the consumption efficiency improvements which can be achieved. The estimated cold and hot water consumption levels can be easily used for calculation of the operating costs connected with the consumed water and the energy required to heat it. In practice the system discussed in this paper can be effectively used for comparing various water supply system designs where the criterion of the operating costs generated by the proposed technical solutions is taken into consideration.

1. Introduction

The level of water consumption by a human being determines the proportional consumption of energy required to prepare that water in a proper way. From the water consumer's point of view it is important that water is supplied in adequate amount and at the required pressure and temperature. The aforementioned elements are closely related with the supply of energy necessary to overcome the resistance occurring in the process of transporting the water from the source to the consumer, create the required pressure at the water consumption points or – in case of hot water – heat the medium. The diversity of water consumption methods is reflected in the development of technological solutions employed in the production of taps designed for specific applications (e.g. thermostatic bathtub and shower taps for a household use or pushbutton or touch-free taps for public or industrial buildings).

The criterion of the possible water consumption efficiency (and the efficient use of the energy required to ensure the water supply) is more and more discussed and taken into consideration in the context of a water supply system operation. Investors and future occupants of residential buildings pay attention to the possible reduction of the operating costs connected with the residential units under construction or those they are planning to buy. Therefore the water consumption efficiency level of the offered design and constructional solutions of the water supply systems is used as the criterion of assessment.

This paper shows an attempt to build an assessment system for various possible water supply system solutions designed for residential buildings in the form of a structural model in order to compare them in terms of the water consumption economy opportunities they offer.

2. Theoretical Basics of Structural Modelling

The modelling of a technical facility operation and maintenance processes is used in the operation and maintenance tests along with the field surveys. A special category of models is used for this purpose, namely simulation models. The latter can cover the operation processes or the maintenance ones, or both.

The simulation models of the operation processes are or a functional character. So far they have been usually tried and developed as stochastic models in a form commonly known as the black box. The characteristic feature of those models is the modelling effect which ensures the cause-and-effect connection between the input and output signal consistent with the reality. The modelling effect is achieved by means of transforming the input signal into the output one in a way that differs from the performance which can be actually observed in the reality. The structural models commonly known as the transparent box are a much less popular category of models. The characteristic feature of those models is their operation in the cause-and effect chain which represents the reality accurately although the realisation differs from the real one – e.g. a computer-based numerical realisation. The use of those models in a simulation format makes it possible to monitor changes in the condition of the examined facilities in the course of their operation and maintenance.

3. Water Consumption Calculation Methodology

The following purposes which cold and hot water is used for in residential buildings can be distinguished (Fig. 1). In order to compare the water saving possibilities existing in the residential buildings some selected components have been taken into account: A, B, C, D, E, F, G. And to simplify the comparative calculations it has been assumed that the components E and F are independent of the pressure, the type of tap or the piece of equipment connected to the system.

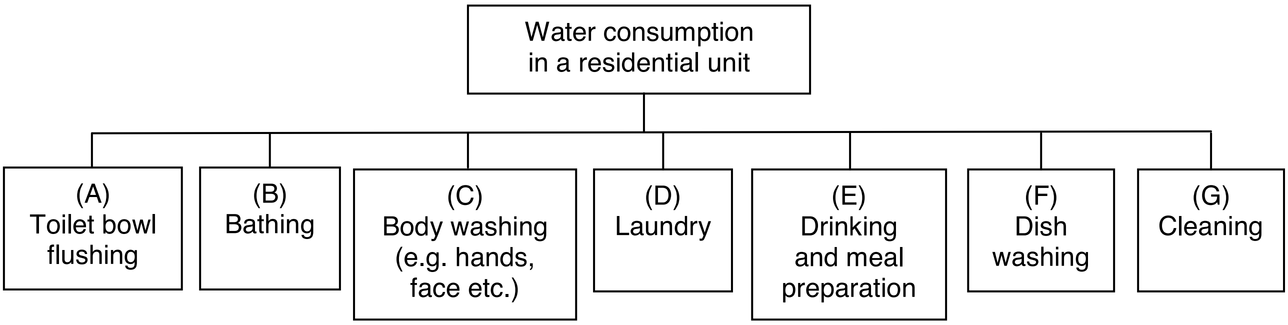

Figure 1 Purposes for which water is used in households.

It has been assumed that in case of the components A and D only cold water is used whereas in case of other components (i.e. B, C, E and G) mixed water is used (at the temperature of about 36÷40°C) in the proportion of 50% to 50% of the cold and hot water. The cold and hot water mixing ratio has been taken on the basis of the assumed cold water temperature of about 10°C and the hot water temperature of about 55÷60°C (in line with the requirements to be fulfilled in Poland and other European Countries).

The input data for the calculations are shown on Fig. 2. The water consumption for the purposes A, B, C, F and G has been calculated on the basis of the following assumptions:

- Water leakage in the water supply system, tap batteries, toilet cisterns, washing machines etc. is not taken into consideration;
- Water consumption in a toilet cistern does not depend on the pressure before the cold water feeding valve – the higher the pressure the faster the cistern is filled up;
- Water consumption during taking a shower depends on the type of the shower battery (the hydraulic characteristics of the battery are given in the form of the following function: P=f(Q)), its design characteristics which influence the way it is used and, in particular, how long the water flows during individual actions, and the pressure before the battery;
- The levels of water consumption for laundry washing purposes are important only in case of the systems which reuse the wastewater from bathing and laundry washing for flushing the toilet bowl (dual systems);

- In about 70% of cases a washbasin and a washbasin tap are used in the process of cleaning rooms in a residential unit and only in 30% of cases a sink unit and a sink tap are used for that purpose. To maintain the sanitary hygiene within a shower cabin and in a toilet bowl taps installed next to those facilities are also used;
- The levels of water consumption for the room cleaning purposes do not depend on the number of people occupying a residential unit;
- It is assumed that the basic body washing activities take place at a washbasin and the washbasin tap is used for that purpose;
- The aforementioned basic body washing activities include: hand washing, face washing and tooth brushing;
- Consumption of water during the basic body washing activities depends on the type of the washbasin battery (the hydraulic characteristics of the battery in the form of P=f(Q)), its design characteristics which influence the way it is used and, in particular, how long the water flows during individual actions connected with the use of water, and the pressure before the given battery (Fig. 3).

The calculation principles have been developed for each aforementioned water consumption purpose separately (A, B, C, D, E, F, G). The model algorithm includes the information about the frequency of using various sanitary facilities (Table 1) and the scenarios of activities involving the use of water developed for individual sanitary facilities and taps/batteries (Tables 2, 3 and 4). The calculations for other discussed water consumption purposes marked with letters A, D, E, F and G have been made in a similar way.

In case of the tap batteries their hydraulic characteristics (showing the correlation between the water flow levels and the pressure in the water supply system before the given tap) have been used.

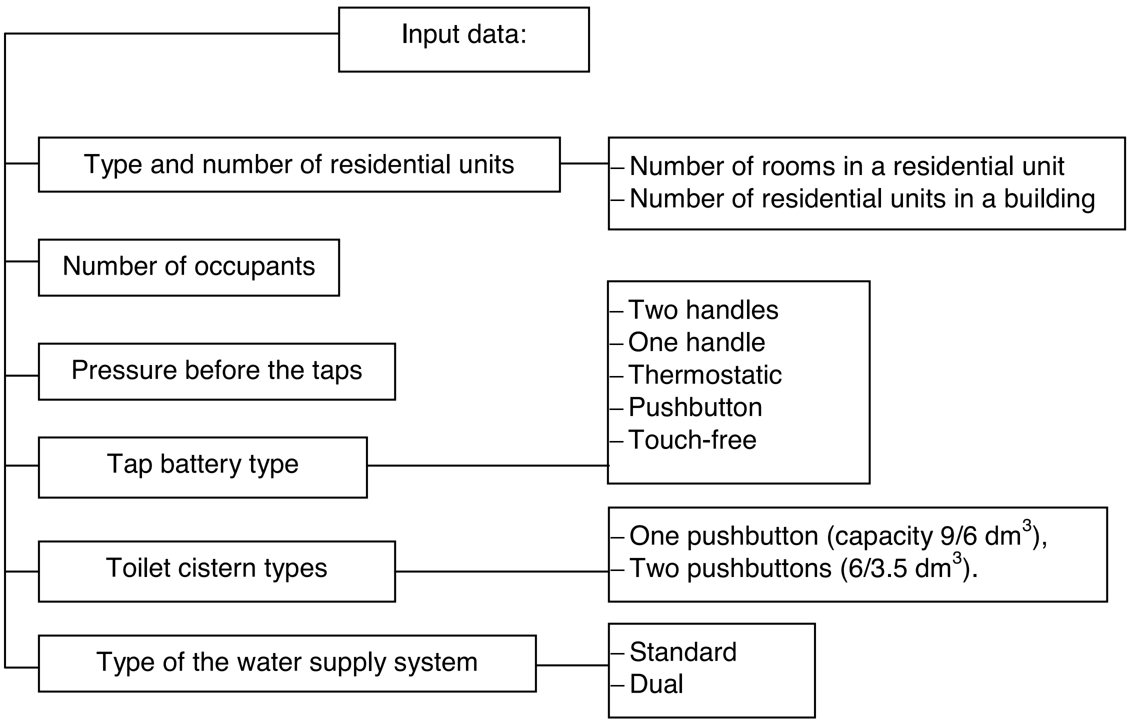

Figure 2 Breakdown of input data for a structural model.

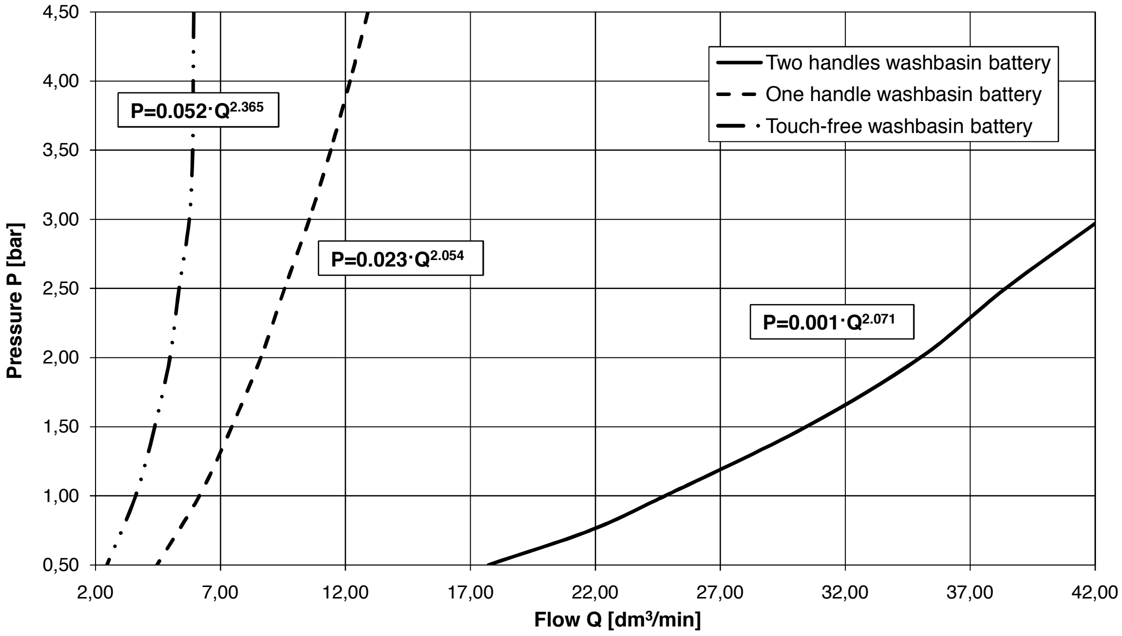

Figure 3 Example of hydraulic characteristics various types of washbasin batteries.

Table 1 Frequency of water consumption for various purposes taken into account in the algorithm of the structural model.

Actions related with and purposes of water consumption				Unit	Frequency of consumption (average value)
A	WC	Toilet bowl flushing	Large	$[(d \cdot person)^{-1}]$	1
			Small	$[(d \cdot person)^{-1}]$	3
B	Bathing	Bathtub		$[(week \cdot person)^{-1}]$	1
		Shower		$[(d \cdot person)^{-1}]$	1
C	Washbasin	Hand washing		$[(d \cdot person)^{-1}]$	2
		Tooth brushing		$[(d \cdot person)^{-1}]$	2
		Face washing		$[(d \cdot person)^{-1}]$	2
		Hand washing in the washbasin in WC		$[(d \cdot person)^{-1}]$	3
D	Laundry washing	Manual laundry washing/using a washing machine		$[(week \cdot person)^{-1}]$	1
E	Sink unit	Drinking and preparation of meals		$[(d \cdot person)^{-1}]$	0.5
F	Dish washing	Manual dish washing or using a dishwasher		$[(d \cdot person)^{-1}]$	0.7
G	House cleaning	Sink unit		$[(week)^{-1}]$	0.5
		Washbasin		$[(week)^{-1}]$	1
		Washbasin in WC		$[(week)^{-1}]$	1
		Bathtub		$[(week)^{-1}]$	0.5
		Shower		$[(week)^{-1}]$	1
		WC		$[(week)^{-1}]$	1

Table 2 Example of a taking-a-shower scenario (B) broken down into individual actions for various types of taps.

Individual actions	Duration of the action [min.]				
	Two-handle tap battery	One-handle tap battery	One-handle tap battery with eco-pushbutton	Thermo-static tap battery	Pushbutton (or touch-free) tap battery
Setting suitable water temperature	0.5	0.1	0.1	0.0	0.0

Soaping the body	1.5	1.5	1.5	1.5	0.0
Rinsing the body	2.0	2.0	2.0	2.0	2.0
Total water flow time:	7.5	7.1	7.1	7.0	4.5

Table 3 Example of a hand-washing scenario (C) broken down into individual actions for various types of taps.

Individual actions	Duration [sec.]				
	Two-handle tap battery	One-handle tap battery	One-handle tap battery with eco-pushbutton	Thermo-static tap battery	Pushbutton (or touch-free) tap battery
Setting suitable water temperature	8	2	2	0	0
Rinsing the hands	5	5	5	5	5
Soaping the hands	15	15	15	15	0
Rinsing the hands	10	10	10	10	10
Total water flow time:	38	32	32	30	15

In the calculation algorithm applied in the structural model two types of water supply systems existing in buildings have been taken into account in terms of the water saving opportunities they offer:

– A standard type: a system fed from the external water supply network, with a lower distribution and centralised production of hot water, where the entire used water is piped off, in the form of wastewater, into the sewage system;

– A dual type where some portion of the wastewater from bathing and laundry washing can be reused (following a preliminary treatment) for flushing the toilet (Fig. 4).

The calculations based on the algorithm included in the structural model produce the results which show the water consumption in a predefined period of time (e.g. a day, a week, a month, a year) for individual flats or for the entire building, or the unit water consumption values expressed e.g. in $dm^3/(Person \cdot d)$. The results can be broken down into the consumption of cold water, hot water and the total consumption, as well as into individual types of the declared water supply system (the standard of the dual one).

4. Examples of Calculations

In accordance with the methodology presented above the water consumption has been calculated for two identical buildings with different types of tap batteries and toilet cisterns installed therein, and the levels of pressure at individual storeys. In order to compare the water consumption levels selected purposes which water is used for in households (A, B, C, D and G) have been taken for calculations. Moreover, versions based on the standard water supply system and the dual one have been calculated for each variant. The results of the calculations can be found in Tables 4 and 5.

The functional characteristics of the buildings No 1 and 2 is as follows:

- Multifamily 4-storey building;
- 55 residential units, 1, 2 or 3 rooms each, 165 occupants.

Water-tapping points in the sanitary rooms in the building No 1 are equipped as follows:

- Toilet cisterns with the cubic capacity of 9 dm^3 each;
- All tap batteries of the standard two-handle type;
- The pressure level at the connection to the water supply system: 3.0 bar.

Water-tapping points in the sanitary rooms in the building No 2 are equipped as follows:

- Toilet cisterns with the cubic capacity of 6/3.5 dm^3 each;
- Thermostatic shower batteries with eco-pushbutton, touch-free washbasin batteries with flow limiter, sink unit one-handle batteries with eco-pushbutton;
- The pressure level at the connection to the water supply system: 3.0 bar;
- Pressure reducers which ensure the pressure equal to 1.0 bar before every water-tapping point in the building are installed on every storey before the connection between the water supply system and the water-tapping points.

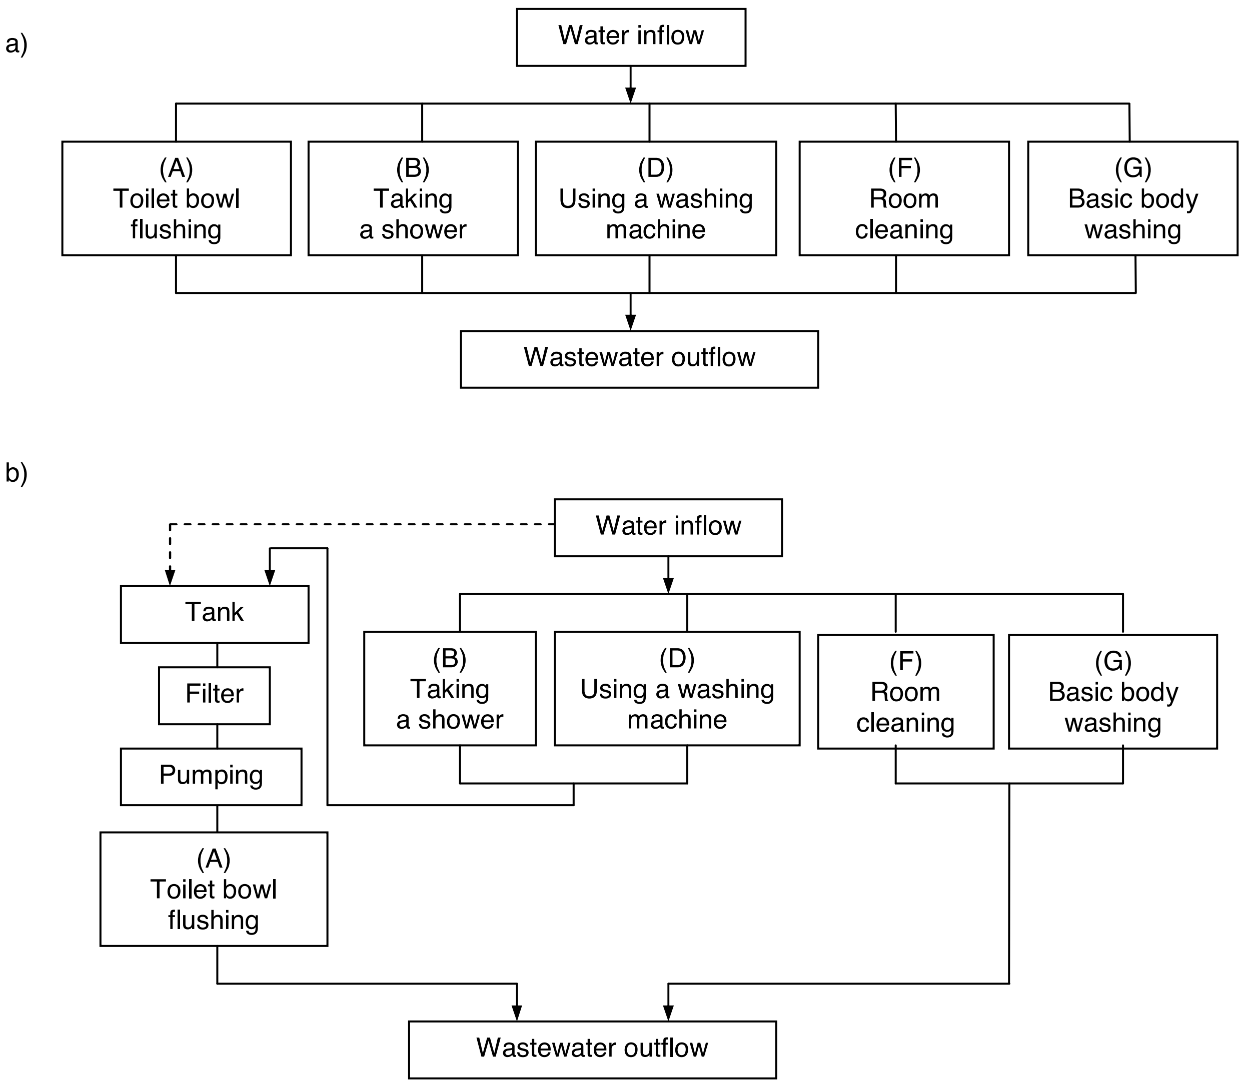

Figure 4 Diagrams of various water supply system types: a) standard type, b) dual type with a partial recycling of the used water.

Table 4 Results of water consumption calculations in the building No 1.

Type of water consumption:		Cold water	Hot water
		dm^3/(Person·d)	dm^3/(Person·d)
A	Toilet bowl flushing	45.0	-
B	Taking a shower	20.2	20.2
C	Hand washing	8.5	8.5
	Face washing	5.2	5.2
	Tooth brushing	16.8	16.8
D	Laundry washing	21.5	-
G	Room cleaning	4.2	1.4
Total:		121.4	52.1
Total cold and hot water for the standard water supply system:		173.5	
Total cold and hot water for the dual water supply system:		128.5	

Table 5. Results of water consumption calculations in the building No 2.

Type of water consumption:		Cold water	Hot water
		dm^3/(Person·d)	dm^3/(Person·d)
A	Toilet bowl flushing	22.5	-
B	Taking a shower	8.2	8.2
C	Hand washing	2.2	2.2
	Face washing	2.0	2.0
	Tooth brushing	3.5	3.5
D	Laundry washing	21.5	-
G	Room cleaning	2.8	2.1
Total:		62.7	18.0
Total cold and hot water for the standard water supply system:		80.7	
Total cold and hot water for the dual water supply system:		58.1	

The results presented in Tables 4 and 5 can be used for comparing the solutions applied in the water supply systems in both buildings in terms of the future water consumption levels and the costs of the tapped cold and hot water. Those figures should not be unambiguously interpreted as the actual water consumption levels due to the fact that some portion of the water-consumption-related needs of the occupants can be underestimated (e.g. as a result of the existing differences in habits, traditions, behaviours, and division into individual gender, age or other groups) and because of the limitations of the assumptions made for the calculations (e.g. unavailability of bathtubs and bathtub tap batteries in bathrooms).

In case of a standard water supply system the economy on the water consumption in the building No 2 amounts to as much as 53% as compared with the same type of the water supply system operated in the building No 1. This economy has been achieved as a result of using toilet cisterns with smaller cubic capacity (it is possible to use 6 or only 3.5 dm^3 of water depending on the need) and replacement of standard two-handle tap batteries with water-saving ones, and installation of pressure reducers on every storey of the building.

The upgrade of the water supply system to a dual one where the wastewater from shower cabins and washing machines is reused for flushing toilet bowls can generate the water consumption economy of about 26-28%.

The modernisation of the building No 1 (equipped with a standard water supply system and traditional tap batteries and toilet cisterns, without any pressure reducers), consisting in replacement of the whole system with a dual one and the upgrade of the water-tapping accessories, and introduction of pressure reducers, can generate the water consumption economy of 66%.

5. Conclusion

Introduction of water-saving technologies, even those which improve the water consumption efficiency only slightly but are applied directly in users' (consumers') homes i.e. within the interior water supply systems in the buildings, contributes directly to the actual reduction of the water consumption levels and this reduction is reflected in lower charges collected from the users for consumed water and energy (the energy used for heating the water and generating an appropriate pressure in the water supply system).

On the other hand the reduced water consumption in individual buildings connected to the municipal water supply system has a substantial influence on the actual amount of water taken from the given water line and, consequently, it may have a direct impact on how individual elements of the water supply system are designed and on the costs of their construction and operation.

The structural model presented herein, designed to calculate the water consumption levels, illustrates the scale of the consumption efficiency improvements to be achieved. The estimated cold and hot water consumption levels can be easily used for calculation of the operating costs connected with the consumed water and the energy required to heat it. In practice the system discussed in this paper can be effectively used for comparing various water supply system designs where the criterion of the operating costs generated by the proposed technical solutions is taken into consideration.

Summary

Rainwater harvesting/storage systems should be evaluated with respect to historic patterns of drought. Patched-point rain guage time series have been used to simulate the performance of rainwater harvesting in seventeen Australian locations as an example of a methodology that could be applied at thousands of other places. The key to sizing rainwater harvesting systems was found to be average daily rainfall (ranging from 0.6 mm/d in Port Augusta to 5.7 mm/d in Cairns), being the annual average divided by 365 days. To further develop rainwater harvesting design, it was assumed that 250 litres of water per day is the nominal household demand, and that an effective roof catchment area (ranging from 87m² in Cairns to 806m² in Port Augusta) is found from twice the ratio of average daily rainfall rate (mm) divided by demand (L/d). The longest drought in 118 years of daily rainfall time-series (1889-2007) was found at each location as the longest sequence of days without a single day experiencing a threshold trigger of at least half of the average daily rainfall (ranging from 58 days in Melbourne to 292 days in Exmouth). The nominal rain water storage requirement was then taken as the product of the daily demand and the number of days of the longest drought (ranging from 14,500 L in Melbourne to 73,000 L in Exmouth). Finally the catchment-storage system was simulated in the seventeen location for the 118 year period of time-series, finding a failure rate ranging from 0.2% in Melbourne to 4.6% in Exmouth. Failure was measured as the number of days that the rainwater harvest system ran dry, and so import of water would be required to meet demand in extreme drought.

1 Background

The Australian Bureau of Meteorology maintains Australia's climate record, including daily rainfall records, some dating back to the early 19th Century, plus other climate observations (temperature etc) which have been computerized from 1957 [1]. The Queensland Climate Change Centre of Excellence's (QCCCE) SILO data service integrates all observations from more than 10,000 rain guages[2] into interpolated daily gridded datasets of Australian rainfall spanning from the late 19th century to the present day in a daily timestep. Similarly, data drom approximately 500 evaporation reporting locations have been interpolated from 1970 onwards. All SILO interpolated datasets have a spatial resolution of 0.05 degree (~5km), from which hundreds of thousands of point time series can be extracted using the Silo datadrill. Other parameters such as temperature, solar radiation, and vapour pressure are computerised since the International Geophysical Year (1957), and these data are most relevant to the analysis of climate influenced design of the built environment [2]. Data for this project has been provided through the SILO datadrill facility [1] http://www.nrw.qld.gov.au/silo/. In the present paper we show how SILO can be applied to size rainwater harvesting system to suit local climate based on over one century of rainfall records. We employ a simplified rainfall/building simulation assumption that personal water requirements are low [3] such that garden use can be meet by grey water recycling.

1.1 Water demand

Australian household usage has decreased with restrictions [4, 5] and so 250 l/d is reasonable household use in drought [2].

[1] Some pre 1957 data have been computerised in the CLIMARC project, http://www.nrw.qld.gov.au/silo/CLIMARC/

1.2 Storage Capacity

Australian rainwater harvesting generally directs rainfall into storage tanks at a maximum of one litre of harvesting per mm rainfall per square meter of roof provided with guttering. First flush diverters may dump a few lites per event, but well maintained systems may have operational efficiencies approaching 100%. Reliability is not ensured with 100% efficient harvesting unless the storage capacity is large enough to carry the household through the longest drought. There being finite limits to practical storage, there will eventually be droughts when the storage tank runs dry and external supplies must be trucked in. In the present paper it is assumed that a small non-zero failure rate is acceptable compromise against unrealistic desire for tank capacity. There tends to be a “law of diminishing return” by preparing for extremely rare droughts, in which case trucking contractors are prepared to cart water from aquifers and/or desalination facilities.

2. Simulation Methodology

2.1 SILO

Figure 1 shows the map of Australian climate[3] observation network with number of years of continuous daily records from which QCCCE derives its interpolated datasets. SILO Patched Point Dataset delivers a timeseries for any of 4729 selected stations, and these are not shown in Figure 1 as they would overwhelm the map. Additionally, the SILO datadrill provides data for estimating rain water harvesting capabilities at all points across the Australian landscape.

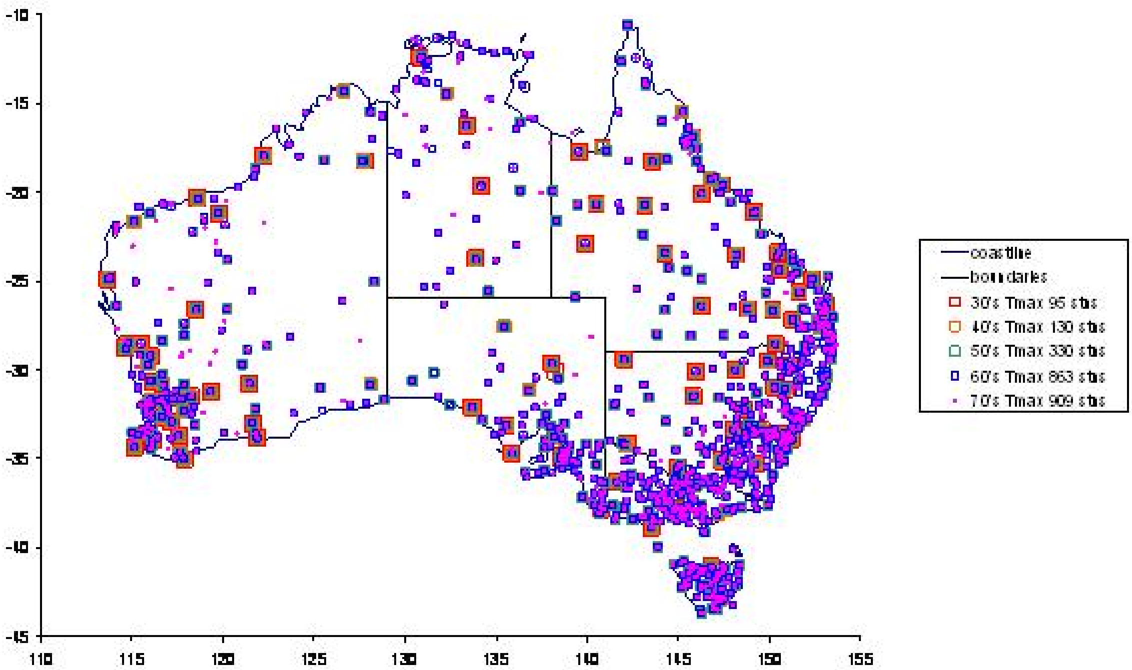

Figure 1 *Observation network employed by SILO includes over 1200 stations covering temperature, rainfall, and generally other coincident meteorological parameters in daily time series*.

[3] ‘Climate’ records are non-rainfall observations of temperature, wet and dry bulb temperatures, evaporation, cloud oktas etc. Not all climate stations report all of these observations.

2.2 Analysis of time series

In the present paper a detailed study was made of rainfall harvesting capability at seventeen location in Australia, but first a case-study of rainwater tank reliability was conducted at Somerset Dam Township, 40 km NW of Brisbane, to explore various combinations of rainwater harvest design.

3 Case Study

The drought stricken township of Somerset Dam, inland from Brisbane, Queensland was chosen to explore the result of combined factors of tank size and roof catchment area. In the end it was decided to find a simple rule of thumb to size rainwater harvesting to meet demand, and then to size the appropriate storage capacity to provide reliable supply without unreasonable demand for external water supplies. One of many simulated daily storage tank levels in the years 2000-2007 are displayed in Figure 2. Numerous combinations of tank size and catchment area were simulated with fifty-year time series, summarized in Figure 3 with the vertical y-axis is the failure rate of the alternative harvest/storage systems.

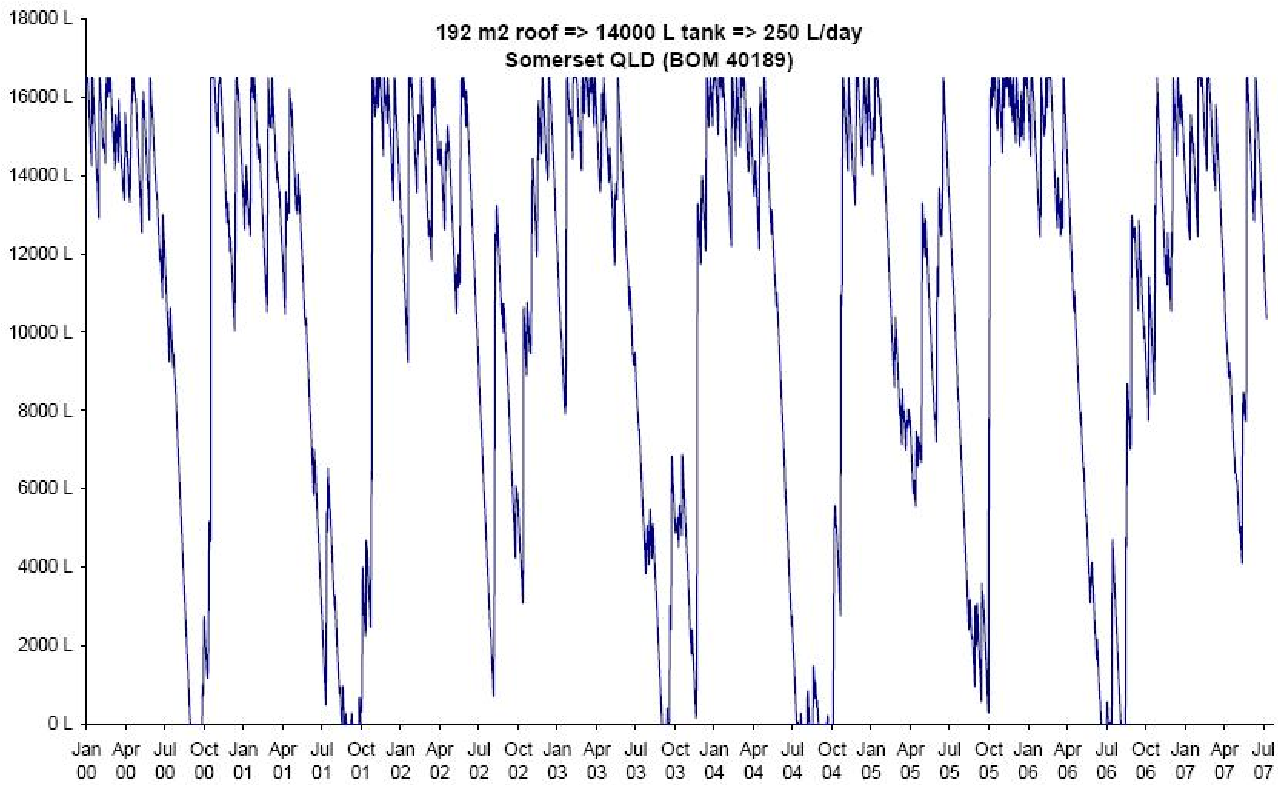

Figure 2 Simulation results for a location inland of Brisbane, Somerset Dam, Queensland.

The effect of changing storage capacity (1, 2, 5, 10, 20, 50, 60, 70, 100, 200 days) is displayed on the left of Figure 3, where the x-axis is the ratio of demand/rainfall. The effect of the ratio of demand/rainfall (1,2,5,10) is displayed on the right side of Figure 3, where the x-axis is the storage capacity measured in days. Inspection of these parametric curves on the right side indicated that sizing roof harvest area in direct proportion to average rainfall would require something on the order of 1000 days storage capacity to achieve low-failure rate system performance, while two times the indicated roof area brings the storage requirement down and order of magnitude to maintain the desired low failure rate. Looking at the left side figures it appears that the 1, 2, 5, 10, and 20 day storages could never achieve the desirable low-failure performance, no matter how much roof catchment could be harvested. It appears that the 50 day storage was wavering on the verge of being able to utilize a large catchment to achieve the desired low-failure rate, and that performance looked to be substantially more stable at 60 day storage and greater.

So we nominal harvest area as twice the ratio of demand over rainfall 2×(250 Litres / 2.7mm) = 185 m² and found that the longest period of time without as much as half of 2.7 mm rain in any one day was 110 days (7 April – 25 June 1946 had a total rainfall of only3.4 mm). From the length of drought we nominated the storage capacity as 110 days × 250 L/day = 27,500 L. Finally we simulated the system performance in (Figure 4) and found the failure rate of 0.7%. A failure demerit is scored for each day that the simulated rainwater harvesting system runs dry.

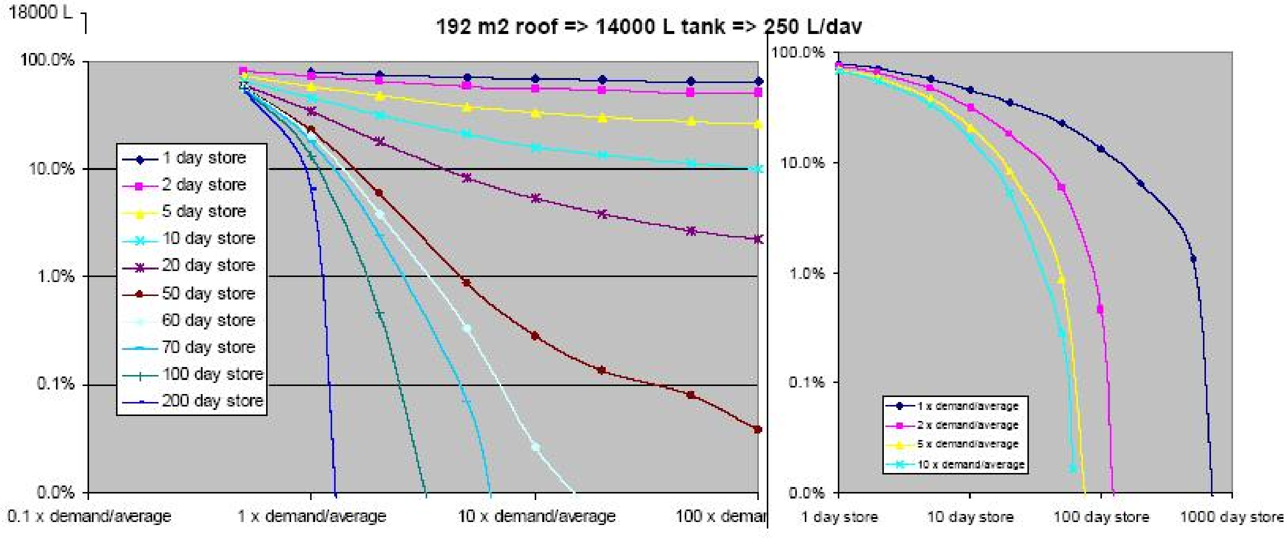

Figure 3 Summary of simulation results various tank capacities and roof catchments areas for the case study of Somerset Dam township, Queensland.

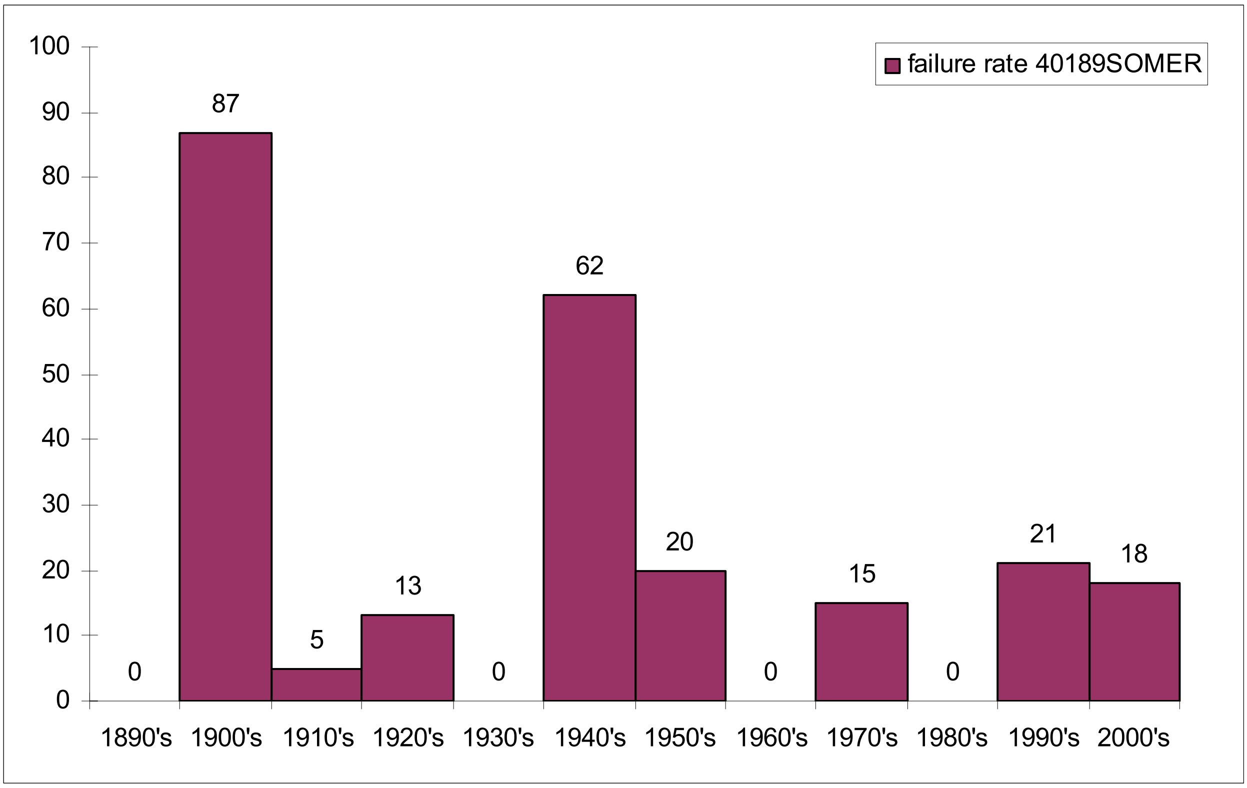

Figure 4 Simulated number of failures per decade serving 250 litres per day for nominated 27,500 L tank capacity and 185 m² roof catchment area for the case study of Somerset Dam township, Queensland. Note that the 2000's bin includes only 8 years of simulation output, and so more failures are possible by the end of this decade.

Having developed a workable model for Somerset, it was implemented as a nominal sizing methodology in sixteen other localities, and their failure rates were simulated and reported herein. A summary of the rainwater harvesting potential of Australian locations is presented in Table 1. The entire premise is that a constant household water demand of 250 litres per day would be met with the rainwater system. In practice there would be a variable rate of demand for garden watering, and so subsequent models of rainwater tank systems should be developed to exploit the SILO estimates of evaporation. This is particularly important since rainwater harvested in urban areas is not suitable for drinking water.

Table 1 Analysis of rainwater tank sizing for Australian locations, based on SILO data drills 1957-2007

location	BOM ID	average daily rain (mm) pa/365	needed area of catchment (m²)	longest period below half of daily average	suggested tank capacity (litres)	empty rate (supplement required)
Western Australia						
Exmouth Town	05051	0.7	675 m²	292 days	73,000	4.6%
Perth Airport	09021	2.2	225 m²	145 days	36,250	1.5%
Albany	09500	2.5	197 m²	62 days	15,500	4.2%
Northern Territory			m²			
Darwin	14015	4.3	116 m²	250 days	52,250	0.2%
Alice Springs	15540	0.8	654 m²	187 days	46,750	3.3%
South Australia						
Port Augusta PO	19036	0.6	806 m²	119 days	29,750	1.1%
Adelaide W Tce	23000	1.3	396 m²	104 days	26,000	0.6%
Queensland						
Cairns PO	31010	5.7	87 m²	133 days	33,250	3.1 %
Townsville	32040	3.2	157 m²	270 days	67,500	0.7%
Rockhampton Air	39083	2.3	217 m²	159 days	39,500	1.0%
Brisbane RO	40214	3.0	168 m²	80 days	20,000	3.4%
Somerset Dam	40189	2.7	185 m²	110 days	27,500	0.7%
New South Wales						
Sydney Airport	66037	2.7	184 m²	68 days	17,000	2.5%
Wollongong	68188	3.9	128 m²	81 days	20,250	1.7%
ACT						
Canberra	70014	1.8	277 m²	64 days	16,000	1.7%
Victoria						
Melbourne RO	86071	1.6	312 m²	58 days	14,500	0.2%
Tasmania			m²			
Hobart Airport	94008	1.4	356 m²	58 days	14,500	0.2%

Mathematical statement of the nominal sizing scheme is presented in the remainder of this section.

The needed catchment area A is proposed to be estimated with equation 1 to recommend the appropriate roof catchment is estimated as twice the daily water demand D divided by the average daily rainfall rate R

$$A = 2\frac{D}{R} \qquad (1)$$

The needed storage tank volume V is from equation is estimated as twice the product of daily water demand D and longest period of time on record where there are no rainfall events greater than half the average daily rainfall rate R for that time, $\max(t_{event} - t_{next\_event})$.

$$V = D \cdot \max(t_{event} - t_{next\_event}) \qquad (2)$$

Supplementary water will need to be delivered by tanker truck or other means is the rainwater harvesting system fails to meet the demand. The failure rate of the nominated rainwater system is determined by measuring the number of days that the tank is dry, divided by the number of days of rainfall records for the location in question. The calculation of tank storage S is determined by equation 3 within the limits of zero and the capacity of the tank V (force to zero if storage is negative, force to rated capacity if overflowing).

$$S_t = S_{t-1} + R \cdot A - D \qquad (3)$$

Conclusion

We find that reasonably reliable rainwater tank performance is expected if roof catchment area is sized from twice the ratio of demand divided by rainfall. Further we nominate a storage tank size large enough to carry demand in the longest consecutive period without any rainfall greater than a threshold of half the average daily rainfall. Unfortunately there will be events when the nominated harvesting system runs dry, and water must be imported to meet demand. The forgoing is an optimistic assessment, and ignores losses from the harvest and storage processes. Harvest area and storage capacity should be scaled up or down with respect to the nominal 250 litre daily demand assumption.

Abstract

As the global shortage for water worsens, domestic water use efficiency becomes more critical. Urban dwellers need to play their part through embracing demand management and using supplementary water supply. However, domestic water supply in New Zealand is a neglected aspect of sustainable development, with much of the population believing that water is a free good. In most of New Zealand there isn't political willingness to take a different message to the electorate with water pricing, even metering being a hotly contested issue.

Of the various factors that influence water use efficiency, well targeted policy and regulation offers most chance of affecting change. Technologies are already available which could reduce mains water use but incentives; cash, carrots or sticks have rarely been used strategically and have had limited success, except in a few cases.

This research has explored all avenues of mains water demand management to determine what policy may be most effective and to work with water supply authorities to assist them to put demand management into practice. International and national water policy best practice has been trawled for successful approaches and it is clear that the inter-relationship between local context, water efficient technologies and appropriate policy and planning is critical and that solutions, designed to be applied by local water supply authorities, should be tailored to the specific context of each location and fine-tuned as each water use efficiency strategy unfolds. One size doesn't fit all.

Introduction

New Zealanders' domestic water consumption is highly variable around the country and with water metering only available in some areas, an accurate figure for domestic water usage for many regions or for the country as a whole, is not available. Reported figures range from a domestic water usage figure of 160 litres/per person/per day in Nelson at the top of the South Island or 167 litres/per person/ per day in Waitakere, a city within the Auckland region, to an average 750 litres per person per day in the Queenstown Lakes District. Table 1 shows the variability of water use reported throughout the country and demonstrates that in general, those places with water metering plus volumetric charging are lower than those without. This is consistent with a UK research study that shows a significant reduction in water use once metering and volumetric charging, often with well crafted tariffs, are introduced, Pezzey (1998).

Table 1 Per capita average domestic water use in New Zealand towns

Water supply authority	Liters per person per day
Nelson	160*
Waitakere	167*
Rodney	179*
Metrowater	184*
Manukau	189*
Papakura	190*
Tauranga	214*
Upper Hutt	227
Christchurch	333
South Taranaki	450
Kaikoura	648
Kapiti	650
Queenstown	750

*Metering with volumetric charging

Most of the interest in water in New Zealand has been on irrigation for rural use which uses 78% of water abstracted, Lincoln Environmental (2000). Overlaid is the issue of water quality and again the rural sector has had most of the focus with some of the North Island Lakes showing eutrophication with toxic algae blooms rendering them unsafe for swimming. For the majority of New Zealanders domestic water supply is not high on their agenda. There is a general view that water is a free good and a lack of understanding of the costs associated with delivering water to the home. There is also a concern about the possibility of privatization of water supply and any move to meter water and pay on a volume basis, in those areas currently paying for water as part of their general rates, is seen as one nail in the coffin towards privatization, even though the Local Government Act (2002) requires a local council to maintain strategic control of water supply.

In New Zealand there is no one over-riding reason why consumers should be concerned about the amount of water they use. There is not the same level of drought as in some countries, especially Australia, where the population can see first hand the severity of the lack of rainfall and its impact on domestic water supply. The rationale for demand management is based on a number of premises, which taken collectively make a strong and logical argument for water use efficiency. Those key drivers are:

- Capital cost savings through delaying or eliminating infrastructure development, both for more supply and increased wastewater services. The national level of estimated investment required is approximately $5 billion over a 20 year period to upgrade water supply, wastewater and stormwater infrastructure. Ultimately that cost would be borne by the consumers.
- Reducing infrastructure operating and consumer costs for water and energy. Consumers do not necessarily link water use efficiency with lower energy costs but energy is consumed in the supply, treatment, removal and heating of water.
- Reducing ecological impacts. Ensuring there are sufficient residual flows in rivers that groundwater supplies are not adversely impacted and that wastewater doesn't leak form pipes into local waterways and estuaries.
- Addressing climate change issues and the need to improve the resilience of the water supply system. For New Zealand, climate change is anticipated to mean more dry weather on the East, wet on the West and more frequent storm events overall.

Water policy in New Zealand currently focuses on education, some social marketing and little else while the range of water demand features available includes:

- Economic Tools; pricing tariffs, incentives/rebates
- Improving technology; water efficient fitments, fixtures and appliances
- Education, awareness and social marketing; promotional material and education programmes
- Regulation and Legislation; the Building Code and various Acts.
- Synergies between combinations of the above approaches.

There is no central water authority in New Zealand responsible for domestic water services, nor any one Act which provides overall guidance. The present regulatory responsibilities are shared between four main Acts being: the Building Act (2004), the Resource Management Act (1991), the Local Government Act (2002) and the Health Act (1956). These Acts can, through their interpretation, appear to provide conflicting requirements so that in general there is wariness about using regulatory routes to implement demand management.

Instead water supply authorities, mainly councils and their water supply authorities (WSAs) have implemented innovative educational approaches which include specified water advisors for indoor or outdoor use; free indoor minor pipe or water fixtures maintenance, school programmes, open days, and a suite of internet advice. Some councils also have financial incentives, mainly rebates or special promotions in association with retailers. These approaches are useful and a necessary element of encouraging water demand management but without education as to why reducing demand is necessary, consumers may neutralise the efficiency of better technology by using water more profligately. Yet education on water use in New Zealand is rarely enough on its own, as exemplified by one of the largest WSAs that has excelled in its attempts to encourage less domestic water use but has had little impact on its ultimate water use reduction goal, with per person water consumption remaining virtually static over the last thirteen years. Clearly more than education is required to get the desired change that the WSA requires to negate the need to contribute to the costs of a major water supply upgrade in the future. In many New Zealand cities and towns with growing populations, the goal could be to keep overall water consumption static while the population rises. What policy and regulatory changes are required to bring about the desired change?

Research approach and methodology

Beacon's research is at the applied end of the spectrum. Beacon Pathway is a research consortium, established in May 2004 with the aim of encouraging and improving New Zealand's sustainability in the residential built environment. It intends to improve the sustainability of the New Zealand housing stock, both new and existing homes, primarily using existing technologies and/or building systems which are currently underutilized. It also aims to keep the dwellings affordable. Reducing the level of water use in homes is part of that challenge.

The hypothesis for our research was that "barriers to water use efficiency can be overcome by well designed policy and regulatory approaches, specific to end-user requirements."

To test the hypothesis policy and regulation relating to demand management approaches both in New Zealand and overseas, were investigated for their effectiveness.

The investigations included the following components:

- A nationwide survey of territorial authorities or associated water supply authorities to establish the extent of water conservation programmes across the country and the key drivers for those programmes
- Four case studies of New Zealand councils that have demonstrated results attributable to demand management approaches including the use of voluntary programmes, water metering and volumetric user charges, changes to district plan rules to achieve water conservation outcomes, leak reduction programmes, and other methods of demand management such as education and training.
- An international literature search then identified policy approaches in other countries that could be applied to the New Zealand context.

The findings of that work was summarised by Lawton (2008) and provided input into the next research component which was to utilise the information in workshops with water supply authorities that wished to introduce a demand management strategy. Critical to the success of these workshops was having a range of people from across the water supply service, eg engineers, policy planners, educationalists, consents officers, all in the room together to start the development of a water demand management strategy that was applicable to their specific circumstances. The workshops were in part designed to inform, encourage and develop a consensus on an agreed plan of action. The workshops also provided material for the research through a discussion on how demand management approaches may best be tailored for any given water supply authority. The interaction between context, at the global, national and local scale, demand management approaches or packages of approaches and the policy and regulations needed to support those approaches is conceptualised in Figure 1.

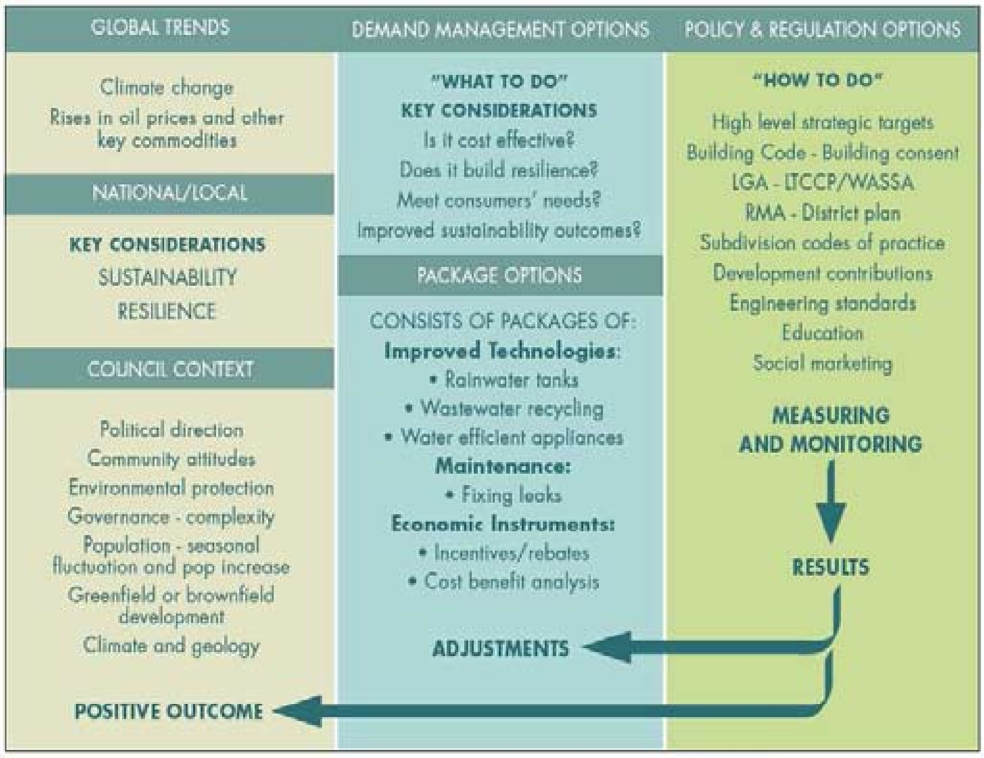

Figure 1 Interactions between context, water demand approaches and policy instruments

The collective results of the research and workshops discussion will be collated to provide a resource for all water supply authorities, guidelines on best practice for water demand management that could be applied to the range of contexts found throughout New Zealand under our current regulatory framework.

Results

The response rate to our questionnaire was 55% of the 76 water supply authorities in New Zealand. From the responses it was obvious that the majority were considering how to implement or increase their level of water demand management. In general they did not need to be persuaded that demand management was desirable, despite their need to balance their financial targets through water sales. The over-riding issue was that they had not managed to convince the consumers of the need for demand management. Additionally in some cases the local politicians had stood for council on a ticket of not implementing metering and without metering, it is difficult to manage the resource effectively, understand the leakage rate or apply incentives to reduce demand.

Many authorities are facing growing population and will have supply constraints in the near to middle future. Due to the long planning horizon needed for major infrastructure anticipated increased supply would need to be considered 10 to 20 years or more before it is required. The case for reducing demand instead of increasing supply must be strong and ideally shown to work prior to committing to that approach. With the need for new supplies looming to match the anticipated population needs, it is critical that demand management practices are implemented swiftly if large capital investments with consequent ecological consequences are to be avoided.

The four New Zealand case studies that were examined in detail provided a wealth of examples of educational approaches which was of general interest throughout the country. It was clear from workshop feedback that a mechanism to share these stories and successes would be a useful role for an industry agency, research provider or government agency. However the educational approaches that offered the best success were hands on, with practical one on one advice sometimes supplemented with in-house water services maintenance. While internet advice may reach the masses it doesn't appear to have the same impact as the personal approach.

Those water supply authorities that had implemented water metering with volumetric pricing had an immediate drop in water use, dramatic in the case of Tauranga where is was reported as being reduced by over 25%. Introducing water metering was considered to be more difficult since the introduction of the LGA which strongly promoted a public consultation process for local authorities. The process known as the Long Term Council Community Plan (LTCCP) with a ten year horizon and three yearly refinements should have been a good opportunity to discuss water management issues with the community but instead appeared by some to be viewed as a barrier, an indication maybe that the current approach to community participation is not working well.

Outdoor water use in gardens for irrigation was a key differentiator of water use between communities. In general those areas with low rainfall and/or sandy soils used significantly more water than those where rainfall was evenly spread throughout the year. While not a surprising result it did emphaise the value of addressing indoor and outdoor use separately and how the use of rainwater tanks and/or grey-water recycling came into their own, especially in high outdoor water use areas. Unfortunately the current application of both those technologies is clouded by Health requirements which, even though they can be technically addressed, can push the use of rainwater tanks and grey-water recycling into the too hard basket.

While local authorities have tended to value their independence a suggestion that came through our workshops was that national legislation which supported water demand management would assist WSAs, especially in considering regulatory routes. They wanted stronger signals from national levels which still allowed enough flexibility to implement those requirements according to their local context although in general they would have welcomed simple requirements such as dual flush toilets and low flow shower heads to be mandatory across the country. Similarly, mandating for metering at a national level would have been welcomed by some WSAs as it would have removed the decision from the local arena where it has become in many cases, a political football.

Legislation in New Zealand is not enabling when it comes to reducing domestic water use. There are a number of Acts which help determine the water use of a home but none of them are provide a clear path to water use efficiency. The Acts are inter-related as shown in figure 3. There are two immediate improvements that need to be made. The first is to make better use of the Resource Management Act, 1991 (RMA) through emphasising the need to conserve water at the national level in a National Policy Statement (NPS) and bringing that principle through the Regional level so that where required, they can direct rules or methods in the District Plan.

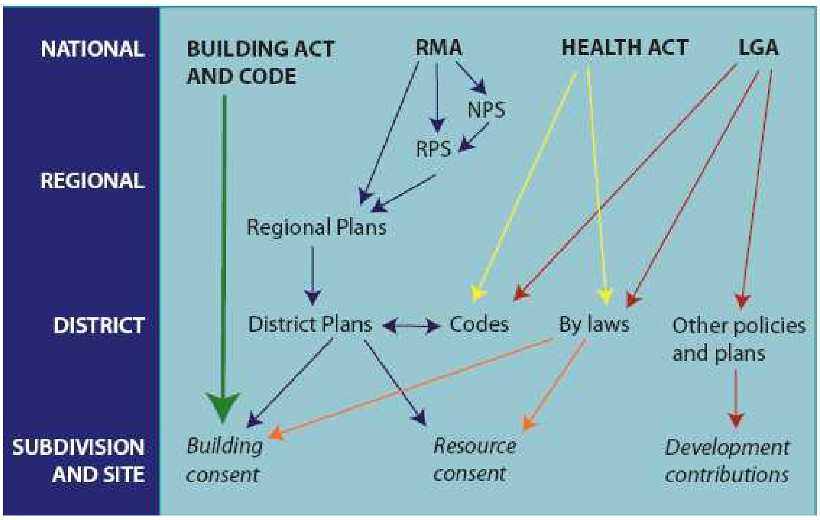

Figure 3: The Acts that impact on urban water use efficiency and their interaction.

The next change is to clarify a conflict which exists between the Building Act, 2004 and the RMA. At present"

"Section 18 of the Building Act 2004 precludes the imposition of performance standards for building work additional to or more restrictive than those specified in the Building Code. Therefore a person who carries out any building work is not required by this Act to:

- achieve performance criteria that are additional to, or more restrictive than, the performance criteria prescribed in the building code in relation to that building work: or
- take any action in respect of that building work if it complies with the building code. (2) Subsection (1) is subject to any express provision to the contrary in any Act".

While there is some ambiguity as to whether this section can over-rule the ability of the RMA to perform its prime function of resource management, the lack of certainty was found to be considered a deterrent by some councils who were not prepared to risk the cost faced by litigation if a legal approach which contested. This affected their ability to mandate for water efficient products from dual flush toilets to requiring rainwater tanks with all new homes.

Despite the lack of legislative encouragement one of the smaller case study authorities has been prepared to try the regulatory route. Despite and maybe because they have not run the metering gauntlet with their community they have implemented a number of other demand management approaches which are leading up to significant regulatory changes at a local level. Kapiti Coast District Council has used a wide range of approaches and brought them together as a model package. The processes include:

- Education packages including a "green gardener" to assist with the choice of plants and irrigation
- A substantial communication process using the Long Term Council Community Plan under the LGA (2002) to discuss demand management requirements with the community
- A sub-division Code of Practice which promotes low impact urban design
- Advertising on local radio and newspapers and websites
- Modeling using PURRS developed by Coombes (2002), which indicated that for Kapiti District Council dual flush toilets can save between 20 and 31% of toilet water use and low water use washing machines reduce water use for that purpose by 50% giving c.15% reduction in household water use. PURRS modeling was also used to identify the optimal size of rainwater tanks that corresponded to Kapiti's annual rainfall distribution.
- What sets Kapiti apart from other councils is that it was the first council to try to introduce a district plan change under the RMA (1991) which will mean that rainwater tanks become mandatory for all new homes or a mix of a rainwater tank with a grey-water recycling system for garden irrigation will be required.

While those actions may not seem revolutionary in some countries, in New Zealand, Kapiti a relatively small community of 46,000 has gone where so far, larger councils have feared to tread. The lack of willingness to push the legal boundaries is in no small part because the process is long and fraught with potential legal challenge, there is little case law to support them and the cost is not insignificant. If successful, they will, given the interest shown in this approach at the demand management workshops, be the first of many to apply for such a Plan change. Given that the RMA provides for a hierarchy of regulatory processes, it would be helpful if water demand management was signaled as a desirable approach in a national policy statement and/or regional policy statements which sit over the District Plans.

Our international literature survey identified a wealth of information on demand management approaches and policy approaches. It shed light on the type of regulatory approaches that work well, again confirming the value of nationally based performance standards or requirements. The introduction of a mandatory labeling scheme, Water Efficiency Labeling System (WELS), when it comes into effect in New Zealand, will undoubtedly also assist in raising both the awareness of and availability of water efficient appliances. It is a national led intervention that will have impact.

The workshops are confirming that differing approaches are required between councils to take account of their individual contexts. Lack of discretionary income in smaller councils calls for more innovative use of community volunteers. Some water supply authorities will focus on retrofitting with low cost water efficient fitments while others will have greenfield opportunities and local developers willing to assist with major changes in their approach. Some councils will be the leaders and others will follow suite. It seems likely however that there is a major shift in willingness to engage and our research results will provide guidelines for differing contexts that ensure we don't have to try and make one shoe to fit all.

Discussion

Through the surveys, case study analysis, overseas literature research and workshops some key findings are emerging.

Consumer acceptance and political willingness will play a major role in how far and how fast water managers and politicians are prepared to promote water use efficiency. The issue of water metering and volumetric pricing is a point of contention in many districts. One perception within the community is that access to "free" water is a right for all people and shouldn't have a charge attached. This completely overlooks the cost of supply and the fact that people have always paid for water in their general rates. Education and awareness raising will in part help dispel the free good argument but it is unlikely that this will affect a wholesale change of attitude without other policy interventions. In addition the value case for demand management for each of its stakeholder groupings, needs to clearly articulate the benefits based on sound data.

The understanding of "water as a necessity" is undoubtedly more pronounced in those areas of the country that have experienced periods of drought in more recent years. It is yet to be tested whether those areas are more likely to offer support for mandatory water conservation approaches and volumetric pricing based on consumption. The degree of necessity relates substantially to water access and climate. Some parts of the country have low rainfall but still enjoy a plentiful supply. Other parts are more obviously short of water with most of the available supply already allocated to hydro, agriculture, industry as well as domestic use.

Councils are in general keen to adopt demand management and recognize the value of conserving water, especially where it will result in the delay or removal of the necessity to find a new water supply source. Councils make most progress when they understand their own context and develop a strategic approach to water demand management which involves a package of interventions. Often demand management was found to be associated with a champion within the organisation, notably a new council employee who was keen to take a fresh approach. Councils in general recognized the benefits of learning from each other and welcomed the idea of a network which focused on demand management and provided for a sharing of resources and experiences.

The degree to which current policy and regulation is helpful or provides barriers will undoubtedly impact on the route of uptake of water use efficiency. The current regulatory route can be long and often needs to be addressed on multiple fronts. Without strong national legislation promoting water use efficiency it is left to councils or water supply authorities to individually determine their policy or regulatory route. Hence there is massive replication of effort, some of which could be avoided by national level guidance or legislation.

In fact New Zealand legislation does not respond well to the need for water use efficiency. Current conflicts exist between the role of the RMA, which as the name suggests is responsible for resource management, and the Local Government Act, which should result in good governance, an approach which incorporates all aspects of sustainability and strong consultative processes but as yet has not delivered anything innovative in terms of water conservation. Then the issues with on-site water supply and water recycling in relation to the Health Act must be clarified and if there are real conflicts, they need to be resolved as the perception of those barriers currently provides a deterrent to using on-site supplementary water supply.

There has been some call for a national structure to oversee and promote water use efficiency initiatives. New Zealand has acknowledged the benefits of an organisation focused on energy efficiency, the Energy Efficiency Conservation Authority (EECA); water is arguably an even more essential resource than power given its status as a resource that is essential for all life and a similar organisation to EECA but focused on water should be created immediately. Australia has introduced the National Water Initiative which provides a potential model for New Zealand.

While national guidance and legislative support is important there will still need to be local solutions, specific to the variables of each water supply authority's context. They reflect the differences in climate, population, socio-economic groupings, local political viewpoints and development opportunities. The suite or package of interventions and the policy to implement them will have considerable site specificity.

Nobody wants a prolonged drought as we have seen in Australia. It has however galvanized the country into a major focus on preserving the irreplaceable resource that is water. Without such a crisis it is likely that New Zealand will take longer to respond to what is now recognized as a global need to carefully manage water use. The regulatory building blocks are there but they could be remodeled and their performance criteria improved. There is a willingness amongst water supply authorities to be proactive but they require support form national and regional levels, a move which would also gain efficiencies through providing model examples of how to reduce water demand. Consumers have a way to go in understanding our water supply but financial instruments will play an increasing role as energy costs linked to water supply and heating continue to rise. Domestic water supply in New Zealand is at the beginning of a major period of change to embrace sustainability which will in turn contribute to reaching Beacon's goal of creating "sustainable homes that don't cost the earth."

Keywords: sustainable property investment, sustainable development, socially responsible investment

Summary

The interest in more sustainable properties has risen strongly in the recent past since the so-called business case for implementing sustainable development principles within property-related decision making processes has been powerfully made during recent years. There has been a shift from anecdotal evidence to well-documented case studies and comparative analyses of environmental, social and economic performance of buildings from around the world clearly indicating that sustainable building is a highly profitable exercise. However, the implementation of sustainable development principles does not only serve the industry's actors to safeguard and increase competitiveness and long-term profit but is required because of the huge responsibility that the property industry is taking towards society and the environment. The development and provisioning of sustainable property investment products and related consulting services offers a major opportunity for property professionals to increase both, financial returns as well as their standing within society and the business world. Yet, this opportunity remains largely untapped due to various reasons. In response to this situation the present paper sets out a strategy for the development, implementation and widespread dissemination of sustainable investment products for the property industry. This is seen as an additional and potentially powerful approach to stimulate demand for sustainable buildings.

1. Status quo & the way ahead

The growing acceptance of social responsibility by organisations, corporations and other actors across all business sectors creates a demand for investment opportunities and products that adhere to the principles of sustainable development. This demand is further strengthened by the growing body of academic research evidencing that socially responsible investing (SRI) and corporate social responsibility (CSR) programmes do not result in inferior financial performance compared to conventional investment and business practices (see: UNEP FI, 2007a). In this context the questions arise whether there are any sustainable property investment options available for institutional and private investors and whether these investment options are in line with the Principles for Responsible Investment ruled out by the UN Environment Programme Finance Initiative (PRI, 2006) as well as with the responsible investment guidelines formulated by the European Social Investment Forum (EUROSIF, 2007)? Besides the products and services offered by a small number of leaders in the field of sustainable property investment and management (see: UNEP FI, 2007b) the answer to these questions is clear: not yet.

Planners, construction firms and facility mangers are able to design, realize and operate sustainable buildings today. However, it apparently requires innovative approaches to increase the demand for buildings that are – at the same time – energy-, resource- and cost-efficient, healthy, and more resistant to obsolescence and offer higher aesthetic, urban as well as technical and functional qualities. Besides informing and taking influence on awarding authorities and clients of direct property investments, an additional approach is seen in the development of new products for indirect property investments. This is the starting point for the authors' research project on the basics of sustainable property investment. The project took place within the research initiative "Zukunft Bau" and has been funded by the German Federal Office for Building and Regional Planning. The project investigated whether, how and which property investment products are appropriate for strengthening the demand for sustainable buildings and which general framework and preconditions would favor such developments. Within this paper the authors report on selected findings.

In 2007 about € 20 billion (10^9) were invested in 110 public SRI funds in Germany – with a growing trend. Across Europe more than € 1 trillion (10^{12}) is invested in this sector and in the USA assets under management in the SRI sector amount up to US$ 2.3 trillion. However, until now property represents an almost entirely neglected asset class within the SRI sector. At the moment only a very limited number of property investment firms or funds make sustainability an explicit goal; in addition, existing SRI funds in the USA as well as across Europe do not offer investors screened and professionally managed property portfolios. If these funds exist, they are simply too hard to find. Given that property improves the risk-return ratio of any mixed-asset portfolio and that an optimal share of property (direct or indirect investment) lies between 10 and 20% (see: Sirmans and Worzala, 2003; Worzala and Sirmans, 2003), the SRI market as a whole is significantly under-allocated from the perspective of optimal asset allocation. Consequently, the untapped market potential for publicly offered sustainable property investment products is immense. The authors assume that this untapped market potential still exists due to an underdeveloped market for certified sustainable buildings, information and knowledge deficits among private and institutional investors and a lack of proactive fund developers and initiators. In order to overcome this situation and for the development, implementation and widespread dissemination of sustainable investment products for the property industry the following steps are recommended of which a selection is further discussed below:

a) Description and analysis of relevant constellations of actors;
b) Description and analysis of the information and cash flows between these actors;
c) Analysis of the interests and motivations on the demand side;
d) Estimation of the market potential for sustainable property investment products;
e) Discussion of appropriate 'designs' and types of investment products;
f) Development of suitable assessment-, rating- and certification-approaches;
g) Strategy development for the development of property fund products; and
h) Development of appropriate marketing and reporting instruments.

2. Steps to sustainable property investment products

2.1 Constellations of actors, information and cash flows

The typical constellation of actors in financial markets in terms of cash flows and value creation regarding financial products can be – in principle – transferred to both, the processes of value creation regarding sustainable property investment products and the relevant groups of actors in property and construction markets. A core element in the constellation of actors is seen in the linkage between planners and construction industry on the one hand (referred to as the 'physical side') and the financial and banking industry on the other hand (referred to as the 'monetary side'). In the process of value creation the monetary side is responsible for granting the financial capital required for carrying out construction works. Identifying incentive-structures for allocating further investment capital from the financial market to the funding of sustainable buildings creates additional impulses for the construction industry. A crucial point, however, is that these impulses for the construction industry are clearly focused on property projects only that adhere to the requirements for sustainable buildings (i.e. 'additional investment capital for sustainable buildings only'). This can create an additional demand for sustainable buildings. The linkages between the physical and the monetary side are provided through financial intermediaries and service providers such product developers and suppliers, rating agencies and institutional funds that collect capital.

Figure 1 provides a simplified description of relevant constellations of actors. The starting point is the demand side; i.e. those institutional and private investors interested in SRI products. Actors on the demand side select an appropriate investment product (i.e. a sustainable property investment product) from one of the available suppliers/initiators in the market by relying on consulting service providers and rating results. The supplier/initiator either acts as a property developer or identifies and buys appropriate property assets in the marketplace.

Figure 1 shows a 'product-level' (left side) as well as an 'assessment/information level' (right side). It is clear that both investors (e.g. pension funds) and suppliers/initiators can be subject to so-called sustainability reporting requirements. In this regard, first labels for SRI-products as well as for 'sustainable buildings' already exist. However, approaches for the certification of sustainable property investment products are yet missing. Nonetheless, such certification schemes would be the logical consequence if property assets are to play a role within the SRI-market. Labels and certification schemes for sustainable property investment products would have to combine assessment criteria from the SRI-sector and from the sustainable building area. In addition, sustainability issues would have to be integrated into accounting and financial reporting requirements for property funds.

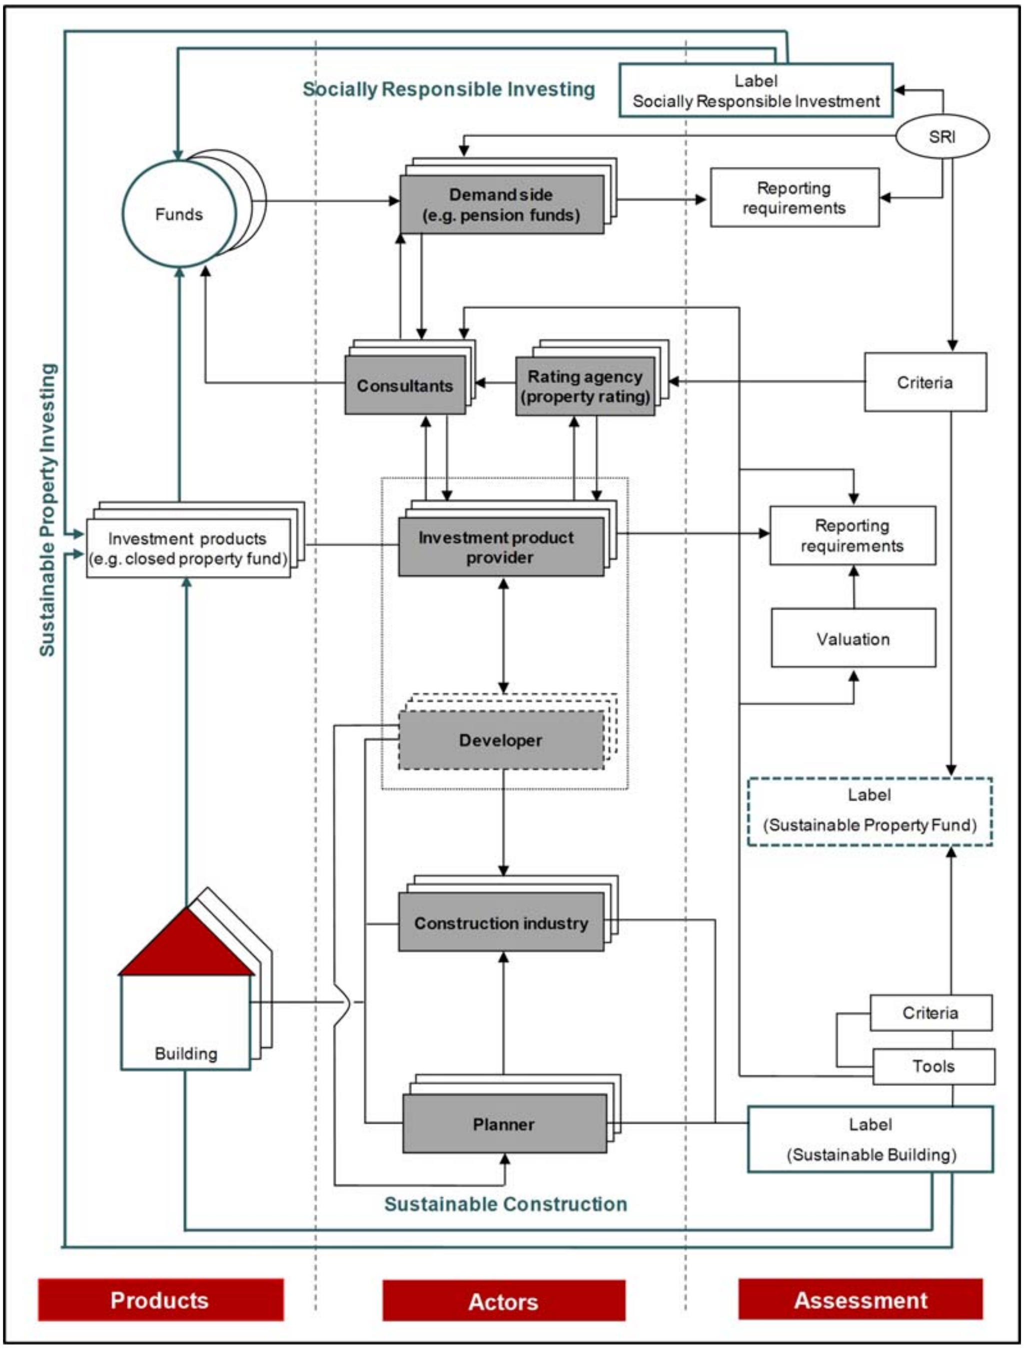

Figure 1 Constellations of actors for the development of sustainable property investment products

2.2 Interests and motivations on the demand side

A major problem in property economic research is the unsatisfactory situation regarding data availability; concerning both, transaction data and information and market participants' motivations and goals. Empirical surveys investigating the interests and motivations of selected groups of actors regarding the issue of sustainable building and property investment are rare (Pivo, 2007). So it does not come as a surprise that the situation regarding sustainable property investments in Germany has not yet been subject to investigation and inquiry.

Therefore, a survey was carried out among German institutional investors in order to gain insight into their interests, motivations, and level of awareness and knowledge regarding SRI-products in general as well as sustainable property investment products in particular. During September and October 2007 a total of 848 institutional investors have been contacted within the scope of a survey; 116 of them (response rate: 13%) responded either by telephone interview or through a web-based questionnaire survey to the following topics: organization and financial structures; importance of property assets in general; importance of socially responsible investing; importance of sustainable property investment. Among the 116 participants of the survey were 13 capital investment companies, 59 precautionary institutions (such as pension funds and life insurance companies) and 34 non-profit-organisations (including foundations, churches and charities aid organisations).

a) Importance of property within the portfolio

Capital investment companies usually diversify their portfolios. The survey showed that stocks, bonds and property make up for about 1/3 of assets under management each. About 69% of assets under management have a planned holding period of at least 5 years. The remaining 31% are split between assets with a medium-term (18%) and a short-term (13%) holding period. The inclusion of different asset classes with different holding periods leads to a broad diversification of investment risk, which is typically for capital investment companies. The exact share of property within the surveyed companies' portfolios is 34%.

Regarding precautionary institutions the survey revealed a risk-averse and long-term oriented investment strategy. On average, bonds have a share of about 60% of all assets under management. In the case of pension funds and life insurance companies the share of bonds is even higher: 70% due to legal requirements. About 3/4 of all assets have a planned holding period of more than 5 years. The share of property within precautionary institutions' portfolios is 13%.

Within the third group of surveyed investors, non-profit-organizations, the survey showed that they also have a longer-term oriented investment strategy. The share of property within their portfolios is 16%.

b) Level of knowledge regarding SRI

The majority of surveyed investors judged their level of knowledge and awareness regarding socially responsible investments as 'very good' or 'good'. A particularly high level of knowledge was reported among the capital investment companies of which 45% judged their level of knowledge as 'very good' (see Figure 2). The following relationships have been identified by making use of correlation analysis of some of the survey's results: (1) The level of knowledge regarding SRI-products increases if investors already have SRI-assets within their portfolios; (2) the higher the share of SRI-assets within the portfolio, the higher the level of knowledge; however, this relationship does not apply to the knowledge regarding sustainable property investments; and (3) the higher the share of property assets within the portfolio the higher the knowledge regarding sustainable property investments.

Given that the overall share of SRI-assets within the surveyed investors' portfolios is rather low (capital investment companies: 4%, precautionary institutions: 5% and non-profit-organisations: 13%), the high level of knowledge reported among investors is, indeed, remarkable.

c) Importance of Sustainable Property Investments

About 50% of the surveyed investors showed a moderate interest in sustainability-oriented open- or closed-end property funds. Among the surveyed investors the group of capital investment companies showed the largest interest. The remaining half of the surveyed investors stated that sustainable property investment funds are not on their 'radar' or that they are not considering this type of investment respectively. Further survey results are as follows:

- The different groups of institutional investors have different perceptions on what product forms would be of interest for sustainable property investment. The preferred forms are direct property investment and closed-end property funds. Capitals investment companies also showed an interest in property stock corporations and real estate investment trusts (REITs). Non-profit-organisations show a tendency to prefer open-end property funds.
- The majority of surveyed investors expect that the rates of return from sustainable property investments are comparable to those of conventional property investments.
- In addition to sustainability certificates for the property assets in question almost all investors argued that continuous sustainability reporting of fund companies and/or initiators would be an important characteristic of a sustainable property investment product. In this context it is interesting to note that 31% of the surveyed investors are already subject to sustainability reporting requirements; this means that if those investors would like to engage in sustainable property investments, the availability of sustainability performance information would be a precondition for such engagement.
- Compared to the level of knowledge regarding SRI products and issues in general the level of knowledge regarding sustainable property investments is judged considerably lower (see Figure 2).

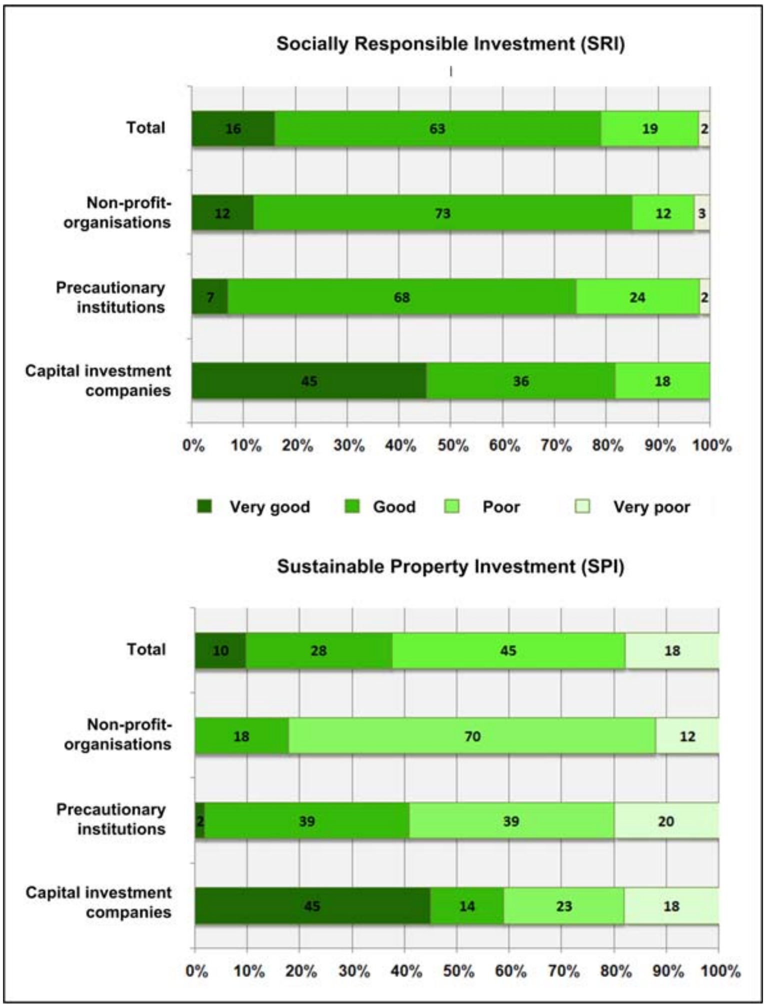

Figure 2 Investors' level of knowledge regarding SRI and sustainable property investment issues

In summary, there is moderate interest among institutional investors regarding sustainable property investment options in Germany. Clearly, this interest is greatest among those investors that are already engaged in SRI and that already have larger shares of property assets within their portfolios. However, these investors must be intensively advised and actively provided with detailed information on new SRI options and products in the property sector. This requires the development of appropriate marketing and reporting instruments.

2.3 Market potential for sustainable property investment products in Germany

The untapped market potential for sustainable property investment products can be estimated by using two different approaches: (1) estimation based on the share of SRI in the total investment universe; and (2) estimation based on optimal asset allocation considerations within the SRI market.

At the moment the share of SRI in total assets under professional management in Germany is roughly 1% (see also: Schäfer, 2005). In 2006 the total volume of property assets under professional management of institutional investors in Germany has been on the order of € 394.8 billion. Consequently, it can be argued that the market potential for sustainable property investment products is about 1% of the volume of property assets of institutional investors; this corresponds with a market potential of about € 4 billion in Germany.

The second approach for calculating the market potential is based on the consideration that from the viewpoint of optimal asset allocation the share of property within a mixed-asset portfolio is somewhere between 10% and 20% (Sirmans and Worzala, 2003; Worzala and Sirmans, 2003). In 2007 about € 20 billion were invested in 110 public SRI funds in Germany (Imug, 2007). As result, the market potential for sustainable properties within the public SRI sector is between € 2 and 4 billion.

The figure of € 4 billion market potential translates into a floor area of about 3 million square metres of office space; this estimate is based on an average price for gross floor area of about 1,400 €/m² for office buildings in average quality (see: BKI, 2007).

For reasons of comparison the following data is worthwhile mentioning: the market for office space in Frankfurt currently has a size of about 12 million square metres; in Germany the overall volume for construction works was ca. € 237 billion by 2004 and about € 5 billion of this sum have been spent for the construction of new office buildings.

2.4 Existing market & discussion of appropriate types of investment products

Although a negligible number of sustainability-oriented developments (closed-end property funds with very small volume only) could have been identified within the scope of the research project, the market for sustainable property investment products is virtually non-existent in Germany. Regarding the market in the USA the Responsible Property Investment Center (see: http://www.responsibleproperty.net) provides an overview on existing products and firms. Additional outstanding examples can be found in a recent publication of the UNEP FI's Property Working Group (UNEP FI, 2007b). For the German property market the following types of investment products are recommend (given that the basic framework for the development and establishment of REITs in Germany are not yet fully sorted, the development of a 'green' REIT appears unrealistic at the moment):

a) Development of smaller closed-end property funds for private investors

An appropriate strategy for new fund initiators is seen in the development of closed-end funds. These can comprise one or more property assets which have been certified with the national sustainable building certification scheme. As this certification scheme is still under development at the moment the idea of developing and marketing 'hot-topic-funds' appears attractive: possibilities are 'climate-protection property funds' and 'energy-efficiency property funds' comprised of net-zero-emission-buildings. The typical fund volume for closed-end property funds in Germany is between € 5 and 250 million; the duration usually is between 10 and 20 years.

b) Development of special open-end property funds for institutional investors

Due to distinct reporting requirements towards investors and possibilities for active portfolio management the investment type of special open-end property funds particularly lends itself for the development of sustainable property investment products. With this type of investment the number of investors, duration and volume is unlimited; typically the volume is at least € 250 million. Given the lack of comparability between different sustainability assessment and certification schemes it is recommend to select properties from regions within the coverage of one certification system only (questions concerning comparability and acceptance of different certification systems are currently intensively discussed in Europe).

2.5 Investment strategies

Sometimes it is argued that one problem for the development and establishment of sustainable property investment products lies in the difficulty of identifying an appropriate number of property assets that would qualify for such treatment. However, the following investment strategies can be applied:

a) "Build, Operate (and sell)" – Project development

If there is a shortage of sustainable buildings in the marketplace fund developers/initiators can act as a project developer and guarantee this way that the property assets are designed, constructed and subsequently managed according to the requirements of sustainable building.

b) "*Modernisation & Refurbishment" – Improving sustainability performance of the existing stock*

Investments into the existing building stock can extend or restart the life-cycle of buildings and improve the buildings' environmental and social performance. In particular in Europe carrying out extensive revitalisation works is partly regarded superior than building new.

c) Cause-based investment – Fostering more sustainable communities and cities

This strategy comprises investments into community projects such as affordable housing and urban revitalisation in order to foster a more sustainability society.

Pursuing the aforementioned strategies leads to additional demand for more sustainable planning and construction works. An additional investment strategy without this effect is:

d) "Screening & Selection" – Portfolio optimisation

Comprises the purchase and/or disposal of property assets (e.g. for portfolio selection or portfolio optimization purposes) that meet / don't meet preset minimum environmental and social performance requirements.

It also includes active portfolio management in order to develop the existing stock towards a more sustainable asset. Almost certainly the quality of the applied management practice will become – besides the quality of the buildings within the portfolio – a criteria for assessing and certifying sustainable property investment products.

2.6 Reporting: Requirements & Possibilities

An essential feature of a sustainable property investment product is the availability and regular updating of a sustainability report. This is because many institutional investors (in particular, pension funds) are already subject to sustainability reporting requirements. For example, in their statement of investment principles trustees in the UK must give (according to the Occupational Pension Schemes Regulations) information about (a) the extent (if at all) to which social, environmental or ethical considerations are taken into account in the selection, retention and realisation of investments, and (b) their policy (if any) in relation to the exercise of the rights (including voting rights) attaching to investments. Similar reporting requirements apply in Germany.

Sustainability reporting is a critical area as there exists a general 'ethical, social and environmental reporting-performance portrayal gap'. This gap has been identified by Adams (2004) and by Hummels and Timmer (2004). It is argued that current ethical and social reporting practice does not provide investors and other stakeholders with appropriate information to assess the material consequences of company activities and behaviour in socially or politically sensitive areas. "Until reports that compare sustainability performance are freely available, as ubiquitous as financial reports, we will remain lost in the quagmire of intriguing anecdotes, unable to determine who performs better […]. In a world with comparable reports, sustainability reporting can fulfil its true potential: providing concise, transparent information that clearly reflects the reality of environmental and social issues, allows for benchmarking, highlights long-term risk and opportunities, and contributes to improved levels of public and investor confidence. […] Otherwise sustainability reporting will remain an exercise in creative writing …" (Rogers, 2005, p. 39).

In fact, the reporting requirements for an innovative product with which the market is unfamiliar with are even harder as for already established investment products. In this regard, it is important to realise that acceptance of and trust in new property investment products will only be achieved by striving for the highest degree of transparency possible and, in doing so, not only delivering attractive products to investors but also the information necessary to meet investors' reporting requirements. Thus, a sustainability report for sustainable property investment products should, at least, contain information on the following issues:

- Impacts on the environment through emissions; expressed through the CO2-equivalent;
- Energetic quality / energy efficiency;
- Amount of drinking and waste water during occupation;
- Waste volume;
- User satisfaction; based on post-occupancy evaluations;
- Existence of local risks through flooding, extreme weather, large-scale catastrophes in adjunct industries, etc.; and
- Extent and manner of regular inspection and maintenance works.

It has to be note that this information refers to the property assets only; more general reporting requirements for the fund companies/initiators are laid down in detail here: AccountAbility, 2003 and GRI, 2006. The information on the property-related issues should be expressed (1) in absolute values, (2) as a trend, (3) in comparison to selected benchmarks, and (4) by indicating appropriate reference values (such as m^2, m^3, number of occupants/employees, etc.). The annual sustainability report of the UK-based fund company Hermes serves as an outstanding example in this regard (see: Hermes, 2007).

3. Conclusion & Outlook

The interest in socially responsible investment and corporate governance issues has risen dramatically in recent years; and so has the availability of SRI products. However, this trend has not yet led to comparable developments within the property industry. This assertion applies to both, the demand side (investors) and the supply side (fund developers and initiators). As a consequence, the current challenge lies in aligning the goals and motivations of socially responsible investing with efforts to increase the share of property assets within investment portfolios. This will create a demand for sustainable property investment products and thus, strengthen the demand for sustainable buildings in general. Coping with this challenge requires (1) increasing the awareness level of such investment products through systematic marketing; (2) delivering more scientifically robust evidence regarding the economic advantageousness of sustainable property investments; and (3) purposefully serving investors' existing sustainability reporting requirements.

The research carried out on the situation in Germany revealed that institutional investors which are already engaged in the SRI market represent a most promising target group for sustainable property investment products. But even though there is market demand and the untapped market potential can be estimated most existing property fund providers/initiators are reluctant in developing appropriate investment products. As a result, there are opportunities for both, fund initiators aiming to enter the property sector as well as for established property fund initiators to successfully extend their product range. These opportunities are major, but they have to be taken, now.

Acknowledgement

The authors thank the German Federal Ministry of Transport, Building & Urban Affairs as well as the Federal Office for Building & Regional Planning for funding the research project. The authors thank also Dr. Neligan (IW Consult, Germany), Mr. Friesenbichler (Friesenbichler Consulting, Austria) and Dr. Scholand (WestLB AG) for their cooperation within the scope of the research project and in the preparation of this paper.

Keywords: sustainable building, decision support, feedback-mechanisms, value, risk, quality assurance

Summary

The mainstreaming of sustainable development in property and construction is not only possible but realistic, even in the short to medium term. But for this to happen, a fundamental change to how we understand and value our built environment has to be achieved and the feedback-mechanisms within the property and construction industry have to be altered. This requires the development and application of new decision support instruments capable of bridging the gap between economic, environmental, social and cultural measures and components of property value. The paper investigates the basis for improved decision support by referring to three deep-seated obstacles currently hampering the implementation of sustainable development principles within the industry which are: (1) the increased application of financial modelling within a property context without taking into account the major differences between financial and property assets, (2) a fundamentally flawed understanding of the concept of property value, and (3) the absence of feedback-mechanisms that incentivise change. It is argued that the prerequisites for the development of new decision support instruments are (1) a sensible integration of property as a distinct asset class within portfolio theory, (2) further development of the understanding of the concept of property value, and (3) an improvement of the information flows between actors of property markets on the basis of building files. Such a framework would provide the basis for more scientific market analysis and would allow developing and applying new instruments for valuation, risk assessment, and overall quality assurance.

1. Introduction

Due to the shift in public perception of climate change and environmental degradation as real phenomena, recently the interest in sustainability has risen almost exponentially; both outside and within the property and construction industry where the topic is now sometimes being marketed as if it were new. The central importance of buildings in achieving sustainable development goals has been well-established for many years; as well as the knowledge with regard to the methods and financial benefits of more sustainable design, construction and management of buildings. What has been missing so far was awareness among market participants that sustainable property investment and management is, indeed, a highly profitable exercise and that refurbishing the existing building stock represents the most cost-effective solution available for tackling the looming environmental crisis. The current situation which sees all major actors more or less concerned with sustainability issues and the pressure for action constantly rising creates a real opportunity for achieving a broad market penetration for sustainable buildings and respective investment and management strategies. But this major opportunity will pass by unused if a restructured approach to how we understand and value our built environment cannot be achieved and if the informational basis and information links (i.e. the feedback structure) within the property and construction industry remain unchanged. Failure in this regard will result in 'greenwashing' the industry without addressing the roots of the problem. To be more precise: any effort solely focused on limiting the negative impacts of poor design and unsustainable property investment and management practices (i.e. anti-social behaviour, hostile public spaces, social conflicts, occupational diseases, contaminated land, contribution to climate change and biodiversity loss, urban sprawl, and the urbanisation of the countryside) without addressing the underlying value-systems and the feedback-mechanisms that motivate behaviour will remain insufficient. Instead, these efforts are "only trying to keep the old world ticking for as long as possible" as du Plessis (2003, p. 2) expressed it while having the majority of current sustainable construction solutions in mind. This diagnosis also applies to narrow-minded endeavours to implement sustainable development principles within the wider and highly influential property and interlinked financial markets.

2. Basics for improved decision support

Sustainable development in property and construction can no longer be perceived as mostly a technical matter of improving buildings' or the construction industry's performance. Sustainable development will not flourish if it is narrowly conceived and executed in a sectoral manner. Linkages need to be drawn with the investment, lending and insurance industries, with the larger social and economic agendas and policies, and between the different jurisdictions of responsibility at the governance level. The sheer complexity of this task requires, amongst other issues, new decision support instruments and information systems. It also requires 'hybrid' qualifications among professionals combining, for example, technical, economic, ecological and sociological expertise. The nature or 'design' of these decision support instruments as well as the necessary information links that have to be established can best be explained by referring to some of the major obstacles currently hampering the implementation of sustainable development principles within the industry.

2.1 Mathematical modelling & the concept of property value

Property is increasingly being seen as a distinct assets class besides stocks and bonds. This is due to an ongoing consolidation of financial and property markets and because it has been demonstrated that property improves the risk-return ratio of mixed-asset portfolios. For this reason, financial modelling and investment analysis practices are now extensively applied within the property industry to problems of risk premium determination and valuation with a constantly growing interest in financial valuation techniques and models such as discounted cash flow analysis, capital asset pricing, so called multi-factor models or real options theory. The aforesaid has been described as "the intrusion of the financial method in the real estate field" (d'Amato, 2008). Although property valuation and investment analysis represent the major mechanisms that allow environmental and social considerations to be aligned with economic return (Lützkendorf and Lorenz, 2005), the problem is that mainstream property valuation and investment counselling practice increasingly treats property as an asset class with just another degree of liquidity, even if we do not have a deep knowledge of the value of liquidity. This practice rests on a dangerous illusion since it fails taking into account that property assets do have major environmental and social impact with tangible consequences for our everyday life and well-being (d'Amato, 2008). Consequently, whenever these techniques are applied without taking into account the specific nature of property assets and investments and without prior adjustment to the subject matter of investigation and inquiry, the advice given on that basis is likely to be misleading.

So it does not come as a surprise that the role of mathematical modelling in a property context is a controversial one: On the one hand, it appears that the 'mathematization' of property economics and investment analysis has 'gone a bit far'; i.e. financial modelling in a property context is sometimes being carried out as an art for art's sake by transforming the original property problems into pure mathematical ones. Within this practice it is the mathematics theory and formal language that forms the subject matter and problem to be analysed and not the real-life problems of property investment, ownership and management. With a focus on economics in general Dillmann et al. (2000) argue that mathematics is a valuable and useful tool which economists should and must apply as long as its use is economically sensible. However, "the dangers of going beyond the 'frontier' of what is economically sensible occur when economists depart from the actual (empirical) subject matter because of the applied mathematical instruments, when the underlying value judgments are not, or only insufficiently, taken into consideration, when the recording and measurement of empirical magnitudes as an economic problem is underestimated or is even subordinate under the requirements of the formal language, and when the process of mathematization is considered as a substitute for the process of 'Verstehen' [i.e. understanding]" (Dillmann et al., 2000, p. 260). This frontier is crossed by the application of mathematical modelling in the property industry whenever it departs from and disregards the subject matter. As a consequence, mathematical modelling in a property context should be regarded meaningful (or even permissible) only in cases when the limits and conditions of validity – such as the underlying value-systems – are clearly displayed (see also: Szira, 2000). On the other hand, however, mathematical modelling is seen as the essential tool for analysing non-economic components of property value in economic contexts. There has recently been a shift away from 'modelling tools' towards the 'market itself' or, to be more precise, towards a better understanding of the market base of property value and the processes shaping it (see: Kauko, 2008). Unfortunately, the theory and concept of property value has been an almost entirely neglected area of property related research and education.

The value of a thing consists in its recognized fitness for attaining an end, or in its recognized utility. Utility can be defined as the capacity of a thing to serve for the satisfaction of human needs. According to Menger (1871, p. 120) the value of goods is always "the necessary consequence of human knowledge that the maintenance of life, of well-being, or of some ever so insignificant part of them, depends upon control of a good or a quantity of goods. […] The value of goods arises from their relationship to our needs, and is not inherent in the goods themselves. With changes in this relationship, value arises and disappears." The basic goal of property valuation is to provide a measure of the utility derived through the access to and control of property. The value of property is determined through the flow of services it is capable to provide for the satisfaction of human needs; i.e. the increment in well-being dependent upon it, or – what is the same – the impairment of well-being which its loss must bring about (see: von Mises, 1949, p. 120). However, the isolated analysis of financial variables and their subsequent transformation into a one-sided understanding of the economic value of property has lead to an artificial separation of economic, environmental, social and cultural measures and components of property value. This understanding is fundamentally wrong and misleading since it fails recognising that, in truth, the different components of property value are intrinsically linked and non-divisible (see Figure 1). Property, or the process of investment and management, has the capacity to create (or destroy) value consisting of different components. A fixation on economic value alone and an understanding of economic value as the end of all things does not make a great deal of sense. The increasing recognition among the wider public but also within parts of the property and construction industry that the maintenance of life and well-being depends – to a significant degree – on the environmental and social performance of buildings and the built environment means that the current understanding of property value needs major revision. In fact, it is becoming evident that a property's economic value also depends on the building's capability to create and protect environmental, social and cultural values and that an isolated analysis of mere financial variables is no longer (and has never been) adequate for capturing the apparently re-discovered concept of property value.

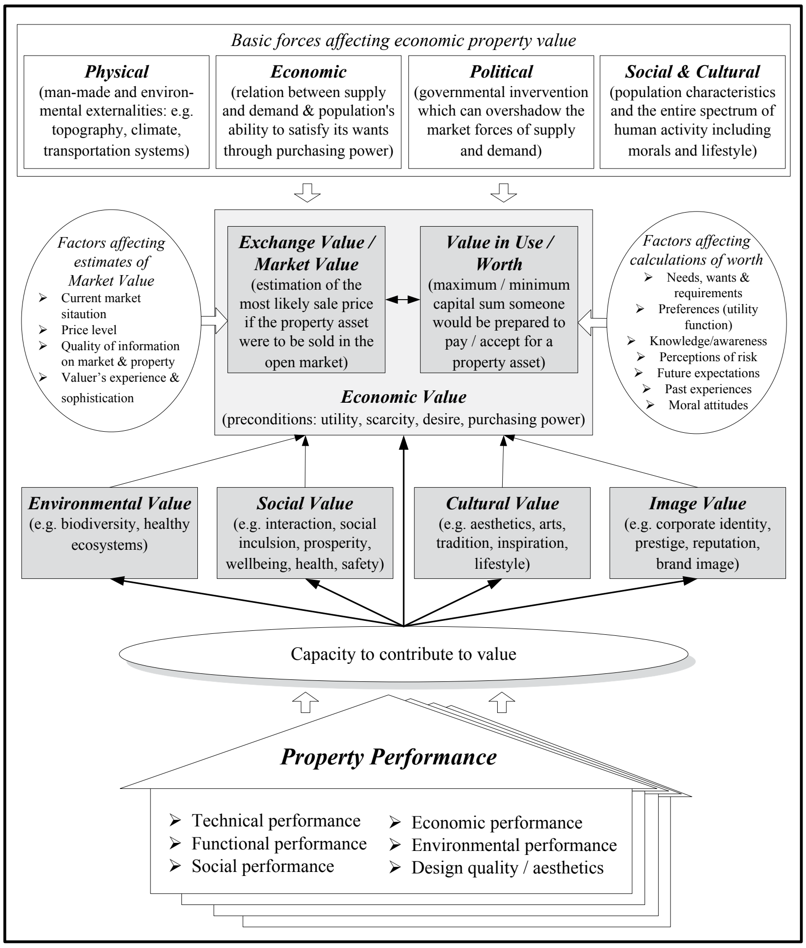

Figure 1 Property value map

In addition, there is an emerging concern that property valuations are conducted without appropriate value theory in place; i.e. a lack of professional foundation. Canonne and Macdonald (2003) investigated in detail the extent to which over 100 major North American textbooks on property valuation as well as a wide number of property valuation manuals, treaties and anthologies cover the theory of economic value and its history. They come to a sobering conclusion: "the theory of value […] is systematically neglected" (Canonne and Macdonald, 2003, p. 113). This is due to the fact that economists in the twentieth century have turned away from the analytical study of value to concentrate on the apparently more tangible econometrical analysis of prices. "To positivists, empiricists and others who value 'fact and logic' over 'vagueness and ambiguity,' any theory of value is vague and ill-determined. For this reason neoclassical economists have given up the notion altogether" (Klamer, 2003, p. 192). It appears that the property profession has put aside the theory of value not because the issue had already been solved but because the issue had appeared too complicated. "It is much more comfortable to technically concentrate on prices and price models than to go into the domain of deductive speculation and intellectual conceptualization, which is prerequisite to the study of the nature of value, and this is quite contrary to the usual inductive nature of economics" (Canonne and Macdonald, 2003, p. 116). However, this is a critical issue because future progress in the field of valuation does not lie in the further development of mathematical modelling techniques but lies in the discovery of the relation between man and his environment (Schmutz, 1948). Given the dearth of valuation literature addressing the theory and concept of property value as well as the links to sustainable development issues it does not come as a surprise that contemporary property valuation practice fails to account for all the factors that determine the competitive position of property assets in the changing marketplace. Consequently, contemporary valuation practice bears the risk that estimates of property values are being distorted and that misinformed and unsound decisions are being made on the basis of these valuations. This may be one of the deeper causes for unsustainable behaviour in property and construction markets.

2.2 Loops of feedback and adaptation & information exchange

It is important to realise that the mainstreaming of sustainable property investment and management is constrained by a misalignment between suppliers and those demanding property assets for occupation and/or investment. This misalignment became known as the *vicious circle of blame*. However, the circle can be broken by providing actors with appropriate feedback on both the environmental and social aspects of building performance as well as on its various interrelations with financial performance and property value. In this regard, the traditional focus on those actors directly involved in construction has certainly been helpful but not sufficient. The involvement of additional groups of actors such as property professionals, banks, assessors and certifiers as well as research and educational institutions is an absolute necessity (see Figure 2).

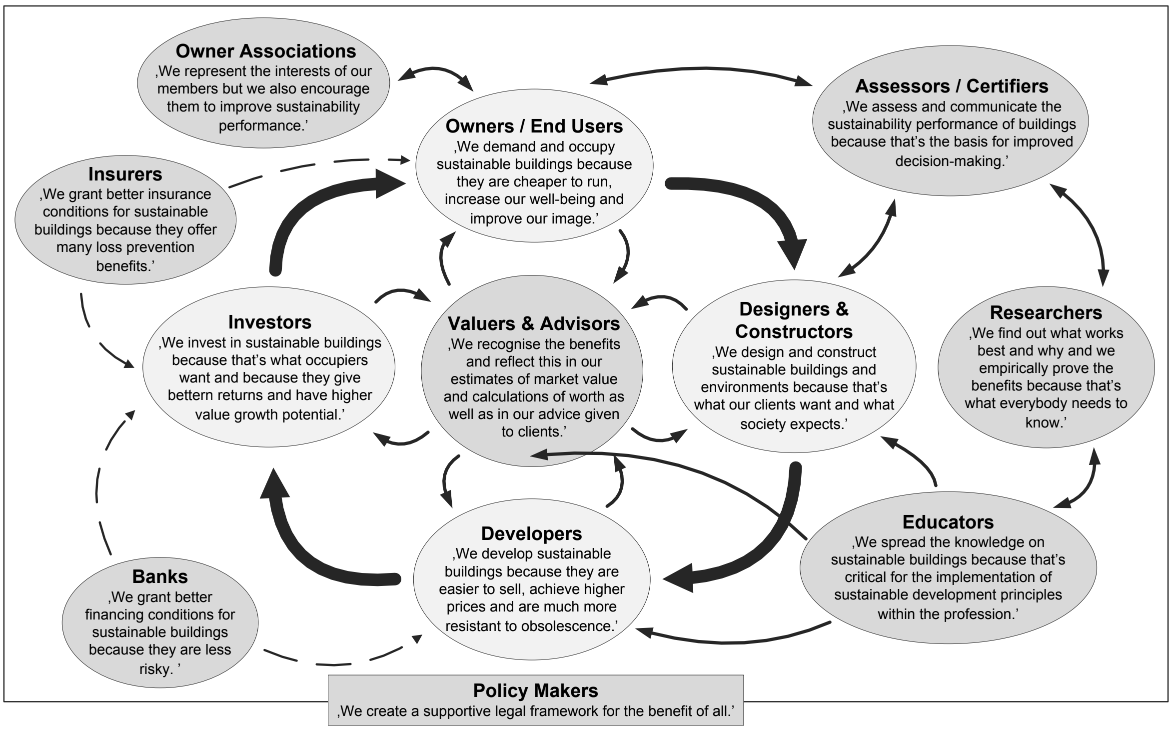

Figure 2 Virtuous loops of feedback and adaptation

The interplay between all these different actors as well as the information flow needs to be organised in such a way that the knowledge regarding the benefits of sustainable buildings pervades all areas and is accounted for within the highly influential processes of valuation, investment counselling and risk analysis. At the moment, the problem is that the feedback-mechanisms that motivate and incentivise change are not yet fully in place. One principle of sustainable development is that measures and actions within all sectors and at all levels of society are adjusted and re-calibrated through loops of feedback and adaptation. However, actors across all business sectors and also in property and construction markets are cut-off from feedback. "They know nothing of their impacts on people, culture, health, or the environment. They subsist only on the shallowest feedback: direct internal financial returns" (Kiuchi, 2003). This is dangerous and leads to a false statement of corporate accounts since huge and growing external cost categories are ignored. Shareholders may not notice these unstated costs while in contrast stakeholders do (Kiuchi, 2003). Expressing this in the property context: if building owners and investors know nothing or very little about the real performance of the buildings they buy, use and operate, (i.e. if they are cut off from feedback delivered by triple bottom line monitoring), then these buildings cannot be improved systematically in pursuit of both individual and collective well-being. The alternative is for property professionals to begin assessing and reporting value creation through sustainable design, incentivising change and more sustainable behaviour. The added value appropriated to sustainable design will underwrite a restructured approach and a radical change to how we understand and value our built environment. The end result is the emergence of a pro-active, self-perpetuating loop driving further change and even more sustainable behaviour.

A precondition for assessing and reporting value creation through sustainable design and for installing appropriate feedback-mechanisms within the property industry lies in overcoming existing information asymmetries. What is needed is a systematic description of major characteristics and attributes of buildings for various purposes such as valuation, risk assessment and certification; i.e. a reliable and cost-effective source of information for property professionals. An appropriate source of information in this regard are building passports or building files which have been discussed in Europe since a considerable period of time. However, building files are yet only issued occasionally on a voluntary basis. In addition, building files are not yet standardised. The introduction and dissemination of building files in property markets is currently hampered by ambiguous and unclear perceptions regarding their informational content and function. Usually building files are either seen as a kind of building manual, as an extended construction and building specification, as a quality assurance system or even as a label or certificate. However, the interpretation of building files put forward in this paper is that of an 'information container' which supports the exchange of information between actors in property and construction markets (see Figure 3).

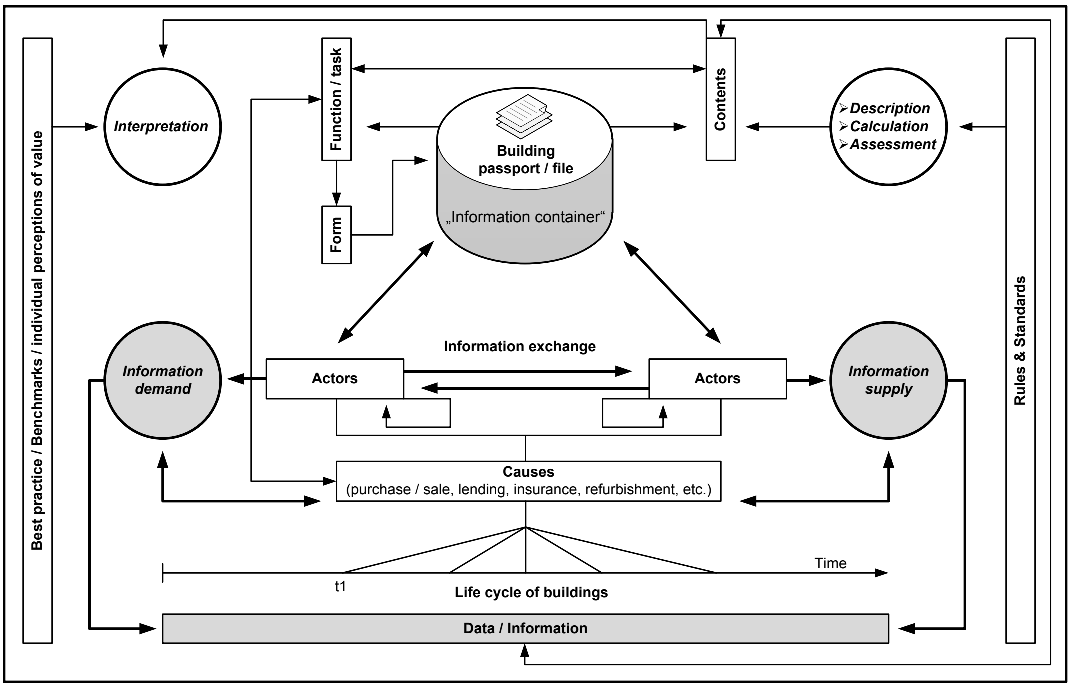

Figure 3 Information flows between actors of property markets on the basis of building files

There exists a clear need for provisioning, extending and updating building related information along the life cycle of property assets. This information has to be gathered and compiled on a scientifically robust basis during the planning phase as well as during the subsequent phases of operation and refurbishment. In this regard it is important to realise that different actors fulfil different roles and have different standpoints and goals. They therefore need different kinds of information in different formats tailored to the requirements of specific decision making problems accompanying the life of buildings. Building files can be used to serve this informational demand as they are capable of providing different kinds of information for different actors. They could contain information on the following issues: construction method; building materials; statics; heat and sound insulation; fire safety; operating costs; maintenance and repair; demand for and consumption of different resources/media; etc. For the further development of the informational content of building files it is recommended to foster the development towards performance-based building information as well as to compile a list of key characteristics and attributes which would best serve different actors in different decision-making contexts. The latter issue could be addressed through efforts undertaken by the large organisations for property professionals such as the Royal Institution of Chartered Surveyors (RICS).

3. Next generation decision support instruments

Next generation decision support instruments for the property industry will have to fulfil a variety of roles and purposes. First, they will have to address the imperfection and asymmetry of information. In today's property markets investors and their professional advisors are forced to analyse and evaluate various aspects of building performance and the attractiveness of a particular location in great detail while they are simultaneously required to take into account a variety of complex institutional influences and externalities at global, regional and national level. The success of property investments and the competitiveness of investors and their professional advisors strongly depends upon knowledge and on the capabilities and sophistication to assess, interpret and understand the increasing complexity of factors from diverse sources of real estate information (see: Castells, 1996). This means that decision support instruments will have to allow for interlinking information from sources such as market and transaction databases, building files, sales portals, land registers, geographical information systems, national statistics bureaus, etc. in order to enable property professionals to fulfill their role as 'information managers' in a market where the distribution of information is traditionally considered asymmetrical. Second, decision support instrument will have to allow professionals to assess and communicate (in understandable formats) the accuracy and reliability of both their estimates of values, risks and costs as well as of the quality of the applied valuation, risk analysis, management, construction and refurbishment processes. This will involve addressing notions of uncertainty and probability as well as the issue of traceability (see: Lorenz et al., 2006). As there has already been a lot of loss of both credibility and faith in the property and finance industry in general and in the valuation and counselling profession in particular (due to overvaluation, misleading advice and speculative behaviour that has recently led, amongst other issues, to a global crisis in property and interlinked financial markets), professionals will have to apply tools and measures not only for 'quality assurance' of products and processes (see Figure 4) but also to make their 'thought processes' explicit and to give clients a better understanding of the nature and risks of property investment and financing.

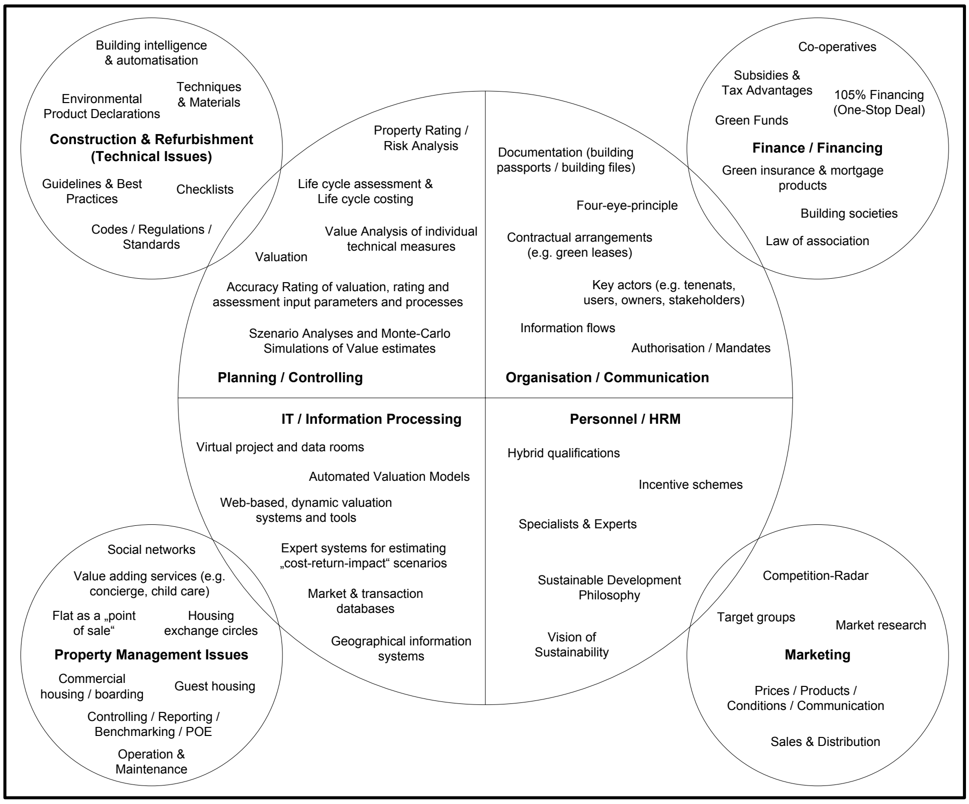

Figure 4 Overview on instruments, tools, measures and key issues for Overall Quality Assurance

Finally and most importantly, decision support instruments will have to bridge the gap between economic, environmental, social and cultural measures and components of property value and help to establish the necessary feedback-mechanisms that incentivise and drive change in the property industry. This requires a synergy we have not seen so far; i.e. an integration of the traditional methods and tools for valuation, risk analysis and cost estimation with the methods and tools developed by the sustainable building community for assessing and communicating the contribution of buildings to sustainable development. The connection, though yet missing, between these two kinds of methods and tools is seen in the introduction and wide-spread dissemination of building files within the property and construction industry. The challenges and difficulties in creating next generating decision support instruments lie as much in the further development of IT-systems and tools as in the improvement of the informational data basis available in the property industry. This will be shown by briefly referring to the development of new instruments for the following areas: valuation and risk assessment.

As the perception of property as a commodity is currently changing to emphasize sustainability-related building characteristics and performance aspects as important determinants of a property's worth and market value, valuation practice must change accordingly. It has therefore been argued that advanced valuation methodology – like hedonic pricing techniques – can and must be applied in order to continuously monitor market behavior and shifts in value perceptions in order to provide a more scientific basis for the price or value adjustments that have to be made to account for the benefits of sustainable design features not solely reliant upon the knowledge, judgment and experience (or inexperience) of the individual valuer alone (Lorenz et al., 2007). But the application of advanced valuation methodology can only provide meaningful results on the relationships between environmental, social and financial building performance if the quality of building descriptions contained in property transaction databases does allow drawing such conclusions. Unfortunately, at the moment this is not the case since we do not yet have performance-based building descriptions in property transactions databases. This issue has been investigated in more detail by a recent survey carried out at the University of Karlsruhe on the content and scope of transaction databases in Germany. The survey comes to sobering conclusions: Only a minority (8%) of valuation expert committees (the major source of property transaction information in Germany) has made preparations to extend the scope of transaction databases by including information from the recently introduced energy performance certificates while the majority is still considering this issue or does not even know about the relevance of the information contained within these certificates (Kertes et al., 2008). However, the state of affairs may not be much better in other countries where property markets are considered to be much more transparent and price information is more readily available; performance-based building descriptions are arguably missing in almost all transaction databases. So valuers are left alone when forming an opinion of value for the foreseeable future as it will take years to accumulate the informational data basis necessary to empirically underpin a valuer's decision to provide a 'valuation bonus' for a sustainable building or a 'valuation reduction' for a conventional one.

The situation is very similar with regard to the further development of instruments for assessing property risk (so-called property ratings). Developers of property rating systems (mainly banks and rating agencies) have started creating links for the direct and indirect integration of sustainability issues within rating methodologies and processes. But if the results of building assessment tools are to be used to support the rating process, then the flow of information can be organized in different ways and the question arises whether partial results of building performance assessments should be used to provide the informational basis for certain aspects of property ratings, or if the overall building assessment result should be integrated into property ratings as a separate rating category? Nonetheless, the use of property ratings in their current form already allows distinguishing more clearly between conventional buildings and more sustainable ones within property financing and risk-analysis processes (Lützkendorf and Lorenz, 2007). But if financial intermediaries acknowledge the economic impact of sustainable design, such acknowledgment will be credible in the longer term only if the sustainability performance of a building is reflected in the lending terms. Some banks are already offering special lending terms for energy-efficient, environmentally sound and/or sustainable buildings. However, there is a need to verify whether this is the result of marketing activities or certain grants-in-aid, or whether it is in fact due to a better understanding of the correlation between risk assessments and lending terms? Only in the last case would this represent a breakthrough with wide-ranging implications. And again, such conclusions can be drawn only on the basis of data combining performance-based building descriptions on the one hand and financial performance information (in this case: loan default rates) on the other hand.

4. Outlook

The challenges imposed by sustainable development for property professionals, their professional bodies and their educational institutions are unprecedented – in terms of importance, urgency and scale. And as the concerns are slowly changing from worries about environmental degradation and loosing species to fears about losing the services that keep our own species – and its civilization – thriving (WBCSD, 2007), the solutions and actions undertaken to address this challenge are likely to be entirely different from current ‘best practice’ in construction, property investment and management. Addressing this challenge will require as much a ‘technical solution’ (in terms of developing new decision support instruments, building knowledge, and establishing new information links) as it will require a ‘moral solution’. Is it so difficult to realise that due to information asymmetries actors in property and construction markets operate in a permanent prisoner’s dilemma and that we would all benefit from more agreeable behaviour (see: Hume, 1751 and Kuhn, 2003)? Apparently, the profession stands at the crossroads of deciding between travelling along ‘the road of value and agreeableness’ (which involves acknowledging the principle of enlightened self-interest which states that individuals who act to also further the interests of others ultimately serve their own self-interest) or pursuing business-as-usual and experiencing the ‘tragedy of the commons’ (see: Lloyd, 1833), a social trap that involves a conflict over finite resources between individual interests and common goods which finally dooms the resources in question.

ENERGY - 'FROM SERIAL RENOVATOR TO SENSIBLE RETROFITTER'

Kay Saville-Smith[1]
Verney Ryan[2]

[1] Beacon Pathway Ltd and Research, Director Centre for Research, Evaluation and Social Assessment (CRESA), Wellington, New Zealand, kay@cresa.co.nz
[2] Team Leader – Energy, Beacon Pathway Ltd, verney@xtra.co.nz

Keywords: energy, sustainable, renovation, retrofit, housing, house typology, willingness-to-pay

Summary

When people move home they often bring with them exciting plans to 'improve' their property. The focus is often on marble bench tops and luxury bathrooms at the cost of improving the energy performance of the home and hence, the comfort and health of the occupants. Why do we place such a high value on aesthetic 'renovation' whilst we ignore the real benefits that can accrue from energy efficient 'retrofit'? Beacon Pathway, a research consortium with the aim of bringing 90% of New Zealand's homes to a "high standard of sustainability" by 2012, is helping to define best practice in the provision of retrofit solutions. Beacon seeks to understand what New Zealanders value when thinking of 'renovating' their home, what people understand and value about 'retrofitting', and how the two can be aligned to raise the value case for energy efficient renovation. Beacon has developed a framework for decision making to analyse the best retrofit solutions for a range of New Zealand housing typologies and specific options for targeted users and consumers. The research is helping to determine the technical feasibility of improving the energy performance in existing stock and quantified the energy efficiency gains possible within the constraints of individual dwelling typologies. The research is also helping Beacon develop a range of appropriate delivery processes and marketing approaches for dwellings with different household and tenure characteristics, including owner-occupied dwellings / rental dwellings; high energy users and recent home buyers.

1. Introduction

Beacon Pathway Ltd (Beacon) is a research consortium that seeks to radically change the design, construction and renovation of New Zealand's homes and neighbourhoods. Beacon aims to bring about a significant improvement in the sustainability of the residential built environment in New Zealand through science-based New Zealand research.

Beacon's current research on energy is directed to a market transformation that will ensure that both suppliers and consumers act to improve the energy efficiency of New Zealand's housing stock. Beacon recognises that improving the energy performance of New Zealand's housing stock is primarily a matter of changing the performance of the existing stock through retrofitting. The issue for New Zealand's retrofitting initiatives, whether publicly funded or privately initiated by householders, is how to develop energy retrofit packages that most effectively improve dwelling performance and fall within the constraints of household affordability and willingness to pay. Beacon intends to use the findings of this research to develop a study of retrofit performance and take-up among 1000 New Zealand dwellings.

Beacon is addressing the problem of developing effective retrofit packages by a three pronged research stream that is directed to:

- establishing the relationship between retrofit and building typology
- identifying how to stimulate take-up among key consumers in the housing market, and
- identifying a set of evidence-based, robust promotional approaches, packages and tools to retrofit existing houses.

In this paper we present the findings from the second of those research prongs. That research has been concerned with four key questions. They are:

- What user/consumer segments are best targeted to achieve maximum take-up of energy efficiency retrofits of New Zealand homes?
- What are the motivations of these user segments and how should they be targeted?
- Are there common features of building typology of the priority user segments?
- What benefits do other end-users in the supply chain gain through retrofit?

Those questions have been explored through two surveys. One survey has focused on households that are high energy users and the second survey has involved households that have recently moved from one house to another. In the following discussion, we:

- set out the rationale for surveying those two sets of consumers
- provide the survey method and comment on the focus and rationale of the questionnaire
- present some of the key findings from the surveys, and
- comment on the implications of the findings for the development of effective retrofit packages and the potential for market transformation and stock sustainability.

2. Recent Movers and High Energy Users

New Zealand is an enormously mobile society. The 2006 census found that 57.7 percent of the population had changed place of residence in the previous five years. Young people and tenants tend to be the most mobile. Nevertheless, approximately 140,000 dwellings change hands annually. Recent Movers are unique in two ways. Firstly, home buyers have immediate selection choices. The factors that inform those choices regarding the energy efficiency and their assessment of the performance of their new home give a very real insight into: the value home owners place on energy efficiency, warmth and healthy living conditions; the characteristics of homes that home buyers use to assess the likely performance of a dwelling; and the probability of accurate assessments by buyers of the performance of a new dwelling. Secondly, home buyers are often in situations in which they chose a home which requires renovation and they finance their purchase to allow for renovation. That tendency allows us to better understand the extent to which energy and associated dwelling performance and retrofitting are elements within any renovation planning and financing.

High Energy Users are also an important group of householders. Energy use by high users dominates the aggregate energy patterns of New Zealand households. Increasing their energy efficiency and, preferably decreasing their aggregate energy use, is critical to improving the overall energy performance of the residential housing stock in New Zealand. The Centre for Research, Evaluation and Social Assessment (CRESA) has established in a recent survey for the Energy Efficiency and Conservation Authority (EECA) that those households that see themselves as high or very high energy users generally are so. High energy use households may make up between 15 and 25 percent of households. That is, between 200,000 and 350,000 households in New Zealand (Saville-Smith, K. and R. Fraser, 2007). High Energy Users have the potential to reap the greatest returns on investment from increasing the energy efficiency of their dwellings. Understanding their patterns of renovation and their perspectives on retrofit is, consequently, critical to developing effective market transformation and a sustainable housing stock.

3. The Research Method

Both groups were surveyed using largely similar questionnaires. The High User Survey, however, was implemented through telephone interviewing and the Recent Mover Survey was a postal survey requiring the participant to self-complete and post back the questionnaire. Although there were some differences between the questionnaires to take account of the different population profiles of the participants and data collection, both questionnaires involved primarily closed-ended, pre-coded questionnaires with some opportunities for the participants to convey information in free-form. The latter were subsequently content analysed and coded.

The questionnaires focused on eliciting information from participants about the: size and physical characteristics of their current dwelling; renovation and retrofit activities in the year prior to surveying and associated costs; intended renovation and retrofit activities in the coming year and intended expenditure; energy consumption patterns and their perceptions of the drivers of their energy consumption; condition and performance of the dwelling in winter and summer including incidence of damp and mould; householders' understanding of retrofit and the impacts of various retrofit components; and the householders' attitudes to retrofit, the benefits they associated with retrofit and willingness to pay. The survey participants were also asked to report a limited set of socio-demographic information around household income, life stage and household size.

For the High Energy User Survey, data was collected from self-identified high energy use households. Participants for the survey were selected randomly from throughout New Zealand using telephone numbers extracted from white pages listings. Interviewing was undertaken over a two week period from 12 October 2007 to 26 October 2007. An initial screening question asked respondents to estimate their energy consumption compared to other households – only those respondents who estimated their household energy consumption as high or very high were eligible to complete an interview. In all 700 interviews were completed and assuming that the sample has captured high energy users, it provides a margin of error of ± 3.8 percentage points at the 95 percent confidence interval.

Participants for the Recent Movers Survey were selected randomly from a data extract of recent movers generated from the New Zealand Post Household Postal Address Directory. A 'recent mover' was defined as someone who had changed address between 1 April 2006 and 31 March 2007. The data extract was also limited to those households who identified themselves as owner occupiers. The data extract included some 33,700 households, divided into 11 broad regions using post code data. The final sample of 3,000 households was a stratified random sample where the number of households included in the sample from each region was intended to be broadly proportional to the total number of recent mover households in that region for the survey period. Surveying took place over a four week period beginning late September 2007. In all 724 completed surveys were received before the due date of 19 October 2007. The margin of error for the recent mover dwelling population is 3.7 percentage points at the 95 percent confidence interval.

The data from the surveys have been entered and analysed in the Statistical Package for the Social Sciences (SPSS) and subject to univariate and bivariate analysis. Statistical testing – usually chi-square tests – was also undertaken to establish whether there was systematic and statistically significant relationships between selected key variables.

4. Dwellings, Energy Use and Dwelling Performance

New Zealand has a homogenous dwelling stock in terms of dwelling size and type. This is evident in the dwellings occupied by the High Energy Users and the dwellings occupied by Recent Movers. The majority of dwellings are three bedroom dwellings and there is a strong preponderance of detached single-storey dwellings (Table 1).

Table 1: Dwelling Size and Type

Dwelling Characteristics	% Recent Movers		% High Energy Users	
	n	%	n	%
1 bedroom	10	1.4	16	2.3
2 bedrooms	104	14.4	75	10.7
3 bedrooms	354	49.0	300	42.9
4 bedrooms	212	29.4	210	30.0
5+ bedrooms	42	5.7	99	14.1
Total	***722***	***99.9***	***700***	***100***
A detached single-storey house	443	61.7	450	64.4
A detached multi-storey house	190	26.5	185	26.5
A semi-detached single-storey house	18	2.5	20	2.9
A purpose built flat or a flat in a converted building	19	2.6	18	2.6
A semi-detached multi-storey house	16	2.2	8	1.1
Other	19	2.6	8	1.1
An apartment (in a block two or more storeys high)	7	1.0	6	0.9
A terrace house	6	0.8	4	0.6
Total	***718***	***99.9***	***699***	***100***

The participants in the High Energy User Survey, by definition, saw their energy use as above average. However, around a fifth (21.5 percent) of the Recent Movers Survey participants also described themselves as high energy users. When compared to the Recent Movers, the High Energy User Survey participants tend towards simplistic explanations for their high energy use. The high energy users among the Recent Movers Survey participants have multi-dimensional explanations. Among the High Energy User Survey participants the common explanations for high energy use refer to having a large number of household appliances, while among the Recent Movers the most common explanation is around the amount of energy their house takes to heat (Table 2). The Recent Movers (including those of them who are high energy users) are much more concerned about the energy efficiency of their homes than the High Energy Users. Recent Movers are also considerably more concerned with the comfort or warmth provided by a dwelling (Table 3).

Table 2: Assessment of Likely Reasons for Their Households High Energy Use

Explanations for High Energy Use	% Recent Movers with High Energy Use (n=156)	% High Energy Users (n=700)
Our house takes a lot of energy to heat	60.3	35.3
House has many lights	44.2	6.6
Large number of appliances	42.3	37.1
Household members are wasteful with energy	31.4	18.0
We have old hot water tanks	25.6	4.3
We have many hot water tanks	3.8	2.9
Our house takes a lot of energy to cool	2.6	0.7

* Multiple Response

Table 3: Considerations of Energy Issues when Acquiring Current House

Energy Issues Considered	% Recent Movers (n=724)	% High Energy Users (n=700)
Comfort or warmth within the house	83.4	59.9
Whether house had insulation in the roof space or under the floor	64.8	47.4
Whether the windows and doors were tight fitting or draught-proofed	44.3	35.0
What the energy bill might be like	35.9	22.4
Whether the house had double glazing	25.4	15.3

* Multiple Response

This concern with warmth and comfort does generate a somewhat different insulation profile in the dwellings reported on by Recent Movers and High Energy Users respectively. Recent Movers are less likely to report dwellings with no insulation. They are more likely to report that their dwellings are fully or substantially insulated (Table 4). Notably, only 6.4 percent of Recent Movers report no insulation compared to 13.3 percent of High Energy Users. There is not, however, a strongly pronounced difference in the appliances that Recent Users and High Energy Users mainly use for heating (Table 4), although the latter show a slightly lower use of woodburners and heat pumps and a higher reliance of electric heaters and portable gas heaters than Recent Movers.

Table 4: Reported Insulation Profile of Recent Movers' and High Energy Users' Dwellings

Insulation	% Recent Movers (n=724)	% High Energy Users (n=700)
No insulation	6.4	13.3
Roof space only	25.8	25.9
Floors only	1.2	1.1
External walls only	3.5	2.7
Roof space and floor	6.9	8.3
Roof space and exterior walls	32.6	27.1
Floor and exterior walls	0.4	1.4
Fully insulated	16.3	15.9
Not sure	6.9	4.3
Total	***100***	***100***

Table 5: Main Space Heating Used

Heater Type	% Recent Movers (n=724)		% High Energy Users (n=700)	
	n	%	n	%
Enclosed woodburner	168	25.9	158	22.6
Heat pump	144	22.2	109	15.6
Electric heater e.g. fan, bar, convection heater	68	10.5	105	15.0
Fixed electric radiator or oil column heater	65	10.0	80	11.4
Fixed and flued gas heater	58	8.9	66	9.4
Portable gas heater e.g. LPG	50	7.7	64	9.1
Open fire	26	5.7	40	5.7

Fixed unflued gas heater	17	3.3	23	3.3
Other	35	2.6	25	3.6
No heating used	*3*	*1.3*	*9*	*1.3*
Total	***649***	***100.0***	***700***	***100***

It is notable that, while only a very small proportion of High energy Users Survey participants explain their high energy use in terms of the age of their hot water cylinders their hot water cylinders have a distinctly older profile than the hot water cylinders in the houses of recent movers. Almost half the hot water cylinders of High Energy Users are aged more than 10 years and less than a third (28.4 percent) of hot water cylinders are less than five years old. In addition, 51.4 percent of High Energy Users report that the pipes from their hot water cylinders are not lagged at all. By way of comparison, 38.4 percent of hot water cylinders in the houses of recent movers are less than five years old and 38.9 percent of the Recent Movers report that their hot pipes are unlagged.

Both household sets report similar patterns of efficient light bulb use. Two-thirds (66.1 percent) of High Users reported using energy efficient light bulbs. However, only around a fifth (21.6 percent) reported that energy efficient light bulbs make up 76 percent or more of the light bulbs in their dwelling with a little over two-thirds (67.3 percent) of High Users reporting that half or less of their light bulbs are energy efficient. Similarly, 70.4 percent of Recent Movers reported using energy efficient light bulbs, but only 14.9 percent reported that energy efficient light bulbs make up 76 percent or more of the light bulbs in their dwelling. Almost two-thirds (61.4 percent) of Recent Movers report that half or less of their light bulbs are energy efficient

5. Renovation and Retrofitting

It appears that both the energy and thermal performance of dwellings of High Energy Users and the dwellings of Recent Movers could be significantly improved through quite simple retrofitting interventions. It is of enormous importance that a considerable proportion of dwellings have been exposed to significant investments in renovation in the year prior to surveying, but few of those renovations have actually involved retrofitting for higher levels of energy efficiency.

Among the Recent Movers, 46.3 percent they have undertaken renovation or retrofit work in excess of $2,000. 43.6 percent of Recent Movers also report intending to expend more than $2,000 on renovations and retrofitting in the coming year. The average reported expenditure on renovations/retrofit is $22,477 and the median is $7,000. Among the High Energy Users, a third (33.3 percent) report renovation or retrofit work in excess of $2,000. 35.9 percent of High Energy Users intend to expend more than $2,000 on renovations and retrofitting in the coming year. The average reported expenditure by High Energy Users on renovations/retrofit is $25,284 and the median is $9,500. Table 6 sets out the renovation activities reported by High Energy Users and Recent Movers.

Most of this renovation work is not prompted by a belief that their dwellings are in poor condition. Among the High Energy Users, 43.4 percent reported that their dwelling was in good condition only needing minor maintenance. Nevertheless, High Users made up 51.7 percent of the High Energy Users intending to undertake substantial renovations, repairs or retrofitting in the coming year. Among the Recent Movers the group that reported that their dwelling is in good condition are also over-represented among those intending to expend more than $2,000 in the coming year on renovations, repairs or retrofitting. This does not mean, however, that renovations do not include attempts to deal with dwelling performance problems.

43.6 percent of High Energy User reported that their dwelling had problems of mould or damp and over a third (36 percent) of High Energy Users and 31.9 percent of Recent Movers reported on ways they have tried to address mould, cold and damp problems in their houses through repairs or renovation or acquisition of appliances. Their strategies are almost entirely dominated by the installation of Heat Recovery Ventilation (HRV), Distributed Ventilation System (DVS), or similar systems with installation of heat pumps and dehumidifiers not far behind. 46 percent of the High Energy Users that reported attempting to address mould and damp in their houses put in HRV/DVS systems, but less than 4 percent installed insulation. Similarly, 28.6 percent of Recent Movers used dehumidifiers while 19.5 percent installed HRV/DVS systems and 17.7 percent installed heat pumps to deal with mould, damp and cold. Less than 8 percent installed some form of insulation despite 83.7 percent of the Recent Movers dwellings having only partial or no insulation.

Table 6: Renovation & Retrofitting Activities

Renovation or Retrofit	Recent Movers (n=724)		High Energy Users (n=700)	
	n	%	n	%
Interior repainting and/or wallpapering	155	45.7	46	19.7
Replacement of kitchen appliances	117	34.5	22	9.4
Carpeting	104	30.7	31	13.3

Replumbing	66	19.5	8	3.4
Installing an extractor fan in the bathroom	64	18.9	3	1.3
Installing a rangehood/extractor fan in the kitchen	64	18.9	1	0.4
Full exterior re-paint	63	18.6	28	12.0
Replacement of bathroom cabinetry	62	18.3	15	6.4
Rewiring full or significant part of the dwelling	54	15.9	5	2.1
Installing ceiling insulation	46	13.6	13	5.6
Installing wall insulation	46	13.6	7	3.0
Installing a new hot water cylinder	44	13.0	7	3.0
Replacement of interior cladding	41	12.1	15	6.4
Installing a ventilation system e.g. HRV, DVS	40	11.8	17	7.3
Installing underfloor insulation	35	10.3	8	3.4
Adding rooms	31	9.1	16	6.9
Installing a wood burner	26	7.7	6	2.6
Roof replacement	25	7.4	15	6.4
Polishing floors	24	7.1	3	1.3
Upgrading hot water systems to instant gas	24	7.1	1	0.4
Venting drier to the outside	23	6.8	1	0.4
Installing a low flow showerhead	21	6.2	1	0.4
Replacement of significant amounts of exterior cladding	20	5.9	7	3.0
Installing double glazing	17	5.0	4	1.7
Installing a rainwater tank	11	3.2	1	0.4
Installing a pellet burner	7	2.1	1	0.4
Installing a solar hot water system	6	1.8	4	1.7
Installing a wet back hot water system	3	0.9	1	0.4
Installing a heat pump hot water system	2	0.6	4	1.7
Installing passive vents in windows	1	0.3	0	0.0

* Multiple response

Not surprisingly, considerable proportions of householders find that they continue to have mould, damp and cold problems. Among the High Energy Users, for instance, of the 313 householders reporting they have a mould in their dwelling, 45.4 percent have previously attempted to address the problem through renovation, retrofit or appliance use. Similarly, of the 252 High Energy Users who have taken measures to rectify problems with mould, 56.3 percent report still having mould problems.

Not only do the participants in the High Energy User Survey and the Recent Movers Survey appear to be misdirected in their efforts to improve dwelling performance, many are unaware of the term ‘retrofit’. Only 28 percent of High Energy Users and 41 percent of the Recent Movers reported that they had heard of the term. In both surveys, the participants showed considerable variation as to the activities they identified as retrofit. As Table 7 shows, installation of ceiling insulation is associated with retrofitting by substantial proportions but many of the lowest cost and most basic options such as use of curtains are less likely to be associated by householders with retrofitting.

Table 7: Activities Identified by Recent Movers and High Energy Users as Retrofit*

Activities	Recent Movers (n=296)		High Energy Users (n=252)	
	n	%	n	%
Installing insulation/batts in the ceiling	238	80.4	66	33.7
Installing double glazing	220	74.3	44	22.4
Installing underfloor insulation	218	73.6	57	29.1
Installing insulation in the walls	213	72.0	46	23.5
Draught stopping the doors and windows	192	64.9	11	5.6
Installing heat pump	167	56.4	19	9.7
Putting in an HRV/DVS or similar ventilation system	158	53.4	11	5.6
Upgrading hot water systems to solar hot water	148	50.0	12	6.1
Installing an extractor fan in the bathroom	148	50.0	4	2.0
Venting the drier to the outside	143	48.3	0	0.0
Installing efficient wood burner	143	48.3	6	3.1
Installing a low flow shower head	139	47.0	0	0.0
Putting heavy thermal curtains with pelmets	139	47.0	4	2.0
Installing a rangehood/extractor fan in the kitchen	133	44.9	3	1.5
Installing passive vents on the windows	121	40.9	2	1.0
Upgrading hot water systems to instant gas	121	40.9	5	2.6
Putting in a wetback hot water system	113	38.2	2	0.0

* Multiple response

6. Wanting Retrofit and Willingness to Pay

There are considerable differences between High Energy Users and Recent Movers in relation to their expressed desire for retrofits. As Table 8 shows, the High Energy Users are strongly oriented towards associating comfort and health benefits with reduced energy costs. Among the Recent Movers, however, over a quarter see comfort and health benefits as being attractive in themselves irrespective of energy cost savings. This is despite the fact that High Energy Users show a substantially higher monthly expenditure than Recent Movers. The average electricity bill for the previous month was $194 for Recent Movers but $282 for High Energy Users. The median electricity bill for Recent Movers for the previous month was $170 compared to a median for High Energy Users of $250. Just as the Recent Movers appear more amenable to retrofitting for comfort without the added incentive of energy cost savings, so too are Recent Movers less likely than High Energy Users to report that expense is a barrier to retrofit (Table 9).

Table 8: Attitudes to Retrofitting Current Houses among Recent Movers and High Energy Users

Attitude Statement	Recent Movers (n=724)	High Energy Users (n=700)
Retrofit for comfort, warmth and health if power bill savings	38.3	46.0
Retrofit for comfort, warmth and health even if no power bill savings	26.9	17.6
Will not retrofit current house	22.0	21.9
Already retrofitted	7.9	8.0
Don't know	5.0	6.6
Total	***100.0***	***100.0***

Table 9: Barriers to Undertaking Retrofit (n= 670)*

Attitude Statement	Recent Movers (n=724)	High Energy Users (n=700)
Too expensive	41.2	50.8
I don't know what my particular house needs and/or how to get the best value for money from a retrofit	27.9	2.6
I don't know how to do it myself	9.4	0.5
I can't get access to credible information	5.7	2.5
It would be inconvenient	4.9	13.5
I can't get trades people	2.5	1.1
I have other priorities	0	4.8

* Multiple response

This is not to suggest that expense and affordability are unimportant. Even among Recent Movers, expense is the most commonly cited barrier to retrofit. However, for Recent Movers, the inability to assess value for money is a strong barrier to retrofit take-up. Financial preoccupations are also evident among both High Energy Users and Recent Movers when they reflect on their willingness to pay for retrofit activities. In Table 10, Recent Movers appear less likely to be prepared to take-up retrofit recommendations than High Energy Users. This may indicate that Recent Movers have selected dwellings to a level of performance and comfort that suits them. Overall, both sets of households are characterised by the low investment that they are willing to make in retrofit. Over a quarter of High Energy Users reported that they might act on retrofit recommendations that cost less than $500. Around another quarter reported that they were either unlikely to take up recommendations or did not know how they would respond, while 18 percent of High Energy Users reported that they would take up measures costing between one to three thousand dollars. Among the Recent Movers, almost two-thirds (63.9 percent) would spend less than $5,000 on recommended measures.

Table 10: Amount Willing to Spend on Recommended Measures for Improved Energy Efficiency

Willing Investment	Recent Movers (n=724)	High Energy Users (n=700)
Less than $100	7.3	15.0
$101-$500	8.4	11.4
$501-$1,000	16.0	11.7
$1,001 to $3,000	19.9	18.1
$3,001 to $5,000	12.3	10.9
$5,001 to $8,000	4.0	3.9
$8,001 to $10,000	2.9	3.4
$10,001 to $15,000	1.7	1.0
$15,001 to $20,000	0.8	0.4
More than $20,000	1.4	2.4
I am unlikely to act on recommended measures	17.4	11.7
Unsure	7.9	10.0
Total	***100***	***100***

7. Getting a Sustainable Stock through Householder Take-Up

It is clear that both Recent Movers and High Energy Users are resistant to investment in retrofitting. High Energy Users show little interest or ability to select dwellings that are likely to be resource efficient. Recent Movers are more likely to seek dwellings that are warm and comfortable, but even their newly acquired dwellings still have very basic sustainability features missing. This data suggests that achieving high standards of sustainability in future housing stock is critically dependent on ensuring that any new housing stock is built to optimise energy, thermal and other resource performance. Rather than being satisfied with minimal standards, the difficulties in getting reinvestment in retrofit suggest that sustainable new housing is a fundamental pathway for the future.

Notwithstanding, the fact is that existing housing stock in New Zealand does not perform well. If that is to be remedied we need to give up on our desire to transform serial renovators into sensible retrofitters. Retrofitting has no resonance. Certainly some householders want to reduce exposure to energy costs and others want improved comfort. But the reality is that while these households are prepared to pay for renovation, they do not do retrofit despite many of their dwellings having basic energy deficiencies easily retrofitted at low cost. Basic deficiencies include draughty doors and windows; poor insulation of hot water cylinders and pipes; partial roof and underfloor insulation, and inefficient heating and lighting. Indeed, it appears that where householders do undertake work that might be considered ‘retrofit’ they undertake to put in complex systems rather than address basic issues of thermal performance.

The data shows that willingness to pay for energy performance improvement is complex among these high energy user dwellings. Less than a third of high energy users reported that they would pay more than $5,000 for measures that would improve the energy efficiency of their homes. However, the median expenditure on renovations in the previous year was $9,500. Nevertheless, High Energy Users and Recent Movers both reported making renovations and appliance investments directed specifically to address mould, cold and damp problems. This suggests that the pathway to improved energy, and probably other resource efficiency lies in: connecting retrofitting to the renovation decisions and investments that high user households make in relation to their dwellings; developing a range of low cost retrofit packages; aligning renovation solutions that improve the thermal envelope to addressing concerns about cold, dampness and mould; and providing advice on the relative impacts and appropriate sequencing of retrofit products and packages.

Summary

This paper presents the results of a study of costs and benefits of sustainability initiatives currently being implemented in the Lochiel Park green village development project in South Australia (SA). An alternative assessment methodology to that offered by a conventional cost-benefit analysis was developed that considers costs and benefits with reference to a framework of sustainability indicators, both quantitative and qualitative, with a particular focus on the operational phase of urban development. Principles reflected in the approach include considering costs and benefits across the life-cycle of sustainability initiatives, taking into account multiple stakeholder perspectives on costs and accommodating both monetised and non-monetised indicators of cost and benefit. An important finding of the study is that analysis of costs and benefits informed by these principles offers a valuable approach by which to consider investment in sustainable building. Applying the framework to Lochiel Park, the costs and benefits of various water and energy sustainability initiatives were assessed and compared, with results indicating that Lochiel Park initiatives are making an important contribution to sustainable urban development. A number of lessons can be derived from the study to inform future investment in green development.

1. Introduction

The South Australian Land Management Corporation (LMC) is responsible for delivering Lochiel Park, an ambitious green village development located in Campbelltown near the Adelaide CBD. In 2007, LMC commissioned the Institute for Sustainable Futures (ISF) at the University of Technology, Sydney to undertake a study to assess the likely costs and benefits of sustainability initiatives being implemented at Lochiel Park.

An approach to identifying and communicating costs and benefits of sustainability initiatives was developed. The approach drew on the principles and tools of cost-benefit analysis, tailored to meet study objectives in terms of assessing both environmental and social values of Lochiel Park and adapted to make best use of available data. Principles reflected in the approach include: consideration of costs and benefits over the life-cycle of sustainability initiatives (in this case explicitly focusing on the operational phase due to scope and data limitations); assessment of multiple cost perspectives including those of Lochiel Park residents and wider society; and consideration of both monetised and non-monetised costs and benefits. Sustainability initiatives were assessed with reference to a set of indicators developed by ISF in collaboration with LMC and other stakeholders involved in Lochiel Park design and construction. The indicators approach was complemented by a survey of government and private agencies with an interest in Lochiel Park to gauge perspectives on the costs and benefits to each organisation of being involved in the development of a landmark green village.

This paper outlines the approach and results of the ISF study and situates the study in the context of wider questions about valuing sustainability in the urban development sector. Challenges associated with undertaking analysis of costs and benefits in the green building sector are discussed and the approach to valuing sustainable building taken by ISF/LMC is described. Results of the analysis are presented, including water and energy resource savings, costs associated with selected initiatives and implications for future urban green development.

2. Lochiel Park Green Village

In March 2004, the South Australian Premier Mike Rann announced the development of a 'nation leading' green village at Lochiel Park, a site 8 kilometres north east of the Adelaide CBD. The site comprises fifteen hectares of land and is located adjacent to the River Torrens Linear Park.

Lochiel Park is being developed during a period of rapid change, in both the residential development sector generally and in community perceptions about the urgent need for action on critical sustainability issues such as water and climate change. The South Australian Government has invested significantly in Lochiel Park with the aim of ensuring that dwellings are affordable and price-competitive, while at the same time demonstrating sustainability potential of green building, particularly in the areas of water and energy conservation. Recognising that cutting edge technology in the early stages of development can be expensive relative to existing technology, and that there is significant demonstration value in building sustainability into Lochiel Park, the South Australian Government has provided a substantial subsidy that is to be passed on to householders to offset the costs of sustainability initiatives.

Initiatives for achieving water and energy savings at Lochiel Park are outlined in a comprehensive Urban Design Guideline document that requires, among other things, achievement of a minimum 7.5 star design using the AccuRate House Energy Rating tool (AccuRate is the second generation version of NatHERS), photovoltaic panels, electricity demand-limiting devices and a triple pipe system for delivering potable, rain and recycled water to Lochiel Park households. LMC has set an overall energy saving target of 66% and a potable water saving target of almost 80% compared with current Adelaide housing stock.

To achieve the ambitious water saving targets, LMC is implementing a broad suite of initiatives including reducing household water demand, installing raintanks to supply hot water and reusing stormwater to supply non-potable water for a number of household end uses. The overall approach to water management in Lochiel Park is to use fit for purpose water, supplying water of a sufficient quality for different end uses.

The 66% energy saving target will be achieved through increased thermal performance, energy efficient appliances and photovoltaic (PV) systems (Blaess et al. 2006). Dwelling designs submitted by LMC building contractors are required to meet a set of specifications that are described in the UDG and quantified through star ratings and targets embedded in a sustainability rating tool designed specifically for the Lochiel Park development. The Lochiel Park energy initiatives intend to push boundaries well beyond the minimum standards required in regulation. For example, the mandated 7.5 star AccuRate rating for dwellings, is significantly higher than the current South Australian 5 star rating requirement.

Based on the outcomes of an earlier scoping study undertaken by ISF and discussions with LMC, it was agreed that the analysis of costs and benefits would focus on the operational phase of a prioritised list of water and energy initiatives. Ideally, an assessment of costs and benefits would consider the full life cycle of sustainability initiatives from pre-production through to disposal. In this instance, the operational phase was selected for analysis due to scope and data limitations. It should be noted that impacts associated with manufacturing and disposal, for example embodied energy, were therefore excluded from the analysis.

Initiatives selected were those that would best demonstrate the value of investment in sustainability at Lochiel Park, and for which sufficient data was likely to be available to provide a realistic assessment of cost and benefits. The initiatives included in the study were:

- Household water demand management including the installation of efficient fixtures and appliances
- Raintanks to be installed for each Lochiel Park house and plumbed to supply hot water
- Stormwater reuse system supplying non-potable water for irrigation, toilet flushing and clothes washing
- Whole of house energy demand management measures including dwelling design and appliance efficiency
- 7.5 star AccuRate rating dwelling design compared to 5 star dwelling design (incorporating a common air conditioning appliance efficiency in both the base case and Lochiel Park)
- 7.5 star AccuRate rating dwelling design plus 6 star efficiency rating air conditioning appliances compared to 5 star dwelling design plus 5 star efficiency rating air conditioning
- Residential photovoltaic systems

3. Cost Benefit Analysis and Sustainable Urban Development

Cost-benefit analysis (CBA) is an analytical tool widely used to assist decision-makers to prioritise investment of public resources between different projects, programmes, policies or activities. It is based on the theoretical premise that if benefits are defined as impacts that increase human wellbeing and costs are those impacts that reduce wellbeing, then aggregating costs and benefits to all individuals will determine whether there is an overall gain or loss in wellbeing to society. This "social net benefit" test, used by governments to determine whether an option qualifies for investment of public money, is also predicated on the idea that even if some individuals may be worse off as a result of a project or policy, in theory the winners' gains could be redistributed to the losers in a way which benefits all individuals – a principle not without its critics (see e.g. Arrow, 1951; Gowdy, 2004).

The Lochiel Park green village residential development represents a new and exciting avenue for governments to invest in promoting sustainable outcomes. However, the application of cost-benefit analysis (CBA) in the area of public investment in privately-owned and constructed residential building developments is less established than other areas of public investment in services or sustainability outcomes. Particular concerns about the application of the "social net benefit" test implicit in CBA for initiatives such as Lochiel Park reflect the limitations of CBA more generally (Pearce et. al. 2006):

- A dollar does not have the same value to all individuals.
- The distribution of impacts is no less relevant than the aggregate net impact.
- CBA results can be biased by omission of key costs or benefits e.g. environmental and other externalities.
- There are challenges associated with the measurement of costs and benefits, mechanisms for taking into account uncertainty and methods for reflecting individual preferences and values.

4. A Stakeholder Approach to Valuing Lochiel Park

In light of the limitations inherent in applying traditional CBA to sustainable urban development, ISF and LMC developed an alternative approach to measuring the costs and benefits of Lochiel Park sustainability initiatives. The approach was informed by the principles and tools of cost-benefit analysis, adapted to make best use of available data and to enable meaningful communication of the value of the water and energy saving efforts.

One of the principles informing the ISF/LMC approach was the importance of considering the multiple cost perspectives inherent in a development such as Lochiel Park, where private and public agencies as well as residents and wider society have a stake in the investment and its returns.

An initial step in developing an approach to valuing sustainability at Lochiel Park was therefore to undertake a stakeholder analysis, identifying the various cost/benefit perspectives relevant to investment in sustainability. There are two ways in which Lochiel Park stakeholders are affected by housing development – firstly, through market exchanges (goods and services, in exchange for money) and, secondly, non-market impacts (externalities that affect stakeholders, but are not monetised or traded in markets). The stakeholder analysis, shows market exchanges and changes to the traditional distribution of money, goods, services and externalities between the various actors and organisations involved in urban development (Figure 1).

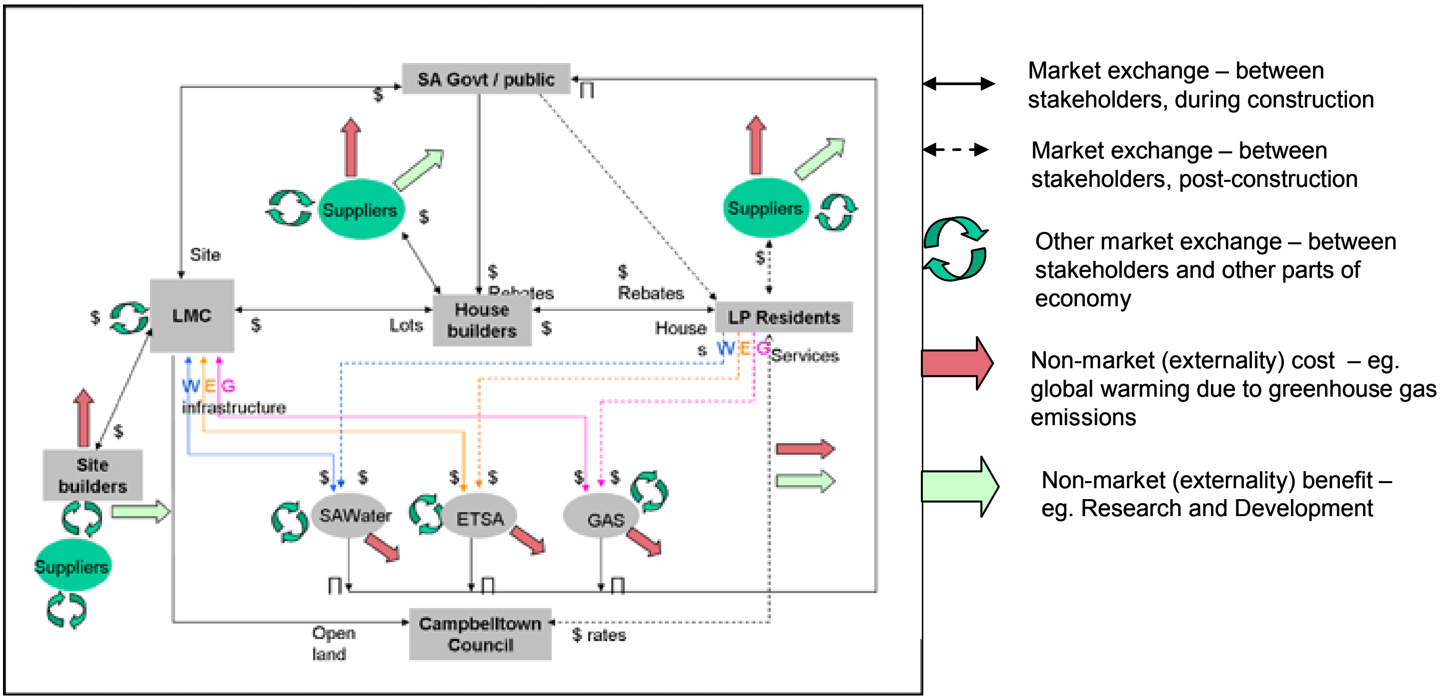

Figure 1 Stakeholder mapping of the distribution of costs and benefits related to Lochiel Park

5. Indicators of Lochiel Park Value

Drawing on the stakeholder mapping exercise, and in discussions with LMC and other organisations involved in the design and/or construction of Lochiel Park, categories for assessment of the benefits of Lochiel Park sustainability initiatives were identified. Categories of indicators selected were those considered to best reflect the range of impacts of sustainability initiatives across the operational life-cycle phase. They were also selected for their capacity to enable consideration of the spectrum of values associated with sustainability initiatives - both monetised and non-monetised. The categories of indicators are:

Resources saved - delivery of services with fewer resources is one of the most effective ways to improve sustainability and a reduction in resource (water and energy) consumption therefore represents a benefit for Lochiel Park residents and for the wider community.

Reduction in household bills - reduced resource consumption results in reduced household spending on water and energy bills and delivers direct financial benefits for Lochiel Park residents.

Greenhouse gas emission reductions - anthropogenic climate change, attributed to increased concentrations of greenhouse gases in the earth's atmosphere arising from human activities, has been identified as one of the greatest challenges faced by humankind. Scientific consensus, as demonstrated through the Intergovernmental Panel on Climate Change, is that there is an urgent need to dramatically reduce greenhouse gas emissions. There is therefore a societal (and global) benefit from initiatives that reduce consumption of fossil fuel-based energy, and thereby greenhouse emissions, in a residential development.

Value for money - an important indicator for assessing the relative costs and benefits associated with sustainability initiatives is value for money or the return on investment in Lochiel Park sustainability initiatives. Value for money is significant for residents (both Lochiel Park and elsewhere) when determining how to invest in sustainable living and also for guiding decision making about public policies, programs and investments for sustainability.

Ecosystem and community services - in addition to quantifiable benefits relating to resource and bill savings, Lochiel Park sustainability initiatives will contribute to the improvement of ecosystem services such as stormwater filtration and increased/improved habitat for birds and other wildlife and also the provision of community amenities such as open public space.

Cultural change towards sustainable living - there are indirect benefits associated with green development in terms of its contribution to a wider societal shift towards sustainability. The cultural and practical considerations associated with sustainable housing and sustainable living are widely promoted through high profile green development initiatives.

These six indicator categories convey the spectrum of ways in which Lochiel Park sustainability initiatives could add value from the perspective of different stakeholders. These were considered with reference to costs, using actual cost data provided by LMC. Where actual cost data was unavailable, best estimates were used based on information from industry sources about costs associated with various fixtures, appliances and design features.

Values relating to resources saved, bill savings, GHG reductions and value for money were assessed with reference to a set of quantitative indicators, as outlined in Table 1. Values associated with ecosystem and community services and cultural change towards sustainable living were assessed qualitatively through a stakeholder survey.

Table 1 Quantitative indicators for measuring the value of sustainability initiatives at Lochiel Park

Resources saved	Resource savings in kL or kWh for an individual Lochiel Park household and for the whole of Lochiel Park (106 households plus water used for park irrigation).
Reduction in household bills	Bill savings as a result of energy or water saved over a 10 year period from the perspective of an individual Lochiel Park household.
Greenhouse gas emission reductions	Avoided greenhouse gas emissions due to Lochiel Park energy initiatives calculated by applying a greenhouse gas conversion factor (in CO_2 equivalents) to the energy savings and an "avoided social damage cost" value to the avoided greenhouse gas emissions.
Value for money	Net present value of each sustainability initiative reported on a per-household basis based on capital costs and discounted operating costs and bill savings associated with the selected initiatives. Cost per unit of resource saved expressed as $/kL or $/kWh saved over a 10 year period.

Modelling exercises, which estimate future energy and water savings and their value necessarily, make a number of assumptions about the future. For example, although site construction had commenced at the time of the study, not all key parameters were yet known with certainty. Modelling also includes assumptions about the choices of future residents, such as technology, and the efficiency of designs, appliances and fittings. Most significantly, all modelling explicitly or implicitly includes assumptions about the behaviour of future residents.

Finding appropriate data, and in particular baseline data against which to compare sustainability costs and benefits was a constant challenge during the study. To resolve data issues and to ensure that the final outcomes of the study were accepted by all participants, a collaborative approach was taken to developing the study parameters and establishing inputs. A two day workshop was held with LMC, Lochiel Park builders and water and energy consultants and ISF worked closely with LMC in all aspects of study design and data collection. This approach meant that LMC was engaged in the process and had a clear understanding of the outputs, outcomes and limitations of the study. The process emphasised the importance of understanding non-financial impacts that are difficult to assess, as well as the monetised costs and benefits of the assessed initiatives. In both respects, the study was different to more traditional cost-benefit or cost-effectiveness analysis.

6. Findings and lessons

The primary conclusion of the study was that LMC and the South Australian government are making an important contribution to change towards sustainable living through investment in the Lochiel Park development. Quantified costs and benefits differed for each of the initiatives considered in the analysis, and some presented a more positive picture than others, as would be expected when dealing with a rapidly evolving field in technological, social and economic terms. The qualitative analysis complemented quantitative indicators of value, suggesting that the long-term impacts of the cultural change potential of the development in the building industry and the wider South Australian community are important. This section outlines some of the findings of the analysis of water and energy saving initiatives and describes results of the stakeholder survey as a means to identify some of the less tangible benefits and costs associated with Lochiel Park.

6.1 Water initiatives

As a result of investment in innovative water infrastructure and improvements in household water use efficiency, Lochiel Park households will use on average 75% less mains potable water than an average Adelaide household. This is an impressive saving, largely due to using recycled stormwater for non-potable needs including clothes washing, toilets and irrigation. Bill savings for residents are also significant, with Lochiel Park residents saving approximately 40% on water bills over 10 years. The most notable bill savings result from household demand management initiatives including the mandating of 4 star WELS rated toilets and 3 star washing machines and showers.

Analysis of bill savings associated with water initiatives in the study was undertaken using a 10 year price path with water prices increasing in real terms by 3% per annum (as advised by SA Water). More recently, with the announcement that a desalination plant will form part of the water supply system for Adelaide, it seems likely that water prices will rise at a much faster rate – a planned price increase of 42% in one year has been reported (Faulkner, 2007). If this increase occurs, bill savings resulting from Lochiel Park water initiatives would almost certainly be higher than those reported in this study.

The cost effectiveness of Lochiel Park water initiatives differs considerably as shown in Figure 2. Household demand management is by far the best value for money, with a cost per kL of water saved of $0.15 over a 10 year period. Raintanks are relatively expensive at around $18/kL. The cost of the stormwater reuse system is about $6/kL including the significant portion of water which will be used for park irrigation and comparable to raintanks at $19/kL when irrigation water is excluded. The analysis shows that investing in household efficiency is a cheap and effective measure for improving water sustainability, while raintank installation and stormwater recycling are relatively expensive resource saving options. However, the magnitude of total water savings in Lochiel Park would not be possible from efficiency alone. To achieve the percentage reduction in household water use the stormwater reuse system is particularly important. There are also additional benefits resulting from the stormwater system in that the constructed wetlands will provide a stormwater treatment service for two sub-catchments, thereby improving the quality of water discharged into the Torrens. Similarly, it is important to acknowledge that there would be additional costs associated with water initiatives such as energy use, which were beyond the scope of consideration for this study.

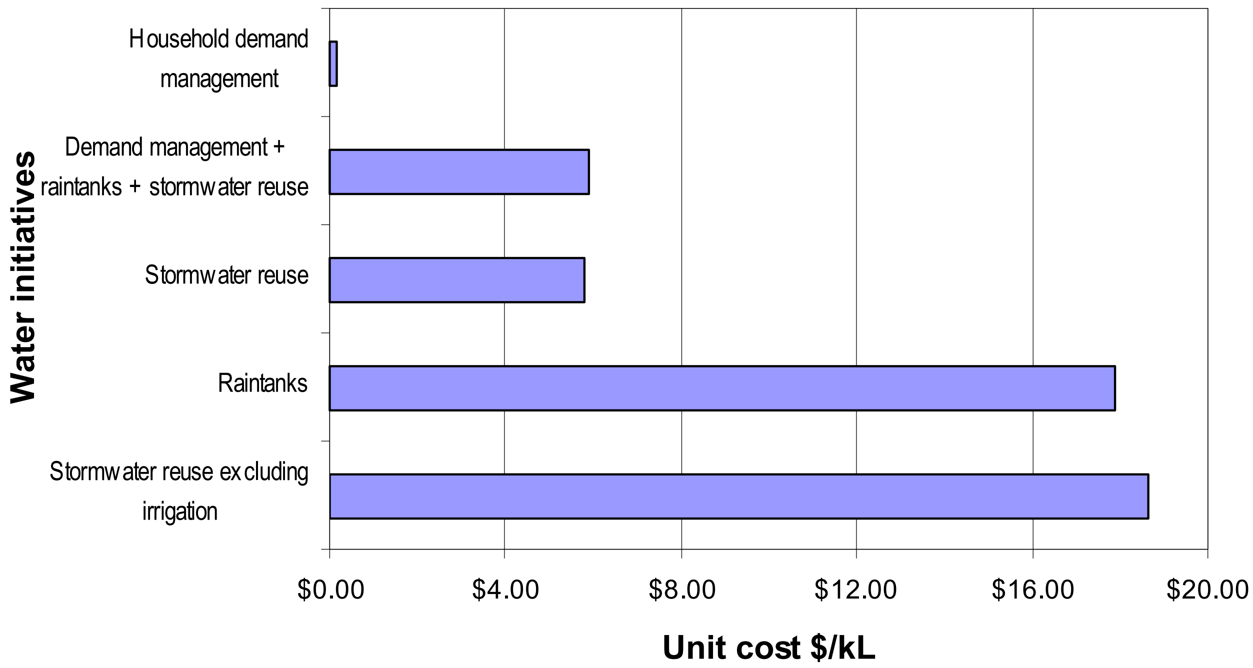

Figure 2 Relative cost effectiveness of Lochiel Park water initiatives

6.2 Energy initiatives

The study indicated that measures implemented to achieve very high energy efficiency in Lochiel Park dwellings are expensive – the marginal net cost to a resident elsewhere of moving from a 5 star to a 7.5 star rating is close to $18,000 over 10 years. There may be more cost-effective ways to achieve the same dwelling efficiency outcomes, however the ability of builders to achieve the rating cost-effectively is highly impacted by client preferences. For example, client preference for large windows leads to a requirement for expensive shading to achieve the necessary efficiency.

Figure 3 shows the results of comparison of unit cost (present value of upfront costs and operational costs, per kWh saved over 10 years and 25 years for PV systems) of PV systems, additional 2.5 star dwelling design efficiency to achieve 7.5 star, and the same design efficiency plus 6 star air conditioning.

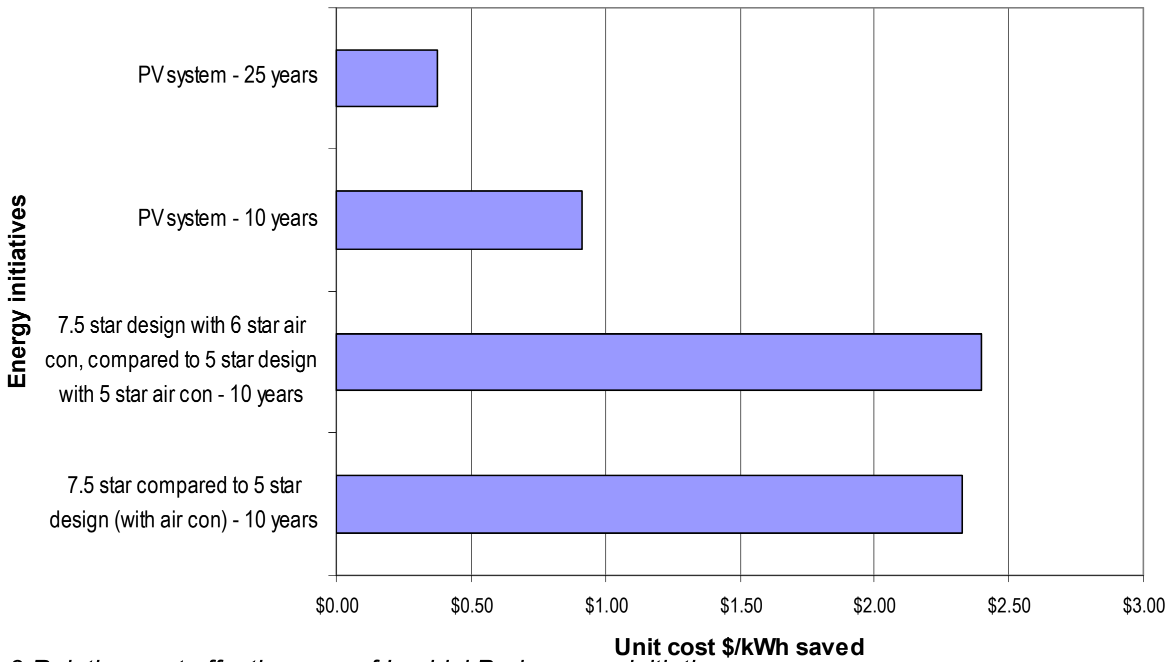

Figure 3 Relative cost effectiveness of Lochiel Park energy initiatives

Overall in this analysis, PV systems appear to be the most cost-effective option with a unit cost of $0.90 over 10 years, compared to $2.30 over 10 years for a 2.5 star increase in dwelling design efficiency from 5 to 7.5 star. PV cells are compared in this study to top-end efficiency measures i.e. the difference between 5 and 7.5 star dwelling efficiency. It is highly likely that more basic efficiency measures, for example dwelling orientation, could contribute to a 5 star dwelling with marginal upfront costs close to zero. These basic measures would be highly cost effective compared to PV systems. The substantial rebates available for PV systems also improve their cost effectiveness from a resident perspective compared to high-end dwelling design efficiency in this analysis.

The absolute marginal resource (and financial) savings of the shift from 5 to 7.5 star rating are small compared to the absolute energy supply from PV cells – 8,000 kWh per household over 10 years saved through the additional 2.5 star dwelling design efficiency, compared to 22,000 kWh of electricity supplied by PV cells over 10 years. There may therefore be an 'efficiency threshold' beyond which further investment in efficiency is less cost-effective than alternatives to achieve a given level of reduction in fossil fuel-based energy consumption. It should be noted that PV systems currently incorporate significant embodied energy and this should be factored into a full comparative life-cycle analysis of alternative energy supply/demand management options.

A further factor affecting the cost effectiveness of all options is the low retail price of electricity and gas – around 18c per kWh for electricity and 1c per MJ for gas. This means that even where resource savings (for example from PV cells) are higher, the financial benefits to residents in terms of household bill savings are not great. Analysis of the impact of a potential feed-in tariff of 44c per kWh for export of PV electricity generation to the electricity grid shows that increasing the financial return (savings) to residents for electricity export increases the private return on investment to residents. The broader implication of this finding is that increases in retail energy tariffs brought about through, for example carbon pricing, are likely to improve the cost effectiveness of the options considered in this analysis. Carbon pricing effectively begins to factor into tariffs externalities associated with greenhouse gas emissions that are currently and have previously not been taken into account.

The study quantified the likely greenhouse gas emissions reductions and associated avoided social damage costs from Lochiel Park energy initiatives. The predicted greenhouse emissions reductions associated with Lochiel Park energy initiatives, in the order of 40-50% per household from energy demand management measures, demonstrate the potential for substantial absolute reductions if the initiatives were scaled up to larger developments. Social damage costs of carbon are an indicator of externalities that are currently not factored into energy tariffs. Using a social damage cost of carbon from the Stern Review of the Economic Costs of Climate Change (Stern 2006), the study quantified likely damage costs avoided as a result of Lochiel Park energy initiatives. The avoided damage costs from all houses collectively through dwelling design and PV systems could be as much as $35,000 per annum. This demonstrates that Lochiel Park energy initiatives may result in important societal benefits that go beyond the level of residential bill savings.

6.3 Qualitative analysis – costs and benefits to stakeholders

A stakeholder workshop and survey was used to assess perceptions of costs and benefits associated with involvement in Lochiel Park design/construction with a view to capturing some of the less tangible outcomes of Lochiel Park, for example benefits related to research and development. Results indicated that a perceived value of Lochiel Park was the opportunity to test cutting-edge technologies, in order to provide valuable information that will enhance the future potential for builders at other developments or applications.

Discussions and surveys of builders' organisations revealed a perception that involvement in Lochiel Park had led to substantial benefits in terms of learning about sustainable new products, technologies and building methodologies, new market opportunities for individual companies, and the opportunity to "lead" the sector as a whole. Builders also identified that they believed that the wider community would benefit by the demonstration of cost-effective sustainability initiatives. However, as supported by the evidence from the quantitative analysis, one respondent noted that the overall demonstration effect of Lochiel Park might be dampened, because the relative incremental cost of building a 7.5 star house over a 6 star house might be disproportionately high compared to the energy savings achieved.

Although surveys of residents and the community was beyond the scope of this study, some stakeholders noted that they expected general benefits for the wider community, in terms of sustainability outcomes of future developments. The visibility of the Lochiel Park development, promotion of the sustainability benefits during the remainder of construction and beyond to broader South Australian and Australian communities has the potential to encourage wide-ranging behaviour and attitudinal change towards sustainable living.

Some sustainability initiatives excluded from this study are likely to contribute significantly to the sustainability value of Lochiel Park. For example, wetlands, a key feature of the stormwater management system, combined with an urban forest, could add significantly to the amenity value not only for residents of Lochiel Park but also potentially for the local community. There is potential for this benefit of Lochiel Park to the local community to be explored through further qualitative research, for example in exploring links between green space and health.

7. Conclusion

Lochiel Park is being developed to demonstrate significant reductions in energy and water use to become a nation leading green village. It has raised the bar. There are a number of lessons from the Lochiel Park study that can inform investment in future sustainable urban development. An important finding is that analysis of costs and benefits that accounts for multiple cost perspectives and addresses both monetised and non-monetised values offers a valuable method by which to assess investment in sustainable building. It enables comparison of various options for achieving sustainability outcomes and ensures that costs and benefits and their distribution are made explicit.

Analysis of costs and benefits of various sustainability initiatives should ideally be considered during the design phase of development to enable comparison of options and to ensure the most context-appropriate initiatives are selected. This would be best done with reference to a sustainable building framework that identifies principles and desired outcomes for green building on a case by case basis, to facilitate transparent decision making informed by consideration of the multiple relevant perspectives on costs and benefits.

The ISF/LMC approach to assessing costs and benefits of Lochiel Park represents an alternative means for determining the value of green development based on sustainability indicators, comparative assessment of initiatives and stakeholder analysis. The approach builds on conventional cost-benefit methodologies by enabling consideration of different stakeholder perspectives and incorporation of some of the less tangible benefits and costs associated with sustainable urban development.

In the case of Lochiel Park green village, the assessment of costs and benefits associated with water and energy saving initiatives indicated that LMC and the South Australian government are making an important contribution to urban sustainability. Quantified costs and benefits differ for each initiative considered in the analysis, and as expected some present a more positive picture than others, however it is clear that LMC is achieving substantial resource savings for the South Australian community by investing in water and energy saving initiatives. With expected increase in water and energy prices in the shadow of carbon emission trading scheme the benefits of the initiatives are likely to increase in value for residents and society as a whole The less tangible values of Lochiel Park – including its provision of ecosystem services and contribution to mainstreaming sustainability in the urban development sector – are difficult to capture comprehensively, but the study suggested that there are long-term benefits associated with cultural change in the building industry and the wider community that will be realised when the development is completed and the community has developed.

[1] TAKENAKA.corporation, Tokyo, Japan, sako.hiroshi@takenaka.co.jp

Keywords: Natural Ventilation, Night purge, sustainable building, Energy saving

•

Abstract

In recent 10 years in Tokyo Japan, the idea of HVAC design for office in Tokyo has drastically changed: from the previous idea of actively air-conditioning super-insulated space, to energy saving air-conditioning using natural ventilation during relatively cool seasons. Detailed planning such as site location, expected wind characteristics around the building, shape of the building and its air inlets/outlets positions, are needed for designing l ventilation for every single building.

This paper reports four office buildings introducing natural ventilation with their design method and observation results of indoor environment and energy consumption. The design methods vary wide in range: under floor air-conditioning in combination with natural ventilation, hybrid air-conditioning system using natural ventilation and air-conditioning machine simultaneously, and natural ventilation applied to super high-rise building.

From the results we have obtained, there was considerable variation of air change rate from 1 to 6 times/hour depending on difference in size of opening for ventilation or effectiveness of ventilator. In addition, it was determined that by using hybrid air conditioning system using natural ventilation and air-conditioning machine simultaneously, for air-conditioning load that were not eliminated only by natural ventilation, to effectively lengthen natural ventilation operation of air-conditioner. As for natural ventilation for super high-rise building, utilizing wind around the building will take in enough air volume by natural ventilation into the building.

1. Outdoor Condition of Tokyo and Possibility of Natural Ventilation

Considering heating in winter, and cooling in other seasons for HVAC system in an office building in Tokyo was common until late 1980. However, due to improvement of thermal insulation and increment of internal heat inside the building, cooling throughout the year became general after 1990. These transition of design condition caused building with super-insulation and fixed window to change into building with openings for ventilation, natural ventilation and night purge in early 1990.

Outside air temperature through the year in Tokyo is shown as figure 1, absolute humidity condition through the year in Tokyo is shown as figure 2. Natural ventilation is effective during seasons except between July to end of September which outside air temperature is higher than 25• •and absolute humidity is higher than dew point of 19• ÐB. Since air-conditioning in the office has changed to cooling for most of the year in recent years, natural ventilation is also effective even during winter seasons to maintain inside thermal environment sound by using outside air.

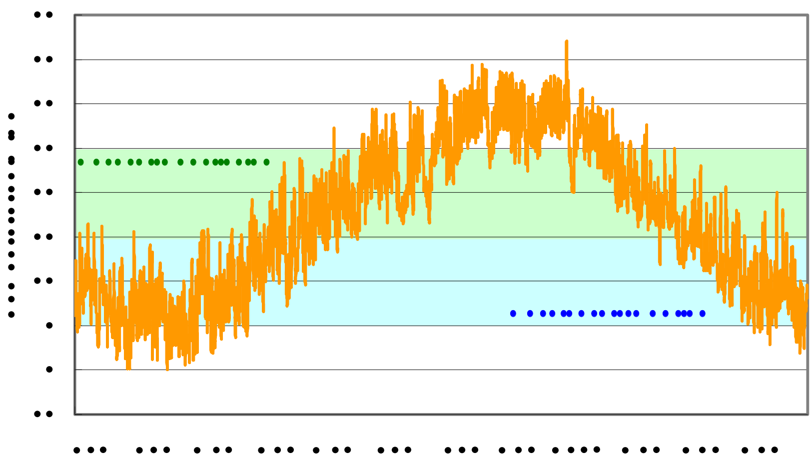

Figure 1 Outside air Temperature, Tokyo 2000.

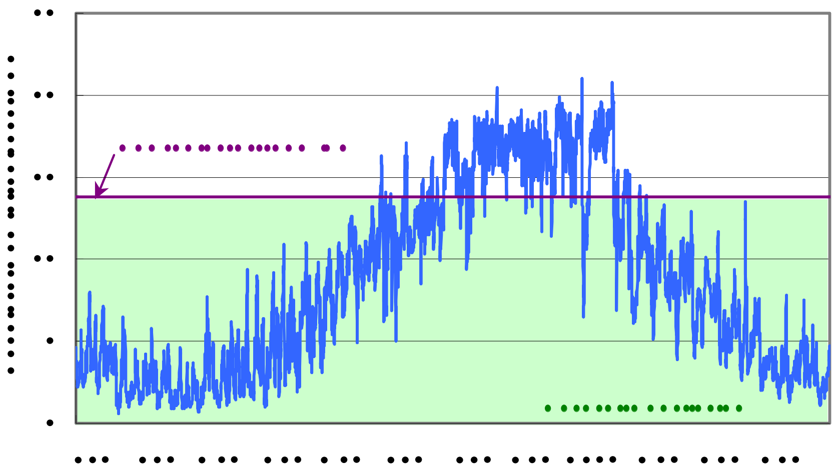

Figure 2 Outside air Absolute humidity, Tokyo 2000.

Outside air temperature-annual rate during air-conditioning hours of 8:00 to 20:00 is shown as figure 3. It shows that natural ventilation is effective during 3/4 of daily hours in a year.

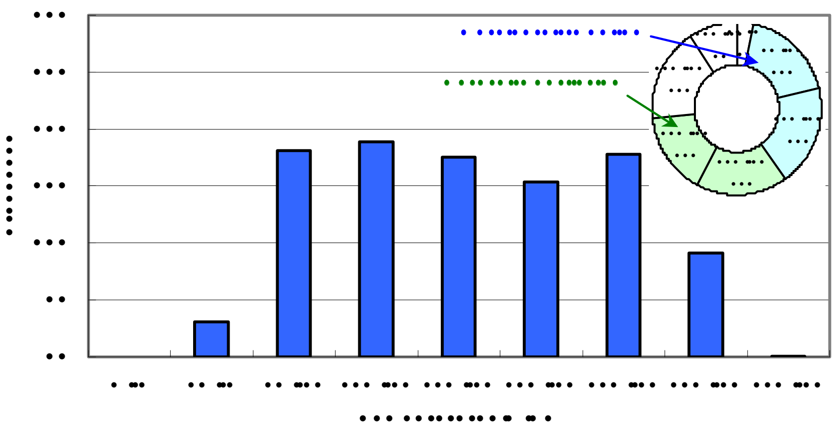

Figure 3 Outside air Temperature-Annual rate, Tokyo 2000

2. Outline of a Building Introducing Natural Ventilation

Outlines of four buildings, which introduced natural ventilation, and methods of natural ventilation are shown in table 1, control point setting is shown in table 2, and comparison of energy saving effect by natural ventilation is shown in table 3. These four office buildings are all built in central Tokyo.

Size of one floor area of building with natural ventilation varies from 476m^2 to 1080m^2. Only building D is high-rise building, with the rest be considered as medium sized building. Building A and B has natural ventilation at the intermediate story, adopting gravity ventilation using temperature difference. Building C adopts combination of gravity ventilation and prevailing wind for natural ventilation since it has floor area of 3,250m^2, which is quite large. High-rise building D is utilizing pressure difference of wind pressure to take natural ventilation horizontally. Opening ratio of natural ventilation (total areas of openings for natural supply and exhaust air per floor divided by area subject to natural ventilation) for all building is listed at last row. Building A shows 99cm^2/m^2 which is quite large while building C and D shows 55cm^2/m^2 and 27cm^2/m^2 which seem quite limited.

Table 1 Building summary and method of Natural ventilation

		A	B	C	D
[illegible]		[illegible]	[illegible]	[illegible]	[illegible]
Total Area	m2	16,567	5,357	29,747	35,015
Total Floor	F	10	9	7	21
[illegible]	F	3-7	2-5	2-7	5-20
Building height	m	39.6	39.8	31.0	112.8
[illegible]	m2/FL	640	476	3,250	1,080
[illegible]	m3/FL	1,728	1,499	9,750	3,240
[illegible]	cm2/FL	99.4	60.5	54.7	26.6

The feature of building A lies on combination of under floor air-conditioning and natural ventilation/night purge. Just like figure 4 shows, outside air is taken inside from external wall into OA floor directly, then delivered to office by fan. The outside air is heated inside and then extracted through vertical shaft by chimney effect.

Building B has concert hall just above the office introducing natural ventilation. Therefore by making vertical shaft taller to create neutral plane at higher location enhancing effectiveness of gravity ventilation.

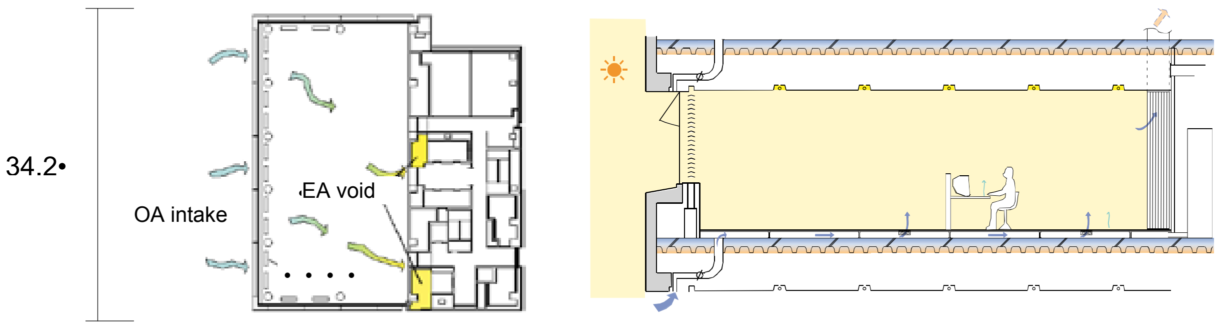

Figure 3 Plan and section of A building

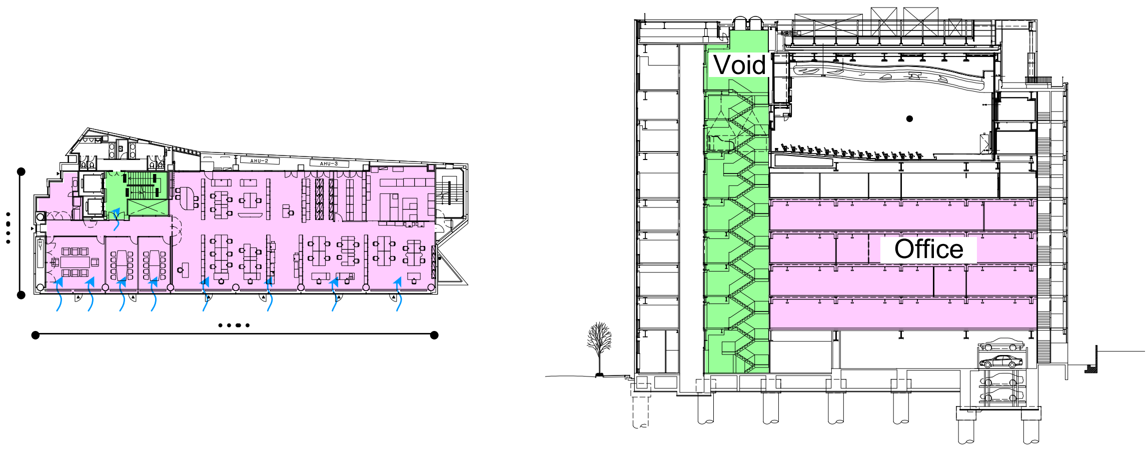

Figure 4 Plan and section of B building

Since building C has large floor area, in addition to natural ventilation introduced at perimeter of the building, allocating a light court at the center of the building for airflow to make vertical route for natural ventilation. Utilizing pressure difference caused by prevailing wind from the sea above natural exhaust also enhances effectiveness of natural ventilation.

Building D is a high-rise building located just by Tokyo bay, prevailing wind is purposely taken inside through the building on horizontal plane. As a countermeasure for pressure caused by the wind, outside air intake ducts are bent several times to absorb the pressure.

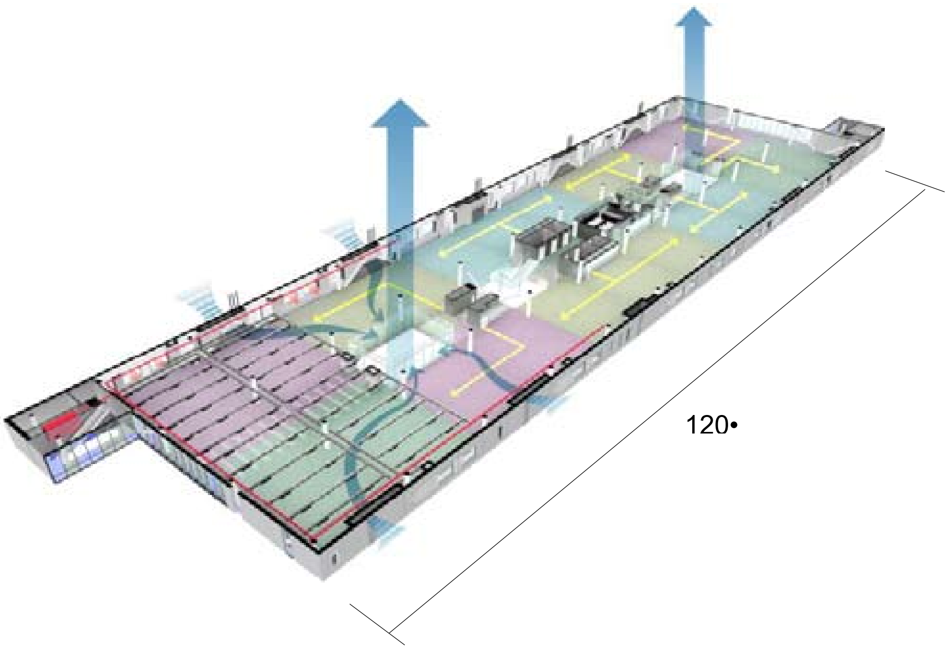

Figure 5 Plan of C building

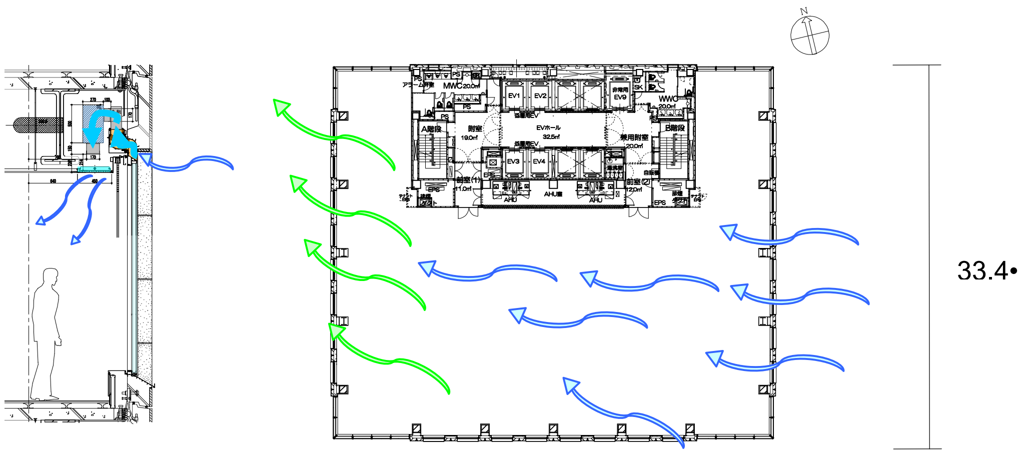

Figure 6 Plan and detail section of D building

3. Controlling Condition and Effectiveness of Natural Ventilation

Conditions for automatic control for natural ventilation is shown as table 2. Building fulfilled conditions determined at table 2 automatically opens natural ventilation damper to start natural ventilation. Since building A and B utilize gravity ventilation, they starts natural ventilation when outside air temperature is 2• • lower than inside air temperature, and when outside air temperature is lower than 15• •they switches from natural ventilation to outside Air-conditioning. Building C and D conducts ventilation by wind pressure, so they starts natural ventilation when outside air temperature is lower than inside air temperature, and like building A and B they switches from natural ventilation to outside Air-conditioning when outside air temperature is under 15• :

Table 2 conditions for Natural ventilation

		A	B	C	D
Outside air temperature for NV	• DB	15<To<Tr-3.5	15<To<23	15<To<Tr	15<To<Tr
Outside air temperature for Night Purge (NP)	• DB	15<To<Tr-2.0	15<To<23	15<To<Tr	15<To<Tr
Outside air temperature for Outside air cooling	• DB	5<To	5<To	11<To<15	10<To
Other Condition		Outside air Velocity<10m/s, No rain			Outside air Velocity <15m/s, No rain

Observation results of natural ventilation are shown as table 3. Air change rate is about 3• 4 times/h when outside air temperature is 18• 19• •for building A and B. Room temperature during natural ventilation is about the same as settings of air-conditioning system of comfortable temperature of 24• 25• • Annual thermal load handled by natural ventilation and night purge for Building A and B are about 60MJ/Am^2• year and 43MJ/Am^2• year. Air change rate of building C is about 1time/h, which is induced from its small opening area for natural ventilation compared to other buildings. Also since it is low-rise building, effectiveness of gravity ventilation is no much to building A and B. However, by operating air-conditioner as supplemental role during natural ventilation (hybrid air-conditioning), thermal environment is maintained at comfortable state. Building D shows good performance of natural ventilation utilizing wind pressure archiving air change rate of about 1• 6 times/h.

Though there are some difference in amount of internal heat generation and ventilation volume, the observed result showed that room temperature during natural ventilation is about the same as air-conditioned temperature of 22• 27.5• CD. Building A had highest value for cooling load handled by yearly natural ventilation of 60MJ/m2• year with large opening area for ventilation with more air change rate. Following building A is building B and C with also fairly large opening area for ventilation. Building A also has thermal storage effect to structure by night purge with a value of 260KJ/m2• day which contributes enhancing effectiveness of natural ventilation and night purge greatly.

Table 3 Measurement result of Natural ventilation

		A	B	C	D

4. Conclusion

- • By utilizing prevailing wind or in case of gravity ventilation by elevating neutral plane higher, natural ventilation has potential of having air change rate of 1times/h• 6times/h.
- • Gravity ventilation affects natural ventilation effectiveness with its size of opening for ventilation and neutral plane.
- • Air change rate of wind ventilation differs drastically depending on outside wind condition.
- • To further improve effectiveness of natural ventilation, outside air with 15• DB or lower be taken inside directly into the room, not through air-conditioner, without disturbing temperature distribution.

Summary

This paper outlines an experimental project for drastically reducing the environmental impact of home energy consumption whilst assuring a high level of living comfort. The project has been applied to an existing dwelling unit within NEXT21, which is the experimental apartment housing in Osaka, Japan owned and managed by the Osaka Gas Company.

The main approaches for achieving the objective of the project have been,

1) To remodel an existing dwelling unit,

2) To improve thermal insulation and shading,

3) To introduce efficient equipment for energy conversion and consumption,

4) To make possible the use of renewable energies and

5) To change the behaviour of the residents related to energy consumption.

The technical items include photovoltaic power generation, condensing gas boiler, hot water floor heating, home-size solid oxide fuel cell (SOFC) and semi-automatic shading / ventilation control system.

The simulation analysis gives figures, evaluated in terms of primary energy, for the expected effect. Compared to the reference model, the heating and cooling load will be lowered by 45% through architectural improvement. New efficient equipment will produce a further reduction of 15% and solar energy 13% of the original consumption. In total, the energy load may be lowered by 78%, including the efforts of residents to change part of their lifestyle.

1. Introduction

It is claimed that to prevent global warming greenhouse gases need to be reduced in the long term by 75 to 82%[1]. These figures might seem unrealistic in relationship to the pessimistic opinion that Japan could not meet the Kyoto Protocol promise to reduce greenhouse gases (GHG) by 6% in the year 2010 (average between 2008 and 2012, compared to 1990). However, the above-mentioned targets are essential to keep the average rise of atmosphere temperature to within 3.5/2.5 degrees Celsius respectively. Therefore, it is acceptable to consider them as the target for the advanced low- energy dwelling of today.

The majority of GHG is carbon dioxide (CO_2) caused mainly by the consumption of conventional energies, not only fossil fuels but electricity. To find effective solutions in the field of urban housing, an experimental project was launched in June 2005, the target for which has been to reduce the energy-based environmental impact to a quarter of the original amount by remodelling an existing apartment dwelling and comparing it with a basic apartment. This could be realised through reducing energy consumption and wherever possible using sources of locally available renewable energy.

The project has taken place within Osaka Gas Company's experimental housing, "NEXT21", which was built in 1993 for the purpose of experimenting with gas equipment within a highly durable "open building" structure and flexible "infill".

Dwelling no.301 was selected for the project. This dwelling unit was originally designed by architect Naomi Tachibana as a "Garden House", which aimed at living in harmony with the natural environment. It enjoyed plenty of indoor / outdoor greenery, day-lighting and natural ventilation.

Many alternatives were examined from the available techniques. This paper describes the methods to remodel the dwelling to consume less energy as follows: • •

Figure.01 NEXT21 in Osaka

[1] Ministry of Environment Brochure based on IPCC 3rd Report

1) Improving the building envelope to reduce the heating and cooling load.

2) Introducing highly efficient equipment and new systems for energy conversion,

3) Incorporating renewable energy, namely solar energy and

4) Reviewing and changing the occupants' lifestyle in terms of energy consumption.

The estimated effect of these methods was examined through simulation analysis.

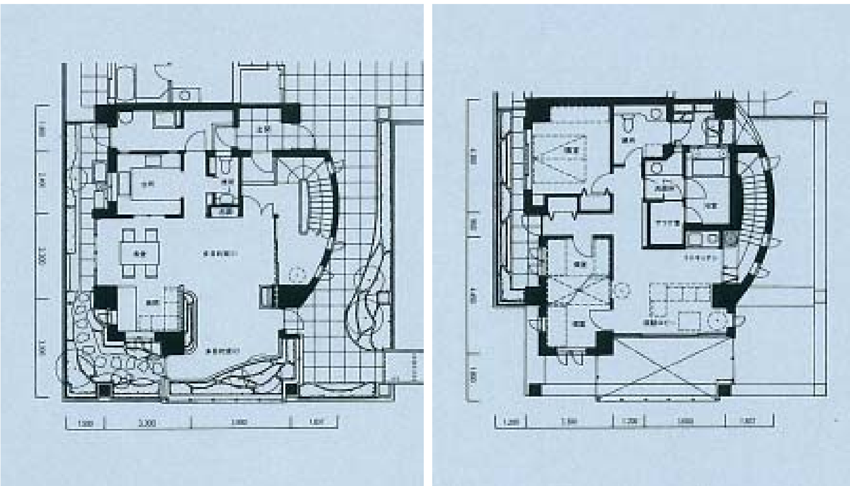
The target of reducing energy to a quarter of the original might appear over-ambitious but the intention of the project was to show people and the company that it was realistic for a household to achieve such an environmental impact. By early 2007 the remodelling work was complete and Unit 301 was given the name "Factor4 Dwelling", after the book "Factor Four, Doubling Wealth - Halving Resource Use" by Ernst von Weizsacker and others.

2. Improvement of Building Envelope

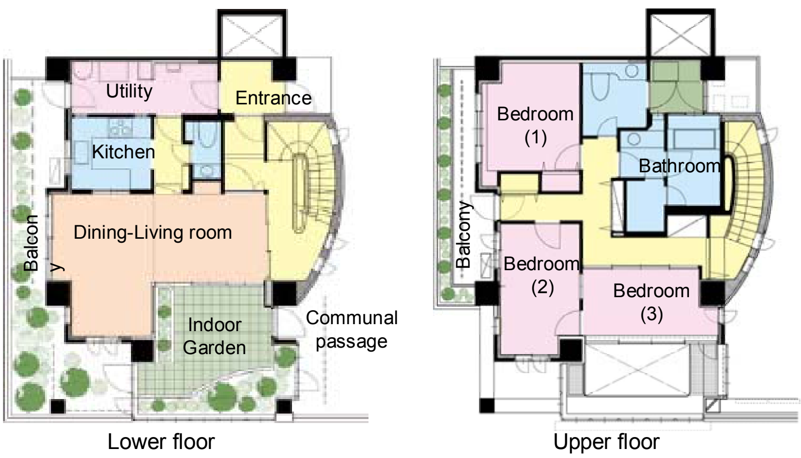
Unit No.301 is a maisonette apartment with external walls and openings on 3 sides, facing east, south and west. Its total floor area is approximately 150 sqm. The improvement of the building envelope has reduced the heating and cooling load. The unit had a relatively high ratio of external wall length to floor area. The total areas of windows were also considerable (Fig.-1). Therefore the heating and cooling load prior to remodelling was similar to that of an average detached house.

The first improvement to be made to the walls and floors was to add thermal insulation in the voids within the walls and the space under the lowest level flooring. In addition the total length of the external wall was reduced by enclosing the set-back porch and a balcony with additional doors / panels, which made these spaces internal. The second improvement was to add internal window sashes to change the glazing from double to triple. Shutters in the form of insulating panels were also provided to put over some small windows during winter. The third method was to reduce the heating load by maximising solar gain from the windows.

The original southern façade was a large area of glass, which created an interior space that had the feel of a conservatory but was effectively part of the living space. In addition the heat loss was greater than the solar gain from the glass so measures were taken to divide the space into separate living room and conservatory. This would prevent heat loss in the winter, and good shading would prevent heat penetration in summer. The actual remodelling method is discussed later. In the intermediate seasons, there would be little difficulty in controlling the indoor climate at the optimal level by closing and opening the windows and shading. The conservatory with internal planting would also be useful for cooling the atmosphere.



Figures.02, 03 Floor plans before renovation



Figures.04, 05 Floor plans after renovation

2.1 Thermal Insulation and Shading

The main objects and methods of insulation to the envelope were:

2.1.1 External walls: There was void between the external panels, backed up with foam polyurethane, and internal panels of gypsum board. It was totally filled with cellulose fibre made from recycled paper. The material was inserted though holes in the gypsum boards, which were finally covered with thin plywood and finished. Fortunately the void width was varied between 140 and 150mm, which enabled a good quantity of cellulose fibre to be inserted. These methods could reduce the heat loss, in terms of U-value, of a typical external wall from 0.62W/m2K to 0.20W/m2K.

2.1.2 Lower level floor: The space under the lower floor of the dwelling is a small auditorium, air-conditioned only occasionally when used. The floor was not insulated except where it was needed to prevent heat-bridging from outside. The former residents had complained about the cold floor. The void between floor slab and the flooring board was therefore filled with 190mm thick cellulose fibre, which was beneficial in terms of thermal insulation and energy saving and also for providing greater comfort.

2.1.3 Windows and doors (except conservatory): The following four methods were applied.

a) Internal sashes, wooden with single glazing, were added to the main windows. The glazing was converted from double to triple in total.

b) The small windows were fitted with insulated shutters to close them off during the winter seasons.

c) The windows in the stair well were fitted with interior Venetian blinds.

d) External Venetian blinds were installed on the western balcony.

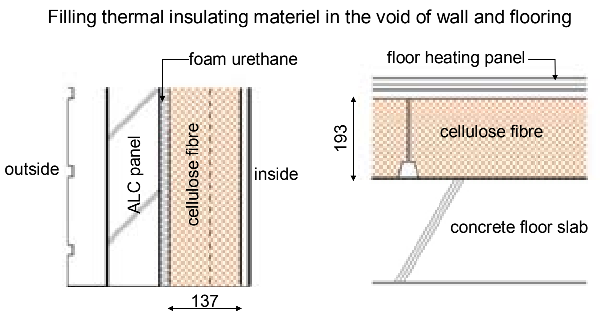


Figure.06 (left) Wall cross-section

Figure.07 (right) Under the floor (lower level) cross-section

2.2 Conservatory (Indoor Garden)

The southern part of the original living room was converted into the conservatory by dividing the space by new sliding doors. The conservatory will serve as the heat collecting space and buffer zone between the living area and the outside. This measure made it possible for the heating and cooling load to be drastically reduced because the conservatory is a semi-external space not part of the air-conditioned zone. The glazing planes separating exterior and interior space were designed so that heat gain, shading, ventilation and closing could be smoothly operated according to the seasons and other situations.

For shading, most of the glazing was covered with external roll-screens, which could be automatically closed and opened according to the strength of sunlight. The special swinging windows for ventilation "Swindows" were introduced for automatically controlling the ventilation. Four were fitted in the top and the bottom parts of the plane (8 sets in total). On sunny winter days, the screens are kept open for taking advantage of solar heat gain. The ceiling fan helps introduce warm air from the conservatory into the living space. The interior sliding doors are closed during the night. During the summer days, on the other hand, the shading screen and sliding doors are both closed and the "Swindows" open or closed dependent upon the indoor / outdoor temperature.

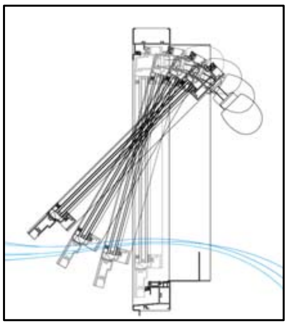

Figure.08 "Swindow" cross-section (product of Sankyo Tateyama Aluminium, Inc.)

The conservatory not only retained the original concept for the apartment to create an indoor green but also enhanced it by creating a secure intermediate space between outside and inside. The depth of conservatory could have been as little as 2m but to make the space a semi-external living area, it has become as large as the remaining living room.

Figure.09 Conservatory

Figure.10 Indoor Garden

The planting zones in the conservatory were filled with light soil and filled with greenery which was anticipated would lower the temperature in summer through water evaporation from soil and plants. The floor finish has been converted from wood to soil-ceramic tile suitable for semi-outdoor living. Eventually the conservatory area was named “Indoor Garden”.

The upper part of the high conservatory was difficult to clean and maintain. A new catwalk has been provided to solve this problem. A ceiling fan has also been installed to carry the warmed air into the lower level living space.

The shading screen can be controlled both by automatic and manual modes. It closes when the solar luminance or wind velocity exceeds a designated level. The “Swindows” can also be operated automatically and manually dependent upon controlling factors such as the combination of indoor and outdoor temperatures and high wind speeds.

2.3 Reducing external wall length

The entrance porch and the upper level service balcony had the shape of a (set back) bay. These were made into internal spaces by adding new doors, which reduced the total length of external wall and created smaller but thermally intermediate spaces. This lowered the heat load whilst the internal floor area increased. As this is effective only in winter, the doors can be left open in other seasons.

Comprising all the measures mentioned above, the Q-value (total heat loss per unit floor area) was to be improved to 2.52W/m2K after remodelling compared to 9.12W/m2K beforehand.

2.4 Greening

As unit no.301 had the name “Garden House”, greening the dwelling was the main design theme. The concept was characterised by interior plants. Besides conserving planting zones in the “Indoor Garden”, the western balconies are intended to have creeping plants for shading in summer using the existing metal trellis. Good maintenance and watering depend on resident participation.

2.5 Additional change in floor plan

2.5.1 Adding a bedroom

The dwelling had only 2 bedrooms although the floor area is more than150m2. The family size had been four throughout the early phases of the project and a regular complaint was that they needed an additional bedroom. This problem has been resolved by converting the upper level lounge into another bedroom. In addition, the kitchenette was abolished and converted into a closet for the newly created bedroom.

2.5.2 Change in staircase

The interior staircase is not within the heating / cooling zone. For preventing the heat transfer from the lower to upper level, however, the gaps between steps, which were intended to allow natural ventilation, have been closed. In this way, the energy saving concept has been given priority over the original design concept.

3. Improvement of Utility and Equipment

High efficiency is one of the most important considerations for saving energy in the home. Therefore the engineers have extra responsibility for equipment that the residents cannot change. The former air-conditioning system was no longer efficient. It has therefore been totally changed from a system serving the whole NEXT21 building to one for an individual dwelling. This has been made possible by the improvement in the quality of heat-pump for individual home use in the last 10 years. In addition, the energy systems have been chosen primarily for their efficiency and not necessarily their saving on the use of city gas.

3.1 Hot water supply and Combined Heat and Power

The solar heating to be installed still required an efficient boiler to cover the amount of heat needed to meet demand. On the other hand, a combined heat and power (CHP) system was to be tested in this experimental dwelling by introducing a developing fuel cell (FC) system. With two systems coexisting in one dwelling, I was possible to run them either separately or simultaneously. The comparison of these could be an interesting theme in terms of use practice and energy efficiency. (Solar heat utilisation will be discussed in the section of renewable energy. As of March 2008, the solar system was not yet installed.)

3.1.1 Condensing Gas Boiler

A condensing gas boiler has the function of absorbing exhaust heat by condensing the vapour into water to gain the latent heat. A latest condensing boiler has been installed. Its heat efficiency is 95% for hot water supply and 85% for floor heating (LHV[2]). This adds extra heat to the amount provided by solar collectors and fuel cell system. A mixing unit has been added to control the highest temperature of incoming hot water.

For the moment, only the hot water tank for fuel cell (FC) has been installed. There will be 2 tanks and the choice between them will be either automatic or manually done by the residents who can watch the temperature of each tank. When the temperature is high enough, they can use hot water directly from a tank instead of taking it through the boiler.

[2] Low Heat Value

3.1.2 Solid Oxide Fuel Cell (SOFC)

Among the developing fuel cell systems, solid oxide fuel cell (SOFC) is the most promising one for apartment houses or small households. The main reasons are the compactness and its high generating efficiency up to 45% (HHV[3]), which is higher than that of ordinary thermal power generation. The rate of usable exhaust heat from SOFC is relatively low up to 30% but it can be used for hot water supply. The dwelling unit No. 301 is one of the testing fields for improvement.

Figure.11 SOFC (Kyocera / Osaka Gas) right

3.2 Space Heating

The former heating/cooling system was a central VAV[4] air-conditioning. Hot water was generated from waste heat from the central CHP system and distributed to each dwelling. The efficiency was not high enough to meet the current target. The newly installed systems therefore include the following:

3.2.1 Floor heating by gas-heated hot water

One of the complaints from the past occupants was about the coldness of the floor at the lowest residential level, below which the space was non-residential and not sufficiently insulated. The heating efficiency of floor heating is lower than that of gas fan-heater and air-conditioning by electric heat pump. As for comfort and healthiness, however, floor heating is an ideal method. The level of comfort is higher because of the radiation from the floor and the direct touch of the feet on a warm surface. The vertical temperature distribution is almost even whilst air conditioning alone could only warm up upper part of the room.

The new system was aimed at lowering energy consumption compared with the existing system. Lower water temperature through larger pipes loses less heat during travel and reduces pumping power. Because of the sub-flooring system, however, there was no choice but to introduce a ready-made floor heating system in the remodelling.

3.2.2 Air conditioning

Air conditioning system for cooling can automatically be applied for space heating. There was no intention to introduce floor heating on the upper level. When the envelope heat loss has become very low, the excess heat at the lower level could warm the upper level. Hence a medium size air conditioning unit (2.8kW) seemed to be sufficient to keep the whole floor warm enough.

3.2.3 Gas cocks for eventual use

A newly installed heating facility does not require gas cocks but there could be a possibility of fault or insufficiency of heat distribution. Gas cocks in each room have been provided just for these cases.

3.3 Space Cooling

The former cooling system was also a central VAV air-conditioning. Cold water was prepared in a heat absorption chiller set in the basement of the building, transferred to dwellings, converted into cold air and finally distributed through duct to each room. The main shortcoming was high electricity consumption for the pump and fan.

However, the efficiency of electric air-conditioning units for home use has been remarkably improved in the last 10 years. Therefore it was decided to change the system from central to individual and adopt the highest performance model in the market. The coefficient of performance COP[5] exceeds 6.

The cooling load could be reduced by a half through the combination of high insulation and effective shading. Then only one system of 2.8kW in each level was estimated sufficient for keeping the room cool in summer.

3.4 Ventilation System

The use of a ventilation system conflicts with aspects of energy saving. For example, when increasing the volume of air ventilated, not only is lost but electricity consumption rises as a result of running the fan. In the remodelled apartment a heat exchanging ventilation system was installed on each level and the air ducts of the former VAV system re-used. In respect of seasonal operation, the compulsory ventilation level stipulated in the Building Standard Law, will be applied flexibly for energy saving. That is to say the mechanical ventilation system in the living space can be cut off during the non-cooling/heating seasons where a number of windows are usually kept open.

3.5 Lighting

[3] High Heat Value
[4] Variable Air Volume: an air-conditioning method manageable under partial load
[5] Coefficient Of Performance

Each light fitting was examined to decide how to improve it. A typical method of reducing electric consumption for lighting is to replace conventional bulbs with bulb-shaped fluorescent lamps, which use only one fifth of electricity to provide equal luminance. In addition, unnecessary lighting should be removed totally or just the bulbs taken out. Where sufficient luminance is achieved, the number of fluorescent lamps can be reduced.

In this way, unnecessary or surplus lamps and fixtures have been changed. The original condition was extravagant and far from the energy-saving concept. There were 49 lighting fixtures in total in the dwelling. The total capacity, according to the design document, reached 3.0kW when all were switched on. However, the length of time the lighting is switched on is unknown so the effect of energy saving is therefore difficult to determine.

3.6 Cooking

Energy saving in cooking could be improved through considering changing ways of daily life. In particular, it has direct effect to minimise the use of electricity for heating food and keeping it warm, because only 40% of the energy consumed in thermal power station reaches home. Although each action is small, there is a considerable room for reducing energy consumption in cooking. This might include the choice of cooking apparatus, developing methods of low energy cooking and other more ingenious cooking methods.

The only change made in the remodelled apartment was to introduce a modern gas cooking table, the heat efficiency of which reaches 56%, compared to 50% of a conventional model.

3.7 Other use of electricity

To stop using “stand-by mode” on equipment is one of the essential methods to reduce domestic electricity consumption. This can be realised with a small amount of investment or conscious efforts by the occupants. In the remodelled apartment, half a dozen electric sockets (taps) with switches have been provided. A small neon lamp indicates the main switch is not cut off and induces the users to cut the electricity from the socket to eliminate stand-by electricity.

4. Solar Energy Utilisation

However hard efforts are made to save energy, it is practically impossible to reduce domestic energy consumption to a quarter of the original amount. It is therefore paramount to take advantage of renewable sources of energy as a means of drastically reducing conventional energy consumption - which is the main cause of global warming. The typical renewable energy for home use is light and heat from solar energy.

4.1 Photovoltaic System

The photovoltaic (PV) system is most promising as a clean and quiet system for renewable power generation applicable to individual houses and low-rise blocks of housing. In the case of “NEXT21”, a PV module of 7.5kW has been set symbolically on the rooftop to generate electricity for use in common areas. One third of the existing PV module (2.5kW) has been switched exclusively to unit 301 for the experiment. A new power conditioner has also been installed.

The surplus electricity, i.e., the electricity that unit 301 does not consume, is transmitted to the electrical grid within the NEXT21 building. The 2.5kW is practically a maximum capacity for five-storey apartment block because the roof area per dwelling is limited to 20m2.

Figure.12 PV module, one third of it serves for the dwelling 301

4.2 Solar Hot Water Supply

If global warming is to be avoided, it is most important to use solar heat to cover a large part of the domestic hot water supply. In Japan, hot water constitutes about one third of the domestic energy consumption. Solar heating is classified into the following categories: 1) natural circulation type, 2) forced circulation type and 3) water storage type. The collector in this instance is a flat type set almost vertically within the concrete framework. The heat is collected in liquid medium then transferred to and stored in the hot water tank through heat exchanger.

5. Pre-evaluations

The effects of the various measures are evaluated through simulation both in terms of energy saving and gaining renewable energy. The first step is to establish the basic model against which the findings of the study will be compared. Standard energy use is calculated according to the energy use categories, which is based on standard data already available and actual data from the previous occupation.

All the energy use is converted into mega-joule (Mj) on a primary energy basis. As the electricity that has reached the users is roughly 40% of the energy consumed in thermal power plants, it is multiplied by 2.5 to give it a primary energy rating. Then, the reduction of each measure in each category is evaluated one by one, which is explained below. Finally, gain from renewable sources of energy, in this case PV for electric power and solar heat for hot water, is deducted from the total amount of energy required, on the premise that PV power and solar heat utilisation has negligible impact to the environment.

5.1 Basic Energy Consumption (Reference Data)

There are several sources of calculation to provide reference data. They are:

(1) Actual energy consumption during the early phases of occupation,

(2) Model data in Osaka from The Institute of Energy Economics Japan (IEEJ), and

(3) Simulation by SMASH[6] modelling for heating and cooling load only.

The adopted method consists of two of the above:

(1) Simulation by SMASH modelling for heating / cooling load, and

(2) Simple average of the actual consumption volume, using average data for a detached home. The Osaka average data from the IEEJ has been adjusted for the project to a household of four persons.

5.2 Effect of Energy Saving

The energy saving results listed below includes effects that have been verified through simulation analysis. Instead of solar heat gain for hot water, the waste heat from the SOFC system is included.

Assuming a basic level 100 (167.2Gj), the energy load has been calculated to be lowered through each measure as follows:

(1) Through architectural improvement (resulting better heating/cooling performance), the energy consumption will be reduced to 55% (92.1Gj),

(2) Through refurbishment or replacement of built-in facilities, to 48% (80.8Gj)

(3) Through replacement of home electrical appliances, to 44% (72.9Gj)

(4) Through expected change in lifestyle of the occupants, to 39% (64.7Gj)

(5) Through utilising the waste heat gained from the SOFC, to 35% (59.3Gj)

Finally, deducing the PV generated power from the residue of energy saving mentioned above, the total consumption was estimated to be 22% (36.8Gj, reduction rate of 78%). These figures represent the consumption level of conventional energy in terms of primary energy, which is comparable to the alleviation of the environmental impact.

Thus, although some presumptions are included, the target of “reducing energy load to a quarter of the original amount” seemed realisable when every measure was taken into account.

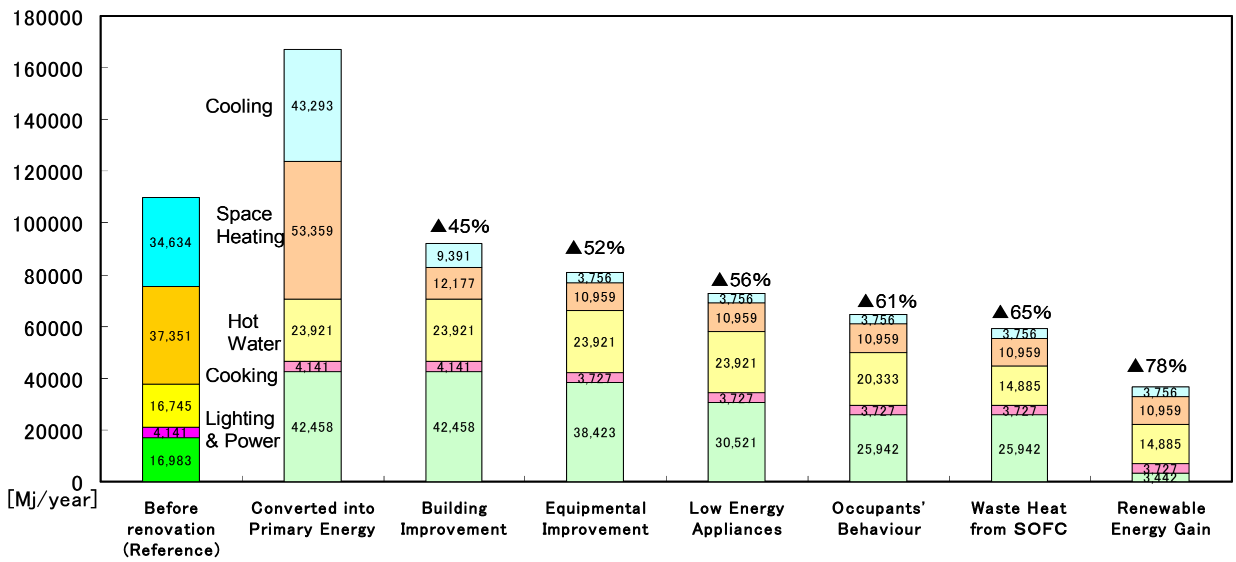

Figure.13 Expected process of Energy Impact Reduction (figures in Mj per year)

5.3 Effectiveness per Invested Cost

The energy reduction or gain of each measure, in term of Mj in primary energy per 1000 yen, was calculated to compare their effectiveness. After every measure, with its performance, had been assessed, the cost effectiveness was prioritised.

[6] Simplified Analysis System for Housing Air Conditioning, IBEC Japan

5.4 Data to be measured

Finally, it is necessary to compare the expected targets against actual data after occupation. This includes indoor/outdoor temperature, electric consumption, gas consumption, PV power generation and heat gain from either SOFC or solar collector. Sensors and meters were installed at suitable locations and the data have been transmitted to the logger installed in the basement of the building. They have been collected regularly and analysed.

6. Experiment through occupied condition

Once the energy saving/gaining measures were ready in April 2007, a family moved into the dwelling. The family consisted of a married couple with two daughters both in junior high school that year. Although the age of children is different, the family size is the same as the ones in previous phases (1st and 2nd).

A study group for "Experiment of Factor4 Dwelling Low Energy Living" has been set up. It has actively watched over the process, analysed the results and determined additional measures to fill the gap between the target and the outcome. This study is to continue for 5 years.

In the first fiscal year, April 2007 to March 2008, the family was not requested to make efforts to reduce energy consumption. The home electrical appliances remained as they had been brought in. The intention was to have basic data for comparison with the later energy saving behaviour.

The data from the first year has been collected sufficiently in spite of some errors and mistakes. At the same time, the weak points of remodelling have also been clarified. Following is a list of the main findings from the first year of occupation. The Fig.14 shows the energy consumption/gain results through the FY 2007 in comparison with the reference and the actual data in previous occupation.

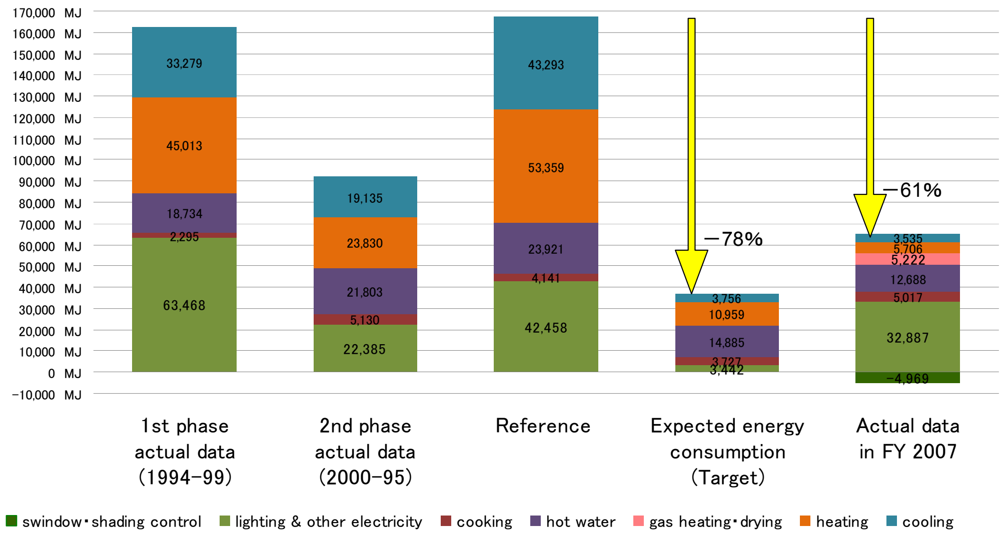

Figure.14 Results of energy consumption in comparison with target, reference and previous cases

Heating: The energy consumption for heating space was as low as expected. The effect of better insulation has been clearly proven.

Cooling: The cooling energy was 6% lower than expected but the way of using air-conditioner was intermittent which is not equal to the presumption.

Hot water supply: The waste heat from the fuel cell seems to have been well utilised. The energy use for this purpose was 16% lower than expected.

Cooking: The energy for cooking was 35% greater than expected but not as significant as other uses. The data during winter is estimated from the other seasons because it is only available for non-heating season.

Lighting and other electric use: This section has been the most difficult part of the project to analyse. The main reasons for the high-level consumption cannot be explained beyond the two old refrigerators in use. More detailed examination is required.

The total reduction rate for the first year was approximately 61%. That figure is still far behind the target of 78%. The electric consumption in particular has been much higher than expected. Patient watch, further improvement of equipment and good guidance to the occupants are required for attaining the target.

PREDICTED IMPROVEMENT OF ENERGY EFFICIENCY FOLLOWING TERRACE HOUSE RENOVATION

Summary

This research is concerned with the energy demands of terrace houses before and after renovation. The studied terrace houses are built in 1968 and situated in Lund in southern Sweden. They are technically outdated. Several possibilities for renovation, inspired by the IEA Task 28 Lindås Park project, are discussed and analyzed from an energy performance point of view. Energy performance is predicted using the DEROB-LTH computer program. An important aspect for the design is the minimal disturbance for the occupant of the house. The renovation concept is divided in four steps; (1) applying additional thermal insulation in the roof, (2) replacing the windows, (3) improving the ventilation system and creating an air tight building envelope and (4) applying additional thermal insulation in the walls. The combined effects of these four renovation steps is predicted to reduce heating demands from 15700 kWh/a to 6000 kWh/a, a reduction of 61.8%. Energy demands of dwellings can be considerably reduced by means of renovation, with minimal hindrance for the occupants.

1. Introduction

The terrace houses that are analyzed and discussed are situated in the Gilleskroken neighbourhood in Lund, Sweden (Fig. 1). The Gilleskroken terrace houses were designed by the Danish architect Bent Jørgen Jørgensen and built in 1968-1969. The terrace houses have high architectural qualities. They do however require renovation. In total 22 terrace houses were constructed. The footprint of an individual dwelling is 8.0 m. wide and 10.3 m. deep. The living area is divided over three floors: a basement with laundry and storage facilities, ground floor with entry, kitchen and toilet, living room and extra room and first floor with bathroom and bedrooms. There is no accessible attic. The walls dividing the dwellings are constructed in brick, facades are constructed in wooden frames with wooden façade panelling.

Dwellings that are built today are more energy efficient than older dwellings. Building energy efficient dwellings have only limited effects on the reduction of the current energy use because new dwellings represent only 1 or 2 percent of the total housing stock. The majority of dwellings is already built and will continue their (high) energy consumption. Renovation of existing housing and making them more energy efficient will have a much higher impact on energy consumption reduction. Finding smart ways to change energy demands of the many existing dwellings can bring about a substantial decrease of current fossil energy use and related CO_2 emissions.

The focus in this project is to develop a renovation method that results in more energy efficient terrace houses. The heating demands of the Gilleskroken dwellings before renovation were measured by asking the occupants for their energy bill. Heating demands upon renovation were predicted using the computer program DEROB-LTH, provided by the Division of Energy and Building Design at Lund's Institute of Technology, Lund.

1.1. Analysis of the Gilleskroken dwellings.

The Gilleskroken dwellings are built in a traditional fashion using different materials for the structure, facades and foundation. For the foundation the top layer of soil was removed after which the foundation was constructed straight on the ground. On top of this foundation the dwellings are erected. The floors were constructed in concrete. Interior walls were built up of wooden studs with gypsum board panels. Walls between the dwellings consist of two brick walls, with 60 mm mineral wool for sound insulation in the cavity. There is a load bearing interior wall that has round steel columns as structural elements. The wooden outer walls consist of wooden studs and rails. Between the studs there is 95 mm of mineral wool thermal insulation. The facades are made up of horizontal wooden panels. Wooden trusses are used as structural elements for the construction of the roof. These trusses span 7.62 meters from wall to wall and are placed at 1200 mm centre to centre. Inside the roof there is a total of 150 mm mineral wool thermal insulation.

The Gilleskroken dwellings are connected to a district heating system. Water is heated centrally in a large heating plant. This water is transported to the dwellings through underground insulated heating pipes. The system is well maintained and very efficient. In the dwellings there are heat exchangers that transfer the heat to the dwellings' heating system which consists of radiators that are placed under the windows in each room. These radiators are heated with hot water that is heated by means of district heating.

Interviews were held with 13 of the total 23 households at Gilleskroken (56%). These interviews provided a clearer picture of the occupants' opinion on their dwellings plus useful information regarding the technology and construction of the dwellings. The usage of household electricity averages 4600 kWh/a for the 13 interviewed households. From a technical point of view the opinions of the occupants regarding the quality of their homes varied. However, many respondents claim that their dwelling requires regular maintenance. The wood needs to be painted every three to five years. Also, many of the occupants had changed the roof covering more than once. Some respondents mentioned the use of cast concrete in the dwelling as a positive feature. Others said that the use of the different materials such as wood, brick, and concrete appealed to them aesthetically. In several dwellings there were ruptures in the brick on the exterior. Nonetheless, on the whole the respondents are very content with their homes.

Figure 1 Gilleskroken gable dwelling

Figure 2 Lindås Park project

2. Materials and Methods

In this research a proposal is made for the renovation of the Gilleskroken terrace houses. This proposal is based on an analysis of energy efficient terrace houses at Lindås Park, near Gothenburg, Sweden. The Lindås Park project was used as an exemplary model for the Gilleskroken renovation. Data is collected from various publications (Wall, 2006; Ruud and Lundin, 2004). Calculations to determine energy use before and after renovation of the Gilleskroken dwellings are done in the computer program DEROB-LTH.

2.1. Reference Project Lindås Park

The Lindås Park project, started in 1997, and designed by EFEM Architects is located 20 km south of Gothenburg, Sweden. The project was part of the IEA Task 28 and sets a good example as energy efficient terrace housing. The project consists of 20 houses, of which 8 are gable houses, which were built in 2001. Heating demands have been monitored continually over the years. The dwellings have an average total energy demand of 7,000 kWh/a. The gable houses use an additional 1,500 kWh/a. This is the equivalent of 58 kWh/m²·a for an average terrace house, and 71 kWh/m²·a for a gable house. These figures show the advantage of the integral approach as an average Swedish dwelling uses 150 kWh/m²·a on heating alone.

The 20 dwellings at Lindås Park use an average of 4020 kWh/a for lighting and household appliances, 1848 kWh/a for domestic hot water, 1742 kWh/a on heating of space and ventilation air, and 668 kWh/a for fans and pumps. The energy efficiency of the dwellings at Lindås Park was achieved by implementing the following measures;

- Very thick thermal insulation of the building envelope
- Air-tight building envelope
- Mechanical ventilation system with heat recovery
- Solar water heater for domestic hot water

The building envelope is insulated extensively in order to reduce transmission losses. There is a minimum of 435 mm thermal insulation in outer walls, roofs and floors. There is little heat transfer through the building envelope, see Table 1. Windows contain three panes of glass with two metallic coats in combination with a Krypton or Argon gas fill.

Table 1 Heat Transfer in the Building Envelope of Dwellings at Lindås Park

Building component	Heat transfer (U) (W/m²·K)
Exterior walls	0.10
Roof	0.08
Ground floor	0.09

The dwellings have been made as airtight as possible to reduce infiltration losses. This has been achieved by overlaps in the vapour barrier, and by placing the vapour barrier at 100 mm from the interior so that nails do not puncture the vapour barrier.

The dwellings are equipped with an air-to-air heat exchanger in order to reduce ventilation heat losses. The heat recovery efficiency is approximately 83%. In summer this heat exchanger is by-passed. The heat recovery heat exchanger forms a very important element of the chain resulting in low energy consumption. Special attention is given to the well-functioning of this ventilation system, as it is there to provide optimal air quality and high comfort.

Each dwelling has a 5 m^2 solar collector facing south and 40% of the domestic hot water is provided by the solar water heaters.

2.2. DEROB-LTH model

The DEROB-LTH computer program a model of a Gilleskroken dwelling was generated. Energy demands for heating before renovation were calculated, and found to be 15700 kWh/a. The model was altered step by step, based on the Lindås Park project. The four steps of renovation are as follows:

1. Roof (Additional thermal insulation in the roof)
2. Windows (Change to energy efficient windows)
3. Ventilation/infiltration (Air tightness in combination with a mechanical ventilation system)
4. Walls (Additional thermal insulation in the walls)

The four steps were implemented in the DEROB-LTH model one by one. Energy demands for heating are calculated for each step and for the cumulative steps.

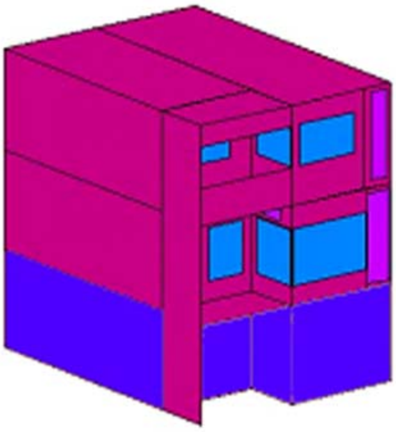

Figure 3 Model of a Gilleskroken dwelling in DEROB-LTH.

2.3. Renovation of the Gilleskroken Dwellings

The Gilleskroken dwellings are quite spacious with living areas divided over three floors. The plans of the dwellings are well thought out and functional. However, all this space is not always used because of the small household sizes, e.g. one or two persons. New plans were made for the dwellings focusing on the elderly, with a proper bathroom and bedroom at ground floor level. Part of the first floor can be used to house a student. A small apartment was created on the first floor, see Figure 4.

Apart from the spatial renovation, the dwellings also underwent some improvements from a technical point of view. The primary issue is that the dwellings have poor thermal insulation. Currently this is 95 mm of mineral wool for the walls. Also, the original windows are no longer sufficient. Secondly, the roof needs revising.

Figure 4 Gilleskroken ground floor level, left the existing situation, right the proposed new situation.

Thirdly, there is the existing ventilation situation in the dwelling. Ventilation takes place by simply opening windows. In winter this is not an optimal solution. Use of passive and active solar energy in the dwellings will cut down energy demands. The varying orientations of the dwellings (north-sound and east-west) require a number of solutions on how to optimally use solar energy in the dwellings. The abundance of space in the dwelling is a positive aspect of the dwelling that should remain even after renovation. The dwellings have plans that are both practical and functional, which is a quality that should remain. The use of different materials gives the dwellings their own character; the combination of wood, brick and concrete makes the dwellings stand out.

3. Results and Discussion

3.1. New architectural designs

A new architectural design for the Gilleskroken dwellings was proposed (Fig. 4 and 5). This design lives up to present-day demands and provides with new possibilities for use of the dwellings and the neighbourhood. The new design can be implemented while renovating the Gilleskroken dwellings for energy purposes.

The dwelling is not only renovated but also transformed into several new dwellings. On the ground floor an apartment can be created for the current, senior-occupants, as is illustrated in Figure 3. This apartment has a floor area of 50 m². It contains a hall, living room, kitchen and bedroom. It also has easy access to the garden. The apartment is very accessible as it is on ground level.

On the first floor two independent student apartments are created. They both have a kitchenette and a bathroom. The two student rooms have floor areas of 30 and 31 m² respectively. The staircase is a common staircase. A shared storage space for bicycles, lawn mover, e.g. is situated next to the entrance. The room in the basement is owned by the occupants of the ground floor apartment. They can use it as a guest room or hobby room. All other storage space is owned by the current occupants.

The Gilleskroken dwellings have two different orientations; some dwellings have a North-South orientation, others an East-West. A sun room was designed for the dwellings that have their entrance on the north side and their living room on the south side. In the DEROB-LTH model a glass wall was constructed in front of the terrace and balcony, creating a sun room at the back of the dwelling. The sun room cuts down the heating demands for space heating. It can be used from early spring to late autumn, and is not heated. Cooling in summer can be done by opening windows both at ground level and near the roof, and by using shadings.

3.2. DEROB-LTH Calculations

Energy demands for heating of the Gilleskroken dwellings was reduced drastically when implementing all the renovation steps as proposed in this research. From the original 15700 kWh/a needed for heating for a Gilleskroken dwelling, energy demands were reduced to as little as 6000 kWh/a. Each of the individual renovation steps will be discussed.

Figure 5 First floor; left the existing situation, right the proposed new situation.

Applying additional roof insulation does not require a complete renovation. This measure can be taken without causing much disturbance for the occupants. An additional 50 mm thermal insulation to the existent 150 mm already cuts down heating demands with 400 kWh/a (Table 2). Because of the available space inside the roof construction the maximum insulation thickness is 400 mm. This decreases heating demands with 1100 kWh/a. This is as much as 7% of the annual heating demands.

Table 2 Thickness of Roof Insulation in relation to Heating Demands
(Calculations in DEROB-LTH on Model of Gilleskroken Dwelling)

Roof Insulation (mm)	Heating Demands (kWh/a)
150	15,700
200	15,300
300	14,800
400	14,600

Replacing the existent double pane windows by triple pane low energy windows filled with Argon gas cuts approximately 3300 kWh/a of the total heating demands. When both the first two steps (400 mm roof insulation and triple pane windows with Argon fill) are implemented 4300 kWh/a can be saved compared to the existing situation.

Ventilation rate and the heat recovery system have a substantial effect on the heating demands of the Gilleskroken dwelling model. Where heating demands are as much as 18000 kWh/a in a model with 1.0 ac/h (air change per hour), this figure is as low as 6000 kWh/a at 0.1 ac/h. Mechanical ventilation rate in practice is 0.5 ac/h, infiltration rate is assumed to be 0.1 ac/h. In the model the ventilation rates after renovation are assumed to be a theoretical 0.15 ac/h. This is possible to achieve using a heat exchanger with 85% efficiency and by making the dwelling as airtight as possible as is done in the Lindås Park project.

At present, the Gilleskroken dwellings have only 95 mm of thermal wall insulation. It is presumed that when the walls are renovated the above mentioned three renovation steps are carried out as well. In the DEROB computer model it was found that applying only an additional 100 mm of thermal insulation cuts back heating demands substantially.

As could be expected from the Lindås characteristics the optimal thermal insulation situation can be found at an additional 200 mm (a total of 290 mm), see Table 3. Applying more insulation material than this would only slightly decrease energy demands whereas it could not compensate for the energy it takes to produce, transport and later demolish and recycle the additional insulation material. Dimensions of thermal insulation are bound to limits and applying lots of thermal insulation does not improve the thermal insulation of the dwelling limitless. Thermal insulation thickness of more than 400 mm is superfluous and hardly contributes to further energy reduction (Sanjee and Ham, 2006). The solution chosen in this research is 195 mm of insulation for the walls.

Table 3 Thickness of Wall Insulation in relation to Heating Demands
(Calculations in DEROB-LTH on Model of Gilleskroken Dwelling)

Wall Insulation (mm)	Heating Demands (kWh/a)
95	7,000
195	6,000
290	5,700
390	5,600

The combined effects of the four renovation steps reduced heating demands from 15700 kWh/a to 6000 kWh/a, a reduction of 61.8% (Fig. 6). The impact on energy use of the individual renovation measures depends on which measure is taken first. If for example only walls are insulated, this measure would have a higher impact on total energy reduction than it has in this research where it is the last applied step in the model.

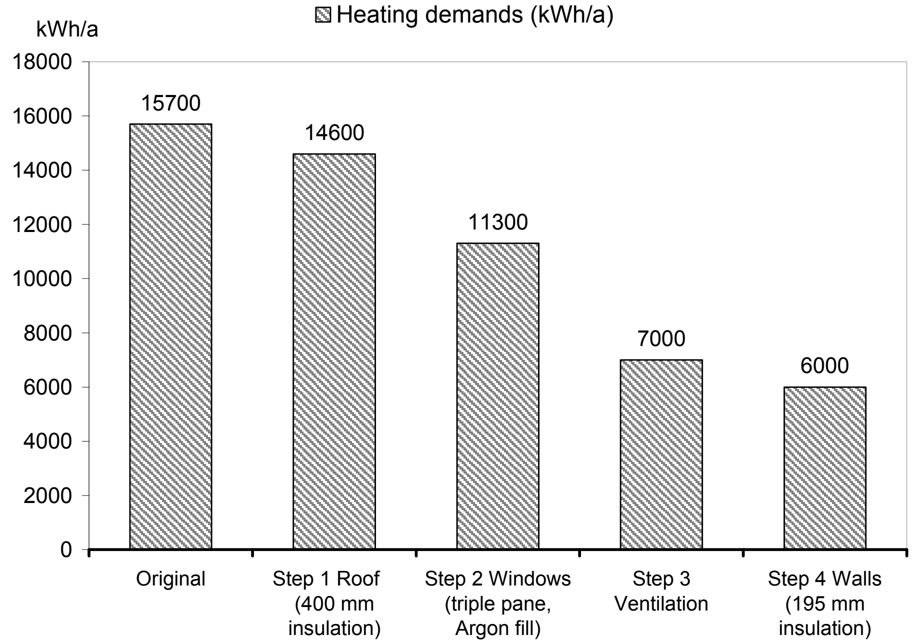

Figure 6 Renovation steps and heating demands for Gilleskroken model in DEROB-LTH

4. Conclusion

This analysis suggests that energy demands of dwellings can be considerably reduced by renovation. In a renovation program many different aspects have to be taken into account and decreasing energy demands of the dwellings is only one aspect. Putting the focus on reducing energy demands of the built environment and showing that this can be achieved with rather average renovation measures could consequentially improve our living environment. This research shows that implementing relatively simple renovation measures such as applying additional roof insulation can decrease heating demands of dwellings substantially.

One of the advantages using the DEROB-LTH computer model is that many situations can be calculated easily and quickly. Varying the thickness of the thermal insulation shows that thermal insulation does not need to be applied endlessly. A thermal insulation layer of 300 mm is sufficient in both walls and roof. However, when carrying out a renovation project, a close eye has to be kept on the right use of materials and renovation measures. Creating an airtight dwelling without providing with a well-functioning ventilation system will cause considerable problem for occupants. Competent builders should be contracted and renovation experts should be consulted before undertaking a renovation project.

Summary

The plant always exchanges the energy and material from the environment interactively (the photosynthesis effect and breathing effect) to supply the nutrient for maintaining the life of itself. The “heat” and “light” from sun are the key factors. This study, was attempted to analyze the characteristics of sunlight (illumination and wavelength on the leaf surface), and then to develop a hybrid lighting system, which connected the daylight with some artificial lights, to mimic the characteristics of sunlight. The fuzzy-control interface for the composition of the light sources was implemented. This device can be utilized in the living space which is intended to green plants but without depending on the sufficient daylight. The performances of energy consumption in various scenarios are also addressed..

1. Introduction

It has been reported that daylight illumination schemes provide the potential for significant energy savings in buildings. For example, Bodart and Herde estimated that the implementation of appropriate daylight access devices can reduce artificial lighting power costs from 50~80% [1]. Previous researchers have explored the feasibility of using daylight illumination schemes to reduce building energy costs in a variety of indoor environments, including hotels [2], apartments [3], offices [1], large atrium spaces [4], daylight-illuminated corridors [5], and classrooms in the tropics [6]. In subtropical climates such as that found in Taiwan, the major sources of power consumption include lighting, air conditioning and automotive power. Of these three sources, the lighting load can account for as much as 88% of the total energy consumption [7].

Hybrid Energy Systems have become one of the major technologies developed recently. Most of them involve engine systems for vehicles. There were few researches and developments of hybrid energy systems in living space. This study which utilized daylight pipes and auxiliary artificial light was attempted to construct a hybrid lighting system for mimicking the characteristics of sunlight. A fuzzy-control interface for composing the light sources was implemented. This device can be utilized in the living space which is intended to grow green plants without strong daylight. The performances of energy consumption in various lighting conditions are also investigated.

2. System Design

To grow plants in living space, the irradiation of four ranges in the light spectrum is the most important: 400-450 nm, 500-550 nm, 600-650 nm and 700-750 nm. To investigate the influence of four ranges of spectrum on plant growing, the study optimizes the light strength ratio of the sunlight guided from the pipes and the artificial light. Different lighting modules are constructed depending on the actual natural lighting condition in Taiwan.

2.1 Daylight Pipes

Aluminum plates with mirror faces and high reflectivity, the coefficient of reflection is 0.85, are used and rolled up to form a section of the daylight pipe. To effectively guide the sunlight into the indoor space and optimize the experimental requirement, the daylight pipes can be disassembled and reassembled section by section into different shapes, named from module A to module E (Figure 1). To assess the performances of the daylight pipes and to compare with the measured results, a software of “Lightscape” was used to simulate the light distribution indoors through the pipes (Figure 2).

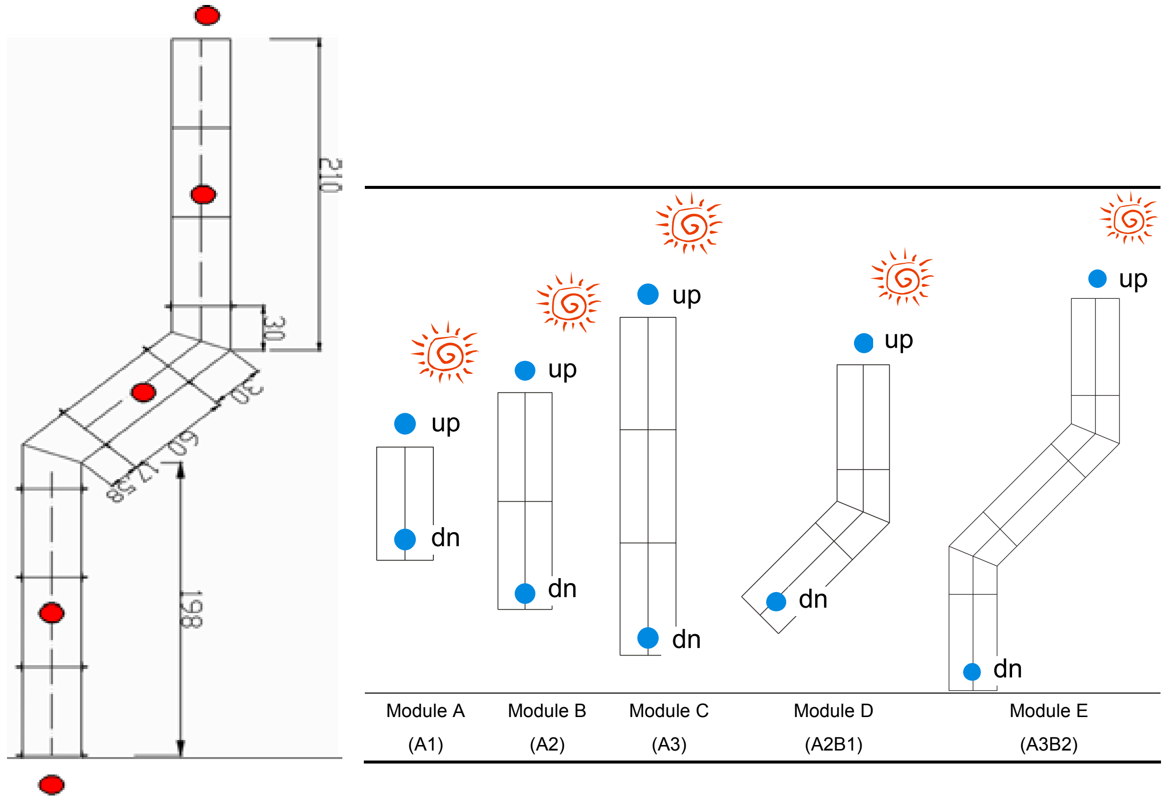

Figure 1 Dimensions and types of daylight pipes.

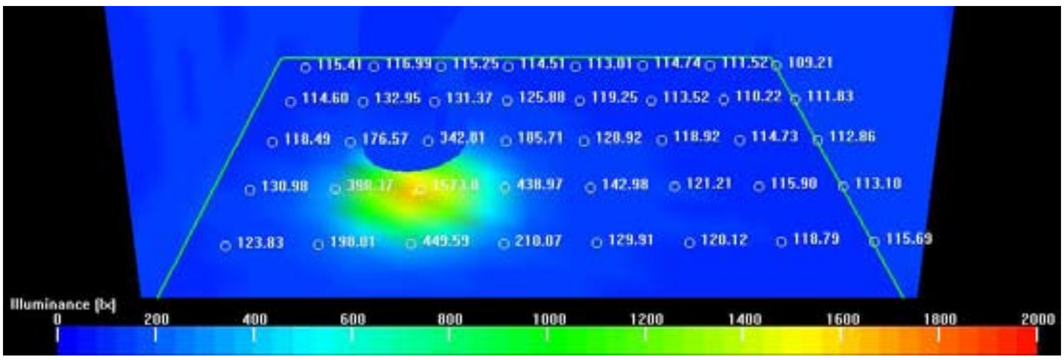

Figure 2 Post-process of simulated result on the light distribution through the daylight pipe.

2.2 Fuzzy control program

To compensate and improve the sunlight introduced into the living space and to construct the independent ecological system with the same physical conditions of the natural environment, a fuzzy control program is designed to make the lighting distribution in the system approach the corresponding environment. The fuzzy control module written and edited by LabView software was constructed to suitably trun on and off the artificial lights in the indoor space.

"If…., then…." is the main rule to state the operation of the fuzzy control program, which was developed by Prof. E. H. Namdani in University of London at Queen Mary, U.K. in 1974. A mathematical model should be constructed before the system is applied through overall investigation of the input and output conditions. In the current study, different lighting distribution from various modules of artificial lighting systems was investigated and analyzed to construct the database of the fuzzy control (Figure 3 and 4). To reduce the error percentage in the lighting performance, detailed investigations of natural and artificial lights were required in the study.

2.3 Calculation of energy saving of the hybrid lighting system

It is reasonable that a large amount of effort is necessary to simulate natural light by artificial lightings. Therefore, it is beneficial to develop a hybrid system to achieve the high fidelity and energy saving. Therefore, we define a factor of energy saving rate (ESR) to assess the reducing rate of power consumption between artificial lighting and hybrid lighting (Figure 5).

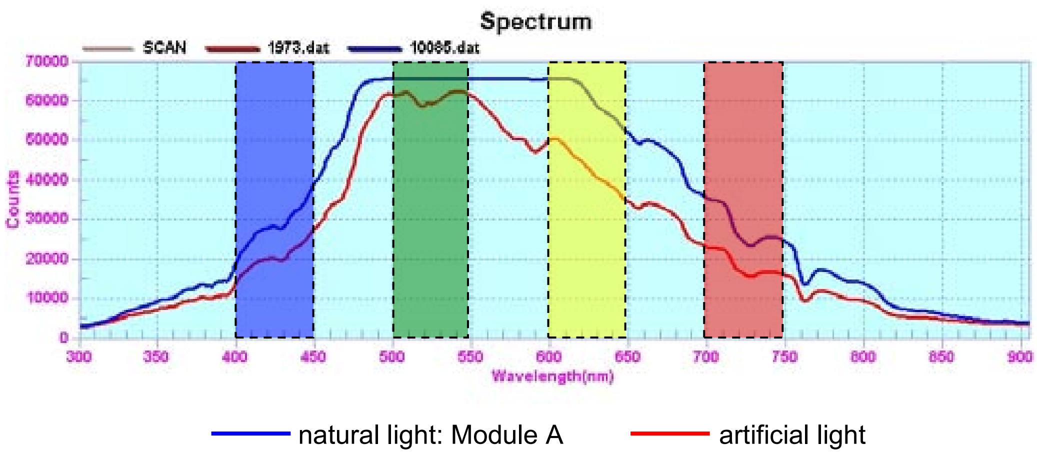

Figure 4 Comparison of the natural and the artificial light.

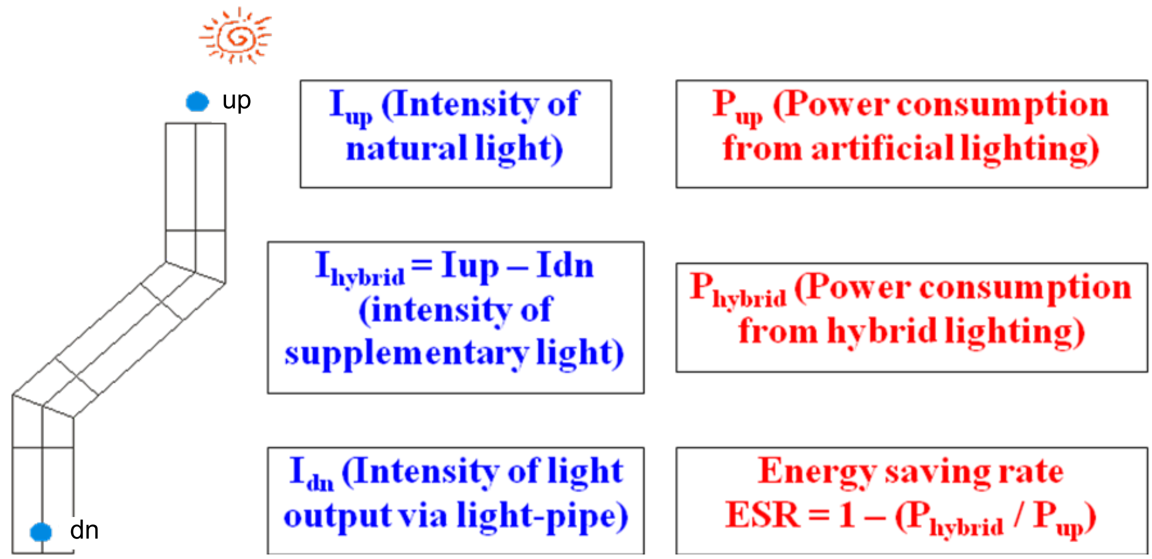

Figure 5 Structure of energy-saving calculation of the hybrid lighting system.

3. Experimental Results

3.1 Comparisons of different daylight pipes

In Figure 6, the sectional pipes are successfully assembled. A detailed investigation of the sunlight strength before and after the sunlight go through the pipe was done (Table 1).

Figure 6 Photographs of field measurements of the daylight pipes.

		D/U ratio	94.9%	72.2%	64.5%	30.0%	21.3%
	16：00	Weather	partly cld.	partly cld.	partly cld.	partly cld.	partly cld.
		Up spot	12040	10794	11210	12031	11778
		Dn spot	7297	4935	4392	2379	1389
		D/U ratio	60.6%	45.7%	39.1%	19.7%	11.7%
	17：00	Weather	partly cld.	partly cld.	partly cld.	partly cld.	partly cld.
		Up spot	4907	4872	4791	4631	4711
		Dn spot	2721	2622	2615	767.7	284.9
		D/U ratio	55.4%	53.8%	54.5%	16.5%	06.0%

* Measured from northern Taiwan in Winter and southern Taiwan in Spring.

** Unit: lx (illumination).

To compare the D/U ratios shown in Table 1, the measured results showed that the ratios from the southern Taiwan in Spring represent better performance than the ratios from the northern Taiwan in Winter at the same time period. The Up-spot and Dn-spot of every case are also measured the light intensity of the spectrum from the wavelength of 300 nm to 900 nm (Figure 7). The reduced parts of daylight intensity can be realized to be supplied by the artificial lighting properly.

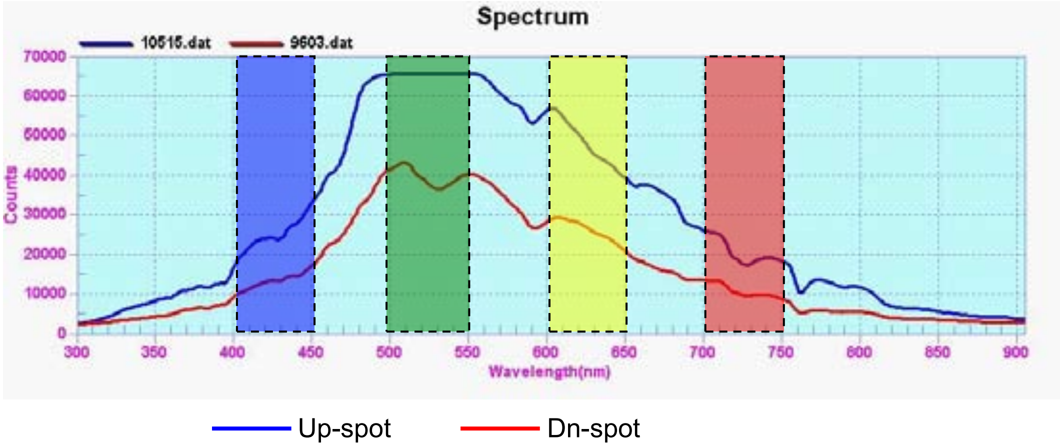

Figure 7 Comparison of light spectrums between the up-spot and the dn-spot: take Module C as an example.

3.2 Output of fuzzy control module

The maximum value of the insufficient light can be obtained by the measured results. This insufficiency can be supplied from several kinds of lamps which can be chosen to perform various spectrums separately. Hybrid module can be calculated by inputting the supplementary intensity (Figure 8). The fuzzy-control module will output the one of the lamp compositions with minimum error.

3.3 Calculation of energy saving of the hybrid lighting system

When we input the set of intensity values measured from Up-spot, The output of lamps module represents that the artificial lighting can perform as natural daylight. Therefore, the power consumption of this lighting scenario can be compared with hybrid lighting system (Table 2). Results show that this system is valuable.

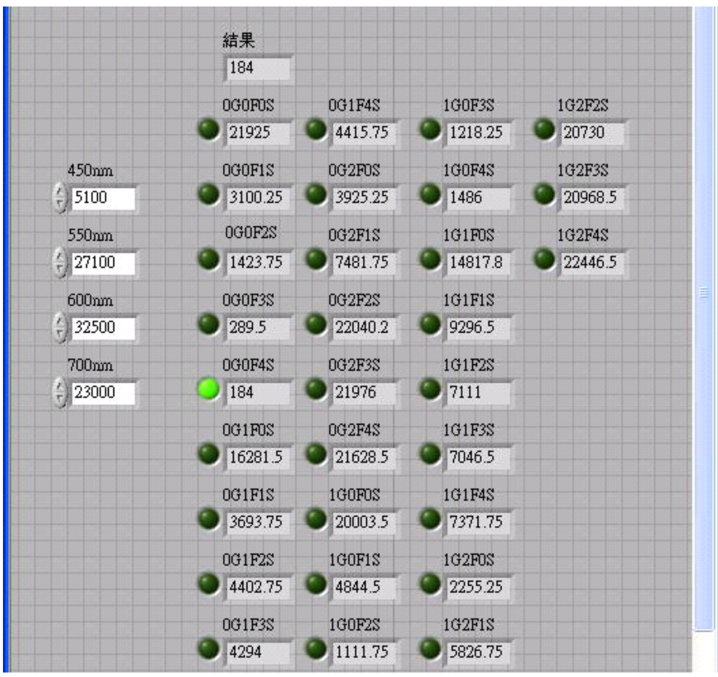

Figure 8 Calculated output by fuzzy control module.

4. Conclusions

The developed lighting system utilizing the daylight pipes and the artificial lighting is an essential element for growing plants in an independent ecological system. With the current system, an optimized lighting system can be realized with low power consumption. The measured results are beneficial for designing the hybrid system to perform vividly the daylight of the site we select for the plants indoor, especially for the eatable greens. The automatic fuzzy control program is introduced in developing.

Table 2 Calculation of energy-saving rate of hybrid lighting system: Module E.

Time	Artificial lighting to simulate the daylight		Hybrid lighting		Energy saving rate
	Lamps module	Power consumption	Lamps module	Power consumption	
9 : 00	0G2F3S*	4000 W	1G1F0S	580 W	85.5 %
10 : 00	0G2F3S	4000 W	1G1F1S	1580 W	60.5 %
11 : 00	1G1F2S	2580 W	1G1F0S	580 W	77.6 %
12 : 00	0G0F2S	2000 W	1G1F1S	1580 W	21.0 %

* G: 80 W per one; F: 500 W per one; S: 1000 W per one.

The reflection of sun-pipe is reasonable with 10-50 % of the remnant intensity but slight spectrum shift. This might be introducing the useful waveband for the growth of plants. A novel light control system which combines the artificial lights and outdoor daylight is under developing. The calculated result will also provide a set of data to suggest the optimum lamplight while renewal.

PASSIVE HOUSES IN AUSTRIA - SUSTAINABILITY MONITORING OF STUDENTS' HOSTEL MOLKEREISTRASSE, VIENNA

Roman SMUTNY MSc.
Martin TREBERSPURG Univ.Prof. Arch. Dr. Msc.

Division Sustainable Buildings, Inst. of Structural Engineering, Department of Civil Engineering and Natural Hazards, University of Natural Resources and Applied Life Sciences Vienna roman.smutny@boku.ac.at.

Keywords: students hostel, passive house, sustainable building, green building, energy monitoring, primary energy, greenhouse gas emissions, user satisfaction, electrical energy

Summary

Austria has a diversified know-how concerning sustainable buildings and the highest rate of passive houses per resident. The students' hostel Molkereistrasse in Vienna was the largest passive house worldwide, when it was opened in Sept. 2005. The facility performance evaluation gave evidence for an extremely high user satisfaction and a very good energy performance and climate protection performance concerning space heating and hot water generation. Further measurements for the improvement of the energy performance and the user satisfaction have been derived from the monitoring project. Future realizations of students' hostels can benefit from studying the successful pilot project in Vienna. And an additional attention should be laid to reduce the energy consumption for hot water generation and for electrical appliances.

1. Sustainable buildings in Austria

Austria has been a pioneer in the realization of eco-friendly and energy efficient houses and has accumulated substantial practical know how concerning passive houses, solar heating systems, and biomass energy production systems (Treberspurg + Smutny, 2005). Currently, it can claim twice as many sustainable settlements per resident as Germany (Wolpensinger, 2008). The following figure shows the development of passive houses in Austria. A passive house is designed to be heated with less than 15 kWh useful energy per treated floor area and year. Austria has the highest number of passive houses per resident worldwide with 200 objects per 1 Mio. residents in the end of 2006 (Lang, 2008). In the last three years, the cumulated total floor area has doubled each year.

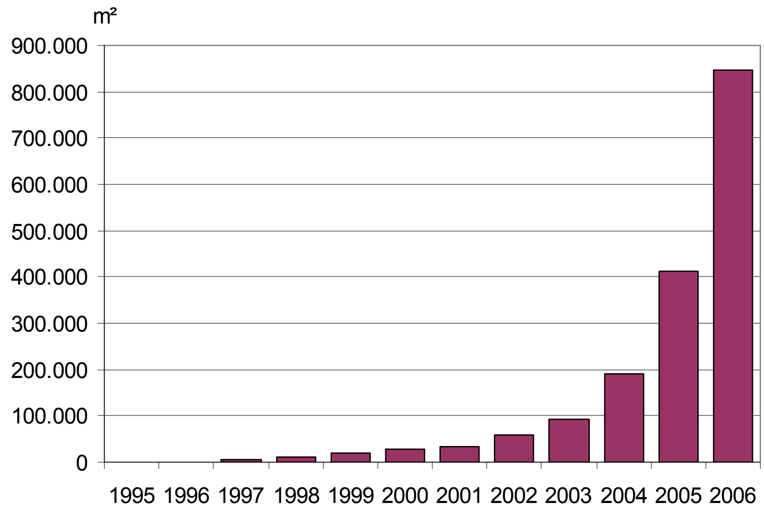

Figure 1: Accumulated total usable floor area [m²] of existing passive houses in Austria (Lang, 2008)

1.1 Presentation of specific passive houses

Approx. 45 % of the documented usable floor area of passive houses is provided by apartment houses, 22 % by one-family and two-family houses and 33 % by other buildings (Lang, 2008). The following pictures provide an overview on selected Austrian passive houses.

Figure 2: Housing estates in passive house standard. From left to right: Mühlweg-Vienna (Source: Bruno Klomfar, Dietrich I Untertrifaller Architects), EBS-solarCity-Linz (Source: Treberspurg & Partner Architects, EBS Linz,), Roschégasse-Vienna (Source: Treberspurg&Partner Architects)

Figure 3: Office buildings in passive house standard. From left to right: SOL4, Mödling (Source: Thomas Kirschner, SOL4), Adobe-Passive-House Tattendorf (Source: Meingast, natur&lehm, Reinberg Architects), Christophorushaus, Stadl-Paura (Source: BBM)

Figure 5: Buildings with thermal retrofit measures that meet the passive house standard. Left: Housing estate Makartstrasse-Linz (Source: Robert Freund, Arch+More Architects), Right: School Schwanenstadt (Source: PAUAT Architects)

A passive house can be designed in different ways. Austrian passive houses have been built in light-frame timber construction, in massive timber construction, and in massive construction with concrete or bricks. There are also some examples of thermal retrofit of existing buildings into passive houses. The renovation of

Makartstrasse, a 50 unit housing estate in Linz, used a super-insulated passive solar façade with integrated decentralized ventilation systems. This resulted in 90 percent savings in heating energy and operational costs. It is obvious, that Austria currently has a lot of diversified planning expertise in the field of passive houses which can be a valuable resource for foreign architects, building engineers, and planners of building services.

1.2 Sustainable energy supply

Austria currently has the highest rate of installed solar collectors per resident in Europe besides Cyprus and Greece (Weiss et al., 2007). The total area of installed solar collectors is 3.3 million m² and is increasing by approximately 0.3 million m² per year (Faninger 2007). To grasp these figures they are compared with the situation in Australia. Even with Austria's much smaller population (8.3 Mio. versus 20.7 Mio. in 2007) and less solar radiation, the annual sales as well as the total installed capacity of glazed solar collector area are about 43 % higher than in Australia (Weiss et al., 2007). This is also an important factor for the economy: More jobs are generated by the solar thermal energy industry than by the Austrian ski producers.

Table 1 Solar heat markets in Austria and Australia according to IEA (Weiss et al., 2007)

Solar Heat Worldwide	Collector Yield 2005 [GWh/a]		Total capacity installed at the end of 2005 [MW_{th}]		Annual installed capacity 2005 [MW_{th}]	
	Hot water, space heating	Total (incl. pools)	Glazed collectors	All collectors	Glazed collectors	All collectors
Austria	860	995	1690	2106	163	168
Australia	701	1971	1192	3605	114	385

Solar thermal energy concepts have been optimized by simulation with TRNSYS and successfully tested in practice. Online monitoring of solar systems has proved to be valuable for owners and occupants, providing safeguards against failure and malfunction and helping to adjust the control settings and thereby increase solar gains. Experience and planning competence are available especially for large volume houses – housing estates, office buildings, hotels, and business/industrial facilities.

Biomass is also an important energy source for heating. About 43 percent of the land area in Austria is forested. Biomass resources are used from forestry, agriculture, and the food industry and timber industries. Since biomass heating has been continuously supported, the regional economy has been strengthened. Meanwhile, Austria is one of the technology leaders in the production of boilers for split logs, wood chips, and pellets.

1.3 Success factors for the realization of sustainable building in Austria

Austria has an effective housing subsidy scheme. High income taxes (30–40 percent) enable several steering mechanisms. About 1.3 percent of the gross domestic product is used for housing subsidies. This stabilizes the building industry and has positive impact on social integration, the overall quality of buildings, and especially the ecological building performance. In early 2006, the housing subsidy scheme in the federal state Vorarlberg was revised. Passive House Standards are now mandatory for subsidized housing estates. As of October 1, 2006, a solar heating system is mandatory for subsidized housing estates in the federal state Styria.

Building laws with mandatory values for thermal insulation. Thermal resistance limits for the building envelope have been increased several times during recent decades and will be further decreased.

A law banning nuclear power plants (Atomsperrgesetz, BGBl. Nr. 676/1978). The use of nuclear power as an energy supply was prohibited after a plebiscite in 1978. This has been an early success on the road to a sustainable energy supply.

Initiatives of individuals had a relevant impact on the development of green buildings. The passive house movement started in the federal state Vorarlberg because of the commitment of individuals. Vorarlberg still has the highest density of passive houses. In the federal state Styria the use of solar collectors has started in the 70ies. Individuals who provided guidance in building the first solar collectors for private homes formed the AEE INTEC, now one of the leading R&D companies for solar heating systems. Meanwhile, individual housing developers who build each new housing estate with a solar thermal system tend to build passive housing estates only.

Funding of research and development: The R&D-impulse-program "Building of Tomorrow" of the Austrian Federal Ministry of Transport, Innovation and Technology (BMVIT) on "technologies for sustainable development" (at:sd) has a focus on sustainable buildings and has supported approximately 200 projects (Paula+Bauer, 2005). Core projects are innovative building and reconstruction concepts and their realization.

Several demonstration buildings already draw international interest, e.g. the S-house that has been presented on SB05 in Tokyo (Wimmer, 2005).

2. Passive house students' hostel Molkereistrasse in Vienna

2.1 Building concept

The building was planned by Baumschlager Eberle P.ARC architects and Team GMI passive house engineers. At the time of completion in September 2005 it was the largest passive house worldwide with a gross floor area of 10 527 m² - this corresponds to a treated floor area of 7 715 m² according to the calculation by PHPP (PHI, 2007). The building holds 280 beds in 133 apartments on seven floors.

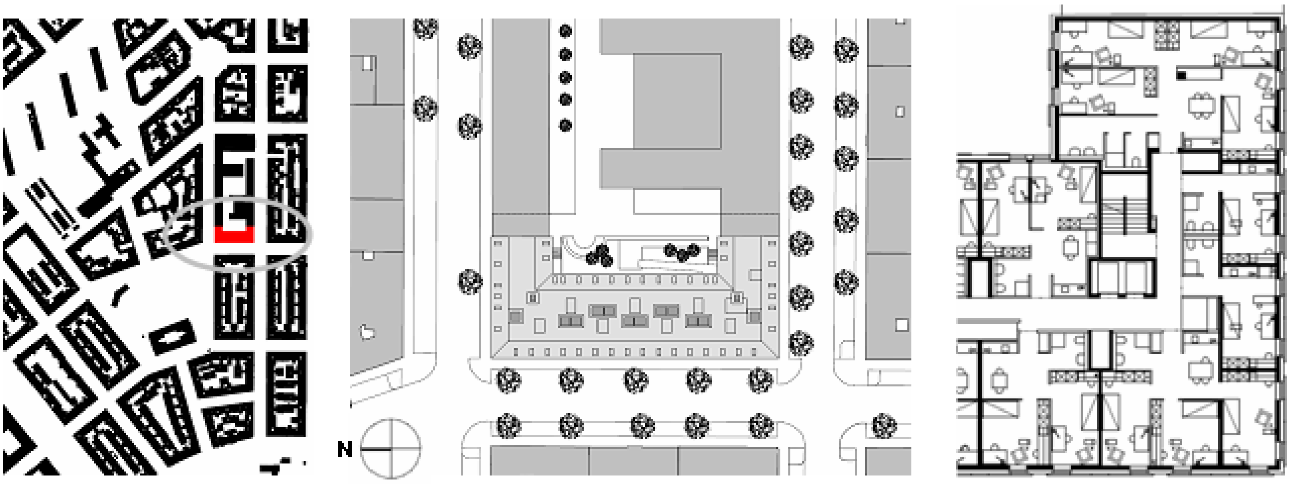

Figure 6: Site plan and floor plan of Students' Hostel Molkereistrasse. Source: Baumschlager Eberle P.ARC

The architects realized several innovative components within the strict financial regulations of the subsidy scheme. Each student has a single room with approx. 14 m² useable floor space and high quality interior equipment (wooden parquet floor, television sets, internet connection, etc.). The brass shadings act as attractive and varying structure for the façade. The shadings are manually operated and can provide a high thermal comfort during heat waves. Due to the high compactness of the building - 18 m depth of building wing -, central corridors are provided with a sophisticated daylight concept. Seven light wells have been optimized by simulation and supply daylight throughout seven floor levels.

The building has an active heating system - supplied with district heating - with mini-radiators in each room that are located above the doors near the supply air opening. Space heating and ventilation are thus separate systems with the advantage that the temperature can be regulated individually for each room by a room thermostat. A window contact automatically switches the thermostat to the lowest level (16 °C) if the windows are opened or tilted.

The distribution of warm water is done by one pipe system instead of a two pipe system (closed circuit). This concept reduces the pipeline length and therefore reduces thermal losses by more than 50 % compared to closed circuit system with the same insulation level.

The controlled ventilation with fresh air is done by small decentral ventilation units - one unit per two apartments. About 30 m³/h air is supplied per person. During cold periods with exterior temperature below 0 °C the air flow is reduced to 20 m³/h to avoid low air humidity. The fresh air is pre-heated or pre-cooled by ground-coupled heat exchangers.

2.2 Facility performance evaluation

Since February 2007 the energy consumption and user satisfaction have been measured. The first research period was analyzed and interpreted in the end of March 2008 (Smutny+Treberspurg, 2008), (Treberspurg et al., 2008). The survey is planned to go on until end of 2009. The aim of this study was to gain experience for future building projects and to improve the ecological and social performance if possible and necessary. The research project examined the actual energy consumption and the wellbeing of the occupants by means of a post-occupancy-evaluation (POE).

The survey concerned the comfort of ventilation, heating and noise and also included the associated needs and requirements of the occupants. Preliminary evaluation results showed good marks for the thermal comfort and the wellbeing of the occupants. More than 80 % of the occupants felt comfortable in the hostel.

The preliminary results were used to intensify the information on special topics (e.g. heating regulation, shading panels, window ventilation, building manual, etc.) that have been appeared to be unclear. A detailed analysis of the user satisfaction is planned to be carried out in the second investigation period. A comparison of 26 Viennese students' hostels showed that the general user satisfaction in the Molkereistrasse is very high. Only one hostel - the recently renovated Albert-Schweizer-Haus - showed better marks, but had a much lower rate of return of the questionnaires (15 %) compared to Molkereistrasse (66 %).

Heat meters and electric meters with electronically data transfer (M-Bus system) have been installed to investigate the site energy for space heating, water heating and ventilating. The site energy is the amount of energy that the user pays to the energy supplier. The calculation of useful energy for heating was done by determining the energy losses of heat distribution with the detailed information of the building services consultant Team GMI. These energy losses accounted for approx. 8 kWh/(m²·a) per gross floor area (GFA).

Useful energy consumption for heating was further converted according to actual climate and actual room temperature with the purpose of comparing it with the planned heating energy demand under standard reference conditions for temperature. The median of the indoor air temperature of 20 rooms was 23.2 °C (standard deviation 1.7 K), putting the transmission and ventilation losses 22 % higher than under design conditions of 20 °C.

The following figure shows the savings of useful heating energy and interrelated operational costs and greenhouse gas emissions compared to conventional Viennese housing estates of the same size with district heating supply. The referenced value is based on the actual heating energy consumption of a high amount of buildings and has been determined by (Hofbauer, 1998). The medium value of 50 kWh/(m²·a) is related to dwellings with more than 10 apartments that have been built about the year 2000. This is already a relatively good energy performance compared to older housing estates (80 kWh/(m²·a); built in 1980) or compared to conventional single family houses (70-100 kWh/(m²·a); built in 2000). Nevertheless, the successfully realized passive house concept showed to reduce this value by approximately factor five to a level of 11 kWh/(m²·a) per gross floor area. This corresponds to approximately 15 kWh/(m²·a) per treated floor area which is the limiting value according to the passive house concept.

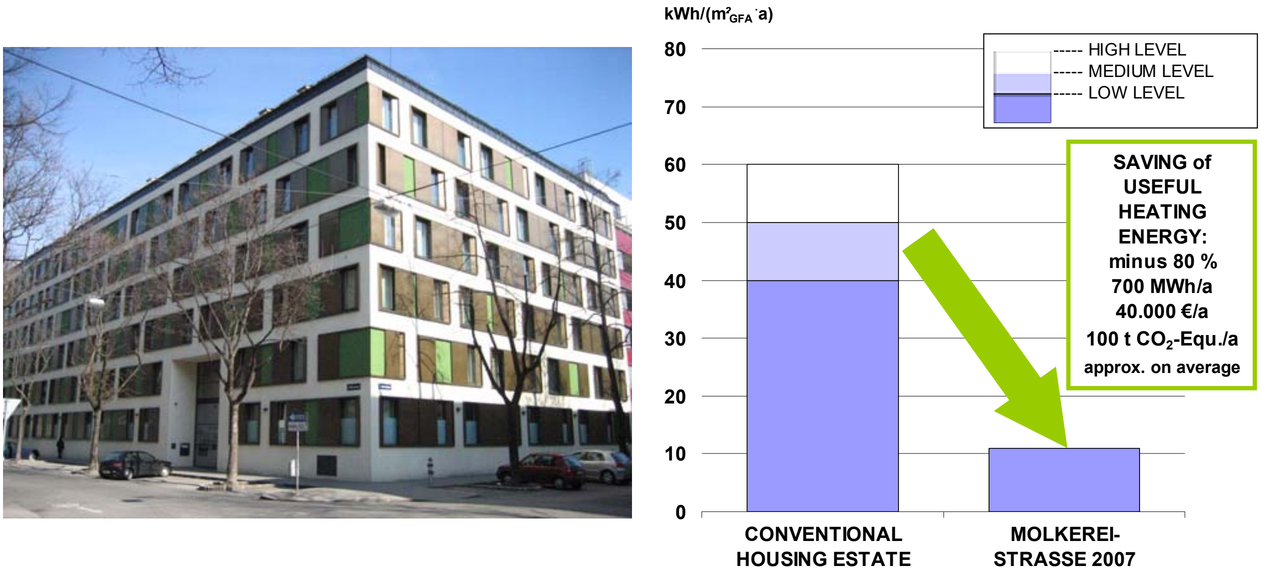

Figure 7: Useful energy consumption for space heating per gross floor area (GFA) under standard reference conditions for temperature. Passive house hostel Molkereistrasse compared to conventional Viennese housing estates built in approximately the year 2000. Foto: Roman Smutny

The second criterion for passive houses concerns the total energy consumption including electricity for household appliances, indicated by the non-renewable primary energy input (PEI_{nr}) with a limiting value of 120 kWh/(m²·a) per treated floor area, calculated with factors from the GEMIS-database. GEMIS includes the total life-cycle in its calculation of impacts - i.e. fuel delivery, materials used for construction, waste treatment, and transports/auxiliaries. With the primary energy factor for the Viennese electricity supply including imports - 2.43 kWh/kWh which equals approximately the average value for Europe according to GEMIS 4.42 (UBA-AT, 2007) - the primary energy consumption of the hostel is 160 kWh/(m²·a) per treated floor area. Measurements have been derived from the monitoring to reduce this value under the limiting value for passive houses in the following years.

The following figure shows the total site energy consumption (EC) per gross floor area, which has been assessed by the total non-renewable primary energy consumption (PEI_{nr}) and the total greenhouse gas emissions (GHG) using the corresponding factors for Viennese energy supply including imports (UBA-AT, 2007). The total values for these three energy services are 88 kWh/(m²·a) EC, 117 kWh/(m²·a) PEI_{nr} and 29 kg/(m²·a) of CO_2-Equivalents GHG. Please note that these values can not be compared to the passive house criteria, because of the different reference floor area. By the way, there is no criterion for GHG in the passive house concept.

	EC	PEInr	GHG
Electrical Energy, total	34	83	18,1
District heating, Hot water	34	22	6,6
District heating, Space heating	20	13	3,8

Figure 8: Site energy consumption (EC), non-renewable primary energy consumption (PEI_{nr}) and greenhouse gas emissions (GHG) for space heating (not standardized), hot water and electrical appliances per gross floor area (GFA) and year. Medium values of the period 09.2005 - 08.2007.

The analysis of the total energy consumption showed the importance of hot water generation for the overall performance, which was underestimated in the planning stage. The design value for water heating (25 litres with 60 °C per person and day as an ordinary value for conventional housing estates) is approximately half of the actual consumption value. The comparison with four other students' hostels (see *Figure 9* and (Engelmann et al., 2008)) surprisingly showed that the hostel in Molkereistrasse had the lowest value.

The analysis of the primary energy input and the greenhouse gas emissions showed the importance of electricity consumption for the overall performance. Electricity consumption causes 71 % of the total PEI_{nr} and 62 % of the total GHG.

2.3 Comparison with other Viennese students' hostels

In order to evaluate the energy performance and climate protection performance of the hostel in Molkereistrasse, three other Viennese students' hostels have been analysed that had been built in the period 1996 to 2005 and are also supplied with district heating. It is important to keep in mind that a direct comparison of the ecological performance of different buildings has only a limited significance due to methodological frameworks. According to the ISO standards for life cycle assessment (ISO 14040 - 14043) the same functional unit has to be used for comparisons of products or processes. The functional unit of buildings should respect the benefit and comfort of the apartments and therefore has to take into account the quality of the building services and equipment as well as the overall quality of the indoor environment. The passive house concept aims at optimising the thermal and hygrical comfort, the air quality and the daylight quality. For that reason it can be assumed, that the indoor environment in the hostel Molkereistrasse has a higher benefit for the students than in the other hostels, which has been verified by the survey of 26 students' hostels in Vienna. Furthermore the hostel Molkereistrasse offers single rooms only with television sets and internet connection, which is not the fact for the other hostels. Nevertheless, the useful floor area has been preferred as functional unit of the comparison due to practical reasons. The difference in the benefit is expressed qualitatively in addition and has to be kept in mind for the interpretation of the results.

The following figures show the comparison of the energy performance and climate protection performance of four Viennese students' hostels per useful floor area (UFA).

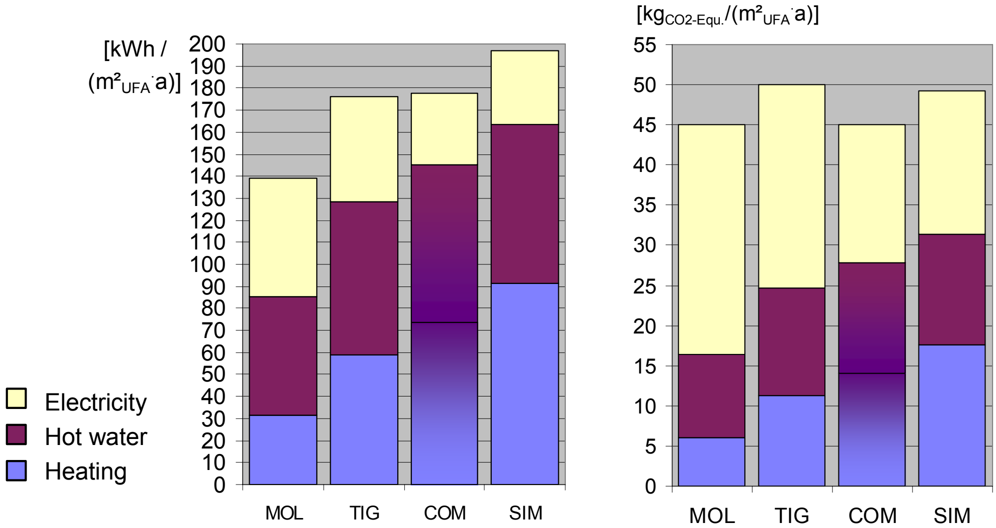

Figure 9: Total site energy consumption (left chart) and greenhouse gas emissions (right chart, factors for Viennese energy supply including imports). Space heating (not standardized), hot water generation and electrical appliances per useful floor area (UFA) and year. Four Viennese students' hostels Molkereistrasse built in 2005 (MOL), Tigergasse built in 2000 (TIG), Comeniusgasse built in 1996 (COM) and Simmeringer Hauptstrasse built in 2005 (SIM). All supplied with district heating. Medium values of the period 09.2005 - 08.2007.

Remark: For the interpretation of the results it is important to take into account the higher benefit of the passive house Molkereistrasse (MOL) concerning thermal comfort, hygrical comfort, air quality, daylight quality, summerly comfort, available TV-Sets, available internet connection, other qualities of the building services and equipment.

The oldest of the four hostels (Comeniusgasse, built in 1996) had the lowest electricity consumption The comparative values of Tigergasse and Simmeringer Hauptstrasse were approximately 50 % higher and of Molkereistrasse approximately 100 % higher. In the survey of the user satisfaction the hostel Comeniusgasse was on 25th position of 26 investigated Viennese hostels. This result can also be referred to the very low building services and equipment quality that causes low electricity consumption. The greenhouse gas emissions (GHG) are dominated by the electricity consumption due to a higher GHG-Factor (533 kg/MWh) compared to district heating (192 kg/MWh) according to GEMIS-Austria (UBA-AT, 2007).

The added value of the hostel Molkereistrasse compared to the hostel Simmeringer Hauptstrasse - with the most similar benefit and quality per usable floor area - is a saving of the total energy consumption of approx. 60 kWh/(m^2_{UFA}·a) - minus 29 % - and a saving of GHG-Emissions of 4.2 kg/(m^2_{UFA}·a) - minus 9 %. With the assumption of the same useful floor area (6 687 m²) the annual savings of district heating amount 520 MWh (78 kWh/(m^2_{UFA}·a)) which corresponds to 34 000 € (5.1 €/(m^2_{UFA}·a) and 100 t CO_2-Equivalents (15 kg/(m^2_{UFA}·a)).

3. Conclusions

The passive house students' hostel Molkereistrasse offers a very good energy performance and climate change performance regarding space heating and hot water generation. The user satisfaction is extremely high. Savings in operational costs for space heating and hot water generation amount approximately 34 000 € per year.

An appropriate design value for water heating in students' hostels is 50 litres with 60 °C per person and day, which corresponds to a low value for hotels with shower (Recknagel et al., 1997). The hostel in Molkereistrasse had the lowest energy consumption for hot water compared with 4 other hostels, which is likely to be caused by the efficient hot water distribution (one-pipe-distribution).

The results of a direct comparison of the ecological performance of passive houses with other buildings have only a limited significance due to a different benefit and comfort of the apartments. The benefit of passive houses is higher (or should be higher if designed and built accurately) regarding thermal comfort, hygrical comfort, daylight comfort, summerly comfort, air quality and larger useable floor area (because of less lost area for radiators and more comfortable area beside windows).

Recommendations are derived to improve the energy performance and the user satisfaction in the students' hostel Molkereistrasse. The consumption of electric energy can be reduced by energy efficient equipment, by a more frequent change of filters in the ventilation units, by a reduction of the ventilation in summer season and other measurements.

For the realization of sustainable students' hostels the passive house concept should be implemented comprehensively including concepts to reduce the consumption of energy for hot water generation and electrical energy, e.g. photovoltaic, energy efficient household appliances and lighting and others.

The passive house concept has proven to be effective to reduce the energy consumption and the fossil energy carriers for space heating and hot water generation. However, it is difficult to reduce the electricity consumption due to increasing comfort requirements regarding electrical equipment (e.g. tumbler, internet usage) and due to more powerful technical equipment (e.g. computer, larger TV-Sets, etc.). An increasing electricity demand has to be avoided to avert new power plants and to protect the climate. Therefore space heating and hot water generation should minimize electrical energy consumption and concepts to reduce electricity should be intensified and promoted.

Summary

In 2006, Energy Efficient Strategies (EES) was commissioned by the Department of the Environment, Water, Heritage and the Arts to determine baseline energy consumption estimates attributable to Australia's residential sector. The study, completed in early 2008, quantitatively benchmarks current and future residential energy consumption by end use, which allows the development of specific greenhouse response measures by industry and government.

For the project, EES developed a "bottom up" end-use model that tracked, at a state level, energy consumption from 1986 to 2005 with projections to 2020. The model predicted that residential energy consumption will increase by about 62% from 1990 to 2020.

The model separately tracked four main categories of end use; space conditioning (11 product sub-types), water heaters (9 product sub-types), cooking products (6 product sub-types) and appliances (major and minor – 32 product sub-types). In addition, the four main fuel types of electricity, mains (natural) gas, LPG and wood were also tracked, this allows for future greenhouse gas emissions to be estimated.

The end-use model developed by EES includes complex stock models of each end use, covering ownership, technical attributes and usage patterns. For example, the model for space conditioning appliance stock was linked to a housing stock model and a space conditioning load module. Space conditioning loads are based on simulation modelling of typical building shells combined with 20 years of historical weather data across 10 climate zones. The complexity of the model is also demonstrated by the water heating stock model, which was able to explicitly model solar contributions in addition to boosting fuels.

The EES model can now be used to evaluate the impacts of a wide range of policy options at a state or national level, ranging from minimum energy performance standards (MEPS) for televisions to retrofitting of ceiling insulation in existing dwellings.

1 Background

The report titled *Australian Residential Sector Baseline Energy Estimates 1986-2020* (EES 2008) published in June 2008 was commissioned by the Department of the Environment, Water, Heritage and the Arts (DEHWA) to determine end use energy consumption estimates in the residential sector and to provide a quantitative foundation for the development of greenhouse response measures by industry and government. The study is an update of the first baseline study that was commissioned by the Australian Greenhouse Office (AGO) and published in 1999 (EES 1999). This paper summarises the bottom up modelling approach developed under this project. The published report (EES 2008) provides detailed documentation model inputs and outputs and associated assumptions.

The study covers Class 1 and Class 2 buildings as defined by the Building Code of Australia - this primarily includes private residential dwellings that are separate (e.g. stand-alone houses) and attached (e.g. blocks of flats, town houses, terrace houses). Energy use by appliances and equipment in households is covered in the study. Minor commercial activities that were undertaken in the home such as home offices were also included. However, residential components of commercial establishments were not included.

The study estimates energy consumption in the residential sector from 1986 to 2020. The study examines all major stationary energy end uses including electrical appliances and equipment, heating/cooling, water heating and cooking. There is particular attention given to space heating and cooling in residential buildings:

the interaction of the thermal performance of the building shell, heating and cooling regimes and the product type, fuel mix and energy efficiency of space heating and cooling equipment together with actual climate data. Fuels covered include electricity, mains gas (reticulated natural gas which is primarily methane), LPG (primarily propane) and wood for space heating. The energy contribution of solar water heating to total water heating energy requirements was also explicitly estimated in this study. Fuels not covered by this study include black coal, coke, brown coal briquettes, kerosene, heating oil, automotive diesel oil (ADO) or industrial diesel fuel (IDF). Wood for cooking and hot water was not estimated, but were considered to be negligible. Energy consumption of vehicles or engines was also not covered in this study.

2 Methodology Outline

The end-use model was developed using a wide range of data sources and provides estimates at a state level for all major energy sources. The model takes the following factors into account when estimating energy consumption by end use, fuel, state and year:

- Number of households over time and the average size of these households.
- Number of each appliance type per household over time (ownership and penetration).
- Key characteristics of new appliances entering the market each year, plus average appliance life and associated retirements, which were used to generate a stock-weighted average value in each year.
- Data on usage patterns and other aspects of user behaviour and interaction that impact on energy consumption of appliances (applied to the stock present in each year).
- Impact of climate on space heating and cooling requirements (all households were divided into one of 10 national climate zones – most states were covered by several climate zones).
- Information on new house construction at a state level (e.g. materials, construction type, size).
- Interactions of climate on water heater energy such as hot water requirements, cold water temperatures and the performance of solar systems.

In all, nearly 60 different end use and fuel combinations were separately modelled using this approach.

Data was synthesised by means of an end-use model to estimate energy consumption from 1986 to 2020 under a base-case scenario (Business as Usual (BAU) with existing energy program measures). The BAU scenario incorporates the impact of Australian energy policy programs that were already in place up to mid 2007 or finalised and scheduled to be introduced before 2009 (e.g. minimum energy performance standards (MEPS) for air conditioners in 2007).

The end use model is based on a series of stock models which accounts for the average technical characteristics of both new appliances and buildings entering the stock and old ones leaving the stock to provide a stock-weighted average from 1986 to 2020.

The main inputs into the appliance end-use model are:

- Appliance attributes – these are typically capacity or other attributes that affect energy consumption, including energy efficiency.
- Ownership – this is data on the presence of the total number of products that consume energy in households.
- Determination of appliance usage parameters (e.g. frequency and duration of use, climate impacts, temperature settings for washers etc).

The housing stock model was complex as it accounted for the key attributes of the building shell stock in each state as well as considering climatic data. Dwellings in each state were allocated into one of 10 climate zones, that were selected to cover the major climate zones/population centres in Australia. Dwellings in each state were apportioned to the relevant climate zone on the basis of the number of households in each postcode area as reported by Australia Post. Appliance ownership data and occupancy information together with estimated zoning within the residential stock was applied to the Building Shell simulation software (a modified version of AccuRate© (www.nathers.gov.au) to generate heating and cooling demand. One of the limitations of the study related to the fragmented nature of regional data on appliance ownership and fuel availability, which meant that it was considered to be uniform across each state.

Having completed the setup and operation of all the end use modules, a calibration check was undertaken. This check involved the collation of all of the energy consumption estimates for each year, fuel type and each state and territory. This was followed by a comparison against actual top down data for the same period. In all cases Australian Bureau of Agricultural and Resource Economics (ABARE) data has been used as the primary top down source. Where possible published data from the Energy Supply Association of Australia (ESAA, formerly Electricity Supply Association of Australia) and the Australian Gas Association

(AGA) was also used for some state-level comparisons. In some cases, state utility data was made available as part of the review process. Some small adjustments to some stock model parameters were required to calibrate the model estimates with actual energy consumption data.

3 Main Findings

3.1 Overall Trends

The study estimated that the residential sector energy consumption in 1990 was about 299 PJ (electricity, gas, LPG and wood) and that by 2008 this had grown to about 402 PJ and is projected to increase to 467 PJ by 2020 (Figure 1). The residential energy consumption is estimated to increase during the Kyoto commitment period (2008-12) by between 135% and 141% compared to 1990 levels. This increase coincides with a continuing trend towards an increased proportion of the total residential energy demand being met by electricity (high greenhouse gas intensity) and a decrease in the use of wood (low greenhouse gas intensity). It is likely that this predicted growth in energy use in the residential sector will be at least matched by the growth in greenhouse gas emissions (ie at least 135% above 1990 levels by 2008). On the basis of these estimates it could be argued that the residential sector will fail to make an equitable contribution to the Kyoto emissions target of 108% above 1990 emissions levels.

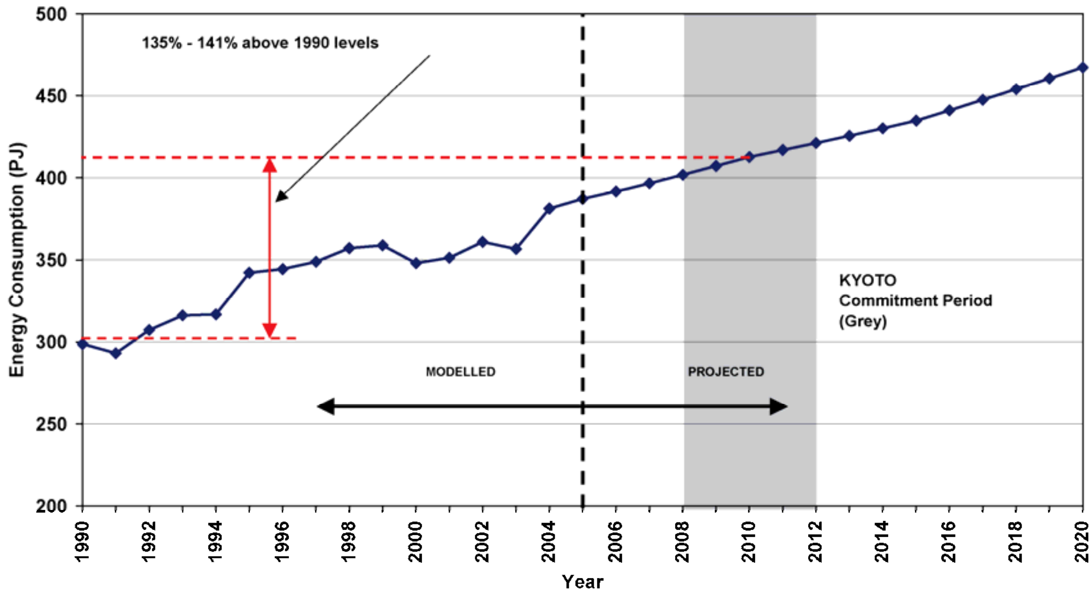

Figure 1 Trends in Energy Consumption in Australia's Residential Sector from 1990 to 2020. The Kyoto commitment period of 2008-12 is shaded grey. (EES 2008)

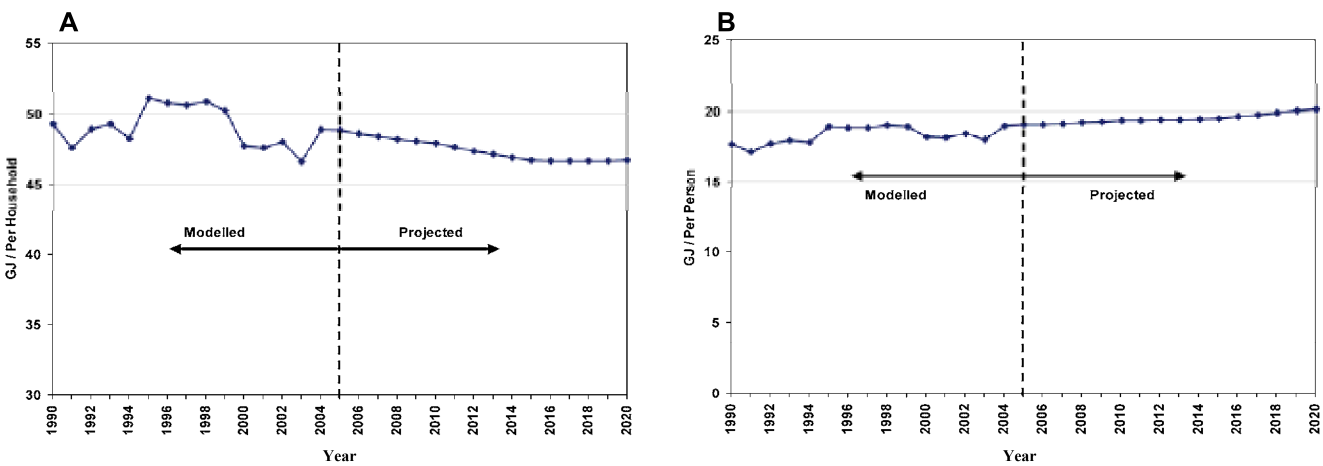

Figure 2 Trends in Australia's Residential Energy Use a) per household and b) per person– from 1990 to 2020 (EES 2008)

Dividing the total residential energy consumption by the estimated number of households in the corresponding year, enabled the energy consumption per household to be estimated. Since 1990 the average energy consumption per Australian household has remained relatively constant apart from the influence of year-to-year climatic variations that impact significantly on space conditioning energy demand (Figure 2a).

Projecting forward to 2020 there is expected to be about a 6% decline in energy consumption per household compared to 1990 levels. This decline is achieved despite expected increases in service deliveries to households, particularly in space conditioning and in a diverse range of appliance types such as larger more power-intensive televisions and an increase in standby energy consumption, lighting, computers and other home entertainment. The decline in energy consumption per household is primarily being driven by existing and planned energy programs designed to improve energy efficiency of appliances and the building shell.

By dividing the total residential energy consumption by the population in the corresponding year, the trend in per person residential energy consumption shows a steady but modest increase from 17 GJ/person in 1990 to 20 GJ/person in 2020, or a 20% increase over the study period (Figure 2b). This increase in energy consumption per person is partly being driven by a decline in persons per household, as there are some forms of fixed energy consumption that are associated with each household.

3.2 Trends By Fuel Type

The contribution of electricity to residential energy consumption is predicted to increase from 46% in 1990 to 53% in 2020 (Figure 3). Gas consumption is also expected to increase from 30% of total energy consumption in 1990 to 37% in 2020 while wood is predicted to decease from 21% to only 8% over the same period. LPG use will remain relatively unchanged and is expected to contribute to 2% of energy use in 2020.

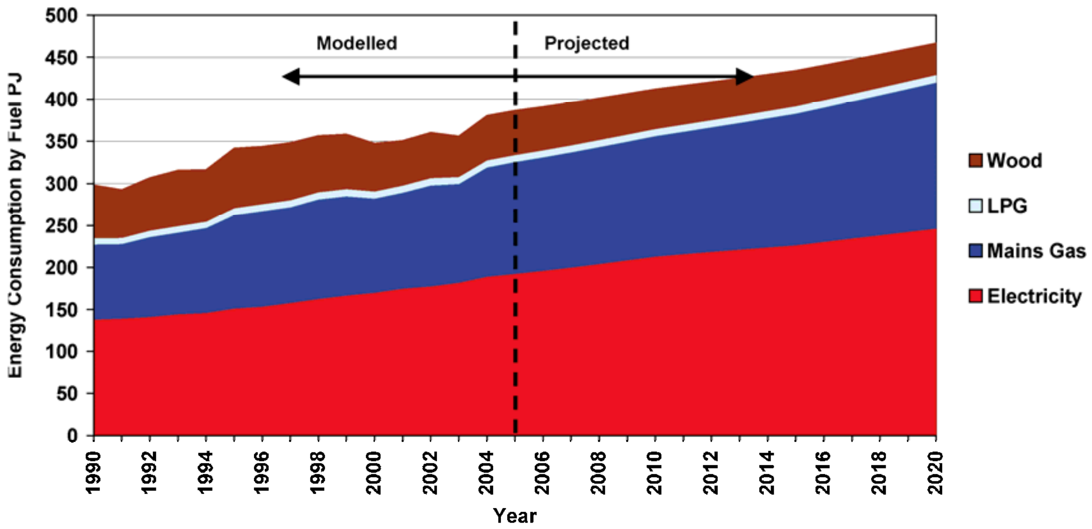

Figure 3 Trends in Residential Energy Consumption by Fuel Type – Australia 1990 to 2020 (EES 2008)

3.3 Trends By End Use

The national trends in energy consumption by each major end use from 1990 to 2020 are presented in Figure 4. Growth in electrical appliance energy consumption was the largest among major end-uses and was estimated to increase from 70.5 PJ in 1990 to 169.4 PJ in 2020, which represents an increase of 4.7% per annum. By 2020 energy use by electrical appliance is forecast to almost match space heating as the largest single energy use in the average Australian household. Energy demand for space heating is forecast to continue to rise but not at the same rate as for appliances (1.3% average growth per annum, 1990 to 2020).

Water heating was the other major energy use and after plateauing in 2004 is expected to decline slowly to 2020. Water heating is the only major energy use predicted to decline over the study period, principally as a result of various energy programs undertaken by Commonwealth and State/Territory Governments. The key drivers for changes in water heating energy are an increase in gas and solar technologies with a corresponding decrease in electric storage hot water. The declining demand for hot water has also resulted from an increase in water efficient appliances such as front loading washing machines and low-flow shower heads combined with a decline in the number of people per household.

Cooking energy is forecast to undergo slow but steady growth of approximately 1.8% per annum over the study period, roughly in line with the growth in the number of households. There is a trend towards gas cook tops and electric ovens, which is driven by consumer preference and overall performance. Cooking energy consumption remains a modest share of total energy consumption.

Of all the major end uses, space cooling is forecast to show the most rapid growth over the study period with an average growth of 16.1% per annum. This growth comes off a very low energy base of 3.0 PJ in 1990, so even with this high rate of growth in total energy terms by 2020 energy consumption for space cooling is only 17.7 PJ or 4% of total residential energy consumption in that year. However, despite its low contribution to total energy consumption, space cooling is an end use that attracts considerable political and policy attention due to its very poor load factor and the potential to create major problems for the electricity generation, transmission and distribution systems on peak summer days.

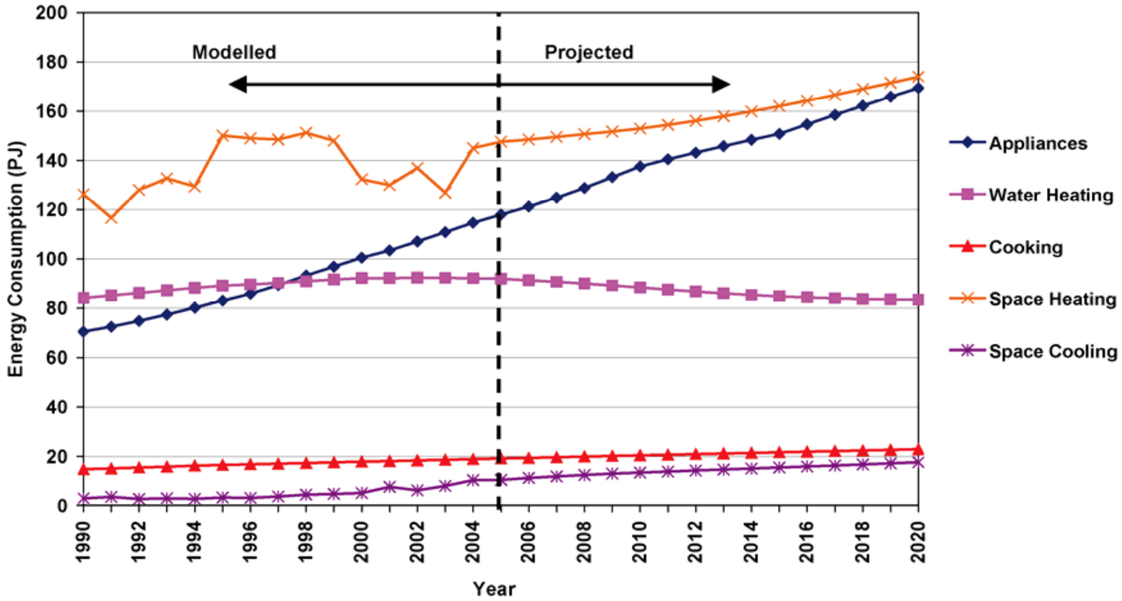

Figure 4 Trends in Total Energy Consumption in Australia's Residential Sector by End Use from 1990 to 2020 (EES 2008).

3.4 Trends in Building Shell Efficiency

Analysis of the building approval data has revealed that the average size of new dwellings is increasing rapidly. To illustrate this, the total number of households and the total floor area of the housing stock is presented in Figure 5. From 1986 to 2020 the total floor area of residential dwellings is expected to increase by 280% and the number of households is projected to increase by 177% over the same period.

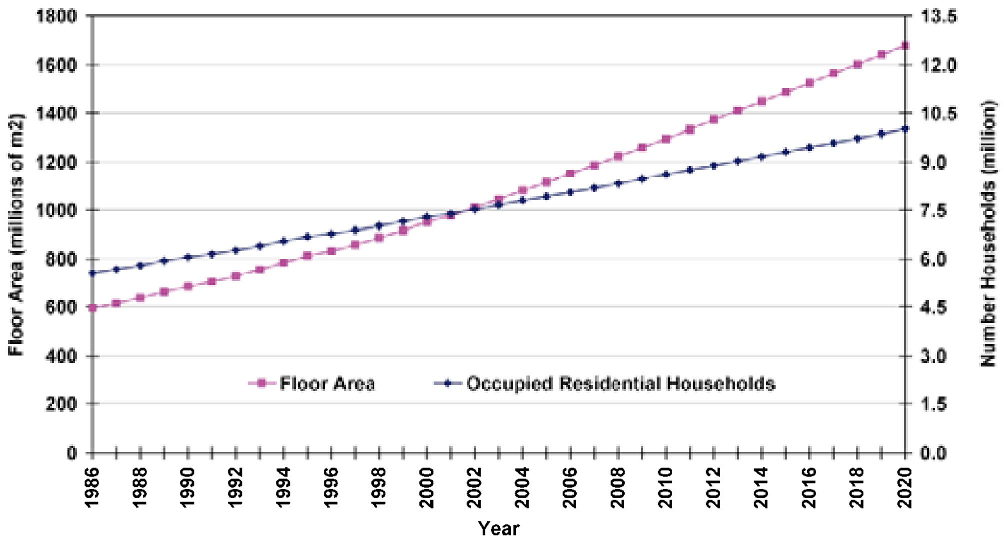

Figure 5 Trends in Floor Area and Number of Occupied Households in Australia's Residential Sector from 1986 to 2020 (EES 2008).

The national trend for building shell efficiency (i.e. total potential space conditioning load per square metre of floor area), shows a modest but steady improvement over the study period, down from 280 MJ/m^2 to approximately 200 MJ/m^2 (Figure 6). This improvement is being driven by policy initiatives that commenced in Victoria and the ACT in 1990 and by 2005 had expanded to include all states through the Building Code of Australia (BCA). Unfortunately the improvement in building shell efficiency over the study period has been outpaced by the rate of increase in average floor area. This has occurred to the extent that on a per household basis the potential space conditioning load (i.e. whole house heating and cooling in accordance with the default schedules of operation in the Nationwide House Energy Rating software - AccuRate) is projected to increase from about 30 GJ to 35 GJ per household per annum from 1986 to 2005 (Figure 6 - secondary "y" axis, blue line). Post 2005, where a standardised climate has been assumed the trend is reasonably steady suggesting that efficiency improvements are offsetting increases in average floor areas.

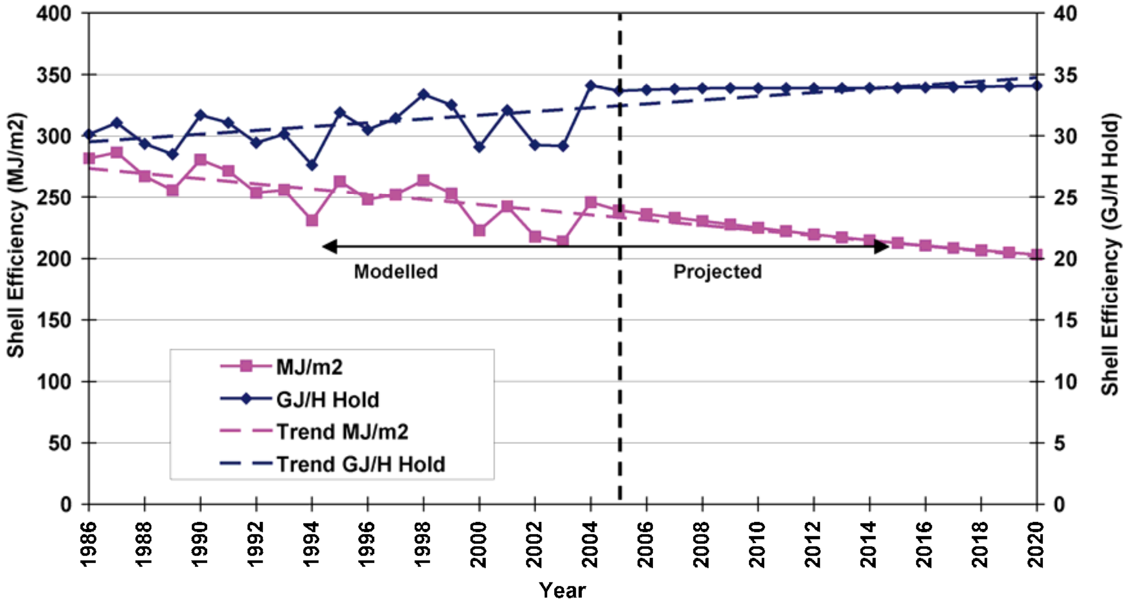

Figure 6 Trends in building shell efficiency in Australia's Residential Sector from 1986 to 2020 (EES 2008)

4 Emerging Trends

Space Conditioning

Energy demand for heating and cooling is projected to increase despite the introduction of minimum building shell performance standards in all jurisdictions. The main factors driving this trend are:

- The floor area of the average new dwelling continues to significantly exceed that of the stock average, thereby driving up the average floor area of the stock of dwellings as a whole over time. In addition householders continue to undertake renovations that increase the floor areas of their existing dwellings, particularly the older detached dwellings.
- The share of dwellings with whole house heating systems, particularly gas heating, is projected to rise significantly over the remainder of the study period, especially in the colder states.
- The share of dwellings with space cooling installed is projected to continue to rise significantly over the remainder of the study period – penetration of air conditioners has more than doubled in the past 10 years to around 65%. While the energy consumption for cooling is still relatively modest, this will have increased by a factor of five from 1990 to 2020 under current trends.
- The relatively recently introduced building shell performance standards only affect approximately 2% of the total stock per annum and in reality provide only a modest level of improvement compared to the BAU case in terms of total energy consumption projections to 2020. Nonetheless, stringent standards for new dwellings will have significant long-term energy impacts, which will continue to accrue beyond 2020. New housing built now with poor building shell efficiency will be a large long-term liability for future generations.

Additional analysis was undertaken for space conditioning loads using actual weather data over the past 20 years. The objective was to simulate energy demand in a set of dwellings where the housing stock characteristics were constant so that the only variable influencing space conditioning was the weather conditions. This type of analysis was designed to reveal the trends in potential space conditioning demand driven by climate variability independently from trends in housing stock type and numbers. Interestingly in all parts of Australia except the tropical north, the trend in predicted potential heating load over the study period was downward and the trend in cooling load was upwards as shown for South Australia(Figure 7). This trend is broadly consistent with predictions for climate impacts associated with global warming.

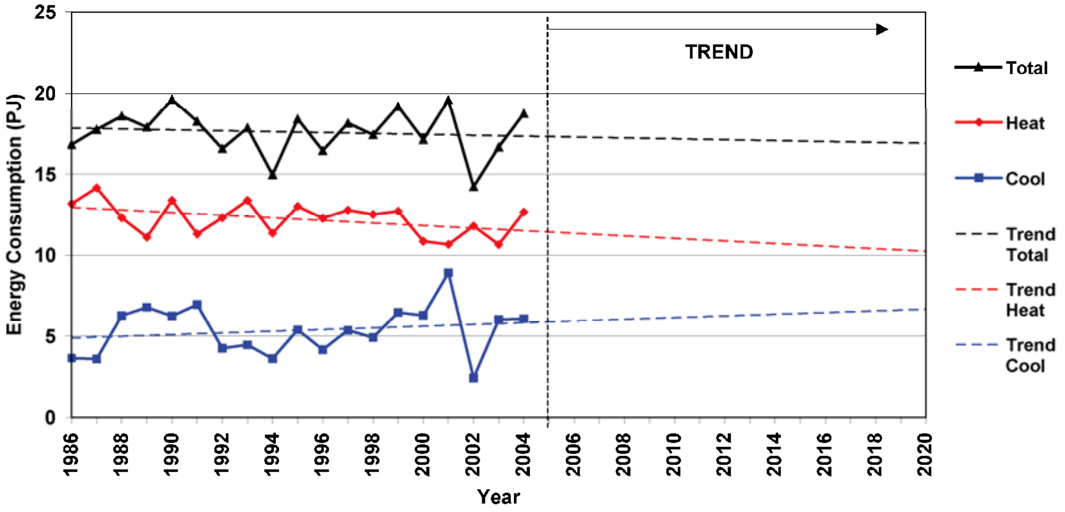

Figure 7 Space Conditioning Loads for Total, Heating and Cooling for Fixed Stock in the Residential Sector in South Australia from 1986 to 2020 (EES 2008).

Water Heating

In 1990 water heater usage accounted for approximately 84 PJ, this is estimated to have peaked at approximately 92 PJ in 2002 but is projected to slowly decline to 84 PJ by 2020, despite an increase in household numbers. The most significant trend over the study period for water heater energy use is the shift away from resistive electric heating (primarily storage systems) towards natural gas or combinations of solar with gas or electric boosting.

Increased natural gas use has coincided with the expansion of the natural gas network, which is growing steadily, but still only covers 46% of Australian households. Instantaneous gas units have also gained favour because of their compact size and their capacity to provide a continuous flow of hot water. Solar boosted water heating has also gained popularity over recent years (although the installed base was relatively small up to 2003 with a national average of about 4%). This increasing trend is being driven largely by initiatives at the state level, particularly the provision of rebate schemes and requirements for new homes to exclude or discourage electric storage water heaters. Some of these schemes are also boosting the stock of heat pump “solar” water heaters, which may become more significant over time as the capital costs are likely to fall.

The application of minimum energy performance standards (MEPS) (1999 and 2005 for electric and 2009 for gas), existing and emerging state and BCA requirements mandating the use of lower greenhouse intensive technologies (GWA 2007) and the various incentive schemes designed to encourage greater use of solar and heat pump technologies all combine to result in an overall downward trend in total energy consumption for water heaters from 2002 to 2020.

Refrigerators/Freezers

Refrigerator and freezer energy use grew slowly at start of the study period but has been in decline since 2004. In 1986 refrigerators and freezers usage combined accounted for approximately 26 PJ and by 2020 this is projected to have decreased to approximately 24 PJ. This decrease is predicted to occur despite an increase in total stock (refrigerators and freezers) from approximately 10 million units in 1986 to an estimated 17 million units by 2020 (70% increase).

Since the early 1990s the average energy consumption of new refrigerators and freezers has improved significantly, with a 40% reduction from 1993 to 2006 (EES 2006). These improvements have been driven by both the energy labelling program and by the introduction of MEPS requirements in 1999 followed by more stringent levels in 2005. The 2005 MEPS levels will continue to place downward pressure on energy growth for these products over the study period.

IT Equipment

Energy use of personal computers, laptops, monitors and miscellaneous Information Technology (IT) equipment has been growing rapidly since the start of the study period. In 1986 energy use of IT equipment was negligible, this was estimated to have increased to nearly 7.9 PJ by 2005 and is projected to continue to rise to almost 15 PJ by 2020.

The main drivers for the increase in energy consumption have been:

- An increase in the total number of households.
- A rapid increase in ownership of personal computer laptops and related equipment over the study period. Since 1986 ownership of personal computers has risen from virtually zero to 0.87 by 2005. Ownership is projected to rise to nominally 1.25 for personal computers and 0.65 for laptops by 2020.
- For personal computers, on-mode power consumption has virtually doubled from approximately 50W to more than 100W at present.
- Hours of use have almost doubled since the early 1990s from approximately 500 hours per annum to more than 900 hours per annum. This is projected to continue to rise to approximately 1200 hours per annum by 2020. There is a large potential for energy management of these products to reduce energy consumption.

Entertainment (Games, STB and TVs)

Games consoles, set top boxes and television energy use has been growing significantly in recent years.

In particular, television energy use has been growing steadily since the start of the study period but is now projected to grow more rapidly over the remainder of the study period. In 1986 TV usage accounted for approximately 3 PJ and in 2005 was estimated to have increased to approximately 12 PJ and is projected to exceed 45 PJ by 2020 (without the introduction of MEPS and energy labelling which is being finalised).

The main drivers for the projected rapid increase in energy consumption are as follows:

- The average number of televisions per household is projected to increase from approximately 1.5 in 1986 to a projected 2.1 by 2020. One in 4 households now buy a new television each year.
- Hours of viewing have been rising steadily over the study period from approximately 1500 per annum in 1986 to a projected 2800 hours by 2020 per TV.
- Newer technologies such as Plasma and LCD have been driving a trend towards a very rapid increase in average screen size. This trend has resulted in a rapid rise in energy consumption from an average on-mode consumption of approximately 65W in 1986 to 100W in 2005 and continuing to grow to an estimated 230W by 2020.

Lighting

Lighting energy use had shown steady and relatively strong growth since the start of the study period but is expected to decline from 2010 to 2015 then begin to rise again for the remainder of the study period. In 1986 lighting energy usage was approximately 13 PJ and by 2005 this is estimated to have increased to nearly 25 PJ with a peak of just over 27 PJ in 2010. Following a dip in energy consumption post 2010, consumption is projected to rise again to approximately 25 PJ by 2020.

Apart from the growth in the number of households and the increase in floor areas of those households the main drivers influencing the general upward trend in lighting energy consumption are:

- Since the early 1990's there has been a strong growth in the use of quartz halogen (QH) low voltage lighting. This change in technology is doubling the power density of these types through increased illumination levels.
- Compact fluorescent lamps have been slowly gaining market share since their introduction in the late 1980's. The penetration of this relatively efficient technology (approximately 50-65 lumens per watt) is expected to increase rapidly with the announced phase out of incandescent lamps in 2009. This is expected to drive lighting energy consumption downwards for the following 5 years.
- By 2015 it is expected that practically all standard incandescent lamps will have been removed from the stock (largely replaced by CFLs). Beyond 2015, increases in household numbers and the expected continuing popularity of QH lamps is projected to drive energy consumption upwards again. However, future regulatory proposals may ameliorate these trends.

5 Conclusions

The titled *Australian Residential Sector Baseline Energy Estimates 1986-2020* (EES 2008) provides one of the most detailed assessments of residential end use energy consumption ever undertaken in Australia. The "bottom up" end use modelling approach, while by no means unique or radical, has been applied in a comprehensive and systematic fashion to the residential sector to cover nearly all significant end uses. The bottom up estimates have been reconciled with state level top down data and there is generally good agreement, although the data suggests that there may be some questions regarding the reliability of national energy data share by sector which has been compiled since 2000.

Due to concerted efforts over many years, many areas now have rich data sets for modelling and therefore good modelling inputs can be developed. Areas such as ownership and attributes for new appliances and equipment are generally well documented. Despite the detailed modelling undertaken, the study revealed that there is a paucity of data in some areas. In particular, there is little individual product end use metering data which is critical to quantify the impacts of human interactions (frequency and duration of use) and climate and weather related impacts. This is one area where data collection efforts need to be expanded. Another area with poor data is average age and the distribution of age – very little documentation on retirements for either appliances or buildings exists. Lighting is another area where there is poor data on the stock and energy consumption.

HOW 'ZERO' IS A 'ZERO CARBON' HOME?- A COMPREHENSIVE ASSESSMENT OF A 'ZERO CARBON' HOME

Yee Chow[1]

[1] Centre for Environmental Strategy, University of Surrey, Guildford, Surrey, GU2 7XH, UK, y.chow@surrey.ac.uk

Keywords: zero carbon, policy, building energy life cycle, microgeneration technologies

Summary

The UK government's domestic 'zero carbon' policy is incredibly challenging, requiring a vastly improved energy efficient home as well as introduction of microgeneration technologies into the dwellings in order to meet the target. However, by achieving the zero carbon status, it neglects the potential increase in the embodied carbon resulting from the increased insulation and microgeneration technologies being implemented. This paper evaluated the life cycle of the zero carbon homes through comparison of three eco-home (energy efficient home and two alternative zero carbon home) against a normal base case dwelling. It found that the additional embodied carbon can account for up to 32% of the total life cycle carbon compared with the base case (40 year life cycle with technology replacement rate of 20 years). The results also showed that different technologies performed better than others, wind turbine for example are less carbon intensive than photovoltaics. The research also highlights the lack of research as well as the difficulties in measuring the embodied carbon of microgeneration technologies. Nonetheless, despite the limitations it is important that the carbon emissions should be accounted for holistically in the policy development and in the zero carbon definition. However, more research should be carried out into life cycle carbon assessment of the eco-homes and the microgeneration technologies in order to substantiate the findings from this paper.

1 Introduction

Buildings consume large amount of energy over its life cycle and hence one of the biggest emitters of carbon dioxide and contributor to climate change. It has therefore been a key target sector for government in their energy and climate strategies initiatives. With UK's reserves of oil and gas declining, reducing energy consumption and energy independence has also been high on the political agenda.

The demand for heat and electricity directly contributes to our carbon impact. Our homes are largely heated and powered by fossil fuels (gas, oil, electricity) with 80% of electricity itself created by fossil fuels (coal, gas, oil) (SDC 2007). Carbon emissions from the domestic housing sector represent around 27% of the total UK emission (41.2MtC), with 73% of the emissions dominated by space and water heating (Figure 1).

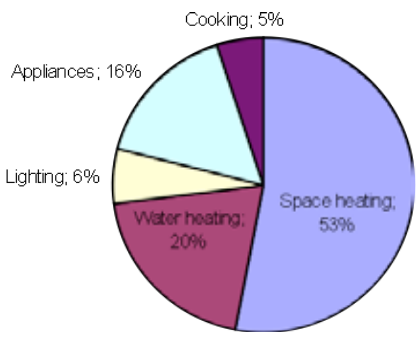

Figure 1: Domestic carbon emissions by end use. Average household emissions 1.54 tonnes carbon per year (DEFRA 2006)

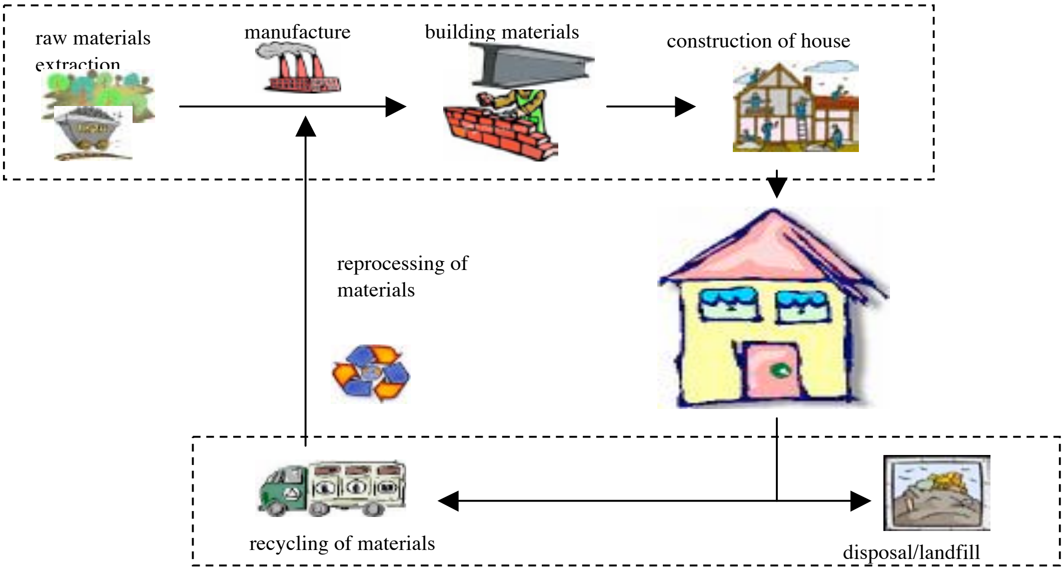
1.1 Building Life Cycle

To evaluate the zero carbon policy it is important to review the building life cycle and appreciate the carbon emissions from the entire life cycle. The environmental impacts associated with each component of the building life cycle vary between different stages. In terms of energy use and carbon emissions, the operation phase account for the largest proportion with the material production phase constituting a significant proportion of energy use as well. The emissions from Figure 1 relates to only the operational phase of the life cycle. However, the embodied carbon has not been factored but can account for a significant proportion of the life cycle carbon of a dwelling, typically up to 20% in a conventional dwelling. More details of the embodied energy/carbon aspects of the building life cycle is detailed in Section 2.2.



1.2 'Zero carbon' policy

The zero carbon policy was announced in December 2006 as a key government initiative to address carbon and sustainability issues in the housing sector. The policy only covers the new build housing. Although, new housing currently represents only 1% of the total housing stock, it is expected to increase to constitute 25% of all housing stocks by 2050 (Barker 2004). Since the possibilities for achieving early improvements in environmental performance are particularly good in new housing (WWF 2003), there is clearly an opportunity to make a significant contribution by incorporating carbon reducing measures at the design and build stage.

The Code for Sustainable Homes, which became effective since April 2007, is the main policy vehicle from which the zero carbon targets will be achieved. It is widely regarded as one of the key government policy initiative to drive forward sustainability in new housing developments. The Code introduces a six star rating scheme similar to that of electrical white goods, and is designed to provide a marketing tool for developers and consumers. The Code sets minimum standards of carbon emissions for each Code level as indicated as follows:

Table 1: Government proposed energy/carbon performance targets over time (DCLG 2006)

Date	2010	2013	2016
Energy/carbon improvement as compared to Part L (Building Regulations 2006)	25%	44%	Zero carbon
Equivalent energy/carbon standard in Code	Code Level 3	Code Level 4	Code Level 6

The Code technical guidance defined a zero carbon home as one with 'zero net emissions of carbon dioxide (CO_2) from all energy use in the home'. The definition encompasses all energy use in the home (including energy for cooking, TVs, computers and other appliances) rather than just those energy uses that are currently part of building regulations (space heating, hot water, ventilation and some lighting) (DCLG 2006).

The precise definition of what is meant by zero carbon is unclear at the moment, and the government is currently in the process of defining what would constitute the definition, for example, whether offsite renewables offset would be allowed under the definition. This has significant implications in terms of how the energy of the dwelling is supplied, and in turn has implications on the embodied carbon of the building life cycle.

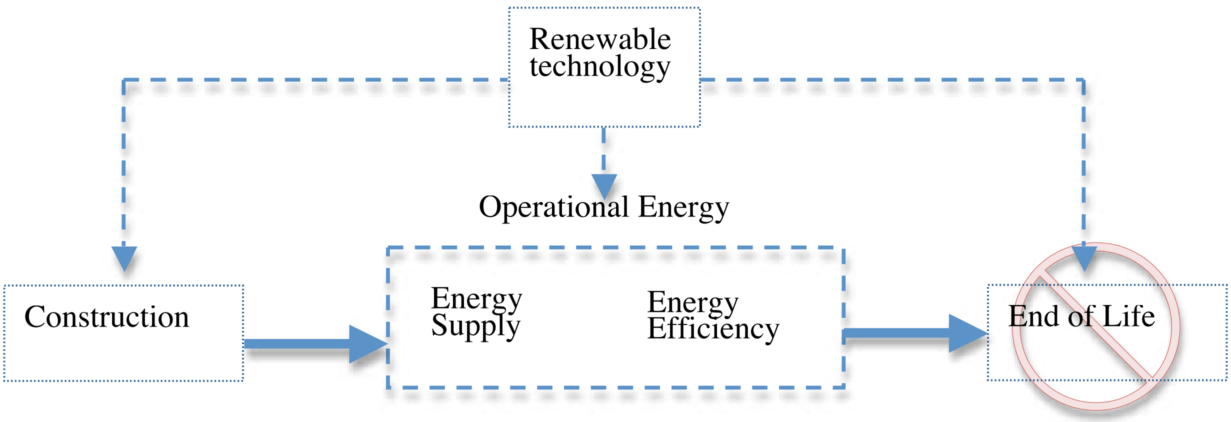
The zero carbon policy also only covers the carbon emissions resulting from the operational phase of the dwelling. It does not account for the embodied carbon from manufacture, transportation and construction of the house and its components.

The aim of this paper is to evaluate the zero carbon policy by assessing the carbon performance of a zero carbon home over its life cycle. It will compare the components of meeting zero carbon through implementation of a range of technological measures, and assess their performance against a base case conventional dwelling. It is intended that the results would provide a more holistic life cycle carbon assessment of a zero carbon home, and hopes that it will help inform policy makers and housing developers on the most efficient ways of achieving the zero carbon targets.

It is important to note that the aim of the paper is not to provide accurate energy and carbon figures, but rather to provide an indication of the rough requirements in order to meet the zero carbon targets and to appraise the zero carbon policy. Nevertheless, the modelling will encompass as much features and details as possible to produce reasonably accurate and confident results.

2 Methodology

A model has been developed to model the life cycle energy requirements of a typical home, including the embodied energy/carbon, operational energy and energy offset from microgeneration technologies. Energy relating to end of life has not been factored into the model as it is quite difficult to model the impacts and in any case, it is assumed that it will not have a significant impact over the building life cycle.



Sections 2.1 – 2.3 describes each stages of the life cycle model and the main parameters and assumptions used in the modelling.

2.1 Operational energy

A simplified operational energy demand model has been developed. The purpose of this model is to obtain a general indication of the energy demand of a typical home that is being modelled. It is not intended to provide an accurate representation of the energy use of a home. As such, only the major energy usage of the home has been modelled, i.e. energy for space heating, water heating and electricity consumption.

The energy demand for hot water has been estimated with a function based on the floor area expressed in Standard Assessment Procedure (SAP) 2005. Estimation of electricity consumption has been calculated based on the assumptions described in Building Research Establishment Domestic Energy Model (BREDEM). Low energy lighting and appliances has been assumed with a consumption level of 40% lower than average electricity usage by normal households. The space heating demand has been estimated based on the degree day method described in BREDEM and SAP 2005 (Mortal 2007). Description of the dwelling modelled is provided in the model parameters in Section 3.

2.2 Technological requirements to meet zero carbon

Meeting zero carbon is incredibly challenging. Previous work (Chow 2008, Mortal *et al* 2007) have identified the most cost effective measures in meeting the zero carbon requirements. The most efficient and cost effective way is to reduce the initial base line energy demand of the dwelling through measures such as increase insulation and use of energy efficient fittings, followed by provision of microgeneration energy technologies

There are a number of microgeneration technologies suitable for reducing the operational energy and carbon emissions of a building. However, the technologies vary considerably in terms of their energy and carbon performance, reliability, and cost effectiveness. A feasibility study of the renewable technologies from previous research identified biomass, photovoltaics (PV) and wind turbine as the best options to meet zero carbon for a domestic dwelling.

Ground source heat pumps (GSHP) was deemed unsuitable due to the substantial additional electricity requirement and therefore requiring additional electricity capacity to be generated from other technologies. Solar hot water was considered suitable, although they are limited to a fixed proportion of annual hot water demand it is able to offset, and therefore it was deemed more economical to have a larger biomass boiler to supply all the space and hot water demand of the dwelling.

Biomass is not considered carbon neutral due to the manufacturing, processing and transportation of the fuel, and therefore additional energy from PV or wind will be required to offset the additional carbon emission. This has been factored into the energy model.

2.3 Embodied energy

The embodied energy refers to all the energy required to produce, manufacture and install/construct a particular product. The most common methodology used for determining the embodied energy/carbon of a product is the life cycle assessment methodology.

Research has shown that the embodied energy of a building can account for a significant proportion of the life cycle energy use. However, in this assessment, only the additional embodied energy/carbon resulting from increase in materials and technological systems will be considered. The assessment will be based on the additional embodied carbon requirements over a defined base case (standard building regulation). It will therefore exclude all the main embodied carbon associated with the basic building materials required for construction of the structure and foundations of the house. However, the additional insulation for a low energy home will be factored into the model.

Measuring the embodied energy/carbon of the technologies is extremely difficult. The life cycle methodologies are dependent upon a number of factors and assumptions used within the system boundary:

- Variation of production methods of the technologies, impacting the quantity of energy required.
- Variation in the transportation requirements
- Variation in the raw materials used for production of the technologies by different manufacturers
- Location of the processing plants, and suppliers, again impacting the transportation requirements
- System boundary definition, for example, whether to include the energy required from the technology installers travelling to the dwellings.

In addition, the carbon intensity of the energy mix varies between different countries, and this will have an impact on the embodied carbon of the technologies. Embodied CO_2 is not directly proportional to embodied energy. Electricity generation generally has efficiencies of around 30%, as compared with heat generation efficiencies of around 80%. Processes that require high grade electrical energy will result in higher CO_2 emissions than those that run on low grade heat energy. It also depends on the energy source for that particular process. In Scandinavia for example, most of the power used in the aluminium industry comes from hydro-electric schemes and therefore has no embodied CO_2 in its manufacture (Bioregional 2008).

Embodied Carbon of Microgeneration technologies

The data used in calculating the embodied energy of the microgeneration technologies have been based on secondary research that has been carried out previously. Little work has been done to determine the embodied impacts of microgeneration technologies and therefore large assumptions are made about the embodied energy figures used in the model.

Photovoltaic cells are considerably energy intensive to produce. Substantial research has been done on the different photovoltaic manufacturers and types of photovoltaic cells (e.g. Wilson Young 1995, Knapp Jester 2001, Alsema Niuwlaar 2000). One of the most comprehensive work on photovoltaic cells have been from Bankier & Gale 2006, where they compared and reviewed some 16 previous research done on photovoltaics. Their research found that the total energy requirement for producing and installing a monocrystalline PV module was 6,400 MJ/m^2 (Bankier Gale 2006).

Comparatively few research has been done on domestic micro-wind turbines. There has been some research on larger scale turbines, particularly from Danish research. They estimated a large scale wind turbine to have an energy payback of a year. However, they are far more efficient than domestic sized turbines and therefore it had been assumed that the energy payback period for a 6kW turbine is a conservative 3 years. A Cambridge-MIT research estimated the embodied energy to be 13,000kWh per turbine (Woolf 2002).

There has been little or no research work done on biomass boilers. However, as this assessment is only focused on comparing the additional embodied energy, it has been assumed that the embodied carbon of a biomass boiler system is equivalent to that of a conventional boiler system. A biomass boiler requires additional infrastructure in terms of storage facilities, additional pipework, flue extractor, but these have been considered to be negligible in this assessment. Some embodied energy have also been allocated to the manufacture of biomass wood pellets. These have been provided by the Standard Assessment Procedure (SAP 2005).

There has been some research into embodied energy of insulation materials. These vary considerably between types of insulant used. Polystyrene insulation has the highest embodied energy (3770MJ/m^3) compared to natural materials such as mineral wool which only has an embodied energy of 970 MJ/m^3) (Canadian Architect 2000). For this assessment fibreglass insulation have been assumed for the model.

In summary, the figures used for the embodied energy calculations are as follows:

Technology	**Embodied energy (converted to kWh/unit)**	**Embodied carbon (carbon intensity assumed 0.083kgC/kWh)**
Photovoltaic (Monocrsytalline)	1,777 kWh/m^2	147 kgC/m^2
Wind turbine (6kW turbine)	13,000 kWh/turbine (6kW)	1,079 kgC/turbine (6kW)
Biomass boiler	Considered similar to conventional gas boiler with negligible increase in embodied energy. However, carbon emissions from biomass fuel have been accounted for.	Wood pellets- 0.007 kgC/kWh
Insulation (fibreglass)	270 kWh/m^3	22.4 kgC/m^3

3 Model Parameters

A simple model was developed to evaluate the life cycle energy consumption of a typical domestic home. Section 2.1 described the basic assumptions used in the model. To compare the impacts of the embodied energy resulting from reaching zero carbon, a case study of four identical homes each with varying energy performance features will be used. The four homes are identical in terms of their specifications but differ in their space heating energy demand and types of microgeneration technologies used.

The base case dwelling will resemble the current UK Building Regulation standards, and is based on the requirements under the 2005 Standard Assessment Procedure (SAP) for calculating energy demand for a domestic dwelling. Table 2 describes the basic reference values for the base case dwelling being modelled.

Table 2: Reference values of base case dwelling

Element or system	Value
House type	Two storey detached house
Total floor area	$128m^2$
Windows	25% of the total floor area
Walls	U=0.35 W/m^2K
Floors	U=0.25 W/m^2K
Roofs	U=0.16 W/m^2K
Thermal bridging	0.11 x total exposed surface area (W/K)
Windows	U=2.0 W/m^2K Double glazed, Frame factor 0.7, Solar energy transmittance 0.72 Light transmittance 0.08
Infiltration	0.5 Air changes per hour

The other three homes modelled against the base case will be significantly more energy efficient consisting of comparatively lower U-Values for the building elements. To achieve the U-values as specified, the insulation of the building elements were increased by 150mm to 200mm thick. Table 3 summarises the different reference values used compared with the base case dwelling.

The increase in embodied carbon in the insulation throughout the building elements has been factored into the model. However, the increase in other building structural elements to accommodate the increased width and associated structural requirements has not been included. It was deemed difficult to estimate the additional requirements and was also deemed negligible. This home will be referred to as an 'eco-home' in the context of this paper.

Table 3: Reference values of eco-home

Element or system	Value
Walls	U=0.13 W/m^2K
Floors	U=0.12 W/m^2K
Roofs	U=0.10 W/m^2K
Windows	U=1.0 W/m^2K Triple glazed

Modelling of the base case and 'eco-home' dwelling produced an estimated of the space and water heating and electrical energy demand, as summarised in Table 4.

Table 4: Estimated energy demand of base case and eco-home dwelling

	Base Case	Eco-Home
Space heating	11,880 kWh/yr	6,850 kWh/yr
Water heating	3,373 kWh/yr	2,867 kWh/yr
Electricity	4,157 kWh/yr	4,157 kWh/yr
Total	**19,410 kWh/yr**	**13,874 kWh/yr**

4 Results

Using the energy demand modelled, the appropriate microgeneration technologies were specified. There are a number of ways to meet all the energy demand to achieve zero carbon in a dwelling. Two options have been presented and analysed in this assessment.

Option 1- It was estimated that 41m^2 of PV panels with an output of 600 kWh/yr/m^2 and 10kW of biomass boiler with a 90% efficiency is required to supply all the energy required

Option 2- Alternatively a 6kW wind turbine with an annual energy output of 3,397 kWh/year and 13m^2 of PV panels are also able to supply all the electrical demand of the dwelling.

Table summarises the estimated energy demand and carbon emissions of the four case study modelled.

Table 5: Summary of energy demand and carbon emissions of the four dwelling type.

	Base Case (Building Regulations Part L)	**Eco-home (energy efficient home)**	**Eco-Home + Option 1 (biomass boiler and 41m^2 of PV panels)**	**Eco-Home + Option 2 (biomass boiler, 13m^2 PV panels and one 6kW wind turbine)**
Space heating	11,880 kWh/yr	6,850 kWh/yr	6,850 kWh/yr	6,850 kWh/yr
Water heating	3,373 kWh/yr	2,867 kWh/yr	2,867 kWh/yr	2,867 kWh/yr
Electricity	4,157 kWh/yr	4,157 kWh/yr	4,157 kWh/yr	4,157 kWh/yr
Annual carbon emissions				
Space heating	629.64 kgC/yr	363.05 kgC/yr	47.95 kgC/yr	47.95 kgC/yr
Water heating	178.77 kgC/yr	151.95 kgC/yr	20.07 kgC/yr	20.07 kgC/yr
Electricity	469.74 kgC/yr	469.74 kgC/yr	0 kgC/yr	0 kgC/yr
Additional embodied carbon over base case	0	573 kgC	6,623 kgC	3,570 kgC

4.1 Life cycle carbon analysis

The results showed that the different features of the homes and microgeneration technologies used result in varying levels of embodied carbon and operational carbon emissions. In order to provide a better and more holistic comparison of the carbon performance of the different dwelling types, a life cycle carbon assessment is performed.

The calculations of the life cycle carbon analysis is based on the following assumptions:

- The microgeneration technologies have been assumed to have a lifespan of 20 years.
- No carbon emissions associated with maintenance and repairs have been assumed.
- No discounting of the initial embodied carbon have been applied to the modelling.
- No change in carbon intensity have been assumed for the primary energy supply for the base case dwelling, i.e. gas and electricity. The same is true for biomass wood pellets.

Figure 2 displays the total cumulative carbon emissions of the four dwelling types over a 40 year life cycle. It shows that despite the initial increase in embodied carbon of the eco-homes due to the increased insulation and microgeneration technologies, the dwellings are still able to save significant amount quantity of carbon over the life cycle. However, the proportion of carbon saved differs depending on the type of microgeneration technology used.

Table 6: Summary of the potential carbon savings of the dwellings over the base case

	Base Case (Building Regulations Part L)	**Eco-home (energy efficient home)**	**Eco-Home + Option 1 (biomass boiler and 41m² of PV panels)**	**Eco-Home + Option 2 (biomass boiler, 13m² PV panels and one 6kW wind turbine)**
40 year life cycle carbon savings over base case (percentage)		22%	68%	80%

Table 6 summarised the potential carbon savings over the base case and showed that a home with energy efficiency measures and microgeneration technologies can reduce carbon emissions by up to 80% compared with the base case dwelling over a 40 year life cycle. However, these 'zero carbon' homes still account for a significant proportion of carbon emissions, up to 15,000 kgC more in embodied carbon.

The results also showed that insulation are very efficient in reducing carbon emissions, being able to reduce a significant proportion of carbon emissions over its life cycle with a little increase in embodied carbon (over 10 tons can be saved over a 40 year life cycle with just a 500 kg increase in embodied carbon).

Sensitivity

The results from this paper have been calculated based on a number of key assumptions made on the embodied carbon of the microgeneration technologies and their life span. These assumptions have been described throughout Sections 2 and 3. Changes in these factors are likely to affect the life cycle carbon performances significantly. As such, it is difficult to evaluate the performance of the microgeneration technologies with any significant amount of confidence. Nonetheless, it indicates that embodied carbon associated with the zero carbon homes can account for a substantial increase in the proportion of the life cycle carbon emissions.

The life cycle carbon calculations are also dependent upon the system boundary of the study and whether indirect embodied carbon, such as those resulting from operation, maintenance and transport of the microgeneration technology industry, have been considered. These can contribute significantly to the embodied impacts of the technologies.

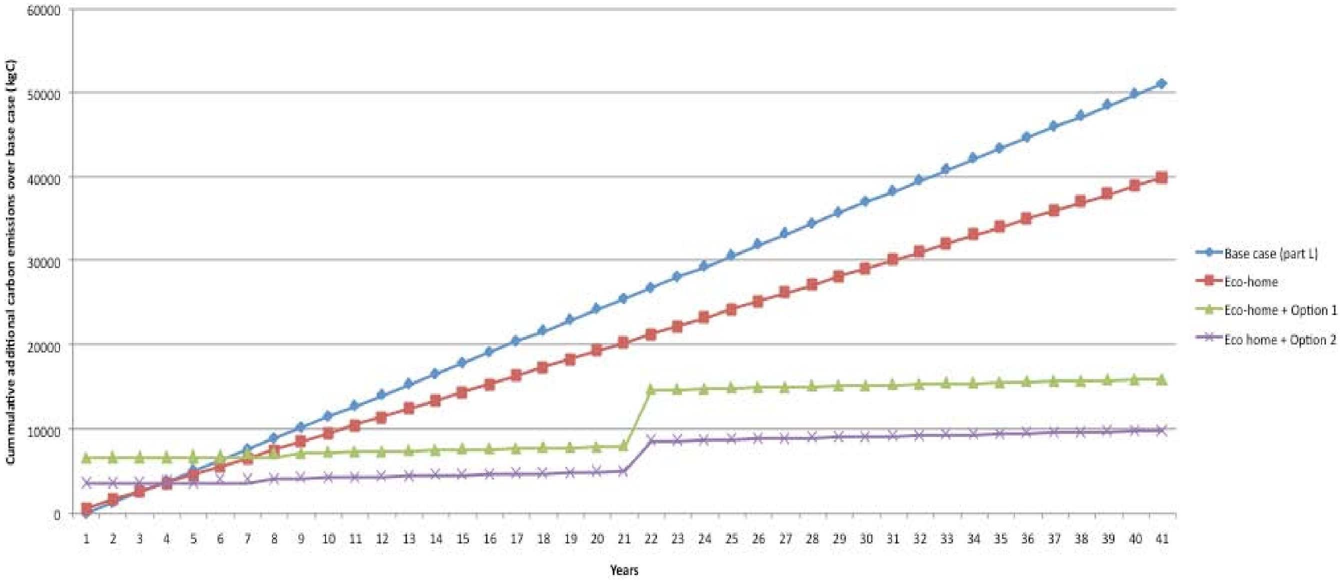


Figure 2: Cumulative additional carbon emissions over a 40 year life cycle for four different dwellings modelled

5 Discussion

The purpose of this paper is to evaluate the zero carbon policy by assessing the embodied implications of meeting the zero carbon targets over the building life cycle. The results have shown that the embodied carbon resulting from increased insulation and implementing microgeneration technologies can account for a significant increase in the proportion of the life cycle impacts, which have been excluded by the official 'zero carbon' definition. Estimates from the research suggest that using energy intensive microgeneration technologies such as photovoltaic panels can account for up to 22% of more carbon emissions compared to a base case normal dwelling. It therefore argues that a more holistic accountability of the life cycle carbon should form some part of the zero carbon definition.

The research also highlighted that different microgeneration technologies perform better than others e.g. wind turbines are more effective than photovoltaics. Again, this is not accounted for in the zero carbon policy which would not differentiate between higher embodied carbon technologies.

However, the research also highlights the potential difficulties in accounting for the embodied impacts of microgeneration technologies as they differ significantly depending on the production processes, location, transportation requirements and carbon intensity of the energy mix of the country. It is therefore essential that a systematic methodology for accounting for these impacts are developed and addressed in the life cycle assessment methodologies, as well as in the definition of zero carbon.

The significant increase in capital costs for incorporating these technologies have also not been considered. Previous research (Mortal et al 2007, Chow 2007, Chow 2008, Kingspan 2007) have concluded that capital costs can add up to 30% to the overall build costs. The relative efficiencies of reducing carbon emissions become more significant if embodied carbon are to be factored into the assessment. Nevertheless, it is still worthwhile over the life cycle of the building to incorporate microgeneration but these have to be considered along with higher embodied carbon technologies and cost implications.

In terms of the carbon and cost benefit of setting and striving towards zero carbon targets, the research suggests that it is perhaps more efficient to reduce demand through better building fabric and to decrease consumption of electricity and hot water than to require implementation of microgeneration technologies into domestic dwellings. The research indicated a significant proportion of carbon can be mitigated with better thermal performance building envelope. Passive house standards, for example, can reduce the space heating requirement dramatically at significantly less costs than integrating microgeneration technologies. It is still able to perform comparatively in terms of its life cycle carbon compared to a zero carbon home if the additional embodied carbon of the technologies are also considered. Therefore, government policies should perhaps focus more on achieving higher standards of building construction with minimal carbon emissions resulting from the operation of the dwelling, while at the same time strive towards reducing the carbon intensity of the national grid energy, than to set zero carbon standards which are relatively inefficient. However, substantial further research would need to be carried out to substantiate the findings from this paper.

Other considerations such as district energy supply or offsite renewables might also impact the embodied carbon and life cycle carbon substantially, and could potentially provide a more suitable and efficient route to achieving zero carbon levels.

6 Conclusion

Meeting the UK government's zero carbon policy is incredibly challenging, and require domestic dwellings to be built to higher energy efficient standards as well as requiring implementation of microgeneration technologies. While the policy is certainly commendable and will substantially reduce the carbon emissions over the operational phase, it does not however, account for the relatively significant increase in the embodied carbon resulting from the additional measures to reach zero carbon. This paper assessed two different zero carbon home and highlighted the substantial increase in embodied carbon, primarily due to the high carbon intensity of the photovoltaic panels.

The research also highlighted the difficulty in measuring embodied carbon of the technologies and more research would be required to develop a more comprehensive methodology for accounting the complete life cycle carbon emissions of buildings. This paper argues for a more holistic accounting of carbon emissions over the building life cycle rather than focusing on operational phase and the inclusion of the embodied elements to the definition of zero carbon.

Summary

Utilizing publicly available utility and property tax records, the energy use of more than 13,000 U.S. commercial businesses from 1994-2006 were analyzed by twelve (12) primary submarkets. Energy use intensity (kWh/m^2/yr) and other energy characteristics were determined for each market. The energy savings and added first cost of viable energy conservation measures (ECMs) were compared to minimally code-compliant HVAC and lighting alternatives in each market. A rate absorption program was devised that offered utility-provided rebates ranging from 15% to 65% of the added first cost of each ECM. The cost of each rebate and corresponding rate of adoption, administrative costs, lost energy sales revenue and utility variable cost savings were absorbed by changes in energy rates. Results indicate that a 65% ECM rebate and 25% market adoption would require a $US 0.043/kWh (50%) rate increase for the utility to remain cost neutral. Businesses choosing not to implement conservation measures (e.g. "non-adopters") would realize an increase in energy costs of between 7%-50%, depending on the level of rebate and percentage of market adoption. In contrast, those businesses choosing to implement conservation measures (e.g. "adopters") could realize net savings of up to 14.4% in spite of higher energy rates. On average, the energy costs for adopters is 19.9% less than non-adopters or, between $US 2,897.00 and 4,094.00 less each year for the average business. The subsequent reduction of 31,900kWh/yr in energy consumption could on average, eliminate the release of 18,821kg of CO_2 emissions each year for each business.

The objective of this study is to demonstrate a methodology for energy utilities to develop market-based conservation programs that produce the greatest energy reductions and carbon offset for the lowest program cost. By conserving energy, the consumer reduces operating costs and improves production efficiency and competitiveness. Similarly, the utility reduces the need for costly peak load generation, capacity expansion and wholesale power purchasing.

1. Introduction

Global warming is the increase in the Earth's near surface atmosphere and ocean temperature. Although climate change is a natural and cyclical process, much debate now focuses on the human contribution to global warming caused by the use of fossil fuels for energy and subsequent release of carbon dioxide and other "greenhouse" gases into the atmosphere. According to former U.S. Vice President Albert Gore in his Nobel Prize winning documentary "*An Inconvenient Truth*", global warming has caused the number of major hurricanes to double in the last 30 years and, the rate of glacial flow in Greenland to double in only the past 10 years. Gore further contends that deaths from global warming will likewise double in the next 25 years to more than 300,000 per year as a result of climate change induced heat, flooding and drought.

The U.S. represents roughly 5% of the world's population, yet, 23% of its fossil fuel consumption. Approximately one-third of all energy in the U.S. is consumed within the built environment, and more than one-third of this energy is used by the commercial business sector (DOE, 2004). Commercial buildings in the U.S. number more than 4,859,000 and occupy more than 6.7 billion square meters of floor area. The average commercial building in the U.S. is approximately 1,300m^2, yet nearly three-fourths (73%) of all buildings are 930m^2 or smaller. Although only two-percent of U.S. buildings are larger than 9,300m^2, these buildings account for 35% of total U.S. commercial floor space. In 2003, the average U.S. commercial building consumed 577kWh/m^2/yr (EIA, 2006).

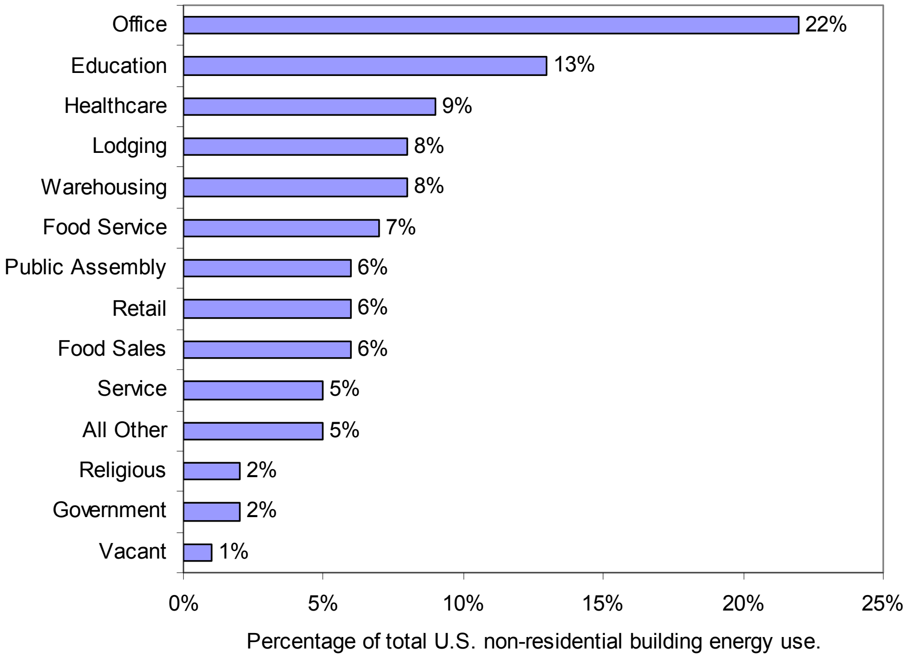

Figure 1. Percentage of U.S. non-residential energy use by market sector (EIA, 2006).

Commercial buildings consist of a variety of building types including offices, retail, service, education, food service and sales, healthcare, government and public assembly, and many other non-residential uses. The commercial office market occupies the largest share of non-residential floor area (17%). With an average energy use intensity of 667kWh/m^2/yr, the office market is the largest U.S. energy user (Figure 1). Combined, office, retail, education and warehousing comprise 60% of the total commercial floor space, 51% of buildings and, 49% of total non-residential energy use in the U.S. However, food service and sales are among the most energy intensive, consuming on average, between 1,646-1,687kWh/m^2/yr (Figure 2). Each of these markets has unique energy needs, but as a whole, more than half of all energy used by commercial buildings is dedicated to space conditioning and lighting (Grosskopf, 2007).

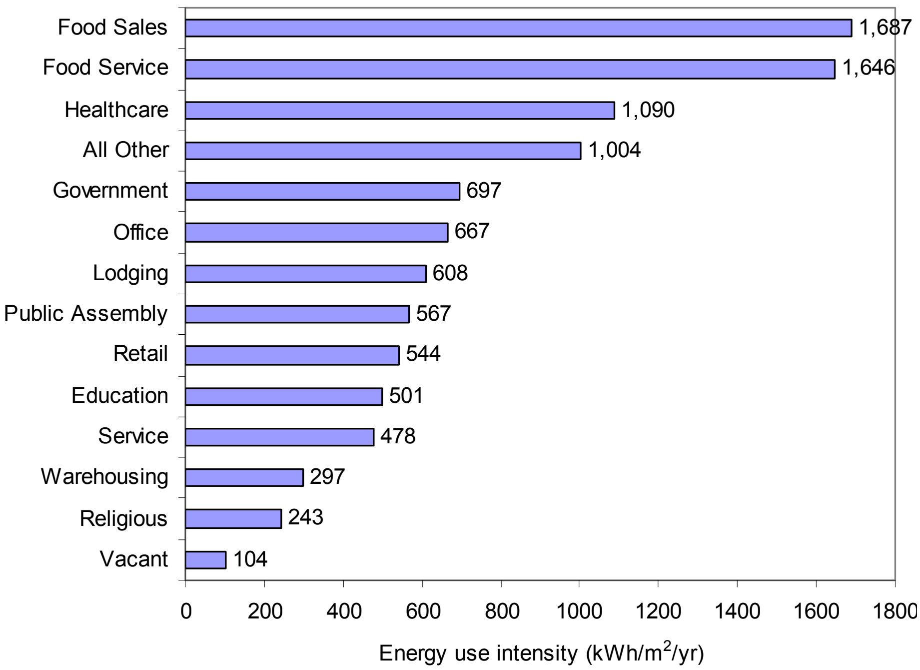

Figure 2. U.S. energy use intensity of non-residential buildings by market sector (EIA, 2006).

2. Traditional Market Barriers

Of 262 utilities selling 75% of all power produced in the U.S., 55% have commercial energy conservation programs. In spite of the namesake, the focus of many programs however, is to reduce peak energy demand (kW) while maintaining energy consumption (kWh). By doing this, utilities are able to reduce supply costs and defer new electric generation capacity while minimizing lost electric sales. As proof, U.S. utilities reduced peak demand 5.3% through "energy conservation" programs in 2000 while reducing net energy consumption only 1.1% (DSM, 2000). The consumer however, is motivated to minimize the added initial costs of implementing energy conservation measures while maximizing energy savings (kWh). Because most ECMs reduce energy consumption evenly throughout the day and throughout the year, most contribute significantly more toward energy reduction than demand reduction. Although many ECMs are cost effective for the consumer, most are not cost effective for the utility. As a result, many U.S. utilities have divested from energy conservation programs. Following years of growth, program expenditures fell from USD 2.74 billion in 1993 to USD 2.5 billion in 1999. From the height of U.S. program investment in 1993, incremental energy savings fell 8.4% from 8,980 million kilowatt-hours (kWh) to 8,229 million kWh in less than 12 months, a trend that continues today (EIA, 2006).

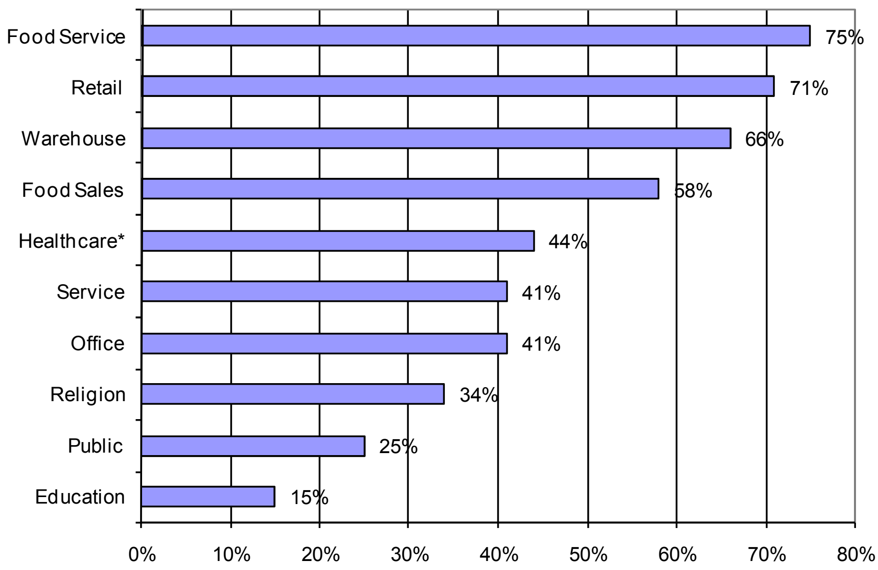

Figure 3. Percentage of space leased by number of U.S. commercial buildings (EIA, 2006).

Another significant market barrier for energy conservation is the disproportionately high percentage of non-residential lease space (Figure 3). More than half of all commercial floor area in the U.S. is leased. Developers of commercial lease space in the U.S. often require tenant businesses to pay their own utility costs. As a result, the developer has little financial incentive to implement energy conservation measures during building design and construction. Unless the leaser is a major "anchor" tenant negotiating a long-term lease, the leaser has very little or no control over building design or performance specifications. Furthermore, tenants generally place a greater premium on location, lease rates and aesthetics when selecting lease space. On average, commercial tenants change lease space every 3-5 years, creating additional barriers to conservation product and service adoption, as businesses with high turnover are unlikely to remain in spaces long enough to realize an energy savings return on investment (e.g. "payback").

Even for owner-occupants, discretionary investments into energy efficiency beyond minimum building code requirements usually require a return on investment that is competitive with other investment choices available to the business. Unlike the residential market, where nearly all housing is roughly the same size, serves the same function, has the same relative occupancy and hours of operation, commercial buildings are considerably more diverse. Therefore, it is more difficult to determine "payback" of conservation investments with any degree of certainty. In addition, many sustainable building practices have competing objectives. Improved indoor air quality (IAQ) that is achieved by introducing added fresh air ventilation into the building for example, often results in added energy to heat, cool, humidify or dehumidify the outside air. Given these and many other market barriers, most U.S. businesses are unwilling implement energy efficiency beyond minimum building or energy code requirements.

3. New Market Enablers

To overcome the market barriers imposed on traditional energy conservation programs, a rate absorption program is proposed that allows the utility to pass along the cost of energy conservation rebates and other incentives to the consumer. In other words, the cost of the incentive program, as well as the utilities' administrative costs and lost revenue are absorbed by increases in energy rates. Reductions in utility supply costs or deferred capital costs may either be credited back to the program or retained by the utility. In theory, businesses choosing not to implement conservation measures (e.g. "non-adopters") would realize an increase in energy costs. In contrast, those businesses choosing to implement conservation measures (e.g. "adopters") would realize an energy savings in spite of higher energy rates. By conserving energy, the "adopter" reduces operating costs and improves production efficiency and competitiveness over the "non-adopter". Similarly, the utility reduces the need for costly peak load generation, capacity expansion and wholesale power purchasing. The goal of this "win-win" market-based approach is to maximize energy conservation and carbon offset at the lowest program cost.

3.1 Case study

To test the rate absorption approach, a case study was developed using a small-to-medium sized city of approximately 200,000 residents in the southeast U.S. A total of 13,827 commercial and industrial (C&I) account records from roughly 4,700 businesses were obtained from a 610MW utility serving this community. North American Industrial Code System (NAICS) identification numbers, which were used to categorize each account by market, were matched to 12,188 (88.1%) records using available utility account information. A confidence code ranging from 1 (low) to 10 (high) was assigned to each NAICS match. Accounts that did not achieve NAICS assignments with a confidence code of "6" or greater were eliminated. A total of 9,650 (69.8%) commercial accounts were assigned a NAICS identification number with confidence code of "6" or greater. Of those records successfully matched with a NAICS identification number, inactive electric accounts were eliminated, resulting in a total of 7,048 (51.0%) remaining accounts. Of 7,048 active electric accounts successfully assigned a NAICS identification number, 4,917 (35.6%) were matched by customer name, service address and other account information to a parcel that had a valid county property appraiser tax identification number. Of those, 4,162 (30.1%) accounts matched parcels having summarized total floor area for that parcel.

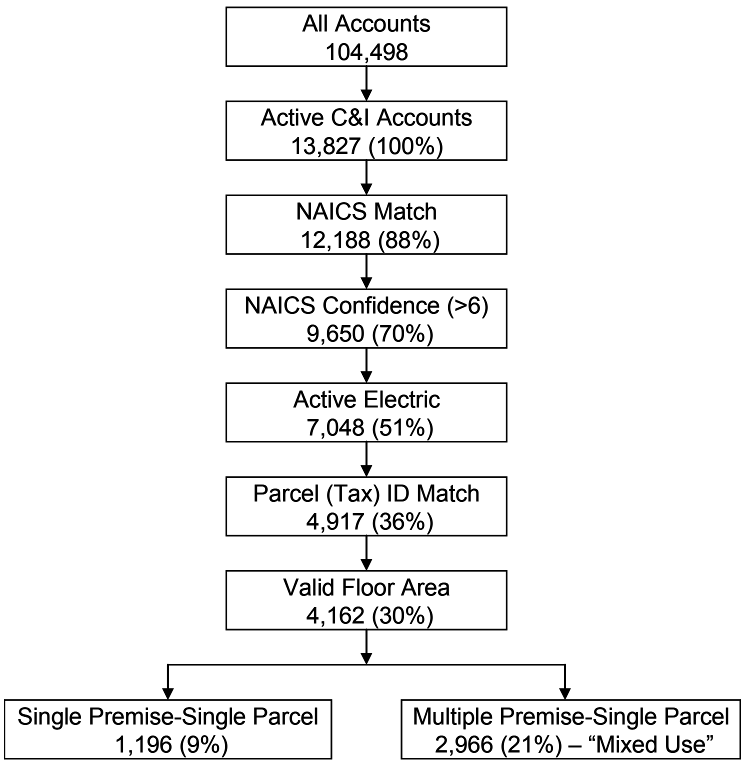

Figure 4. Methodology used to determine energy use intensity (kWh/m^2/yr) by market.

The remaining 4,162 records were distributed across 1,844 unique parcels. Of these, 1,197 (28.8%) were single accounts located on single parcels. The remaining 2,965 (71.2%) accounts were located on 647 parcels having between 2 and 115 accounts each. Since floor area could not be readily unbundled and allocated to multiple accounts, each having different use, NAICS designation and energy use history, a "mixed-use" NAICS designation was created to represent the combined floor area and energy use history for these largely "strip mall" businesses aggregated on a single parcel. The number of account records remaining in each NAICS market segment was compared to the number of pre-filter account records to determine if any NAICS market segment experienced a disproportionately high rate of attrition.

Next, monthly energy use records dating from January 1994 to December 2006 for each account were merged with building floor area data. Inactive billing periods resulting from building vacancy or transition of ownership (e.g. customer account changes) were identified and excluded from the analysis. Since energy use intensity was measured by the total energy use of the building in relation to its floor area, natural gas consumption (if any) was converted to equivalent units of electrical energy (kWh). The total annual energy consumption of each account was divided by total floor area to determine the average annual energy use intensity (kWh/sf/yr) for each account in each market. For the purposes of this study, it was assumed that the same (or similar) type of business occupied each building space from 1994 to 2006, and that no significant changes to building area or composition had been made during this time.

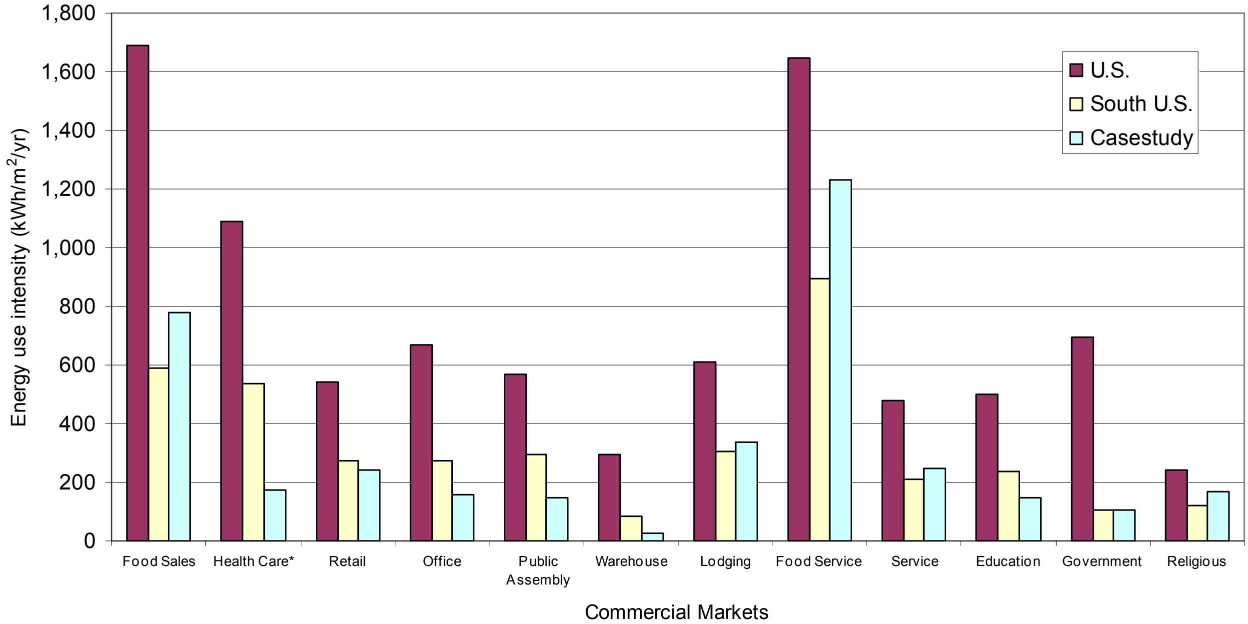

Figure 5. Comparison of U.S. and case study energy use intensity (kWh/m^2/yr) by market.

The average annual energy use intensity of buildings within the case study region was 301kWh/m^2/yr, nearly half (52%) the U.S. average, yet somewhat consistent with similar market sectors in the southeast U.S. having an average energy use intensity of 360kWh/m^2/yr. Other market specific findings include:

- Office and retail markets comprised roughly one-quarter of all accounts. Office, retail, food service (restaurants) and food sales (grocery stores) comprised more than half (53%) of the total commercial market energy demand (kW).
- Food service and food sales were consistently 3-5 times more energy use intensive compared to the aggregate commercial market, ranging between 7.9-20.9kW/100m^2 energy demand and 729-1,252kWh/m^2/yr energy consumption.
- Healthcare stores and gasoline stations were the 2-3 times more energy demand intensive (8.7-11.0kW/100m^2) compared to the aggregate retail market from 1994-2006. Gasoline stations were more than twice as energy use intensive (420-480kWh/m^2/yr) as the rest of the retail market.

- The "bottom 10%" (worst) energy performers in each market were 3-7 times more energy use intensive than the market average. The greatest ratio disparities were found in religious (7.1:1.0), services (6.3:1.0) and lodging (4.8:1.0) sectors. The greatest numerical disparities were found in food sales (1,746kWh/m^2/yr) and food service (1,604kWh/m^2/yr) markets. The "bottom 10%" of accounts in each market were among the largest by size and consumption, averaging 146,053kWh per account per month from 1994-2006.

- Electric load factors (the percentage of average demand relative to peak demand) for food service, food sales and lodging averaged between 40%-50%. Load factors for service, religious and education were among the poorest, averaging less than 20%. Load factor for retail averaged roughly 35%, although load factors for gasoline stations and healthcare stores exceeded 45% and 70% respectively due in large part to continuous hours of operation. Load factors for postal services and assisted living exceeded 50% and 60% respectively.

- Lodging, food service, food sales and retail were on average, among the largest individual connected electric loads (57.4-109.2kW per account) and largest electric energy users (averaging 40,061kWh per account per month).

- Individual building material, sporting goods and general store retailers as well as assisted living, lodging, postal service and entertainment accounts all averaged 100kW demand or greater and consumed between 22,596-62,651kWh per account per month.

- No significant differences in energy use intensity with respect to building age or building size were found when compared by market, except for buildings over 9,000m^2. For all markets, buildings greater than 9,000m^2 had 2-3 times the energy use intensity of the market average.

- Service markets were found to have the highest account turnover rate with a customer change every 2.9 years on average. Education had the lowest turnover rates with a customer change every 14.3 years. The core of the C&I market, office, food service and sales, retail, and healthcare, experienced account turnover every 3.9-4.8 years on average.

Next, the energy savings and added first cost of energy efficient HVAC and lighting alternatives were compared to minimally code-compliant alternatives in each market. The scope of this investigation was limited to only HVAC and lighting alternatives since roughly half of all energy consumed in U.S. commercial buildings is used for thermal comfort and lighting. For measures likely to have the same or similar energy use impacts regardless of location or climate, energy use data from the following resources were used:

- 2004-05 Database of Energy Efficient Resources (DEER), version 2.01, California Public Utilities Commission, http://eega.cpuc.ca.gov.deer
- 2006-08 Demand Side Management (DSM) Program, Pacific Gas & Electric and Southern California Edison, http://www.californiaenergyefficiency.com/matrix.html
- 2007 Integrated Resource Plan, Appendix K, Puget Sound Energy, http://www.pse.com/energyEnvironment/pse2007irpView.aspx

For measures likely to be affected by climate, energy use data from the following source representative of the study area was used:

- 2007 Potential for Energy Efficiency and Renewable Energy to Meet Florida's Growing Energy Demands, Report Number E072, American Council for an Energy Efficient Economy.

HVAC alternatives evaluated included unitary (packaged) systems and water and air-cooled chillers of various types, efficiencies, capacities and control capabilities. Lighting alternatives evaluated included T-5, T-8 and compact fluorescent (CFL) lighting, pulse-start metal halide, high pressure sodium (HPS) and light emitting diode (LED) technologies and control systems used in place of less efficient incandescent and mercury vapor technologies with limited or no control capabilities. The performance of each of these energy efficient alternatives was characterized for buildings of varying sizes in each of the twelve (12) markets. The minimum and maximum energy savings and added first cost for HVAC and lighting upgrades are presented for the commercial market in the study region (Tables 1 and 2). The market most representative of the average energy savings and added first cost for HVAC and lighting upgrades is also presented.

Table 1. Investment costs and annual energy savings for select lighting upgrades.

	Min	Max	Avg	Market	Upgrade	Base

[1] SIR, savings to investment ratio
[2] Unitary systems - 15 year service life, chillers - 20 year service life, $US 0.085/kWh "blended" energy rate (energy, demand, account fees, etc.)

Using market specific energy use intensity data and, the average costs and energy savings of lighting and HVAC upgrades for the commercial market as a whole, a rate absorption program was devised. Rebates ranging from 15% to 65% of the added first cost of each upgrade were factored into the analysis. Corresponding rates of adoption from 5% to 25% of the total commercial market were used. Multiplying the average added first cost ($US/$m^2$) for an HVAC and lighting system upgrade by the rebate (%), and again by the total commercial market adoption (m^2), the one-time, total rebate program cost was calculated. Next, lost sales revenue resulting from the conservation effort was calculated by factoring the average energy savings (kWh/100m^2/yr) for an HVAC and lighting upgrade by a "blended" commercial rate of $US 0.085/kWh, inclusive of all energy, demand and account fees. These values were weighted by the average energy use intensity of each market (Figure 5) and, the size of the market by floor area (m^2) relative to the entire commercial market. Administration costs for staffing to coordinate and monitor the rebate program were assumed to be 20% of the rebate cost each year.

Table 3. Casestudy electric generation, transmission and distribution supply costs. (Regan, 2004)

Cost	Cost Component	Value of Reduction (USD)
Avoided T&D Facilities	Fixed	104.94/kW
Avoided T&D Personnel	Fixed	6.15/kW/Yr
Avoided Generation Unit	Fixed	1,452.00/kW
Avoided Generation Personnel	Fixed	5.52/kW/Yr
Avoided Generation O&M	Variable	0.0049/kWh
Avoided Generation Fuel	Variable	0.01864/kWh
Fuel Cost Escalation		3.9%/Yr
Inflation		4.0%/Yr
Line Loss Percentage		6.0%
Cost of Capital		8.75%

Avoided utility supply costs resulting from the conservation effort were credited back to the program. For conservancy, only avoided variable operating and maintenance costs ($US 0.024/kWh) were considered. Avoided fixed costs, such as deferred infrastructure expansion costs, personnel, etc., were not considered since the electric generation, transmission and distribution (T&D) capacity to meet (and in most cases, exceed) the pre-conservation effort demand would have already been in place. Avoidance or delay of capital expenses, if any, would likely occur many years into the future and only if a significant demand reduction (50MW or greater) were to occur as a result of the conservation program.

Next, the present value (PV) of the initial rebate program and, future lost sales revenue and administrative costs were calculated using an average service life of HVAC and lighting upgrades equal to 15 years. A discount rate of 8.75% factoring the utility's cost of capital, inflation, energy costs, risk and uncertainty was used. The present value of avoided supply cost benefits was credited back to the program under the same constraints. The net present value (NPV) of total program costs was then calculated for rebates ranging from 15% to 65% and, corresponding adoption rates ranging from 5% to 25% of the total commercial market. The resulting NPV of program costs for each rebate and corresponding level of adoption was divided by total commercial energy sales for (MWh/yr) to determine the required energy rate adjustment necessary for the utility to remain cost neutral.

Table 4. Rate absorption schedule.

Rebate (%)	Market Adoption (%)	Energy Savings (MWh/yr)	Rebate Cost ($US)	Admin Cost ($US/yr)	Lost Sales ($US)	Avoided Cost ($US)	NPV of Costs ($US)	Rate Change ($US/kWh)
15	5	6,219	199,804	39,961	528,636	146,401	3,653,807	0.006
25	10	12,438	666,015	133,203	1,057,272	292,802	8,009,915	0.013
35	15	18,658	1,398,631	279,726	1,585,908	439,203	13,068,325	0.021
50	20	24,877	2,664,059	532,812	2,114,544	585,604	19,531,338	0.031
65	25	31,096	4,329,097	865,819	2,643,180	732,005	27,047,804	0.043

* Discount period, 15 years; discount rate, 8.75%

Results indicate that 15%-65% rebates on HVAC and lighting upgrades and 5%-25% market adoption would require a $US 0.006-0.043/kWh (7.1%-50.6%) rate increase for the utility on a base rate of $0.085/kWh to remain cost neutral. Businesses choosing not to implement conservation measures (e.g. "non-adopters") would similarly realize a 7-50% increase in energy costs. In contrast, those businesses choosing to implement conservation measures (e.g. "adopters") could realize net savings of up to 14.4% in spite of higher energy rates. On average, the energy costs for adopters is 19.9% less than non-adopters or, $US 2,897.00-4,094.00 less each year for the average business. For simplicity, this analysis assumes that the total implementation process and, present value of all current and future program costs are recovered within the same year. To lessen the financial burden on the consumer, this cost may be spread over several years.

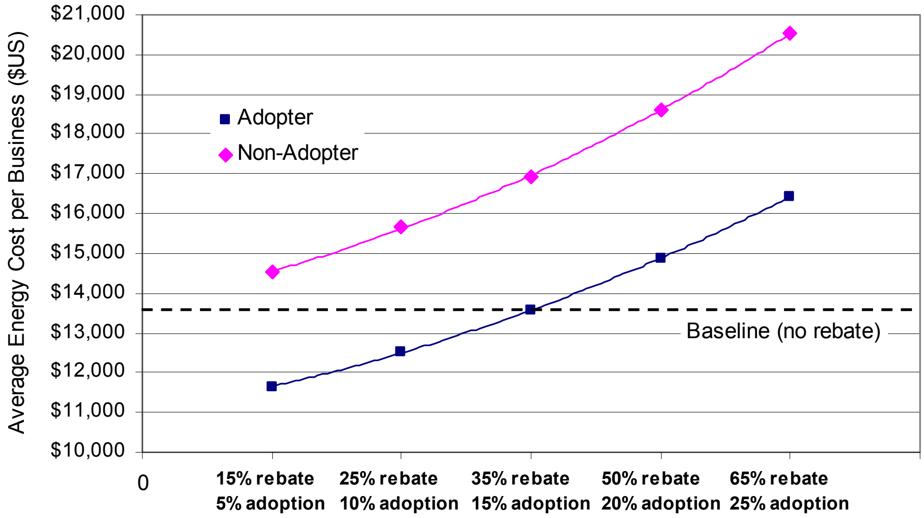

Figure 6. Rate absorption impact on average consumer energy costs.

The uncontrolled release of NO_x, SO_2 and CO_2 emissions alone contribute significantly to the global greenhouse effect. Aggregating emissions proportionately across Florida's coal, petroleum, gas and nuclear generation output, it is estimated that 0.0036kg of SO_2, 0.0023 kg of NO_x and 0.59kg of CO_2 are released for every kilowatt-hour of energy used by the consumer (U.S. DOE, 1995). The reduction of 31,900kWh/yr of energy use per business in the study area could on average, eliminate the release of 18,821kg of CO_2 emissions each year. Depending on rates of adoption (5%-25%), the study market consisting of 4,700 businesses each averaging 70m^2 of useable floor space and having an average energy use intensity of approximately 301kWh/m^2/yr, could reduce up to 18.4 million kilograms of CO_2 emissions each year.

4. Conclusions

The objective of this study was to demonstrate a rate absorption approach where the risks, costs and benefits of a conservation program, traditionally borne by the utility, shifts to the consumer. Adopters of the HVAC and lighting upgrades evaluated in this study achieved an average savings-to-investment ratio of 6.5 and a simple return on added first cost investment within 1.9-2.5 years. The implementation cost of the energy efficiency upgrades was absorbed by incremental increases in energy rates, which were disproportionately passed along to non-adopters, or those businesses choosing not to improve their energy efficiency. In essence, non-adopters financed the costs of production efficiency improvements for their competitors, or those businesses choosing to improve their energy efficiency.

4.1 Limitations

Although the results of this particular study show that energy use is most closely correlated to type of market (e.g. type of use), the energy use variance of buildings within the each market was found to be very high. Combined with other building characteristics (e.g., size, age, climate, changes in use, etc.) the task of estimating energy savings from even a limited number of HVAC and lighting upgrade options is extremely complex. Although the methodology developed herein may be applicable and replicable in other study regions, the results should not be generalized to any other study area.

4.2 Further Research

The rates of consumer adoption corresponding to the levels of rebate incentives in this study are hypothetical. Although the author(s) have performed research in the U.S. residential market identifying levels of market adoption relative to varying levels of incentives, no similar research for the commercial market has been completed to date. There exists a critical need to assess the "tipping points" necessary to stimulate the greatest level of market adoption for the lowest program cost, and, to separate true adopters from "free riders" or those individuals and businesses who would have implemented energy efficient upgrades with little or no incentives.

TITLE: GOVT³: HELPING THE NEW ZEALAND GOVERNMENT GET SUSTAINABLE BUILDING

Chris Wood.[1]

[1]Leading Government Sustainability Team, Sustainable Business Group, Ministry for the Environment, Wellington, New Zealand, chris.wood@mfe.govt.nz

Keywords: Govt³ programme; sustainable building; environmentally regenerative design; New Zealand

Summary

The Ministry for the Environment's Govt³ programme has been working with core Departments and Ministries to encourage sustainable practices since 2003. One area of sustainability these government agencies are now starting to embrace, and is being reflected in their building projects, is sustainable building practices. The Govt³ programme helps and supports these agencies by working with other government agencies on policies that support sustainable building objectives, and with industry to develop the products and services required to make sustainable buildings possible. This paper highlights what the Govt³ agencies are currently doing and to meet the programme's requirements of 'best practice' sustainable building and what the Leading Government Sustainability (LGS) team is planning to develop to help them. The support shown for the Govt³ programme also highlights the New Zealand Government's commitment to 'walk the talk' on sustainability.

The '*Value Case for Sustainable Building in New Zealand*' has shown that sustainable buildings need not cost much more up front and any premium will be paid back many times over during the life of the building. Using whole-of-life costing, Govt³ agencies are able to lease, or own buildings with dramatically reduced environmental impacts. These buildings also provide healthier more pleasant working environments for their staff. Examples include the Department of Conservation's new head office that has converted a former cinema into one of New Zealand's best performing office buildings. However, reducing impact, although noble in its self, will not get us to true sustainability let alone start to restore the damage caused by our past short-sighted development practices. There is now a conversation developing that looks beyond reduction to neutral, restorative, or even regenerative development strategies. It will require a collective approach from industry and government to achieve. If this happens New Zealand could be on the way to being the first truly sustainable nation.

Introduction: environmental concerns with the built environment

Governments around the world are waking up to the environmental impacts associated with the built environment. Globally these impacts are immense. According to the United Nations, the building and construction sector is becoming known as "the 40% industry". This is because 40% of all energy and material resources globally are used to build and operate buildings, 40% of CO_2 releases come from building construction and operation, and 40% of total waste results from construction and demolition activities (United Nations, 2007). On top of these figures are the impacts of buildings construction, operation, maintenance and demolition on land, water, air quality and human health.

In 2003 the United Nations warned that if current patterns do not change the expansion of the built environment will destroy or disturb natural habitats and wildlife on over 70% of the Earth's land surface by 2032 (UNEP, 2003). It is not surprising then that the United Nations Environment Protection programme sees the building and construction sector has having more potential to contribute to the achievement of sustainable development than any other sector (UNEP, 2007).

The environmental performance of New Zealand's building and construction sector varies from global averages due to local resource availability, climatic conditions, and the fact that the majority of New Zealand's electricity is generated by hydroelectric power schemes. Although variable to global averages the impacts remain immense. Therefore it is not surprising that a growing number of public sector agencies, private sector organisations, and individuals are calling for a change in the way New Zealand's buildings are designed, constructed, operated and demolished.

This call for change has been greatly bolstered by the New Zealand Prime Minister's February 2007 announcement that "New Zealand can aim to be the first nation to be truly sustainable". The New Zealand Government also acknowledged that "it is important that government shows leadership on sustainability, and gets its own house in order when it is encouraging individuals and business to take actions for sustainability".

As government undertakes approximately 30% of all new construction in New Zealand, it has the ability to influence the market from a demand side. It has signalled its intention, through government procurement, to improve the sustainability of a growing number of sectors, including the wider building and construction sector. The main focus of this paper is how the New Zealand governments Govt^3 programme is going about empowering its members to achieve more environmentally sustainable building results. The paper also looks at the programme's inspirational goal of going beyond reducing impacts to how we can build truly sustainable buildings in the New Zealand context.

The Govt^3 programme

In September 2003 the Ministry for the Environment started the Govt^3 programme with the aim of increasing capacity and knowledge on environmental sustainability within government agencies. The name Govt^3, meaning government and "3" - the three pillars of sustainability: economic, social and environmental. The Ministry for the Environment's Leading Government Sustainability (LGS) team, leads and manages the Govt^3 programme and have been working with the programme's 57 government agencies to assist them to "walk the talk" on sustainability. The programme does this by identifying best practice and promoting practical solutions to achieving it.

One topic area of sustainability these agencies are now starting to embrace, and is beginning to be reflected in their building projects is the use of sustainable building practices. The LGS team assists and supports these agencies by working with them directly to encourage and support their efforts. The LGS team also works with other government agencies, and wider industry to encourage the development the policies, products, and services that make sustainable buildings possible. The LGS team provides Govt^3 agencies, and the professionals working for them, with tools, recourses, and guidance to make the process of getting sustainable buildings easier.

Value case for sustainable building

One of the obstacles the LGS team identified as needing to be challenged was a perception that sustainable buildings cost a lot more than conventional buildings. A value case was commissioned to look at local case studies to quantify whether there was any substance to the 20 plus percent premium being talked about by the New Zealand building industry. The resulting '*Value Case for Sustainable Building in New Zealand'* identified that although there was a premium it was more likely to be between

2-6 percent (Fullbrook et al, 2006). It also showed that buildings with lower environment impacts need not cost much more in upfront capital costs and any premium would be paid back many times over during the life of the building. One of the main reasons for this premium was attributed to the extra time and resources the building and construction industry needed to become accustomed to a different way of doing things. This is in line with the finding from other developed countries that have introduced environmental considerations to building projects.

In December 2007 the New Zealand Treasury launched its new Capital Asset Management (CAM) framework that requires government agencies to take a longer-term view of their assets. This means Govt[3] members are now able to use whole-of-life costing to make asset decisions over a forty-year timeframe. This will foster the use of practices and technologies that have better sustainability outcomes, as they are paid for over a timeframe that is more conducive to their use.

What constitutes a sustainable building?

Another hurdle government agencies have had to overcome is the question of 'what constitutes a more sustainable building' and what level of performance should these buildings be achieving. It should be made clear that in New Zealand we are currently not building sustainable buildings, but use the term "sustainable building" to indicate an intention to do so in the future. To this end, the Govt[3] programme adopted a variation of the Sustainable Building Centre's definition as it reflects a changing view of the environmental impacts associated with buildings.

Buildings are "sustainable" when they are designed, built and operated with low environmental impacts (or actually start to have a positive environmental impact) while enhancing the health, welfare and quality of life of the people that live and work in them.

(Variation on that used by British Columbia's Sustainable Building Centre)

Most of the earlier definitions of sustainable building only focused on reducing impacts. Whereas, the Sustainable Building Centre's definition hints at the possibility of using building developments to improve environmental and human impacts and outcomes. Putting this definition into a commercial procurement context however, would have proved difficult without some associated performance indicators. The New Zealand Government recognised this and in May 2006 directed the Govt[3] members to accelerate the adoption of sustainable building practices. This was to be achieved by specifying best practice sustainable building indicators (performance standards) for government building tender documents for new and existing buildings.

Environmental rating tools

After looking at what other governments had done to set best-practice sustainable building standards, it was decided to engage the newly formed New Zealand Green Building Council (NZGBC) to select a sustainable building assessment scheme appropriate for a New Zealand context. The project's purpose was to identify, and then develop a project plan to implement the selected scheme. As government agencies occupy a large amount of the office accommodation the LGS team were particularly interested in the development of environmental rating tools for the commercial office-building sector. The LGS team realised that industry would need to be encouraged in come up with solutions to the environmental issues associated with the building and construction sector. Therefore, a key component of the project's brief was to engage with the wider building and construction sector and gain their support for the chosen rating scheme. The NZGBC developed the Green Star New Zealand rating scheme with the input of almost 500 people from New Zealand's wider building and construction sector.

Although based on the Australian Green Star rating scheme the New Zealand scheme was the first rating scheme of its type to base final certification on a building's actual performance. Most other rating schemes base certification on a buildings predicted performance at the design stage. This result is a tribute to the collaborative working style of NZGBC and the support shown by the wider building and construction sector. It also reflects the importance and value of involving the users of these tools in the decision making process as it was industry that felt the tools short acknowledge actual, rather than predicted performance. The resulting Green Star New Zealand commercial office-building rating tool was adopted by the government for all new government commercial office building, owned or leased, from 1 July 2007.

The NZGBC is currently working with a number of Govt[3] agencies to investigate the possibility of rating tools for their specific building needs. Examples include the Ministry of Education, which is working with the NZGBC to develop rating tools for schools and the Housing New Zealand Corporation, which is assessing the need for a residential rating tool(s). The Ministry of Education had already required the inclusion of environmentally sustainable design practices for all new schools. The use of rating tools will offer a more consistent way of gauging a school building's performance against a set of known environmental performance criteria. One of the criteria being trailed on four new schools under development is educational value, whereby the building's design is awarded credits if it contributes to the education of the user.

In October 2007 the New Zealand Government further acknowledged the value of using the NZGBC's Green Star New Zealand rating tools by setting a target that all new government buildings are to meet a minimum 5 star rating (New Zealand excellence) from 2012. This was a suggestion put forward by the LGS team as a key means of setting targets that would lead to operational changes. The LGS team will continue working with the NZGBC and the wider building and construction sector to ensure rating tools are available for all major government building types by this date.

In the LGS team's opinion rating tools are best used to verify a buildings environmental performance rather than to determine a buildings design. In this way the Green Star New Zealand rating tools have become the government's eco-verification tools for government buildings environmental performance.

Building design through to commissioning

The best time to incorporate sustainability into a project is before the design process even starts. This is because by the time the first 1% of a project's upfront costs are spent, up to 70% of its lifecycle costs may already be committed (Fullbrook, et al, 2006). Pre-design therefore takes on increased importance and requires a new set of skills for those typically involved in a conventional building project. Ideally the pre-design period would have the involvement of the users, developer, investor, design team, builders, and facilities management team. This collaborative approach is known as an 'integrated whole building design process' and is a prerequisite for achieving better environmentally performing buildings.

The LSG team is currently developing a sustainable building toolkit that includes guidance in a number of areas such as integrated whole building design, and passive solar design, principles. The toolkit covers the life-cycle of a building from pre-design through to deconstruction. Govt[3] members, or the professionals working for them, will provide evidence on how they have incorporated sustainable building design considerations (figure 1). It is hoped that the toolkit will become a requirement for all government commercial building projects. It will be targeted at commercial buildings. Over time the toolkits can be extended to include topics such as distributed renewable energy technologies, green roofs, regenerative design, and other positive environmental design principles.

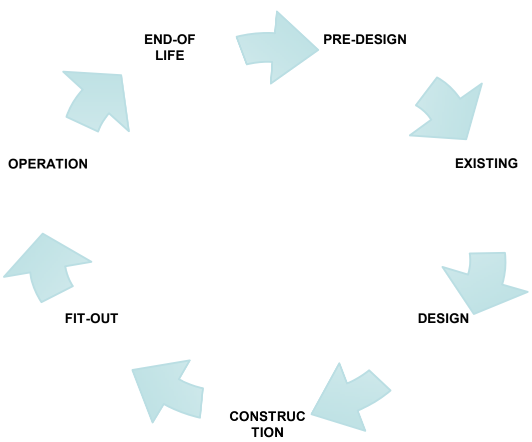

Figure 1: Sustainable Building Toolkit life-cycle topics

The best-designed building however, will not achieve its performance potential without proper commissioning. Proper commissioning of buildings has historically had a very low profile and priority in the construction industry and is often done poorly, if at all. Sustainable buildings by their very nature require a high level of performance (Fullbrook, 2007a), and they're commissioning and management therefore requires extra focus. When the LGS team looked for guidance on how to undertake best-practice commissioning there were few examples available. It was decided to commission 'A Best Practice Approach to Building Commissioning, Completing and Ongoing Operation' to fill this gap and ensure new government buildings operated as intended. The commissioning guidelines became mandatory for government buildings over 2000m^2 as of 1 July 2007. Given that government is a significant tenant of commercial buildings in New Zealand it is hoped that these guidelines will act as a catalyst to improve the building and construction sector's overall commissioning practices.

The importance of education

One area that the LGS team is focusing a lot of time on is educating the Govt^3 members on the opportunities that sustainable building can offer them. A small, but very experienced group of sustainable building practitioners have volunteered their time to help the LGS team to inform and educate these agencies about best-practice sustainable building practices. An important component of this education has been up-skilling and empowering these agencies so they are able to use what they are learning in real-life building project situations. Individual member of the Govt^3 programme sharing their achievements in the area of sustainable building has also proved important. Seeing others achieve positive results justifies the extra time and effort put into these projects. It also shows that individuals in organisation similar to their own can do it so why cant I. The Govt^3 programme now holds regular sustainable building network meeting so that members can share their experiences. The power of this kind of networking should not be undervalued, particularly if the members are encouraged to personalise what they are doing to their own organisational needs.

An example of a government building that utilised sustainable building principles

The Department of Conservation's new head office in Wellington is a good example of what is possible when you combine sustainable building principles with an organisations purpose. The Department of Conservation's mission is "to conserve New Zealand's natural and historic heritage for all to enjoy now and in the future". So when the Department of Conservation started looking for new accommodation, it saw an opportunity to express these values in its new building.

The Department of Conservation approached the LGS team early on to help with the preparation of their request for proposal documents to consolidate their Wellington staff into on site. They had already done a lot of preliminary work that included extensively surveying their staff to ensure their needs were understood and reflected in the new buildings design brief.
The Department of Conservation's new home is a retrofit of an existing cinema into a commercial office building which:

- Utilises rainwater storage and efficient fixtures and fitting that have reduced water use from the town supply by 60%;
- Has achieved a 40% reduction in energy use through the use of natural day-lighting, an efficient lighting system - including the use of motion sensors to turn off unused lighting, and a modern building management system;
- Has automatically opening windows and a highly efficient ventilation system that combines passive ventilation with chilled beams;
- Has inbuilt recycling facilities on each floor, and recycled much of the construction and demolition waste materials during the construction process;
- Has cycling facilities to encourage staff to the use of alternative transport options. The building is also located on Wellington's main bus route.

Figures 1 and 2: Pictures of the Department of Conservation's new head office with the atrium on the left and chilled beams on the right (Source: Pictures courtesy of the Department of Conservation)

Although the Department of Conservation had a number of new building options to chose from it took the riskier, and ultimately more sustainable option of using an exist building that was not ideally suited for use as an office building.

The future direction of the Govt^3 programme

During the latter half of 2007 the LGS team undertook a strategic review of the Govt^3 programme. This was the first major review of the programme since its start in November 2003. During the intervening years the programme had evolved from voluntary to mandatory participation. It has also moved from looking at improving the corporate functions of government agencies to include operational elements. An example is the requirement that all government buildings meet a minimum 5 star Green Star rating from 2012.

What was lacking from the programme was 'where were we collectively going with sustainability'. The Govt^3 agencies were starting to ask 'how can we use our collective good will and effort in the area of sustainability to have a wider positive effect on the New Zealand as a whole'. Therefore the strategic direction for the Govt3 programme now looks at the linkages on wider society including the built environment.

From individual buildings to the wider built environment

There is growing recognition that the environmental impacts of a building go far beyond the site boundary (Fullbrook, 2007b). Figure 3 shows the impacts that include transport, emissions, material manufacture, waste, public health, land use and ecology. Many of the projects Govt^3 members undertake are large in scale and require connection with sustainable infrastructure – urban design, transport and community – to realise their full sustainability potential.

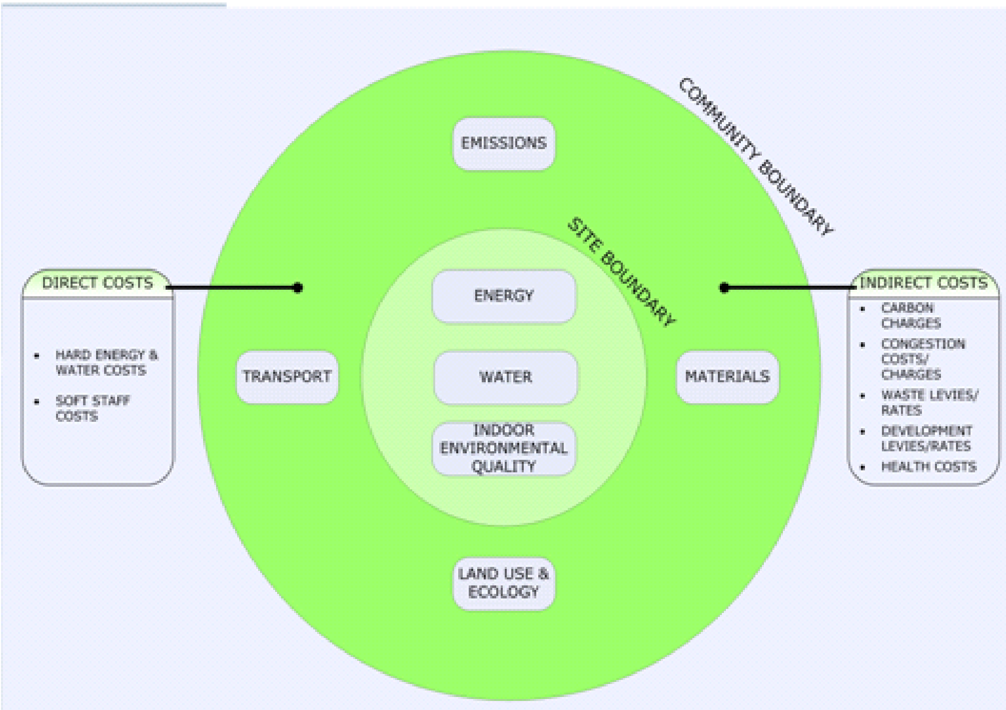

Figure 3: Environmental impacts beyond a building's site boundary.
(Source: Fullbrook, 2007, unpublished)

The current sustainable building topic area of the programme has been expanded to include these other topic areas. The phrase "built environment" refers to the manmade surroundings that provide the setting for human activity, ranging from the large-scale civic surroundings to the personal places. Buildings, transport, infrastructure, and urban design now all fall under the new title of "sustainable built environment". The Govt[3] team will continue to develop guidance on sustainable building but also now works with other government agencies and industry to develop guidance on sustainable infrastructure, transport, and urban design.

Decisions about sustainable development however, are more often that not done in isolation from one another. Many scientists, economists, and planners have started to recognise that integrated approaches to problem solving lead to more efficient, cost effective solutions when developed with natural principals and elements in mind (Centre for Sustainable Community Development, 2004).

From green to sustainable and beyond
By signing up to the Govt[3] programme the members have agreed to use 'best practice' sustainable building practices. Yet the current usage of the term 'environmental sustainability' is arguably framed in the context of reduced environmental impacts as opposed to long-term environmental balance. Although reducing environmental impacts is a worthy goal and an important discipline it is far from striving for sustainability (Nicholson, 2005).

In 2006 the New Zealand architect Graeme Finlay presented a challenge to some of the Govt[3] agencies at a network meeting designed to inform them of emerging sustainable building issues. Graeme asked why we, as participants in the building industry, are not designing New Zealand buildings as net GENERATORS of energy, as CARBON sinks, manufactured from WASTE materials, and improving BIODIVERSITY. Internationally, there is a call by those who have mastered the basics to go further. In the area of the built environment a 'low environmental impact design approach' by itself cannot achieve sustainable development over the long term. It could be argued that a broader and more sustainable design approach must move beyond simply avoiding environmental damage to embrace environmental positives.

Taking a long-term view of the impacts on the ecological health of ecosystems it could also be argued that sustainability, even true sustainability, is only part of the answer. This is because sustainability is fundamentally about creating a steady state that still leads to degeneration of the system, as a whole, over time. New Zealand's biodiversity has been adversely affected by the actions of people and these effects are continuing (Craig, et al, 2000). But what if sustainable development was good for the environment? Figure 4 showcases a trajectory of environmentally responsible design that describes the transition from conventional practice and green architecture (negative environmental impact), to sustainable architecture (zero impact), through to design with positive environmental impact (Reed, 2007).

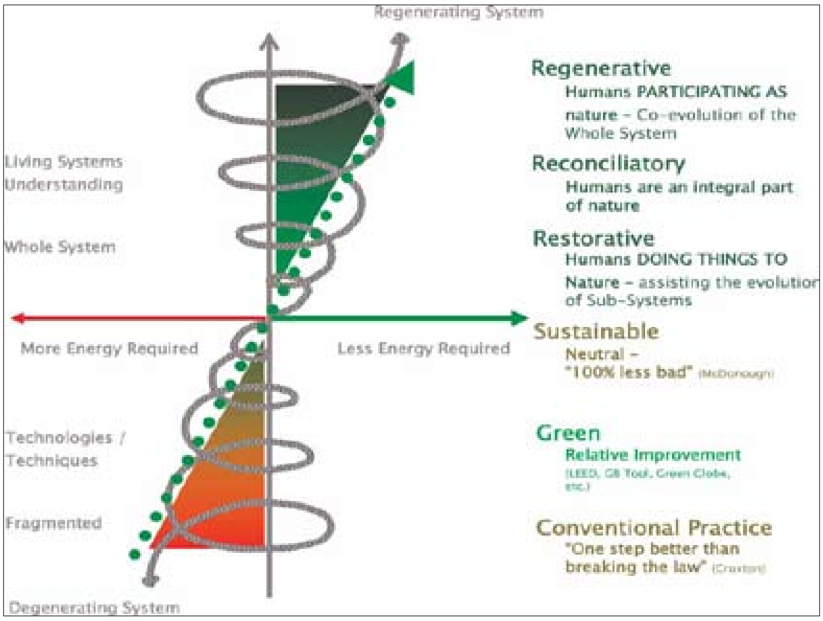

Figure 4: Trajectory of environmentally responsible design (Source: Reed, 2007)

From uniformity to a distinctive New Zealand building style

In the past a regions buildings were a reflection of the local culture, resource availability, and building traditions. What we have today is an "international style that has evolved into something less ambitious: a bland, uniform structure isolated from the particulars of place – from local culture, nature, energy, and material flows" (McDonough and Braungart, 2002). Apart from these buildings reflect little, if any, of a regions distinctness or style they are not intimately connected to the natural flows of the 'place' they are suppose to be a part of. Is it any surprise then that development has all the negative environmental baggage associated with it?

The prevailing approaches to building design also rarely, if ever, address the human biological and ecological need for contact with nature that has been increasingly identified as a prerequisite of human physical and mental health and productivity (Kellert, 2004). Given the imperative of reducing the continued loss of New Zealand's biodiversity and the recognition that contact with nature is good for us why not combine these two needs. The programme has therefore set an aspirational goal of regenerative design that promotes the co-evolution of the whole system. Over time the LGS team may also develop a regional approach to the delivery the Govt^3 programme which will foster difference - individual solutions - sense of place - and a connectedness with a regions natural resources and ecology. The LGS team will also play a leadership role by facilitating connections and collaboration between stakeholders that lead to the promotion of an integrated sustainable built environment design approach.

Bring industry on the journey

Making these changes to the Govt^3 programme however, will not be possible without the industry's goodwill and active participation. This is because although governments are expected to take the lead, other stakeholders are just as important to ensuring success in achieving sustainable development (UNEP, 2007b). At a workshop In February 2007 the LGS team brought together thirty organisations representing a large part of the building and construction sector to map their sustainability initiatives. The intention was to show that by working more closely together, government and industry organisations could leverage off each other's sustainability initiatives. At this workshop the group identified the development of a clear vision for improving the sustainability of the building and construction sector, and leadership to drive these improvements as priorities going forward.

The interest shown at this workshop led to further discussions during the remainder of 2007 to develop a mechanism that would coordinate and foster a shared industry/government vision for a sustainable building and construction sector. The management group currently includes Building Research (BR), the New Zealand Green Building Council, the Department of Building and Housing, and the Ministry for the Environment. The Ministry for the Environment is currently talking to other relevant government agencies and key industry stakeholders to find out what they would like to see happen and what their motivators for involvement might be.

There is general agreement within industry and government that there is a pressing need to improve the environmental performance of the building and construction sector. There has also been general agreement that what is currently lacking is a mechanism to coordinate and drive these improvements. A Sustainable Building Pathway (working title) could provide an opportunity to foster and coordinate these improvements and provide a feedback mechanism whereby the whole sector and relevant government agencies can learn from each others experiences.

It is envisaged the Sustainable Building Pathway would focus on fostering and coordinating environmental improvements of the wider sector but will also develop strategies that help to accelerate these improvements. Whilst the Sustainable Building Pathway will look at the wider built environment to ensure an holistic view is taken it could also allow the investigation of specific topics (examples could include education, water, energy, buildings, infrastructure etc). If industry and government are to be true partners in this initiative there needs to be plenty of flexibility to incorporate their respective views into the overall shape and direction of the pathway. The success of the Sustainable Building Pathway depends on gaining both government and the building and construction sector's buy-in and support. Work is currently underway to establish government's role in this initiative thereby ensuring an appropriate and integrated policy approach.

Conclusion

There is no disputing the environmental impacts of the building environment are immense and it is time to change our building and construction practices to reduce, even reverse them. The adoption of sustainable building practices is still relatively new in New Zealand but is gaining traction at a relatively quick pace. The Govt^3 members have started to use sustainable building practices to reduce the impacts associated with their building projects, and there is now a cross-fertilisation of these ideas between members. The governments adopting of the NZGBC's Green Star New Zealand rating tools and general consumer interest in green building has regenerated the demand needed to convince the market to improve the environmental performance of the commercial building industry.

However, if New Zealand is to become the first truly sustainable nation we will need to make a step change in the way we design our buildings rather than taking a slow transition approach. The Govt^3 programme has adopted an aspirational goal of regenerative design not just for buildings in isolation but as part of a wider sustainable built environment approach. Bu using an integrated design and local context approach it is hoped that Govt^3 members building projects can act as a catalyst to transform New Zealand's built environment. This will require a collaborative approach that includes the active participation of the whole building and construction sector. The possibility of developing a shared vision and strategy for sustainable building in New Zealand will be an import step in gaining this support.

Acknowledgments

I would like to acknowledge the great work the Govt^3 members have already achieved, and the persistence, fortitude, encouragement, and willingness in sharing their challenges as well as triumphs. I would also like to commend those in industry who continue to support the work of the Govt^3 programme; you know who you are.

Keywords: stakeholders, decision making, energy saving, real estate

Summary

In this paper a research framework is presented for a better understanding of how actors take decisions on adopting and applying energy saving techniques in an inter-organisational context. Based on a literature study these actors are expected to be influenced by the network in which they operate during different phases of building projects and their expectations, partially based on experiences in the past, regarding the feasibility of the project's objectives. Because of different degrees of experience and social responsibility or accountability of individual actors in building projects, four different types of building projects are distinguished that cover a large part of all the building projects conducted. The characteristics of these four types are described for the Dutch situation. For two of them some first empirical results are given.

1. Introduction

The energy consumption in the built environment accounts for more than forty per cent of the total energy consumption in Europe (EC, 2002). Improving the energy performance of the built environment is an important issue to come to sustainable development and to reduce carbon dioxide emissions. Particularly after the first oil crisis, many innovative techniques have been introduced to lower the energy consumption or to use renewable energy sources, but not all techniques have been broadly adopted. The differences between these innovative techniques are large. An energy saving technique can be relatively simple or rather complex and in some cases it can directly replace the conventional product or large adjustments in the building design must be made.

Energy saving techniques and the use of renewables can reduce costs and society in general agrees upon the necessity of adopting them. Although high ambitions regarding the energy performance of the forthcoming building are often expressed during the initial phase of a building project, these ambitions are only in a few cases resulting in buildings incorporating many energy saving or renewable techniques. In this paper we intend to make a contribution to the knowledge on decision making processes on adopting energy saving techniques by identifying the relations between stakeholders involved in building processes. The framework is based on decision making theory and innovation adoption theory in order to generate insights in the influences of the organisational environment, in which different types of building processes take place. The central question is:

How can the adoption process of innovative techniques that lower the energy consumption or use renewable energy sources in the building industry be positively influenced?

It is expected that the organisations or persons involved in the building process are of influence on the adoption process, whereby the ambitions stated by the principal before construction and the actual energy performance after construction often do not correspond with each other. In a building process some organisations or persons are only for a limited timepath involved and all have different interests and targets. Therefore, many reasons to install or to reject energy techniques can exist, but they do not always coincide.

Firstly, the theoretical framework will be formulated in which the innovation adoption theory of Rogers (2003), Dieperink et al. (2004), and Hartmann et al. (2008) play an important role. Secondly, the research framework will be explained. Thirdly, the basic characteristics of the main types of building projects will be addressed. The research methodology is described in section five and, finally, in section six the first empirical results are discussed.

2. Theoretical framework

Rogers (2003, pp. 12) states that: *an innovation is an idea, practice, or object that is perceived as new by an individual or other unit of adoption*. In this paper the *idea, practice, or object* are techniques that lower the energy consumption or techniques that make it possible to fulfil the need for energy in a renewable way. The *individual or other unit of adoption* will be looked for within building projects and will in this paper be called actors. The diffusion (*the process in which an innovation is communicated through certain channels over time among the members of a social system,* Rogers, 2003, pp. 5) and rate of adoption (*the relative speed with which an innovation is adopted by members of a social system*, ibid, pp. 23) can differ strongly per technique. *The rate of adoption is the relative speed with which an innovation is adopted by members of a social system* (ibid., pp. 221). Five variables are distinguished which determine this rate of adoption. The first variable, perceived attributes of innovations, brings five attributes together, which are:

1. Relative advantage: the degree to which an innovation is perceived as being better than the idea it supersedes. The relative advantage of an innovation, as perceived by the members of a social system, is positively related to its rate of adoption (ibid., pp. 229, 233);
2. Compatibility: the degree to which an innovation is perceived as consistent with the existing values, past experiences, and needs of potential adopters. The compatibility of an innovation, as perceived by members of a social system, is positively related to its rate of adoption (ibid., pp. 240, 249);
3. Complexity: the degree to which an innovation is perceived as relatively difficult to understand and use. The complexity of an innovation, as perceived by members of a social system, is negatively related to its rate of adoption (ibid., pp. 257);
4. Trialability: the degree to which an innovation may be experimented with on a limited basis. The trialability of an innovation, as perceived by members of a social system, is positively related to its rate of adoption (ibid., pp. 258).
5. Observability: the degree to which the results of an innovation are visible to others. The observability of an innovation, as perceived by members of a social system, is positively related to its rate of adoption (ibid., pp. 258).

The five attributes all join the same aspect "as perceived by members of a social system". A social system is defined by Rogers as a set of interrelated units that are engaged in joint problem solving to accomplish a common goal. The members or units of a social system may be individuals, informal groups, organizations, and/or subsystems (ibid., pp. 23). In this research the social system consists of stakeholders of building processes. Therefore, a stakeholder is in this case a person with an interest or concern in a building project. Not all stakeholders can exert influence on the progress and outcomes of a building project. The particular group of stakeholders that can exert influence is called actors. This research will focus on them.

These actors or the organizations they operate in are influenced not only by the characteristics of the innovative technique itself, like expressed by the five attributes of Rogers, but are also influenced by the context in which the decision making process has to be taken. Dieperink et al. (2004) stresses the importance of studying adoption in its context. The framework of these authors links companies' characteristics and the decision making process & assessments on the one hand with macro developments, technical aspects, economic aspects and the company's context on the other hand. Especially in building projects, where organisational connections exist adjacent to inter-organisational connections, decisions are taken in a complex context. Insights in these structures can contribute to decision making theory.

Vermeulen et al. (2006) have translated the framework of Dieperink et al. (2004) to specify first and second level variables, which explain the adoption of energy innovations for new office buildings. They mention that the actor's characteristics and the networks in which the actor participates have impact on the decision making process and therefore on the rate of adoption. But in their research only the adoption in commercial real estate has been addressed and not the adoption in residential real estate. In residential real estate installations account for a much smaller part of the building costs. This offers interesting opportunities for further research, because the energy consumption is in residential real estate as high as in commercial real estate (PEGO et al., 2007).

Besides the fact that variables and attributes are defined that can accelerate the adoption process, there also exists a perspective in which barriers are defined that decelerate or block adoption processes. By debating on these barriers these scholars (e.g. De Man, 1983; Painuly, 2001) also address the need to include variables that can explain the influence of the context in which innovations are introduced to the potential adopter. Painuly (2001) states on barriers to renewable energy penetration for example that *there are different barriers that need to be overcome…through various actions by stakeholders and governmental policy measures* (ibid, pp. 77). Research of DeCanio (1998) also showed that *data on the profitability of lighting upgrades…strongly support the conclusion that organizational and institutional factors are important determinants of firms' investment behaviour and outcomes* (ibid, pp. 453). Furthermore, it is stated that profitable investments to save energy are possibly not implemented, because of internal barriers in private and public organizations. To be able to understand adoption of energy saving techniques the specific context has to be taken into account. Regarding public organizations Hartmann et al. (2008) offer a model of the adoption process that links the public dimension and professional dimension of the client with the innovation perception (see Figure 1). However, the fact that different levels of public involvement are present (for example because of building regulations on energy performance) has, as far as we know, not been included in existing innovation adoption theories. In general public involvement takes place on two different levels:

- Micro: Individual building projects where the government is involved by means of regulation and inspection. In some situations local governments can be more actively involved or even be the principal or user;
- Macro: Many decisions to stimulate the adoption of techniques that reduce the energy consumption are taken on a national level or supra-national level.

This research distinguishes four different clients and two sorts of buildings to come to a meso scale:

1. Residential real estate developed by social housing corporations;
2. Residential real estate developed by private ownership;
3. Commercial real estate developed by investors;
4. Commercial real estate developed by the government.

Every type of building process needs to be analysed regarding decision-maker, underlying motivations and moment of decision-making in adopting or rejecting energy saving techniques in a project specific context.

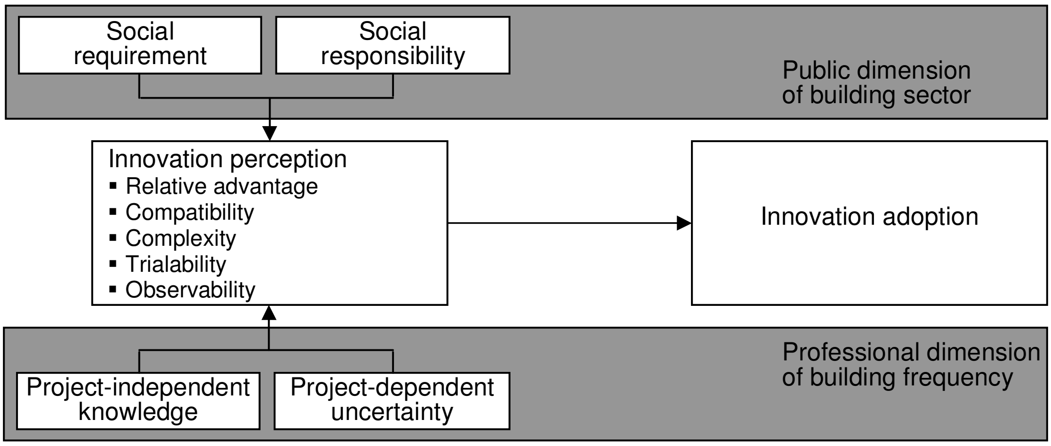

Figure 1: Influences on the innovation adoption of professional public clients (Hartmann, et al., 2008)

3. Research framework

In analyzing the four building projects three research questions reflecting on the deciding actor, underlying motivations and timepath of involvement are formulated:

1. Which actors decide on the adoption and application of energy saving techniques?
2. Which arguments and motivations are underlying their decisions?
3. When and how are adoption decisions taken in the design and construction process?

3.1 Allocating decisions to actors

In the construction industry the social system consists of a great variety of stakeholders related by one or more specific building processes. As mentioned before, a stakeholder is in general a person or organization with an interest or concern in a building project. In a research on the perceptions of stakeholders on alternative energy technologies in buildings, Cooke et al. (2007) distinguish eight different stakeholders: architects, building service engineers, clients, specialist consultants, planners, project managers or quantity surveyors, technology suppliers and contractors. Based on forty-one interviews Cooke et al. (2007) drew up the perceptions of stakeholders on alternative energy technologies. These stakeholders could be so called potential adopters. Vermeulen et al. (2006, pp. 2720) explain what potential adopters are: …*by 'potential adopters' we mean those persons in a decision making position in a project development organization who decide what technological innovations to incorporate in the construction of a new office building.* In this research this select group of stakeholders is called actors.

Besides the term stakeholders another term, "building professionals", is often deployed. Lo et al. (2006) use it for addressing practicing construction engineers, civil engineers, and architects, who are qualified and have at least three years of working experience. However, within the development of residential real estate by private ownership the client can not be expected to be qualified or to have at least three years of experience, therefore in this research the term building professionals is probably not appropriate for all stakeholders or respondents, especially those involved in developing privately owned residential real estate.

Furthermore, it is necessary to be aware of the differences between the communication process and the actual decision process. Rogers clearly addresses the communication process as a preliminary phase. Lo et al. (2006) speak of the influence of building professionals in the decision-making process without giving more insights in which consultation took place before adoption or who exactly took the decision. In this paper the term actor will be used to refer to the specific group of stakeholders that can directly influence the building project and its result. In this research nine different actors are distinguished, which are described in Table 1. It could be that two actors in one project do not have direct communication, but that one of the two still strongly is influenced by the estimated needs of the other. For example an architect will probably give thought to how a building is going to be used.

Table 1: Descriptions of the nine actors regarded in this research

	Actor	Description
Granters	Client – Principal (Cl)	Person or organisation requesting the constructive service of a professional person or organisation
Granters	Customer- User (Cu)	Person or organisation making use of the provided building
Granters	Warden (W)	Person or organisation responsible for the supervision of and maintenance on the building and its location
Granters	Property developer (PD)	Person or organisation that converts land to a new purpose, especially by constructing buildings
	Municipality (Mu)	A town or district having a local government that enforces building regulations
Takers	Architect (A)	Person who designs buildings and in most cases supervises their construction
Takers	Consultant (Cs)	Person who or organisation that provides expert advice professionally
Takers	Contractor (Co)	Person who or organisation that undertakes a contract to provide materials and/or labour for a construction project
Takers	Subcontractor (Sc)	Firm or person that carries out work for a company as part of a larger project
Takers	Manufacturer (Ma)	Firm that fabricates construction components and/or materials

3.2 Arguments and motivations

The reasons to adopt or reject certain energy saving techniques can have a broad background. Past research addresses the use of multicriteria decision-making frameworks (e.g. Haralambopoulos et al., 2003; Banaitiene et al., 2006) and the role of decision support systems (e.g. Hersch, 1999) to chose for the adoption of a specific technique out of a range of alternatives. However, in that case the actors of the building project should already be familiar with all existing alternatives.

Rogers' attribute "relative advantage" often gets more attention than the other attributes when in the social system known energy saving techniques are compared. The final choice for an energy saving technique can then be based on variables like fuel saved, return on investment, number of created jobs, environmental contribution and involved risks (Haralambopoulos et al., 2003). In this research attention will be paid to the preliminary phase of becoming familiar with the existence of energy saving techniques by addressing the five mentioned attributes of Rogers that influence the rate of adoption and by setting an environmental context in line with the model of Hartmann et al. (2008).

3.3 Design and construction processes

This paragraph addresses the different phases of the design and construction process, because *it should … be recognized that any given decision is likely to be part of a series of decisions or decision processes rather than occurring in isolation* (Hersh, 1999, pp. 397). In other words preceding and following phases can be of influence on the phase in which decisions are made. By using a scheme of the phases in a standard building process it will be possible to get more insights in when the decisions are taken. Process schemes of Arditi & Gunaydin (1997) and Turin (2003) link actors and phases of the building project directly, but by insinuating these relations in advance, different process schemes need to be prepared reflecting on different project organisation forms. Therefore a process scheme will be used of the University of Salford (Kagioglou et al., 1998), that does not mention any actors or stakeholders yet.

Decisions on the adoption of complex energy saving techniques can be taken in early phases of the building process to minimize efforts and costs of installation. It is expected that the early phases in construction projects are in general most suitable to address rigorous energetic requirements, because…*the early phase of a project development is the most important time for innovative activities and for planning a project execution that will optimise project value generation* (Kolltveit et al, 2004, pp. 545).

4. Characteristics decision making processes in building projects

We are aware that the list with the four types of building projects, mentioned in section 2, is not complete regarding construction types and possible ways to come to project development. We use this distinction because of the different levels of expertise, accountability of the principals, and the specific energy consumption patterns of the regarded objects. In this section some characteristics of these kinds of real estate and the actors involved in the building processes will be mentioned regarding the Dutch situation.

4.1 Residential real estate developed by social housing corporations

Social housing corporations own more than one third of the Dutch houses. By the end of 2003 the total number of houses owned by corporations was 2,420,500 (Dekker, 2004). The objective of these corporations is to provide affordable housing of a proper quality even for households with a minimum income. It is hard to achieve this objective in a market with relatively high land prices of € 341.- /m^2 on average. Besides, the average building costs of a rented house are € 86,000.- (excluding VAT) (Bouwend Nederland, 2007) and the adoption of energy saving techniques makes even higher investments necessary.

A subsidy on the rent is provided for the tenants of this type of residential real estate, when their income minus the cost of renting are below certain thresholds. These thresholds are solely based on the basic costs of hiring without service costs or energy costs. On average the basic costs are € 402.- per month (Bouwend Nederland, 2007). This means that extra investments that go beyond the basic regulations of the Building Code[1], can not be earned back by raising the monthly rent, because an increase will result in a subsidy stop for the tenant. However, the tenant does receive a lower energy bill and therefore will benefit from the investment done by the housing corporation.

De Man (1983) specified certain barriers that obstruct the adoption of energy saving techniques in the social housing sector. He distinguished structural, regulatory, and interpretive barriers. These barriers only addressed misfits in the relation between the national government and the social housing sector, but the organisation of the building process itself was not addressed. Nowadays social housing corporations are considered to be highly experienced principals or property developers regarding real estate, but based on the investments costs less experience is expected to exist on the adoption of innovative techniques.

4.2 Residential real estate developed by private ownership

In recent years the Dutch government stimulated the development of residential real estate by private ownership. This type of development is considered to be favourable because of the higher level of differentiation in building designs and of customer satisfaction. In most cases these houses are detached and are middle to high-priced. Regarding the adoption of energy saving techniques the financial aspect could form a smaller barrier compared to the development of social housing, but the principal’s acquaintance with existing energy saving techniques is expected to be a bigger barrier.

In developing residential real estate by private ownership the role of the principal is only in some cases ascribed to environmentalists that wish to adopt several energy saving techniques. However, in most cases the Building Code will be used to specify the quality level and just some basic energy saving techniques are applied. When the principal is not familiar with the broad range of energy saving techniques that is available nowadays, an important role can be played by the other actors that are involved in the project. Some architects for example are specialists in sustainable building and have progressive designs of houses available. In other cases it is the municipality that stimulates the adoption of energy saving techniques by offering information, subsidies or certificates. In these projects macro, meso and micro scale considerations can have an interesting overlap.

4.3 Commercial real estate developed by investors

The development of commercial real estate can take place on demand of a company that is in need of work space to provide service to its customers. However, in this research the development of real estate by (institutional) investors will be regarded, because in this design and building process the principal and user are not one and the same actor.

In the Netherlands the total number of offices is approximately 60.000 (Prendergast et al., 2006) with a value of 250 billion Euro (DTZ Zadelhoff, 2007). Although commercial real estate uses large quantities of energy, the building regulation on the energy consumption of commercial real estate is not as hard to comply with as the regulation for residential real estate. An obstacle in adopting energy saving techniques forms the fact that in many projects the future user of the building is not known yet. Therefore, the investor does not know what the energy consumption of user pattern will be, and if the future user is willingly to pay for the extra energy saving techniques in exchange for lower energy bills.

[1] The Dutch Building Code specifies the minimum quality of new buildings, among the prescripts is an Energy Performance Coefficient that specifies a maximum energy consumption per object.

4.4 Commercial real estate developed by the government

In many countries governments play an important role in developing commercial real estate. In the Netherlands the national government alone owns offices with a gross surface of 3,2 million m^2 (Min. VROM, 2007). By being principal and (dedicated) user at the same time a government (department) should be able to benefit from the investments during their whole lifespan. Furthermore, it is assumed that governmental principals set an example for the building industry by adopting state of the art energy saving techniques or by adopting energy saving techniques that are not profitable yet, but are considered to be sustainable. The government could be an experienced client (like Hartmann et al. (2008) already mentioned) with a strong social responsibility.

5. Methodology for future research

The research will be conducted by using structured questionnaires. The respondents will be chosen in such a way that they can reflect on one or more of the four building processes specified. Seven preliminary interviews among a social housing corporation, municipality, province, architect agency, and project developer demonstrated the need for a structured questionnaire, but with the possibility to include personal reflections on the questions and on the answer options. A scheme (see Figure 2) reflecting on the roles of the actors within the decision making process will be used to structure the answers regarding the first and third research question. The second research question on arguments and motivations is expected to result in figures comparable to Figure 1 of Hartman et al. (2008).

Furthermore, the first few interviews already demonstrated the relevance of financial aspects of energy saving and the necessity to operate demand based. This means that the client or user needs be willing to pay for the techniques. Without this willingness the Building Code and local regulations form the basics to achieve a certain energy performance.

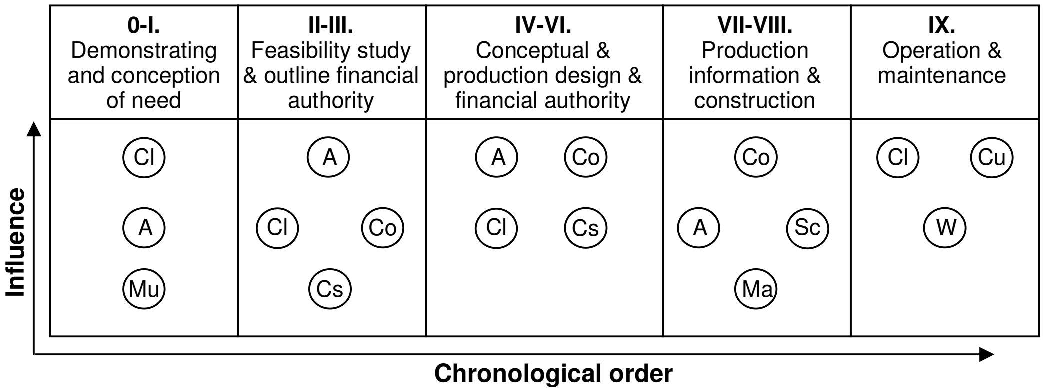

Figure 2 Possible representations of empirical data resulting from research on decision making actors in different phases of a building process.

6. First empirical results

Two preliminary projects had taken place to get insights in the adoption of energy saving and renewable energy techniques in the four building processes. The first project consisted of a research among social housing corporations regarding the decision to adopt or reject passive house designs. This research was conducted to reflect on the first phases (0-III) of buildings projects of the first category "residential real estate developed by social housing corporations" The second project focused on the possibilities to reduce Life Cycle Costs (LCC) by using Service Level Agreements (SLA) in commercial real estate. The LCC and SLA included among others heating systems and energy costs. This project considered commercial real estate in the existing building stock (phase IX) developed by investors.

6.1 Adoption of the passive house concept by social housing corporations

By using the integrative framework of Dieperink et al. (2004) research was conducted on which factors are of influence on the decision making process on adopting passiv houses by social housing corporations. In general the main categories that influence these processes were: government, market & society, company's characteristics, economic aspects, technical aspects, and macro developments. A methodology of reviewed surveying was used in which surveys were preceding extensive interviews among ten respondents of different housing corporations in the eastern part of The Netherlands.

Although these corporations have a strong social responsibility within the Dutch community, the surveys made clear that the economic aspects were considered to be the most important drivers to implement energy saving techniques (Dekker, 2008). The respondents could define, within the main categories, which aspects surrounding a project are influencing the decision making process most strongly. The results are given in Table 2. Furthermore, the results of the interviews showed that the corporations are well-disposed towards innovations that can reduce the energy consumption. One of the reasons for this sympathy is the rising energy price that increases living costs of their tenants.

Table 2: Relevance of aspects within main categories that influence the decision making process on adopting passiv houses according to respondents (Dekker, 2008).

Government	Market & society	Economic aspects	Technical aspects	Macro developments
1. Policy & regulations	1. Demand	1. Investment costs	1. Reliability	1. Energy prices
2. Incentive programs	2. Vertical collaboration	2. Pay back period	2. User-friendliness	2. Environmental considerations
3. Subsidies & credits	3. Influence of suppliers	3. Efficiency	3. Complexity	3. State of economy
4. Support	4. Rate of R&D		4. Technical practicability	4. Developments involving energy supply
5. Knowledge transfer	5. Union		5. Alternative options	
6. Convenants			6. Organisational practicability	
			7. Problems at startup	

6.2 Importance of life cycle costs and service level agreements among investors

In the research of Lenters (2008) the acquaintance with LCC and SLA among Dutch and German commercial companies and their vision on the possibilities to reduce costs by using SLA were revealed. Six Dutch and six German respondents have been interviewed. The interviews were again preceded by surveys.

Two out of twelve respondents were unacquainted with LCC. Five of the respondents indicated to be able to compute LCC themselves. Six persons mentioned that they were already familiar with the concept for more than five years. Regarding the energy consumption of commercial real estate SLA are used in the field of maintenance of building installations, climate control systems, heating systems, and electric equipment. In these situations the respondents state that these services are in most situations provided to the owner of the real estate object and not to the user. Services involving the maintenance of building installations and climate control systems are more often incorporated in SLA than services involving heating systems and electric equipment. These results are relevant to gain insights on how actors involved during design & construction phases of the building process and actors involved during operation & maintenance can match there interests.

7. Conclusions

This research aims at improving the understanding on how actors are involved in the processes of adopting and applying energy saving techniques. Interviews and structured questionnaires among social housing corporations shows that the bottom line for the energy performance of buildings given by the national Building Code or in some cases given by additional regulations provided by the municipality, and not surpassed willingly because of the involved investment costs. However, these regulations make sure that the corporations are requesting for energy saving techniques in an early stage of the building project. Furthermore, it seems at this moment that these regulations are their strongest motivation in applying energy saving techniques.

The foreseen methodology of structured questionnaires will give direct insights on micro scale. Insights on meso scale, reflected by the four distinguished building processes, can be generated by using a) a process protocol that specifies actor involvement in combination with b) a higher number of respondents than in former research was done. In the end we expect to be able to provide multi-actors strategies to enhance the adoption of energy saving techniques.

Acknowledgements

This research is part of a research project named “Exergy in the Built Environment” that uses the triple bottom line (people, planet, and profit) to address three main aspects involving the exergetic performance of the built environment. One of the three Dutch technical universities involved, namely the University of Twente, contributes to the third aspect by allocating financial benefits and costs to different actors in the building projects. The authors would like to express their gratitude to the SenterNovem for providing financial support for the present research.

[2] School of Architecture, Victoria University of Wellington, New Zealand, Brenda.Vale@vuw.ac.nz

Keywords: sustainability, suburbia, Thailand, self-sufficiency, self-reliance.

Summary

Sufficiency Economy is one of the major goals for sustainable national development in Thailand, initiated by the present King of Thailand, along with a people-centred approach. New Theory Agriculture, the most famous and practical implementation of the philosophy of Sufficiency Economy has also proven useful among Thai farmers in rural areas. One of the major successes is the achievement of the key principles regarding self-reliance and self-sufficiency. Its implementation plays an important part in encouraging a better lifestyle, physical and emotional wellbeing, and resource management, specifically land. It helps to harmonise simultaneously individual, social, economic, and environmental development.

As New Theory Agriculture sets a good example of a move towards sustainable development in Thailand another step forward would be to apply it to a more complex scale of community such as suburbia. This paper investigates the importance of the philosophy for sustainable suburban development in Thailand and the possibility for its implementation and application, as well as benefits that might come from this. Case studies have been chosen to illustrate a clearer view of the current situation and present capabilities. The findings should encourage adjustments ranging from individual lifestyle, household planning, better relationships in the community, to those with the environment, as well as contributing to sustainable suburban community development in Thailand.

1. Introduction

Sufficiency Economy has been used as a Thai version of sustainable development and is meant to serve as an underlying principle to all activities for a sustainable future. Even though there is not enough evidence of comparative study between sustainable development approaches and Sufficiency Economy, which have similarities, it is possible to point out the potential sharing of key interests. The main idea of Sufficiency Economy; to live with what one can have and not be extravagant, suggesting that when one only has what one should the sharing of resources is fairer, will greatly contribute to a sustainable future. The philosophy of Sufficiency Economy is believed to be leading the nation to develop in a more secure way, producing a more resilient and sustainable economy, better able to meet the challenges arising from globalization and other changes (NESDB, n.d.: 1). The concept of this philosophy is understood to be capable of application to all people in society (NESDB, n.d.: 2). However, there is still little evidence of its practical implementation except for the famous New Theory Agriculture, a theory aimed at farmers in rural areas.

New Theory Agriculture has proven successful among rural communities, so it would be reasonable to take the further step of its implementation in a more complex society as found in suburbia, as this should be significant for overall national performance in the direction of sustainable development. Moreover, an earlier study (Hengrasmee and Vale, 2007) which tested the benefits of suburban agriculture to the Thai economy concluded that agricultural activity in suburban areas is necessary to maintain Thailand's economic status. Because New Theory Agriculture is aimed at meeting family consumption needs before providing goods for sale, the study hypothetically investigated the situation of national food supply and export capacity under the circumstance that all farmers practice New Theory Agriculture. It appears that surpluses produced by farmers are enough to sustain Thai national consumption. However, there would not be enough food for export which is one of the main sources of income for the country. Therefore, suburban agriculture could be a solution. When suburban people are partially responsible for food production it would lessen the farmers' burden of feeding the whole country and provide goods for export at the same time. This involvement would leave farmers with the job of feeding themselves, producing some foods that cannot be grown in suburbia, and investing their available land, labour, and time in other cash crops.

Accepting the need for food production in suburban areas and the need to establish the next step forward for the implementation of the philosophy of Sufficiency Economy, this paper explores the possibility of implementing the philosophy in suburban areas. The current capabilities of the selected areas are tested to see to what extent Sufficiency Economy can be applied into the suburban situation in Thailand.

2. Sufficiency Economy and New Theory Agriculture

The philosophy of Sufficiency Economy has been bestowed by His Majesty King Bhumibol Adulyadej (Rama IX) to his subjects through royal remarks on many occasions, and the origin can be traced back to the year 1974, even though only later in 1997 was it known as "Sufficiency Economy" (NESDB, n.d.: 1). The philosophy has been officially adopted as a vision for national development since production of the Ninth National Economic and Social Development Plan (2002-2006) (NESDB, 2002).

The concept of a Sufficiency Economy is adapted from Buddhism by stressing the "Middle Path" as an overriding principle for appropriate conduct by the populace at all levels (NESDB, n.d.: 2). According to the "Middle Path", "Sufficiency" is implemented as the three significant parameters of moderation, reasonableness, and the need for self-immunity for sufficient protection from impacts arising from internal and external changes (NESDB, n.d.: 2). So, in short, Sufficiency Economy is about encouraging people to know what is enough for each person, learn to be satisfied with what each can have, and try to be more self-reliant and self-sufficient without being too extravagant. This principle applies to all conduct starting from the level of families and communities, up to the whole nation (NESDB, n.d.: 2).

In terms of practice, the most important example of the implementation of the philosophy to date in Thailand is the famous "New Theory Agriculture" also given by King Rama IX in 1994. The emphasis is on practical implementation and has proved successful among rural communities. The theory recognises land capital and uses it as the basis of resource availability. The key idea is to make the most of the immediate environment at a manageable scale as well as maintaining harmony with it at all levels. It outlines the idea of what one can have. New Theory Agriculture is aimed to help people to have the ability to provide themselves with enough food to eat and enough essentials for everyday life, with much less dependency on outside factors. Then the surpluses can be exchanged or sold. The theory consists of three steps to be completed, from the smallest scale of a step to be taken by a family to the third step for the wider community. The essential part of the theory is about proper management of land use and how to develop the economy. The three steps of the theory are briefly described below.

The first step is based on producing enough products to be consumed in the family with some extra products to sell. This step is about the agricultural system, and encourages farmers to grow a diversity of plants to balance the ecological system and the needs of everyday life. The Theory suggests farmers proportionally manage their land by divided it into the four parts of a rice field, a pond, a farm plants/crops part, and a part for housing and other necessary buildings. An approximate proportion was suggested, but the key is for the farmer to divide the land reasonably according to individual needs, ability and available labour.

After successful practice of the first step, it is expected there will be enough food for each family. The second step is to pool efforts and look for co-operation within a community. The co-operative setting suggested by the second step will help to create a strong relationship based on interdependence in a community. Every family gets a reasonable benefit and a well planned society is created. In short, the second step of the New Theory is aimed at co-operation between people at every level in a community. The third step is creating a relationship to the outside community for improving local economic status. This step can help a community to reduce its capital costs and progress into a stronger position in the production and marketing field. This step will lead farmers to be more efficient and have an economic marketing operation.

New Theory Agriculture is not only well known as a theory, but has already been proven useful for farmers who are practising it. There is evidence of farmers having a better family life in terms of a well-fed family, less expenses, more income from selling their surpluses, and the family has work to do all year round, thus reducing the need for family members to migrate to find jobs in the city outside planting seasons (Promthong, 2001; The Chaipattana Foundation, 1997; 1998; 1999). It can be inferred from New Theory Agriculture that if the smallest scale of society, the family, especially in a rural area, can improve their economic position by trying to supply their own needs at less cost or undertake agricultural activities with far less capital cost than before, this might be the beginning of creating a sustained life for them and their community. The successful practice of New Theory Agriculture lies deeply in the self-reliant lifestyle and consciousness of self-sufficiency adopted by rural people. A major lesson drawn from the successful experiences of the farmers is that the combination of a self-reliant and self-sufficient attitude and practical arrangement of available land to suit the lifestyle is the key to success.

3. Process of the Study

This study aims to explore the possibility of implementing the Sufficiency Economy into suburban areas of Thailand. The process chosen for the task consists of four stages. The first stage is to identify the key ideas from Sufficiency Economy and New Theory Agriculture suitable for suburban implementation. Then an investigation of the general characteristics of an average household in suburbia will be undertaken. Stage three involves a series of investigations into the average consumption by a family, which will help to set a standard for demand. The last stage is to test the physical ability of average suburban households to supply the estimated demand.

3.1 Stage One: Key Issues for Implementation

This first stage is to identify the key areas of the philosophy that can be implemented in suburban areas. The successful implementation of the philosophy for rural areas in New Theory Agriculture was taken as the basis for this. The main idea behind the application of the first step of New Theory Agriculture is the method of land management, with the following steps being about building relationships within and between communities. The theory first suggests farmers divide their land into several parts with each having a different purpose and producing different products. Since New Theory Agriculture is an implementation of Sufficiency Economy, the main idea is also that the farmer, whose work is to provide food for others, should be able to provide his family members with their basic food needs. The suggestion for land arrangement is based on the amount of food each family needs to consume each year as well as the need for water for food production and family consumption, especially during the dry season. Surplus land can be used for producing extra products for sale, but only if the family can do this without overstretching themselves. The recognition of the Middle Path or moderation and self-sufficiency play an important role in the farmer's decision making. So, to be successful in practicing New Theory Agriculture, as well as building a good foundation for the family's economic status, the basic requirements are a combination of good judgment in terms of self-sufficiency as well as good practice in land management.

Implementation of Sufficiency Economy for a rural community using New Theory Agriculture suggests three scales of application, these being family, community, and national. Implementation of the philosophy in suburban areas can also use this structure. According to New Theory Agriculture, focus on the family is the first step before moving on to the second and third steps. The family level is centred on a self-sufficient lifestyle and practical land management that will enhance the ability to have a self-reliant lifestyle. This study investigates the possibility of applying the first step of the implementation process to suburban areas, so the physical characteristics of suburban households and the ability to support such a lifestyle will be tested.

3.2 Stage Two: Suburban Household Characteristics

In this study, implementation is focused on the first step, at family level. The physical characteristics of a representative residential area in suburban Thailand are needed for testing the capability for implementation. A suitable definition of Thai suburban areas is also needed, in order to identify the physical characteristics of average suburban households. The characteristics of average land holdings and housing footprints are identified for testing against consumption levels. This also means that any households outside the identified suburban areas but having equivalent characteristics should be able to comply with the study findings.

After careful consideration, two Tesban Thambol in Phitsanulok province were selected as examples of representative Thai suburban areas. According to the investigation, the most common areas for land holdings in the case studies range from 200-400 m^2 with an average 50-100 m^2 building footprint. In addition to the average range, six more housing models were selected from the standard housing plans provided in 2004 by the Department of Public Works and Town and Country Planning (n.d.) as these have footprints related in size to the averages discovered in the case studies. These also represent the average number of family members in suburban households and show a general understanding of contemporary housing trends for Thai people. These housing styles provide a foundation to work from, especially in terms of roof styles, when considering the potential for energy production and water collection.

3.3 Stage Three: Levels of Consumption

The average household size for the whole country when surveyed in 2004 was 3.4 people/family, so four family members (two parents and two children) have been assumed in this study (NSO, 2005). In general, suburban people will probably not be familiar with the idea of self-reliance, since the location of suburbia is normally close enough to facilities so people can buy all they need. However, better practice of self-reliance in suburbia or other places will support sustainable development in Thailand. A series of investigations into suburban consumption examined three areas of basic consumption for a family living in a suburban house. As New Theory Agriculture suggests farmers should live with less dependency on others for food and water, the basic needs for a suburban family which will increase their self-reliant lifestyle are assumed to be in the areas of food, energy, and water.

3.3.1 Food Consumption

How much a person eats is actually a personal issue. However, average consumption for Thai people can be estimated by using the average diet suggested by the Nutrition Division, Department of Health (2003). From the fact that suburban households have limited land, complete self-reliance in food will not be possible. Fruit and vegetables are seen as the most suitable types of food for home production on limited land as well as being appropriate in terms of the level of skill involved. Accordingly, only the consumption of fruit and vegetables will be presented here. The level of fruit and vegetable consumption suggested by FAO and WHO (2004) is a minimum of around 400g/person/day. More fruit and fewer vegetables are also mentioned. As a result, in this study it is assumed a family of four people will need 350kg of fruit and 234kg of vegetables each year.

3.3.2 Energy Consumption

Average energy consumption for Thai households can be traced from several national statistical data sets provided by government authorities. For example, data for different types of energy consumption in the residential sector are provided annually by the Department of Alternative Energy Development and Efficiency (DEDE, 2005b). Average electricity consumption for a household can also be traced by using data drawn from payment of electricity bills, with the latest data of this type in 2004 coming from a survey by the National Statistical Office (NSO, 2005). Along with information on the average price per kWh (unit) from the DEDE (2005a) in the same year, a rough picture of average electricity use per household per month can be built up.

However, in this study, estimation of energy consumption for a family is based on demand, and calculated from the types of appliance and period of use in a household with four people. The study also chose to use only electricity as the source of energy, in order to avoid complication. Two examples, one of low users and the second of intermediate/high users were created based on different types of appliance ownership and levels of use. Types of appliance selected in this study[1] are from a series of ownership surveys done by NSO (1996; 1998; 2000; 2002; 2004). The study estimated use of 5.9 kWh/day for a low user household and 18 kWh/day for an intermediate/high user household.

3.3.2 Water Consumption

Average water consumption data at national level is regularly provided by both Metropolitan Waterworks Authority (MWA) and Provincial Waterworks Authority (PWA). Water consumption per capita from 1997 to 2006 reported by MWA (2006) and PWA (n.d.) revealed that around 240 litres/person/day is used within MWA areas, and 150 litres/person/day in PWA areas. So, average water consumption in Thailand turns out to be around 200 litres/person/day. Even though the suburban example chosen for this study is inside a PWA area, a more generalised 200 litres/person/day is used to account for rising aspirations in suburbia.

In general, water is used for drinking, sanitation, and washing in a household as well as for outside activities such as watering plants and car washing. Average water consumption for different activities (Manager Online, 2003; Energy World Journal, 2003) in Thai households is shown in Table 1. The table also provides two alternative sets of consumption values based on water conservation practice appropriate for suburban households aiming for greater self-reliance. The first is based on installing better fixtures and the second on using greywater for the out-of-house use. In fact more actions involving behavioural changes can be done to reduce water consumption, but the two alternatives represent water conservation methods that can be easily achieved by all.

The study concludes that a family with conventional fixtures will require around 292,000 litres/year, a family with water conservation fixtures who are not using their greywater will use 208,780 litres/year, and a family with both water conservation fixtures and greywater use will need only 122,640 litres/year.

Table 1 Estimation of household water consumption per person

Types of use	Proportion (%)	Consumption per capita					
		Conventional fixtures		Water conservation fixtures			
				Without reusing greywater		Reusing greywater	
		litre/day	litre/year	litre/day	litre/year	litre/day	litre/year
Household cleaning	2	4	1,460	4	1,460	4	1,460
Kitchen use	5	10	3,650	10	3,650	10	3,650
Washing clothes	9	18	6,570	18	6,570	18	6,570
Wash basin and shower	23	46	16,790	27.6	10,074	27.6	10,074
Flushing toilet	26	52	18,980	13.5	4,928	13.5	4,928
Out-of-house use	35	70	25,550	70	25,550	10.4	3,796
Total	100	200	73,000	143	52,232	84	30,478

3.4 Stage Four: Potential for Self-reliance in Suburban Thailand

The physical characteristics of current suburban household models selected in stage two have been tested to see to what extent they can provide the basic needs for a family of four people as estimated in stage three. First, the ability to supply food is tested based on available land areas and appropriate levels of fruit and vegetable production. The capability for energy production and water collection is based on the size and type of roof from the selected housing models.

3.4.1 Potential for Food Production

The study selected three types of fruit[2], 13 vegetables[3], and 10 herbs[4] to represent the types of fruit and vegetables to be produced in suburban Thailand. The investigation involved the area needed for each plant, and length of time of growth and production on a monthly basis, to allow for the family being able to plant and harvest all year round. An area between 133 m^2 and 150 m^2 is needed for all plants. The different areas come from shifting plots between short-life plants.

Using the average range of current plot sizes (from stage two), the housing footprints of six standard housing models provided by the Thai government as well as two average housing footprints from the chosen suburban case study were calculated, with an allowance for a driveway. This was done to find out how much unbuilt area is left for food production. It is assumed vegetables are planted first due to their higher

[1] Types of appliance owned by a low user number 11, these being a television, electric fans, electric pot, rice cooker, lighting, washing machine, electric cooker, refrigerator, water pump, radio, and video player. For the intermediate/ higher user, 15 appliances were chosen including all of the appliances owned by the low users and four extra, these being air conditioners, water heater/boiler, microwave oven, and a computer.
[2] Guava, papaya, and banana.
[3] Cabbage, cauliflower, Chinese kale, Chinese flowering cabbage, leaf lettuce, Chinese cabbage, water spinach, yard long bean, cucumber, pumpkin, tomato, angled gourd, and okra.
[4] Coriander, long coriander, kitchen mint, galangal, ginger, chili, lime, lemon grass, sweet basil, and holy basil.

productivity compared to fruit for the same area. As a result, as shown in Table 2, the minimum that can be produced is 50% of yearly household consumption. When the housing plot reaches 350 m^2, all housing models can reach the stage of complete self-reliance for fruit and vegetables.

Table 2 Productivity levels of selected housing models on different plot sizes

Plot size	Productivity levels							
	Housing Type 2	Housing Type 3	Housing Type 4	Housing Type 5	Housing Type 6	Housing Type 7	50 m^2 footprint house	100 m^2 footprint house
200 m^2	N/A	50%	N/A	50%	N/A	N/A	60%	N/A
300 m^2	100%	100%	70%	100%	80%	70%	100%	80%
350 m^2	100%	100%	100%	100%	100%	100%	100%	100%
400 m^2	100%	100%	100%	100%	100%	100%	100%	100%

3.4.2 Potential for Energy Production

The potential for energy production in suburban areas is investigated by assuming all electricity generation comes from natural resources. The location of Thailand provides a good opportunity for exploiting solar radiation using photovoltaic (PV) cells for electricity generation. The average solar radiation for the whole country is 18.2 MJ/m^2-day (Janjai, Laksanaboonsong, and DEDE, 1999). For Phitsanulok, data obtained from the Regional Office of Energy Development and Promotion 9 shows average global solar radiation for the province ranges between 15.8-22.3 MJ/m^2-day and average insolation is 4.4-6.2 kWh/m^2-day.

The estimation of energy consumption presented earlier in stage two shows that 5.9 kWh/day is required for a low user household and 18 kWh/day for the intermediate/high user. The two systems for using PV panels for electricity generation are stand-alone and grid-connected. However, suburban areas are normally located where necessary facilities, such as electricity infrastructure, are already in place, so the stand-alone system does not seem appropriate. A grid-connected system would be a better choice in terms of smaller area requirement and less capital cost, as well not needing batteries for energy storage in the system. This paper presents the areas needed for PV grid-connected systems, which are also likely to be the main choice of suburban people due to the support for them given by Metropolitan Electricity Authority (MEA) and Provincial Electrical Authority (PEA) through the Very Small Power Producer program (VSPP) (MEA, n.d.; PEA, n.d.). The grid will act as the backup system for the house with surpluses put into the grid as necessary.

The investigation into using a grid-connected system is based on average insolation (5.2 kWh/m^2-day). In general an installation with a nominal power of 1kW_p requires an area of 9-20 m^2 (Hermannsdörfer and Rüb, 2005) depending on the type of photovoltaic cell. A project carried out by the Electric Generating Authority of Thailand (EGAT) and DEDE, which started phase one in 1997 with 10 houses and later expanded in 2002 with 50 houses, introduced the use of several types of PV panel to the general public (EGAT, 1998; 2004). Experiences of the project give a rough estimation of the relationship between PV nominal power and installation area. It appears from the project that the average area for a nominal power of 1kW_p using monocrystalline silicon or polycrystalline silicon is around 9 m^2, while an amorphous PV panel system requires 15 m^2.

The potentials for electricity generation for each housing type for a grid-connected system are listed in Table 3. Note that the southern side of the roof is used in this investigation, since it is the most suitable for PV installation in Thailand. Almost all roof types of the standard models provided by the government are hipped, so only around 1/3 of each roof is available for the installation. With a gable roof, there will be more area for PV installation, so both types of roof (hipped and gable) were applied to the 50 m^2 and 100 m^2 footprint houses in the investigation. It can be seen that nearly all housing models can produce enough electricity for a low user household whatever types of PV panel they use. The use of monocrystalline or polycrystalline panels allows the intermediate/ higher users to produce at least 60% from a grid-connected system. The amorphous type needs more area, so it is harder for the intermediate/ higher users to produce enough electricity with the current hipped roofs. The use of a gable roof would give more roof area and therefore more electricity.

Table 3 Potential for electricity generation of the selected housing models for a grid-connected system

Description	Housing Type 2	Housing Type 3	Housing Type 4	Housing Type 5	Housing Type 6	Housing Type 7	50 m^2 footprint house		100 m^2 footprint house

3.4.3 Potential for Water Collection and Storage

Investigation into the potential for water collection was divided into two parts. The first tested the estimated out-of-house water requirement (shown in stage three; 3.3.2) against the possible collection. The second compared rainwater harvested from the available roof area against total water requirement.

An area of 150 m^2 is needed for fruit, herbs, and vegetable production at home. An estimate from the New Theory (Promthong, 2001) of water needed for these plants other than natural rainfall is equal to 625 litres of water per square metre of productive garden. A 150 m^2 garden will, therefore, need 93,750 l/ year. The current 70 l/ person/ day for out-of-house use would give 102,200 liters of water for watering the plants each year. It is, therefore, assumed that 102,220 litres/year will be sufficient for all out-of-house use including growing the fruit and vegetables for home consumption.

Currently in Thailand rainwater remains one of the main sources of drinking water for many people even though there is much concern about human health and poor water quality because of the increase in pollution, causing alarm to many Thai people living in urban or industrial areas (Department of Health, 2007). The main reason for impurities is understood to be from improper design of collection and storage systems, as well as lack of maintenance, rather than the quality of rainwater itself (Department of Health, 2007). If rainwater is used as an alternative water supply, it can be treated appropriately either by boiling or passing through filters, especially if used for drinking. (Food and Water Sanitation Division, n.d.).

Phitsanulok has an annual average rainfall of 1,300 mm. Using the available roof areas of the housing models, the potential rainwater harvest is shown in Table 4. Only the household using water conservation practices involving water saving fixtures and reusing greywater can harvest enough rainwater for their annual consumption. The others will have to combine rainwater collection with conventional water supply.

Table 4 Potential rainwater harvest and levels of water use

Description	Housing Type 2	Housing Type 3	Housing Type 4	Housing Type 5	Housing Type 6	Housing Type 7	50 m^2 footprint house	100 m^2 footprint house
Catchment area (m^2)	166	110	142	109	121	160	96	159
Amount of rain harvested (litre)	215,800	143,000	184,600	159,900	185,900	208,000	124,800	206,700
Conventional consumption	74%	49%	63%	55%	64%	71%	43%	71%
Water conservation fixtures	≥100%	68%	88%	77%	89%	≤100%	62%	99%
Water conservation fixtures and reusing greywater	≥100%	≥100%	≥100%	≥100%	≥100%	≥100%	≥100%	≥100%

It is possible to harvest enough rainwater for family consumption. However, a container for rainwater storage is also required. Even though the average rainfall of Phitsanulok is quite high, the dry season is quite long. Rainwater storage would have to be big enough to hold between 38-48 m^3 depending on the roof area available even for the family with water conservation fixtures and greywater reuse. This size of water storage will greatly affect the land area available for food production if it is intended to install storage tanks above ground. In general, Thai people normally store water sufficient for up to two day's consumption as a general precaution in case of water cuts. Water tanks commonly used in the residential sector are, therefore, normally 1.5-4 m^3. Bigger water tanks are intended for use in public buildings and are harder to obtain for individual households. However, if collecting rainwater is seen as an appropriate practice by the majority of people, bigger water tanks would be more common.

4. Sufficiency Economy and Sustainable Suburban Community Development in Thailand

The first step of the implementation of Sufficiency Economy through the guidelines of New Theory Agriculture suggests self-sufficient lifestyle and practical land management are needed. These have been used as the key for testing the ability of current Thai suburban areas to become more self-reliant. The study shows that the current sizes of suburban property in Thailand have the ability to provide at least some of the basic needs of food, energy, and water. The overall results of the study show what is needed to achieve complete self-reliance in all areas. Current suburban households in Thailand could implement the idea of Sufficiency Economy and make a suburban version of New Theory Agriculture a reality. However, the major key to success lies in change in behaviour.

For example, the investigation into fruit and vegetable production shows that a sufficient amount of fruit and vegetables could be produced, if a family adopts agricultural activity as part of their normal routine. Similarly, a reasonable amount of electricity can also be harvested from the current available roof area, but, instead of installing enough PV panels to meet current energy demand, a family can also choose to reduce their energy use to match the roof area available, which will be a cheaper option. Moreover, the study shows Thai people use a lot of water, as much as 200 litres/person/day. In addition to the two technical alternatives for water conservation used in this study, more can be done to reduce water consumption by change in behaviour. For example, the time for showering could be reduced, and water supply can be turned off when soaping or brushing teeth. Even though total independence from the central water supply is not necessarily a goal because there is access to a water supply in suburban Thailand, some use of rainwater would help lessen impacts on the environment from the process of supplying water centrally. A life cycle study of residential water supply in New Zealand by Mithraratne and Vale (2007) suggests use of a rain harvesting system with a concrete rain tank can significantly reduce the life cycle energy and CO_2 emissions compared to the central supply. Moreover, in the case of newly developed areas with limited access to infrastructure, an increase in self-reliance could be seen as more appropriate practice than expansion of the central supply. The same study found that a concrete rain tank also has lower life cycle costs compared to the reticulated supply. However, the initial cost is much higher, which may be a discouragement. This condition is related to the situation in Thailand where bigger water tanks are not common for family use and are therefore more expensive. Promotion of the idea of rainwater collection or subsidy from the government instead of investment in expansion of public infrastructure and services would be a helpful support.

By practising self-reliance, a family would directly benefit from having fresher food, better economic status by less expense, and more understanding about their resource consumption. Even though the aim of this study is to test physical capability, which is only related to the first stage involving the individual or family level, when considering implementation of Sufficiency Economy and New Theory Agriculture for suburban areas as a whole, complete individual or family self-reliant lifestyle would not seen as necessary as for rural communities where access to infrastructure is limited. Reasonable implementation is required depending on each family and community condition. Co-operation within a neighbourhood and beyond, as in the second and third stages of New Theory Agriculture, would be a support for a self-reliant lifestyle for all individuals. A co-operative community would effectively provide assistance for exchanging products, labour, and services as well as strengthening relationships within the community and with other communities.

Community scale co-operation over basic needs, such as providing a community reservoir, local electricity service, community kitchen garden, and local market, could be managed so all community members can participate and benefit. In addition to these basic demands, services such as waste management could be a next step for all community members. After co-operative practice in this step is achieved, strong community building based on having strong families is established. The community will be related to the idea of sustainable development through the self-reliance rooted at family level. Wider connection to other communities as the last step in the implementation will build a network of services between communities as well spreading the ideas and practices through the connections.

5. Conclusion

The investigation into the possibility of implementing the philosophy of Sufficiency Economy through the guidelines suggested by New Theory Agriculture into suburban communities in Thailand proved that a self-reliant lifestyle in three basic needs, food (fruit and vegetables), energy, and water can be achieved. This paper shows that housing styles and plot sizes of current suburban households in Thailand can produce enough fruit and vegetables, electricity, and water for an average rate of consumption by a family of four. From the location and lifestyles of suburban people, a complete self-reliant lifestyle should not be necessary. The study cannot suggest how much each family should produce, because self-sufficiency as the main criteria for decision making is subjective and depends on each individual, but if practiced widely it will benefit households directly and contribute to sustainable suburban and national development as a whole.

The idea behind implementation of the philosophy is intended to encourage individuals in terms of adjustments to lifestyle and behaviour. It also provides a rough idea of what households in Thailand with the same physical characteristics could achieve. According to the three steps of implementation, successful application of the first step will contribute to a strong foundation for community. Further steps with the individual and community working alongside each other will help to build stronger and more sustainable community development as well as a better environment.

HOW THE RESULTS OF THE EQUILIBRIUM™ INITIATIVE COULD AFFECT THE FUTURE OF CANADIAN HOUSING

Woytek KUJAWSKI, M.Arch., LEED® AP

Canada Mortgage and Housing Corporation, Ottawa, Ontario, Canada, wkujawsk@cmhc.ca

Keywords: net zero energy, passive solar design, sustainable housing, sustainable community, healthy housing, environmental impact

Summary

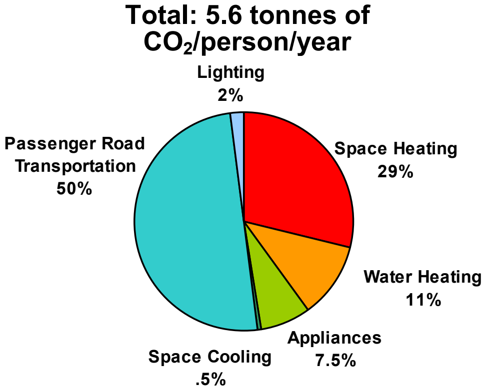
Faced with rising energy costs, environmental and health problems, Canadians are beginning to consider housing options that are healthy, energy-efficient, durable, environmentally friendly and less expensive to operate and maintain. This paper provides an overview of how Canada attempts to balance all those aspects while trying to introduce the sustainability principles for both housing and communities. In view of past and future scenarios of the environmental impact of housing, the Canada Mortgage and Housing Corporation (CMHC), a national housing agency, created the EQuilibrium™ Sustainable Housing Initiative to encourage a move towards sustainability across Canada. Projects including both new and retrofits in urban, suburban and rural environments were selected in 2007and 2008. Several have already been finished providing invaluable data. The technical requirements specified that the housing be healthy, energy and resource efficient, affordable, and with a low environmental impact all the while producing as much energy as it uses on an annual basis. This paper provides various Canadian housing scenarios followed by a short analysis of EQ approaches, focusing particularly on energy performance. It also provides the overview of used technologies offering possible solutions to sustainable living and, in the long term, optimization of future Canadian housing.

1. Environmental Impact of Residential Sector in Canada - Rationale for Action

In order to understand the rationale behind the EQuilibrium™ Initiative one must look at the reality of all aspects of environmental impact associated with past and current housing developments. The truth is that for the entire world to live as an American or Canadian two more earths would be required. The average Canadian footprint is approximately 8.5 hectares per person (it almost doubled over last 15 years) while there are only 2 productive hectares available for each person on the planet. A recent study led by Marbek Consultants for CMHC related to the environmental impact of housing in Canada (up to year 2025) had several findings. Residential sector environmental outputs have regional and global environmental consequences - the magnitude of environmental outputs to air, water, soils and land alterations of this sector are significant enough that they can be expected to contribute to broader environmental impacts including acid rain, smog, climate change, biodiversity decline, and Arctic contamination. The implications of different scenarios for dwellings, neighbourhoods, and infrastructure were evaluated to develop the future mechanisms for establishing long term goals and objectives.

1.1 The Relevant Housing Data Findings *(Marbek et al 2007)*

- There were 12 million dwelling units in Canada in 2004, with single detached houses accounting for about 57% of the total. They will continue as the dominant dwelling type until at least 2025.
- Only 25% of the estimated 16 million dwellings projected for the 2025 will be built after 2004. Reductions in environmental impacts would be limited unless the condition of existing dwelling stock is upgraded.
- There are significant opportunities in new housing in terms of “getting it right the first time”.



According to a Natural Resources Canada report on energy efficiency trends published in 2006, GHG emissions from the residential sector were up 10 per cent in 2004 (76.7 Mt) compared to 1990 (69.5 Mt). Without the energy efficiency improvements made in that time span, energy use would have risen by 31 percent.

Note: one transcontinental flight can add as much as 5-10 tonnes to the production of CO_2

Figure 1. Emissions of CO_2 per capita

1.2 Residential sector - overall resource use and environmental outputs:

- The operating stage dominates overall environmental outputs consisting of roughly 75%–95% of the total life-cycle environmental outputs during 2004–2025.
- Operation of dwellings and residential transportation dominate life-cycle energy use accounting (for over 50% and almost 45% respectively) of the total life-cycle primary energy use during 2004–2025. Choices such as neighbourhood and dwelling, dwelling conditions (e.g., envelope, equipment), and daily behaviours (e.g., heating/cooling, hot water use, etc.) have a huge influence over how much life-cycle energy is needed.

1.3 Residential Sector Impacts *(Marbek et al 2007)*

- A single detached house has the highest environmental outputs per dwelling, requiring significantly more life-cycle resources and producing significantly more life-cycle air, water, and soil pollutants. On a per-dwelling basis, single detached house would require roughly 30% more life-cycle resources than row/town house, and roughly double that of low-rise apartment/condo unit, as shown in Figure 2. These increased environmental outputs could be assumed to result in higher environmental impacts than other dwelling types.

Impacts to Resources:

	Total Primary Fuel Use	Total Water Use	Total Solid Resource Use
Single	100%	100%	100%
Row/Town	68%	80%	78%
Low-rise MURB	39%	52%	58%
High-rise MURB	41%	50%	101%

Figure 2: Life-cycle Resource Use per Dwelling during 2004–2025, by Dwelling Type, Normalized to Single Detached *(Marbek et al 2007)*

- The location of dwellings and our associated behaviors have tremendous impacts requiring solutions to reduce impacts through good design and construction practices and operational stage behaviors in order to reduce these impacts.

	Extract & Mfring	On-Site Constr.	Indirect Oper.	Direct Oper.	Maint. & Repl.
Res. Transp.			2.9E+03	3.3E+04	
Road, Water & Wastewater Infra.	8.9E+02	5.9E+01	1.3E+02	3.1E+02	
Dwellings	2.0E+03	1.4E+02	7.8E+03	3.3E+04	3.9E+02

Housing accounts for 17 per cent of secondary energy use in Canada and 16 per cent of the country's greenhouse gas (GHG) emissions (Natural Resources Canada, Energy Use Data Handbook August 2006).

Figure 3: Life-cycle Primary Energy Use by the Residential Sector during 2004–2025, by Life-cycle Stage & Structure/Activity[1] *(Marbek et al 2007)*

Impacts to Air:

[1] *Secondary energy* includes only the energy commodities paid for by end users (e.g., electricity, natural gas, propane, fuel oil, diesel, gasoline, wood, etc.), while *primary energy* also includes all raw energy resources (e.g., crude oil, coal, etc.) used to produce and distribute that secondary energy

- Annual carbon monoxide (CO) emissions from the residential sector are about eight times higher than the total of the industrial sectors for which data were available (not all of sectors release that information).

Impacts to Water
- Annual water use in existing dwellings is expected to decline by 20% during the study period primarily due to improved plumbing fixtures installed during kitchen and bathroom renovations. However, water use in new dwellings more than makes up the difference.
- In 2004, Canadians consumed 335 litres of water per person per day, at 65% above the Organisation for Economic Co-operation and Development (OECD) average totalling 3.7 teralitres — equivalent to about 15 days of water flow over Niagara Falls and representing 60% of total annual water use in the country.

Impacts to Land and Soil:
- With expected neighbourhood development patterns, such as significant decline of suburban expansion and associated consumption of land, the effects of housing development and use in existing neighbourhoods have to be mitigated even if existing neighbourhoods will absorb most of the new dwelling stock to 2025.

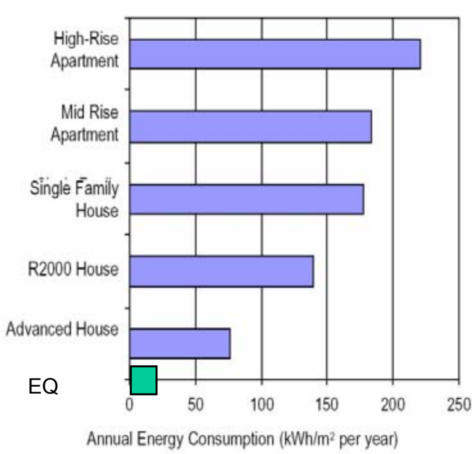
2. EQuilibrium™ Initiative

The word "Sustainability" tells us about the possible equilibrium - balance between 3 pillars / principles of sustainability: ecological, economical and societal (social, cultural, ethical etc, while social itself = health/safety, neighborhood impact, quality of life etc.) - the balance in high performance housing within sustainable community where all principles would be applied and where people could enjoy healthy lives while their impact on nature, including all developments, would be minimal.

2.1 EQuilibriumtm Housing Definition

EQuilibrium™ (EQ™) is a Canadian housing initiative, led by CMHC. The initiative evolved from the initial Net Zero Energy Healthy Housing with the ultimate goal of developing demonstration housing that would produce as much energy on-site as it consumes on an annual basis by applying measures of energy efficiency and using renewable energy. The housing is to also provide safe, comfortable and healthy living spaces for occupants, resource conservation and reduced environmental impact on land, water and air.

A (net) zero energy building can be defined in several ways *(Crawley et al, 2006)* and different definitions depend on factors such as the project goals set by the design team and by relevant legislation or guidelines. Different stakeholders have different perspectives: for example government is interested mainly in primary energy that provides national energy numbers, while building owners are usually thinking about energy costs and measures to reduce them, and designers are dealing with on-site energy use and energy code requirements. Others may be interested in reducing emissions from power plants.
There are four commonly used "net zero" definitions such as: net zero site energy, net zero primary energy, net zero energy costs, and net zero energy emissions. The EQuilibrium™ initiative is based on the net zero site energy meaning that an EQ™ site produces over the year at least as much energy as it uses and it can be monitored on-site, while source energy or emissions cannot be measured directly due to site-to-source factors, or too much oscillation such as in case of net zero energy costs.
The secondary and primary types of energy play a major role in environmental impact analysis and the country performance in that area is a good indicator about the current "state of affairs" and about intentions. The *Figure 4* below indicates the problem in Canada.



The Government of Canada's 20 plus years old R2000 Program for energy efficient housing has never reached its intended market share, while the Advanced Houses Program was only a one-time initiative to demonstrate and monitor new technologies needed to achieve levels higher than R2000.
Thus came a need for a tangible program with aspects of both house and community, which would achieve much better performance while its results, after being monitored closely for a year, will create a base for a country large House/Community program.

Figure 4. Annual Energy consumption in residential sector in Canada with the predicted EQ™ performance.

Peter Pfeiffer, a "green architect" from Austin, Texas, said:

"Using energy production strategies before energy conservation strategies is like (smoking) a vitamin-enriched cigarette – a house should be green by design instead of green by device".

2.2 Features and Advantages of EQuilibrium™ Housing

The EQ™ teams were asked to design the best housing to minimize energy (and resource) consumption and only then use the appropriate technologies to achieve the goal of balancing optimized energy use with its production on site. The concept integrates climate specific issues, energy efficient construction, reduced energy use, passive solar design, indoor environmental quality, grid interconnected renewable energy systems, water, land and natural habitat conservation and strong community context to reduce home's environmental impact to an absolute minimum.
The intention of EQuilibrium™ initiative is to combine and integrate these design and building practices into practical solutions that meet the needs of both occupants and builders alike.
The benefits and advantages offered to owners include:

- ***Lower energy bills*** – net zero energy consumption annually means dramatically lower energy bills and protection from fluctuations and increases in future energy prices.
- ***A reliable source of energy*** – integrated on-site renewable energy systems can be designed to continue functioning even during blackouts.
- ***Healthier living*** –better indoor air quality and non-toxic, healthy materials and finishes.
- ***Greater comfort all year*** – an energy-efficient building envelope, more natural light and better acoustics.
- ***Reduced pollution and CO2 emissions*** – with better building design and reduced energy demand.
- ***Affordable sustainable development –*** vital and healthy communities with efficient infrastructure, attractive green spaces and vibrant neighborhoods that combine places to work, live and play. Initially, houses are expected to cost more than conventional housing. But a higher purchase price will be offset, depending on ever increasing energy prices, by the significantly lower energy and operating costs.

Subsequent to Request for Proposals, CMHC selected 12 winning projects in 2007 and 2008 to build EQuilibrium™ demonstration homes in all regions while giving them technical, marketing and financial support. The builders will acquire the experience and expertise to access new business opportunities and to promote such homes across Canada.

Six examples of EQ™ homes below represent rural, suburban and urban settings

Figure 5 Eco-Terra, Eastman, Quebec

Figure 6 Avalon Dicovery III - Red Deer, Alberta

Figure 7 Riverdale, Edmonton, Alberta

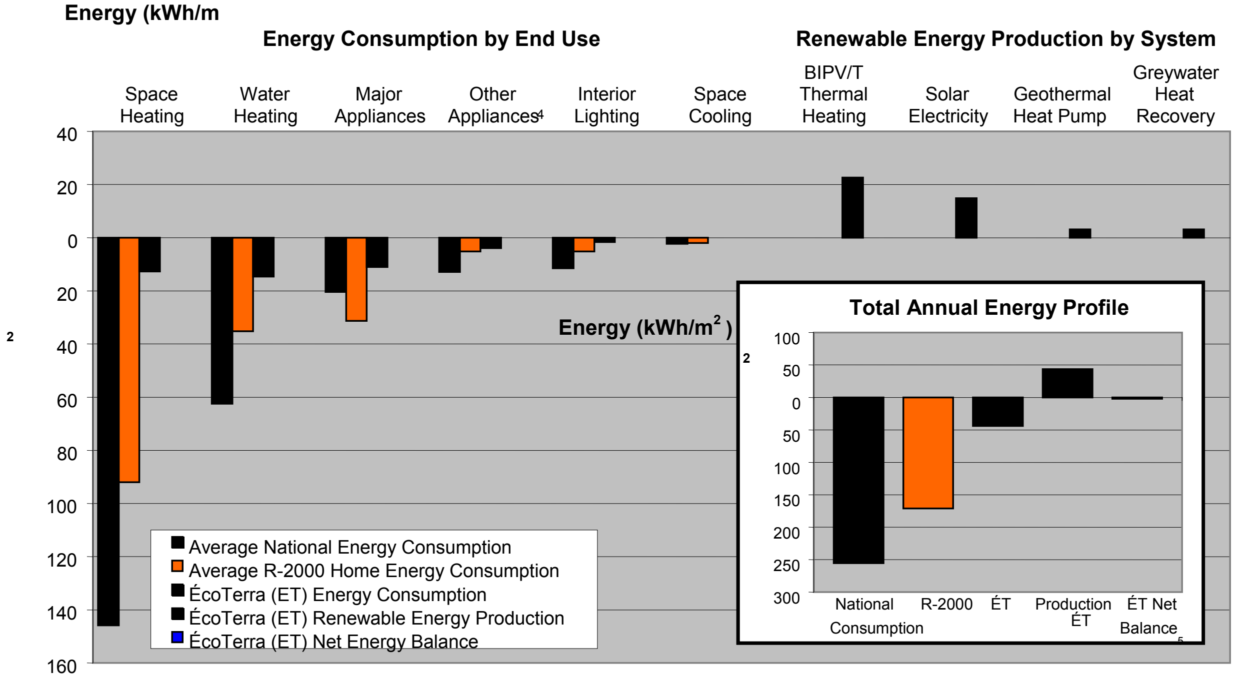
Figure 8 Annex Townhomes, Toronto, Ontario

Figure 9 Minto EcoHome, Ottawa, Ontario

Figure 10 CHESS, Red Deer, Alberta

In their original submissions most of the EQtm teams show very high average levels of insulation in walls and roofs of R52 and R65 respectively (R value; 1 R = 0.176 RSI) despite the decreasing efficiency and significant increase in cost in relation to heating energy savings. Several teams however, such as for example EcoTerra, with energy consumption data shown in *Figure 11* below, achieved good enough results looking instead for energy efficiency and savings in other areas like very strict passive solar design and high quality of construction, equipment, appliances and materials.
Average use of PVs (photovolaics) reached approximately 5.5 kW per project, which meant that teams attained the initial requirement for a very good envelope performance. The design's pre-requisite was to achieve a higher level of performance than current R-2000 standards, which has set the bar for many years. For example, all finalists had to pass the computer simulations on HOT2000 program to verify the required values above R2000 in envelope design. The net energy performance achieved average of 98.8 with a 100 established as a net zero energy performance over a year as per definition.

Figure 11 - Comparison of Canadian National Average , R-2000 Home and Predicted ÉcoTerra (ÉT) Annual Residential Energy Consumption and Production (Sources: NRCan, ET)



Profiles of most other houses show similar relative energy values, but all of them are still based on predicted yearly design values and not the operational data. The mandatory monitoring during the first year of occupancy will ensure that the final project evaluation will be based on actual performance.

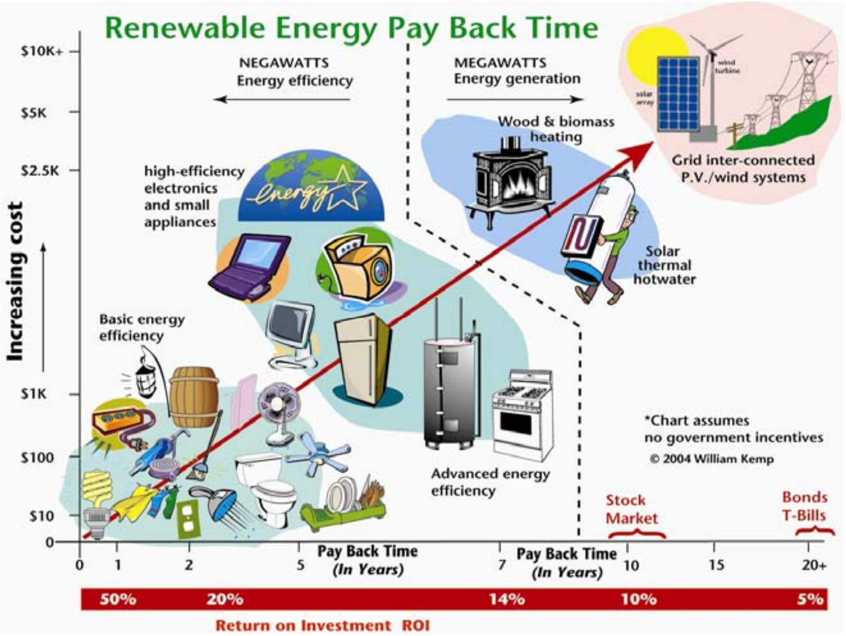


Figure 12. Renewable energy payback time *Source: Natural Resources Canada, 2007*

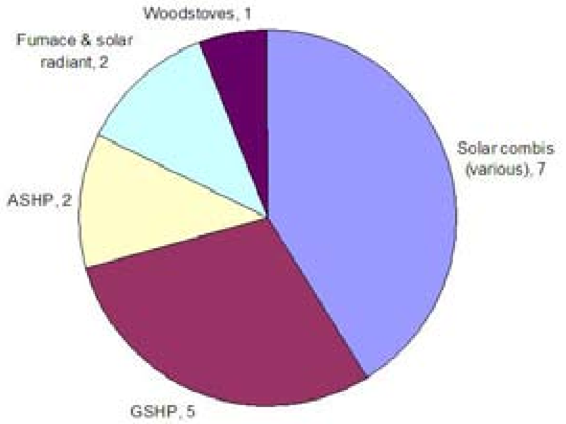
Another very important aspect is the payback time for necessary investments in technologies.
As the Figure 12 shows, the payback period for items such as solar thermal hot water and photovoltaics are still beyond what average people consider reasonable.
There are also many institutional barriers, codes and regulations which, while not being updated for decades, are blocking use of efficient technologies. Very often by-laws go to the anecdotal levels like for example one in major Canadian city banning use of PVs on residential buildings due to "(energy) manufacturing process" for which re-zoning to industrial would be necessary.



ASHP- Air Source Heat Pump
GSHP- Ground Source Heat Pump
Solar combi- solar heating system that provides both space heating and hot water heating. The primary heat source is solar energy with the balance provided by backup heater(s) fuelled by gas, oil, electricity or biomass.

Sources: Natural Resources Canada, 2007; CMHC

Figure 13. Heating system types in EQ^{TM} projects as shown in original submissions - some projects utilize more than one type.

The proposed heating systems reflected the willingness to use (and pay for) any system which would improve the performance and help achieve a Net Zero Energy goal, thus underlining the research purposes more than affordability, required to a certain extent by the design guidelines.
It was clear that the task to promote the "solar" challenge will be very difficult and mainly due to incorrect perception that in Canada as a Northern country, no solar technologies would ever work well enough. However, the latitude of Ottawa (45° 25') is close to that of Nice in France(43° 42') and Canada's most populated areas along the US border enjoy much more sun that the solar leader – Germany.

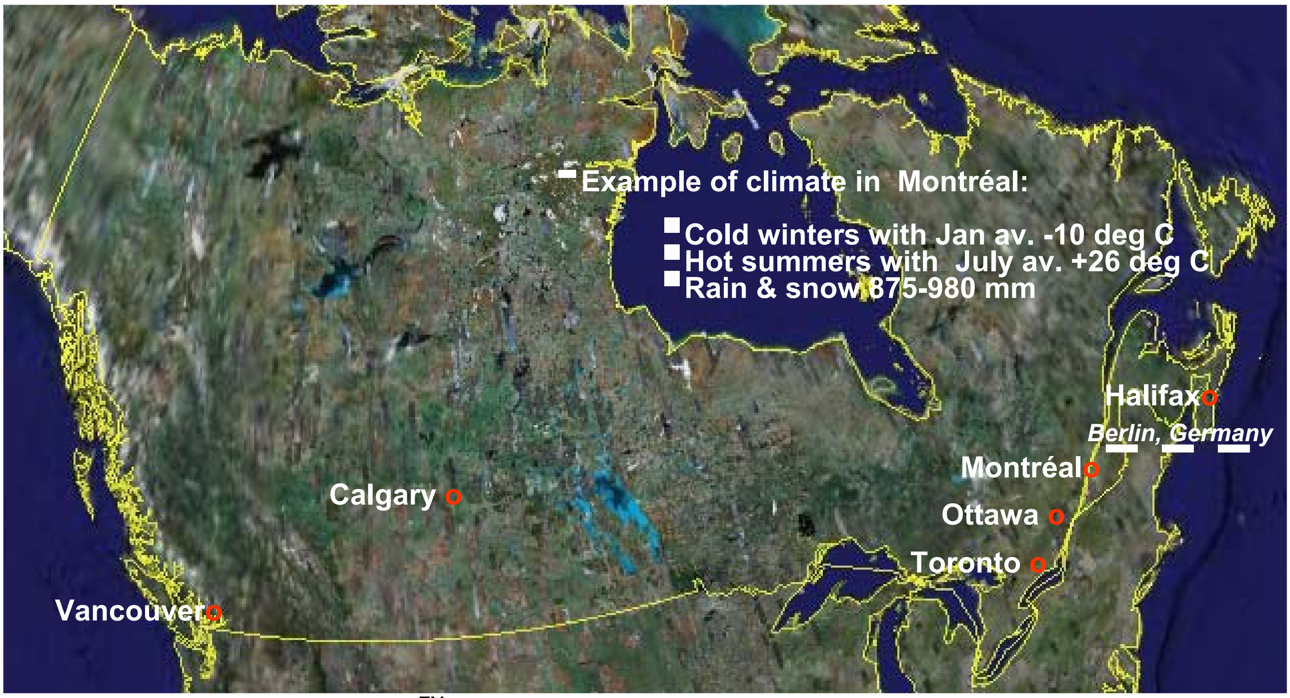


Figure 14. Map of Canada with EQ^{TM} approximate locations and latitude of Berlin, Germany for comparison

Process conclusions

After several homes have been started and one finished, preliminary conclusions started to emerge such as:

- The public was afraid of too much technology versus "equally good, but simpler" approach
- Large scale builders use of "regular" workers is not enough and professional teams are required with the necessity to market good workmanship and an explanation of the approach without compromising community and health issues.

- Too much faith was put into increased insulation without an extensive "building as a system" analysis, especially in regards to building envelope and leakage control.
- Education of consumers and professionals is crucial to future follow up especially in areas such as passive solar design concepts for house and community, basic definitions of energies, renewable technologies (solar heating and solar electrical energy) use and installation.
- Necessity of life cycle cost analysis combined with mortgage payments and with respective energy cost saving - the optimization of investment with specifics such as current energy price, availability of fuels, price and predictions of renewable energy technologies. windows technologies
- Understanding of sustainable community, public transportation, necessity of large scale, high performance retrofits as a main component of the future in housing

The goal of the EQuilibrium™ Housing initiative in limiting resources use is directly related to the looming climate change or in other words, to the ever increasing destruction of our planet, if the current *Business As Usual* building practices are not adjusted to the fact that the resources are not limitless and that life for future generations will be endangered. It is a small, but a significant, step to develop a vision and approach to build capacity and to lower or eliminate existing barriers for Canada's future residential and renewable energy industry sectors. It will soon be followed by the creation of sustainable EQ™ communities across the country with demonstrations of 1500 houses by 2010 and achievement of market acceptance of such communities with highly energy-efficient healthy houses.

3. Conclusions

Thus the EQuilibrium™ housing initiative represents a significant step forward in the future reduction of the energy intensity of Canada's housing sector, supporting the growing need for renewable energy solutions and it is also an ambitious attempt at applying high performance, healthy housing principles to reduce the future environmental impacts of an entire sector.
Some of these leading-edge EQuilibrium™ Initiative houses are clearly winners in a design stage, but none have yet been verified in the real world over an extended period of time. We can expect however, that most of them, if not all, will achieve a site Net Zero Energy goal and that the results from this initiative will help Canadians plan further research and explore appropriate solutions to properly address the ever increasing environmental impact of the residential sector. Canada is the fourth largest producer of GHG emissions per capita and it is getting worse.The long term EQ™ initiative's goal to build all houses as Net Zero Energy in 2030 will probably be revised to much earlier years. It is enough to look at the European Union to see how the immediate action could be implemented. The value of research coming in the next few years from monitored homes will be priceless in many technical aspects however, the barriers such as conservatism and fear of anything new, constrains from financial institutions and market confidence can only be achieved through education on all levels and assistance through regulatory frameworks.

There is a lot of interest for EQuilibrium™ Initiative coming from builders, developers and architects, and from progressive government agencies as well as from regular people not interested in just "building the best", but also looking for answers why to do it in a first place. The results of that interest vary from a change of regulation, a new university curriculum, educated builder to more tangible outcomes, such as energy efficient subdivisions and even Net Zero component in the Olympic Village in Vancouver being built for the 2010 Games. These results show that maybe we can slow down our insatiable expansion where it is still possible, and limit our impacts on nature, which is (repeating after P.Curry in *"Ecological Ethics"): "…an ultimate source of all value. Unless it gets our consideration, the richest and most wonderful places and most of the mankind probably will not survive this century and that will be our great crime against our children and grandchildren".*

SUSTAINABILITY INDICATORS FOR BUILDINGS: STATE OF THE ART AND CHALLENGES FOR DEVELOPMENT IN BRAZIL

Vanessa Gomes da SILVA Dr. Arch.[1]
Maristela G. SILVA, Eng, Dr.[2]

[1] School of Civil Engineering, Architecture and Urban Studies, State University of Campinas, Brazil, vangomes@fec.unicamp.br
[2] Technology Center, Federal University of Espirito Santo, Brazil, margomes@npd.ufes.br

Key-words: sustainability, indicators, assessment, buildings, built environment.

Summary

Sustainability indicators of the built environment describe its environmental, economic and social impacts for designers, owners, users, managers, policy makers and other stakeholders in the building sector. Such indicators capture trends to inform decision agents, guide policies and strategies development and monitoring, and to facilitate sustainability reporting. An indicator therefore has, three major functions: quantify, simplify and communicate.

Sustainability indicators rose initially at the nations' sphere, most of them in response to Agenda 21, but sustainability metrics are necessary at all levels. In Brazil, there are several efforts to define sustainability metrics for the built environment at its different scales that, however, vary greatly and are defined by criteria and methodologies not necessarily replicable. This paper has four major goals: to revise international literature and define sustainability indicators; to stimulate a strategic reflection on difficulties and barriers for the establishment of indicators of sustainability of the built environment in Brazil; to identify research needs to promote effective advance in this field; and to discuss methodological procedures to develop indicators at the building level.

To advance on the development of sustainability indicators for the built environment in Brazil it is necessary to: (1) define a framework and methodology for developing sustainability indicators, (2) define common indicators to be monitored at national level, as well as groups of local indicators, selected as appropriate; (3) create a national database; and (4) make these data publicly available and up-to-date. A network effort at national level is needed and should be specially considered by R&D funding agencies.

1. Introduction

Indicators are parameters (measured or observed property) or values derived from parameters that provide information on a given phenomenon (OECD, 1993). An indicator has synthetic meaning and is developed for a specific purpose. These two characteristics make their meaning transcend the properties directly associated to the parameter value, as the number or measurements and needed parameters to describe a given situation is reduced, and the information process that deliver the results of such measurements to the final user, simplified.

The establishment of sustainability assessment supposes the use of reliable, representative, comparable and traceable indicators. To be useful, and indicator should, therefore, allow for an explanation of the reason of changes in its value through time, be sufficiently simple in the way it describes problems usually complex, and use common definitions of key-components and normalization to enable comparisons (COLE, 2002).

Sustainability indicators were created first at nation's level, noticeably as a response for Agenda 21. However, metrics are needed at all levels (Figure 1), as they can not only show the way, but also show if and how occurs the movement of the society, the construction industry, an organization or the production of buildings in relation of national sustainable development goals (SILVA, 2003). At building/built environment level, such metrics are necessary to simplify and communicate complex information, and can be used for (ISO, 2005):

- Evaluation (against reference values or performance targets);
- Diagnosis (to identify factors affecting sustainability);
- Comparison (among alternatives and buildings); and
- Monitoring (change across time).

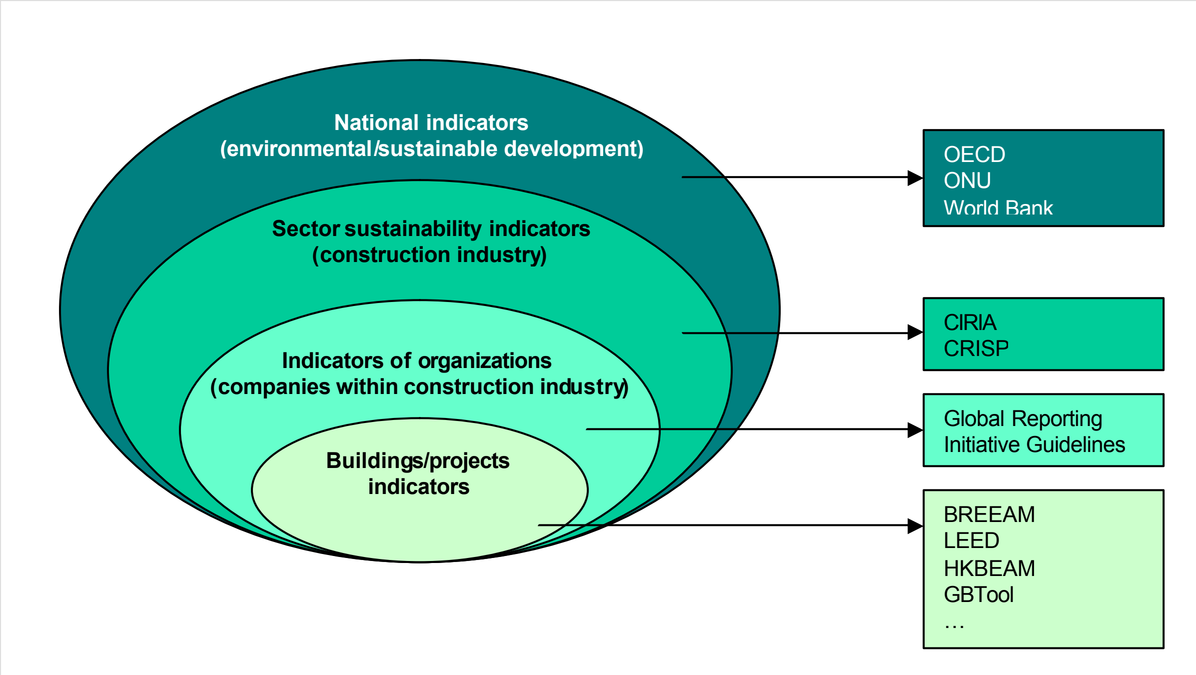

Figure 1 - Scales of action of major initiatives on sustainable development/environmental indicators.

Despite being fundamental to help unifying economic, social, environmental and institutional decision-making, indicators *per si* are not capable to promote performance improvement. Performance targets and benchmarks, for each indicator, are equally necessary to, at one's hand, calibrate the analysis (i.e. define performance scale) and evaluate progress (SILVA, 2003) and, on the other, encourage appropriate resource allocation to reach the aimed progress rate (CIRIA, 2001).

Next sections present a panorama of the major international initiatives as well as of the challenges posed to advance in the development of sustainability indicators of the built environment in Brazil.

1.1. Goals and methods

This paper aims at (1) stimulating a strategic reflection regarding barriers and challenges for the establishment of national indicators of sustainability of building and the built environment; (2) identify research needs to promote effective advances in this field; and (3) discuss methodological procedures for definition of sustainability indicators of the built environment in Brazil.

Study and discussion methodology is based on a broad review of national and international literature and previous initiatives, and analysis of (1) the relationship between application of environmental/sustainability assessment, projects life-cycle and users needs and expectations; (2) perspectives adopted by existing assessment methods, regarding use of indicators; and (3) recommendations and approaches internationally accepted for the establishment of sustainability indicators.

2. Initiatives at national, construction sector and building levels

At nation's level, the Organization for Economic Co-operation and Development (OECD) pioneered the development of indicators in 1989, and started regular publication of environmental indicators in 1991. UN involvement dates back to 1972, when the Stockholm UN Summit made evident that environmental issues had steadily become object of social/economic international policies. Twenty years later, in the UNCED at Rio de Janeiro, it was consensually agreed that (1) strategies for sustainable development should integrate environmental aspects in development policy and plans and (2) for that purpose, such instruments would require support of environmental and social/economical data. Published at the very UNCED, Agenda 21 (United Nations, 1992) listed specific recommendations for the development and implementation of environmental and economic accounting, and of sustainable development indicators (UNSTAT, 2002b).

The United Nations Commission for Sustainable Development (UN CSD) was another Rio 92's result, and carried out a vast work program on sustainable development indicators between 1995 and 2000 (DESA, 1999a). OECD and UN paths crossed after 1993, when OECD published its core set of indicators (OECD, 1993). This was the major inspiration for sustainable indicators lists published by UN CSD in 1996 (DESA, 1996), as a first response to Agenda 21 demand, and in 1999 (DESA, 1999b).

From mid 80's on, several frameworks were developed to organize nation-level indicators, particularly environmental indicators. Most of the initial work on environmental indicators focused on the state of the environment, through monitoring of physical alterations of the natural environment. To explicit the causes of the identified problems and what could be done to solve them, gradually more encompassing pressure-response models were developed like pressure-state-response (PSR) model, adopted by OECD and its variations: driving force–state-response (DSR), adopted by UN CSD; driving force–pressure-state-impact-response (DPSIR), adopted by the European Environment Agency (EIA) and by Statistical Office of the European Communities (EUROSTAT). Combinations of media and pressure-response approaches were used by the Environment Statistics Section of UNSTAT (UNSTAT, 1984) and by the CSD Theme Indicator Framework (DESA, 1999b), which organizes indicators according to four major dimensions (social, environmental, economic and institutional indicators), divided in themes and sub-themes. The structure of the Agenda 21 was no more strictly followed, but the themes/sub-themes refer to the appropriate chapters. This framework formed the basis for development of several works, like the European networks BEQUEST and CRISP, and SILVA (2003), a discussion for the Brazilian context.

The most relevant initiatives to be highlighted at sectorial level are probably the work carried out by the Construction Industry Research and Information Association (CIRIA) for the United Kingdom (CIRIA, 2001) and by CIB W82 Construction Related Sustainability Indicators – CRISP (June 2000 and August 2003) at European level, partnering with four other countries, captured in publications like Bourdeau et al (1998), CIB W82 (1999), CRISP Network (2001) and Häkkinen et al (2002). At building level, studies at University of Michigan (REPPE, 1999), and within Green Building Challenge (GBC) scope to analyze and compare buildings across different national contexts (COLE;LARSSON (2000); TODD;JOHN (2001)) and within ISO/TC59/SC17/WG2 (ISO, 2005b) effort for specific standardization framework deserve recognition.

There are fundamental distinctions between the pure concept of sustainability indicators and the indicators used – or possible to be presently used – in building assessment systems. Assessment methods currently available typically do not consider social and economic aspects of sustainability and are directed to individual buildings, while the broad discussion on sustainability indicators refers to more general measures of society, that are not easily related to the scales of organizations or buildings (COLE, 2002; TODD;JOHN, 2001). A last significant difference in approaches is the crescent trend of assessment methods aggregate performance metrics to summarize a building's global performance, while sustainability indicators are usually kept as discrete entities (COLE, 2002). COLE (2002) also points out the limitations imposed by time, first, because of the different time scales as sustainability is a concept based on equilibrium on the long-term and building effects are perceived in a much shorter timeframe; secondly because assessments are valid only for the particular point in time in which they were carried out, as environmental performance of buildings is – explicitly or not - relative to a typical performance level and are not able to capture continuous improvements on individual buildings and both cutting-edge and typical practices.

For all these obstacles and also due to the difficulties to access accurate and continuous data necessary to formulate and maintain indicators, existing building rating systems refer to (environmental) sustainability targets theoretically or empirically established. Empirical indicators have been adopted and later on validated or excluded, based on practical experience on implementation in the cases assessed by each system

3. Methodological challenges and research needs identified

Use of indicators basically consists of three major steps:

1. Choice of relevant indicators that should reflect needs and concerns of stakeholders (sectorial agenda) and the adequate representation of the assessed object. Such selection depends on decision limits, of the object and construction context and of practical availability of information.
2. Research of adequate methods and information to evaluate indicators values;
3. Information collection and use of relevant methods to attribute value to the selected indicators.

In Brazil, several efforts are noticeable for definition of indicators of sustainability of the built environment that, however, vary largely and are defined according criteria and methodologies not necessarily replicable. This work suggests six steps to methodological development for creation and validation of sustainability indicators of the Brazilian built environment:

1) Delineation of the state-of-the-art on sustainability indicators of the built environment

CRISP Network carried out a unique work on identification and systematization of sustainability indicators for the European construction industry, including some non-European methods. SILVA (2003) carefully review existing sustainability indicators and added some reflection as to their applicability in the peculiar Brazilian context. Such initiatives configure an encompassing state-of-the-art and lay the foundations for future development.

2) Definition of a methodology for data collection and organization

Even more important than the numbers attributed to indicators is to have accurate control over what the indicator effectively describes and the circumstances in which the values were obtained or attributed. This control provides traceability and reproducibility and allows for value adjustment or refinement according to scenario alterations and available data across time.

To build upon previous research efforts, and for international comparability purposes, it is suggested that the indicators characterization charts developed under CRISP's auspices are tested, at the possible extent and at the different scales, observing eventual data availability limitations in Brazil.

3) Creation of a sustainability indicators database applicable to the built environment

Besides describing the nature of the different sustainability indicators of the built environment, the approach given by ISO presents four main requirements for indicators systems:

- Sustainability should be described based on an encompassing set of indicators expressing environmental, social and economic aspects, as well as their relationship;
- Selected indicators should describe essential (environmental, social and economic) building impacts;
- Relevance of selected indicators should be justified and, when necessary, validated;
- Indicators development and application processes should be transparently reported.

Consideration of potential final users' feedback is a powerful instrument for validating indicators. Selection of most relevant indicators from cited reference lists should be therefore done considering compliance with the essential requisites that validate a good indicator (relevance, objectivity, accessibility, range, measurability, sensibility and traceability) and aiming at answering questions such as the following:

- Who are the final users?
- For which purpose will the indicator be used?
- How to proceed in relation to contradictory indicators?
- How to use the indicators?
- Is it possible to measure? If not, how to attribute a value for the indicator?

As indicators are needed in decision-making processes of several agents, the starting point for their development is the identification of the main users, their information expectancies and needs. The intended use for an assessment system may therefore vary according to the life-cycle stage it is intended to be applied in. Information character, quality and availability also depend of the project life-cycle stage. Indicators that describe the same aspects can be initially related to values estimated in design stage that, during operation, would be replaced by real-time measurements, satisfaction surveys or other performance evaluation instruments. Consequently, indicators used to characterize building performance in each application should be adjusted to the proposed end use.

While individual indicators should be the most independent possible, practice has shown that it is more efficient to employ indicators sets, on their turn dependent of the user's perspective and of a certain life-cycle stage, able to include a broad representation of sustainability aspects.

4) Definition of a set of indicators for national monitoring, complemented by core set of relevant local indicators

Assessment methods of buildings intend, at the extent possible, to link the building contribution for achievement of broader sectorial and national targets. Definition of an agenda for the Brazilian construction sector is, therefore, the initial basis for proposition of a sustainability assessment framework, finely tuned to national context and aspirations.

JOHN et al. (2000) and JOHN;SILVA;AGOPYAN (2001) initiated the discussion on an Agenda 21 for the Brazilian civil construction, pretty much like the original structure used by CIB (1999). In posterior contributions SILVA et al. (2002) e SILVA (2003) proposed an sectorial agenda organized according to the international molds for sustainability reporting, given by UN's Agenda 21, in which the triple bottom line is complemented by an institutional dimension, related to provision and strengthening of intra and cross-sectorial platforms. The institutional agenda was proposed due to the lack of sufficient normative instruments, governmental policies, articulation of sectorial strategies pro sustainability and or sustainability report of construction-related organizations and products.

The indicators list proposed by Silva (2003) follows CRISP's format general lines. ISO TS 21.929 recommendations (ISO, 2005b) could be used for screening and selecting the set of national indicators.

5) Creation of a database of indicator values (local, but able to be regionally and nationally aggregated)

Database construction is a labor-intensive, long-term work. It is important to highlight that, the CRISP network, taken here as a methodological reference, had the goal to systematically register currently used construction industry-related sustainability indicators, but not the values measured or attributed to them. The creation of a benchmark database for each relevant indicator is fundamental to provide meaningful assessment results and to drive establishment and updating of sustainability goals. In the Brazilian case, this gap that can only be bridged through gradual refining or substitution of the values initially extracted from literature and research, as a considerable number of assessments and measurements are carried out and following a consensual, replicable methodology.

6) Continuous update and broad data dissemination

As assessments only make sense when the performance reference is explicitly defined, it is necessary to keep the database continuously updated, to lead to more reliable numbers and evaluations and more realistic target setting. Dissemination of reference values is important to make the assessment procedure replicable within the country, while recognizing regional peculiarities that interfere in result interpretation.

4. Final remarks

Indicators are sought to clarify national and international trends of social, economic and environmental development and to closely chart progress towards sustainable life patterns.

Performance indicators are also used by environmental assessment methods to demonstrate improvement in – and allow for comparisons among – individual buildings. In both applications, indicators provide their users with the necessary feedback through performance benchmarking and illustration of progress rate and extent, helping to raise awareness regarding environmental issues and their social and economic (or vive-versa) reflexes, and level a comparison basis between decision-making and strategic planning.

Most identified metrics in the review of international initiatives for development of sustainability indicators focus on the environmental dimension of sustainability and is more appropriate to measure health and sustainability of ecosystems, communities or specific environmental components, such as water or air. Most of these metrics can not be applied to the building scale, or is effects, as they do not distinguish between the relative contribution of buildings or the built environment to health and sustainability of a certain ecosystem, community or environmental component of interest. It is therefore recognized in this work the difficulty of relating information obtained at the building scale to progress of the construction sector or of a country in any of sustainability dimensions. It is advocated, though, the validity of extracting relevant indicators for buildings, even though their immediate aggregation is not yet possible to form a global metric of society, indicate the path for cooperation in compliance with sectorial or national goals of producing a built environment driven by more responsible attitudes, based on the reflection on their long term effects.

CRISP network began the organization of sustainability indicators for the built environment used in different countries. Similar efforts will probably be impelled by the implementation of specific ISO standard. Even though generic, ISO recommendations shed some light on the need for standardization of definitions and methodologies for data collection and aggregation, and for indicators interpretation.

Brazil already counts on some efforts to establish sustainability indicators that, however, vary largely and are defined according criteria and methodologies not necessarily replicable. In order to advance in the development of sustainability indicators of the built environment, it is paramount that the country defines consensual framework to structure indicators, and methods for data gathering, definition of national indicators (aligned to international trends and experience) as well as of a core of local indicators relevant for each case and typology; value measurement or attribution, and for interpretation and aggregation of indicators. A robust database should be created and kept updated and broadly accessible.

DAC/FEC/UNICAMP began the creation of an environment for housing and monitoring of indicators of sustainability of the built environment. First figures available at the database refer to office buildings. School buildings will be added across the next two years. Part of them are applicable to other parts of the country, but it should be kept in mind that some of these data are unavoidably regional in essence (parts of the State of São Paulo) and could result in misleading conclusion without previous definition of equivalent figures for other regions. An effort with national range is needed and should be carefully considered by research funding agencies.

Certification In The Hotel Sector; Does It Actually Reduce Global CO_2 Emissions?

Aoífe HOULIHAN WIBERG B.Arch., M.Phil., R.I.B.A.[1]
Nick BAKER Ph.D[2]

[2] The Martin Centre for Architectural and Urban Studies, University of Cambridge, 1-5 Scroope Terrace, Cambridge CB2 1PX, United Kingdom NickVBaker@aol.com

Keywords: Global warming, tourism, certification, hotels, CO_2 emissions, fuel source, green electricity, carbon offsetting

Summary

The research poses a simple question, ‘Does Certification in the hotel sector signify lower CO_2 emissions per guest night?' The research examines whether certification schemes are rigorous and whether the results are credible. The paper discusses climate change and global tourism, the issue of ‘green’ electricity and carbon offsetting, provides a critique of current methods of certification used in the hotel sector and examines the environmental impact and the accounting method used.

Global CO_2 emissions were compared and calculated from the delivered electricity and fuels consumption data from seventy selected certified hotels worldwide. No corrections were made in the calculations for climate, quality of services, existence of services etc. The performance indicator used is $kgCO_2$ per guest night.

The analyses shows no clear pattern. In some cases emissions reduced after certification in others no change. Certified hotels do not necessarily have lower emissions than uncertified hotels and a comparison of before – and after – certification shows no significant improvement. Most dramatically emissions from certified hotels widely vary by a factor of 7. Although it is arguable a number of corrections should be made to account for different climates, the research highlights that hotels with high CO_2 emissions are being awarded certification and it questions what message ‘certification’ gives to guests and other stakeholders. At worst it appears ‘business as usual’ can achieve certification with no obvious improvement in performance. The authors conclude a simple, accurate method of CO_2 emissions calculation needs to be developed which can be adopted universally.

1. Introduction

The scientific community is unequivocal in its acceptance of the connection between climate change and green house gas emissions yet there are no international benchmarks for CO_2 emissions in hotels although there are in existence published energy benchmarks. Although transport is commonly identified as a major emitter, accommodation receives much less attention, in spite of the fact that it typically accounts for 1/4 of the total emissions from global tourism (Table 1).

We estimate hotels are five times more CO_2 intensive than people living at home yet CO_2 emissions are not accounted for in audits and are not included as a mandatory category in certification. There is a widespread problem of false accounting in certification. Hotels are claiming reduced or zero CO_2 emissions through ‘green’ electricity deals and carbon offsetting schemes.

1.1 Climate Change and Global Tourism CO_2 emissions

International arrivals are expected to reach nearly 1.6 billion by the year 2020 from 25 million in 1950. (WTO) Tourism growing at such a rate affects both transport and accommodation equally. If carbon intensive transport reduces then this proportion could become much higher as the focus will tend to shift onto accommodation.

Table 1: Emissions from Global Tourism in 2005 including same day visitors (DAVOS, 2007)

	CO2 (Mt)
Air transport	517
Other transport	468
Accommodation	274
Activities	45
TOTAL	**1,304**
Total world	**26,400**
Share (%)	4.94

1.2 Carbon Offsetting

Carbon offsetting is the act of mitigating greenhouse gas emissions. It involves calculating emissions and then purchasing 'credits' from emission reduction projects which would prevent or remove an equivalent amount of carbon dioxide elsewhere. Due to its indirect nature, carbon offsetting is difficult to verify. Hotels were found to be making false CO_2 claims. For example, a major chain hotel in London markets itself as being 'carbon-free' and 'offsets all its emissions' yet the results of our analysis indicate its emissions to be 20 kgCO_2 per guest night which even increased after certification. The extra cost to the guest of offsetting their stay was 2 Australian dollars (less than 1% of the cost of a room for one night).

1.3 'Green' Electricity – How green is it?

In response to growing climate and environmental concerns, certification and self-certification of "green" electricity (with different and often conflicting definitions) have proliferated in the marketplace. Many products do not contribute to *additionality* (i.e. the development of new low or zero-carbon generation) but instead favour double selling of electricity already paid off by consumers. The lack of minimum common standards cause significant confusion in the public and undermines the future uptake of green electricity. (CLEAN-E, 2006)

It would be expected that if the price charged by green providers were significantly higher than fossil-electricity, then increasing the demand for green electricity might generate extra cash for investment in more green power. A believable increase would be a 50% to 150%, whereas extra costs for green electricity are typically 10% and sometimes significantly lower. This unrealistic extra cost is almost proof that it is only a marketing exercise.

1.3.1 Additionality and The Eugene Standard

Green power consumption can only lead to additional low or zero carbon power generation if *additionality* is proven. The Eugene Green Energy Standard is an international standard to which national or international green electricity labeling schemes can be accredited. It confirms that energy supplied under the accredited schemes: 1) Is produced from genuinely sustainable energy sources; 2) Will result in a real increase in renewable generation beyond the requirements imposed by government ('additionality'); 3) That the demand from consumers is matched by renewable generation. Two variations of the standard, 'gold' and 'silver', differentiate between schemes depending on the additionality of new renewable energy supplied. Currently only two national labels (German *ok-power* and Swiss *Naturemade)* are accredited by the Eugene Standard. out of one hundred and ten European labels listed on Eugene website(Eugene, 2005) Despite this fact, it has been found many certified hotels rely on claims of zero carbon or neutrality based on purchasing 'green' electricity, which is not accredited.

2. Certification and Benchmarking

Certification schemes are created by privately operated companies and NGO's and are based on voluntary initiatives by the hotels themselves. Around the world, there are some 260 voluntary initiatives, including tourism codes of conduct, labels, awards, benchmarking and "best practices." Of these, 104 are ecolabelling and certification programmes offering logos, seals of approval, or awards designed to signify socially and/or environmentally superior tourism practices. (Honey, 2002)Certification delivers a certificate which claims the participant is "green", sometimes that is done by looking at processes. A benchmark measures something quantitatively with a view to comparing it to a given value regarded as a datum. Most certification schemes can be categorized and analyzed by their methodology – as performance-based (using benchmarks) or process based (using environmental management systems) and by sector of the tourism industry they cover (conventional tourism, sustainable tourism or ecotourism). A hybrid of process-based environmental management systems and performance benchmarks are more effective. (Honey, 2002)

There is a confusing proliferation of a wide range of certification schemes with varying criteria, which is compounded by the overuse of 'eco-terminology' for marketing purposes. In most cases methods of calculation, data about baseline indicators and algorithms for use in the performance assessment are not disclosed to the hotel operator or available in the public domain. There is concern that the complexity and cost of certification systems preclude smaller businesses.

Certification of a *design* represents a *potential* for a building and does not indicate how that building is going to actually perform. Even that potential is open to question as much of the performance of a building depends upon things that are uncertain or do not perform as well in reality as assumed in the model that predicts energy use. There is no correlation between the two and on no account should there be any confusion between certification that goes to design.

2.1 Accountability of CO_2 emissions in schemes and tools

Only one certification scheme calculates CO_2 emissions but this is included in a non-mandatory category for certification. As a result, a hotel could in fact have low energy consumption and high CO_2 emissions yet still become certified. Differences were found between our CO_2 emissions calculations and those reported in the benchmarking assessment report. Since the accounting method was not disclosed it was not possible to verify the differences in calculations of emissions.

It was found that the actual calculations of CO_2 emissions are dependant on the assumptions about electricity production emissions. In our CO_2 emissions calculations, the figure of 0.48 kg CO_2/kWh (BERR) has been quoted for the UK average electricity production but it should be noted that this figure may be 0.52 kg CO_2/kWh. (DTI – DUKES, 2006) Although even these figures are debatable because if we were reducing energy use then we would clearly be aiming at the marginal effect and could reasonably apply the highest emissions intensity of 0.67 kg CO_2/kWh corresponding to the least efficient power stations.

2.2 Adding delivered units of electricity to delivered fuels

The most serious error in all schemes analysed is the adding together of delivered electricity to heating without first converting the figures to primary energy (or CO_2 emissions) before adding together. As a result, the energy performance indicators used by the majority of hotels and certification schemes are erroneous. In many cases, when asked for raw data, the only figures provided by a hotel were these performance indicators with no separate breakdown for delivered electricity or heating in which case neither the performance nor the CO_2 emissions of the hotel could be reliably calculated.

2.3 Weighting of categories in awarding credits for certification

Most schemes involve five or more assessment categories yet success in only one or two categories (energy is not always mandatory) enables a hotel to become certified despite having poor environmental performance. In 2007, Nordic Swan made energy performance a compulsory category. Green Globe includes an indicator for CO_2 emissions and Renewable energy (percentage) used but does not affect the overall benchmarking evaluation. In LEED, it was found that five of the ten LEAST popular (and most difficult to achieve) credits were made up entirely from the Energy & Atmosphere category, which deals directly with CO_2 emissions. (Kramer, 2006) Where LEED has been used for hotels there is some uncertainty as to what building type is being used to establish the benchmarks against which the subject hotel is being judged.

3. Method

Four analyses were made; a time series analysis of CO_2 emissions per guest night for chosen fuel mix for a selected certified hotel before and after certification; the same as previous but including delivered energy; an example of CO_2 emissions for 2006 for six certified hotels in different schemes and finally, an example of CO_2 emissions for 2006 for 29 hotels certified within the same scheme.

The consumption data for delivered fuels, electricity and heat was extracted from invoices, meter readings, monitoring data in excel files, intranet access of hotel databases and benchmarking assessment reports. The delivered fuels consumption data differed in units and was converted to CO_2 emissions using the conversion factors from The Carbon Trust and IPCC. The national average electricity fuel mix breakdown and conversion factor was collected from BERR for UK, government and academic sources for each respective country. In order to know which conversion factor to apply for, the district heating information was collected from the supplier about how the heating was generated.

Information was also collected on the physical and operational parameters of the building including: date of certification, total number of guest nights, size, structure, age, orientation and design of the building, number of bedrooms, floors, total area, number of facilities and level of services offered, geographical and climatic location, the type of energy system installed and how they are operated and maintained.

3.1. Dependency of CO_2 emissions calculations to chosen fuel mix: Sweden

Sweden is connected to the other Nordic countries through the Nordic electricity market, NordPool, which also has connections to the European continent. The energy production mix in these three areas is very different as seen below. The collected heating and delivered electricity consumption data for a selected certified chain hotel located in Stockholm, Sweden was using three methods of accounting. The first scenario is where we accept the argument that the electricity is 'green', i.e. 100% renewable. The second scenario assumes an average Nordic electricity mix and the third scenario assumes an average European mix which is more diversified with mainly nuclear, coal, hydro and natural gas fired power production (as shown in Fig. 1). The district heating is supplied by CHP so the CO_2 emissions have already accounted for in electricity production and shall therefore be considered zero.

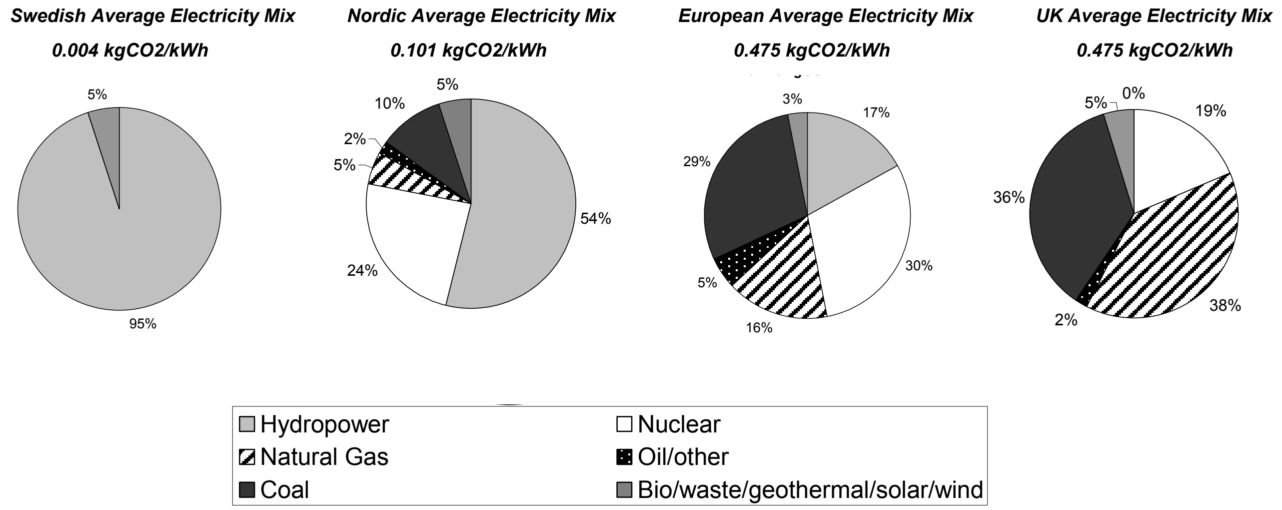

Figure 1 Fuels used in "Green", European and National (Nordic / UK) electricity power production

3.2 Time series analysis of CO_2 emissions per guest night for chosen fuel mix for a selected certified hotel before and after certification.

The graph below (as shown in figure 2) shows a more significant reduction in emissions attributable to switching to ‘green’ electricity rather than to certification alone. However it is acknowledged there is a 10-15% reduction in emissions after the hotel became certified which may be explained by the skilled expertise of the newly appointed environmental manager around the time of certification. The graph clearly shows the significant impact on emissions of the choice of fuel mix chosen. The CO_2 emissions have been calculated in kg CO_2 per guest night.

The graph below shows the results of the third scenario which uses the average European electricity mix (0.475 kg CO_2 /kwh) before the hotel switched to ‘Bra Miljövil’ green certified electricity in 2006. Heating is supplied by district heating (CHP) and is considered to have zero emissions. By selecting the average European electricity mix, we are presenting the worst-case scenario, which we consider to be reasonably justified due to Sweden’s connection to the European continent via Nordpool compared to the totally unjustified switch to ‘green’ electricity as demonstrated by the graph below.

The marketing of the hotel implies that its remarkable reduction in CO_2 emissions are a result of being certified yet the graph shows that until the switch to a different electricity supplier in 2006, certification has had very little effect on reducing CO_2 emissions.The graph also shows despite all the hype surrounding certification it has been shown to have no real effect on reducing CO_2 emissions, irrespective of whether or not the carbon emissions can be decimated overnight by simply switching to a different power company.

CO_2 Emissions per guest night (kgCO2/gn)

Pre-switch - Average European Electricity Production (0.475 kgCO_2/kWh)

District Heating (CHP) - assumption zero CO2 emissions

	1998	1999	2000	2001	2002	2003	2004	2005	2006
kgCO2/gn	8.21	8.39	8.30	8.31	8.04	8.09	7.45	7.07	0.06

Figure 2 Time series analysis of claimed CO_2 emissions for chosen fuel mix for a selected chain hotel in Stockholm, Sweden before and after certification (kg CO_2 per guest night) Note reduction after switch to “green” electricity.

3.3 Time series analysis of CO_2 emissions and energy consumption per guest night for a selected certified hotel, before - and after - certification.

The purpose of the two graph’s below shown below is to establish if certification has directly resulted in reduced energy consumption and/or CO_2 emissions per guest night. Heating is supplied by gas and delivered electricity is supplied from the grid (EDF). The hotel does not purchase ‘green’ electricity. The graph shows that certification has had no effect on either energy consumption or CO_2 emissions, which has in fact increased. It should be acknowledged that a consistent reduction in emissions is recorded from 2002 to 2005 after which the emissions increase. The reduction may be explained by the drive to achieve certification as well as to the individual expertise of a skilled environmental a manager who then left in 2006. He was then replaced by a new less skilled manager who has now since left. The marketing for the selected hotel implies the hotel is ‘carbon free’ and ‘to offset all its emissions’ yet only the conference facilities have been ‘offset’. Furthermore, due to the lack of transparency in accounting methods, it is impossible to validate the claims made for that improvement and to explain how the energy consumption and CO_2 emissions of that area has been distinguished from the overall area (if there is no sub-metering.)

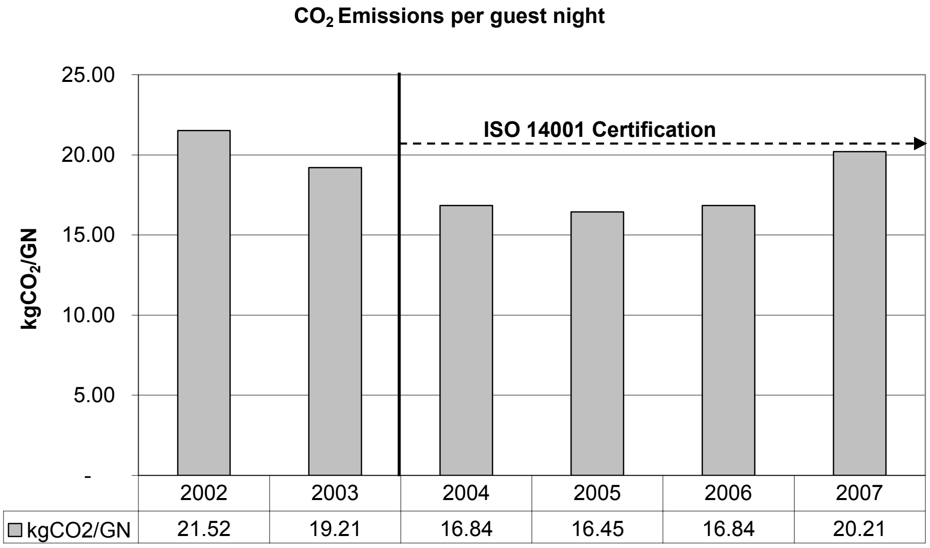

Figure 3 Time series analysis of CO_2 emissions per guest night for a selected chain hotel in London, UK, before and after certification.

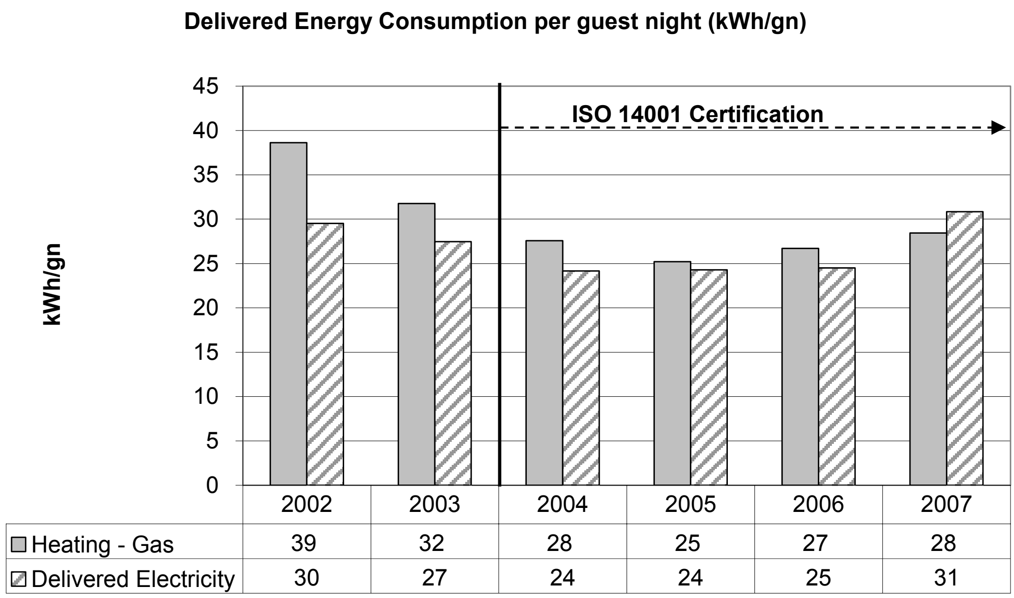

Figure 4 Time series analysis of CO_2 emissions and energy consumption per guest night for a selected chain hotel in London, UK, before and after certification.

3.4 An example of CO_2 emissions for 2006 for eight certified hotels in different schemes

The purpose of the graph below is to compare the CO_2 emissions per guest night for a series of certified hotels for a particular year. Despite the wide range in CO_2 emissions, all have been awarded certification. In one case, there is almost no difference in emissions between a certified and non-certified city hotel located in the same country. In another case, a city hotel having achieved gold certification actually emits almost double the CO_2 emissions than a non-certified city hotel in the same country. Based on the figures given and the assumption made in the calculations, is it justified to certify a hotel sustainable that emits 73.7kg CO_2 per guest night as another certified hotel that claims to have zero CO_2 emissions? Is it justified that some certified hotels are decimating their CO_2 emissions overnight by simply buying non-accredited, "green" electricity certificates yet still awarded certification?

	Green Globe, Australia	GTBS GOLD, Scotland	LEED-NC (av. US) SF	ISO 14001, UK	Nordic Swan (av. EU) Oslo,	EU Flower (av.EU), Greece	Nordic Swan (HEP)	Not Certified, UK
kgCO2/gn	73.7	29.5	18.3	16.8	12.0	4.9	0.1	17.5

Figure 5 A series of certified hotels claimed CO_2 emissions within different certification schemes for 2006.

3.5 An example of CO_2 emissions for 2006 for 29 hotels certified within the same scheme

The graph below shows the range of CO_2 emissions within the same scheme and have received the same level of certification. Based on the figures given in the graph, is it justified to certify a hotel sustainable that emits over 70 kg CO_2 per guest night and moreover, to give it the same level of certification as a hotel that emits only 1 kg CO_2 per guest night?

The calculated CO_2 emissions are based on the figures given in the certification benchmarking assessment report sent to the respective hotels. However, it should be noted that numerical errors in reporting have been found between the CO_2 emissions calculations provided by the benchmarking assessment report and our calculations. For example, in one of the hotels quoted in the graph above, the reported CO_2 emissions were 73 kg CO_2 /GN but by our calculations this should be 30 kg CO_2 /GN. In addition, there may of course be some that are declared low in the graph below but by our calculations should be three times higher. These numerical errors in reporting undermine confidence in the scheme.

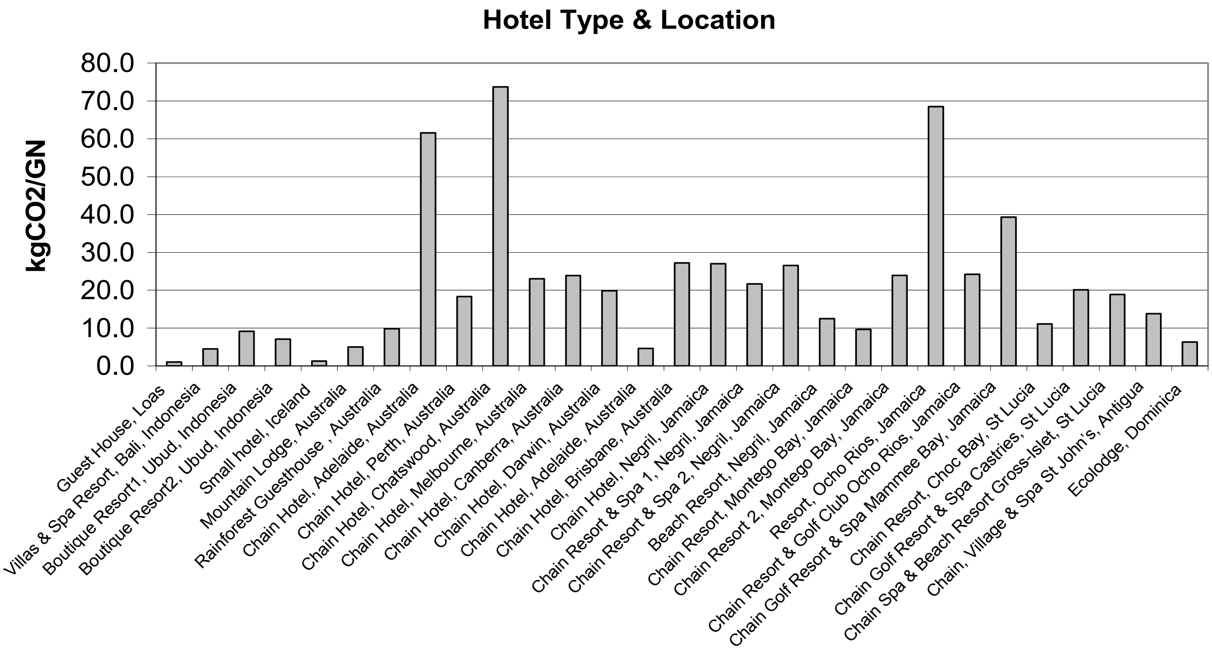

Figure 6 Range of reported CO_2 emissions within the same certification scheme with the same level

4. Conclusion and Further Work

The environmental performance of certified hotels, with respect to CO_2 emissions, was investigated to study the effectiveness of certification in reducing global CO_2 emissions in the hotel sector. Preliminary results from the analysis of the primary raw data collected from the selected hotels have shown no direct reduction in CO_2 emissions attributable to certification alone.

Several fundamental weaknesses were identified:

- No benchmarking of CO_2 emissions in schemes (*except one*)
- Incorrect accounting for CO_2
- Adding different types of energy together *i.e delivered electricity and fuels.*
- Weighting of categories in the awarding of credits for certification.
- Numerical errors in calculations
- Confusing proliferation of certification schemes with varying criteria and benchmarks.
- Lack of transparency
    - in the publication of benchmarks in the public domain which allows a wide range of emissions to occur within the same scheme.
    - in the declaration of the criteria used by the certifying bodies to judge the data from the hotels. For example, they may be using out of date benchmarks and there may be some occasions where they are using average rather than good / best practice for comparison.
    - in the way the data is collected and sent to the certifying body and the accounting of numbers of people *i.e. night, day, resident staff* and areas included.[1]
    - in identifying different parts of the hotel that may have different performance and identifying the difference between where an improvement is made and claims are made for that improvement (if there is no sub-metering.)
    - in the identification of final energy use *i.e is it representative of the whole building, a conference hall or a only a bedroom*
    - as to what building type is being used to establish the benchmarks against which the subject hotel is being judged *i.e. LEED*
    - in what benchmarks have been used in the award of certification.
    - Lack of disclosure to the public that the certification has been awarded for design intent or for operational performance *i.e. LEED, BREEAM is for design and simulated data whereas Green Globe, Nordic Swan is based on operational data.*

Certification is commendable for addressing a wide range of impacts but it does not account for CO_2 emissions in audits. Certification must make the calculation of CO_2 emissions a mandatory category which has to be properly computed. The weighting of this and other categories must be rigorous and reflect the level of impact on global CO_2 emissions.

A simple, accurate method of CO_2 emissions calculation needs to be developed which can be adopted universally. The calculation method needs to be transparent and standardized. This should be made a compulsory requirement of any performance analysis. The calculation of CO_2 emissions per guest night, would enable comparisons between different size hotels. The setting of benchmarks should follow the reference function constituting part of the hotel[2] rather than a single benchmark or the concept of a reference hotel.

Compulsory sub-metering, to monitor consumption in energy intensive facilities such as kitchens, laundries or swimming pools, would be a pre-requisite to ensure accurate data collection and feedback and to identify exceptional or unusual patterns of energy consumption.

An independent assessor or dedicated in-house team would decide the monitoring points and specify or install the sub-meters on site to ensure accurate data collection and feedback.

Three levels of assessment could be made; 1) Calculation of global CO_2 emissions based on fuel bills; 2) Separation of *architectural e.g.* space heating/cooling and lighting, and *domestic* energy use e.g . hot water, laundry etc. and identification of associated fuel use for each separated function. 3) *Sub-division* within architectural and domestic energy categories i.e. is the laundry outsourced or in-house; use of electric or gas driven tumble dryer with timer and humidity control. Compulsory sub-metering would identify exceptional or unusual patterns of energy consumption, help diagnose the cause enabling recommendations to be made to rectify the problem thus reducing the environmental impact of the hotel.

1 In some cases there is some confusion between the equivalence of a day and overnight guests. However, Green Globe certification accounts for this and allows one day guest equivalent to 1/3 guest night and Nordic Swan allows one day guest equivalent to ½ guest night.

2 Bohdanowicz (2006) originally proposed to disaggregate hotels into modules with individual energy indicators rather than a single indicator for whole hotel as currently the case.

This method is the first step of the diagnostic process leading to a solution to rectify the problem thus reducing the environmental impact of the hotel. However, tourism-induced CO_2 emissions are unlikely to be reduced only through voluntary, "soft" instruments such as our proposed method of CO_2 emissions calculation but need to be coupled with indispensable "hard" instruments such as the removal of tax exemptions on aviation fuel or the introduction of a mandatory carbon tax. This would start hotels focussing attention on their CO_2 emissions.

Keywords: Assessment tool, Market transformation, CASBEE, Productivity, Human sensitivity

Summary

Lively debate is continuing internationally regarding sustainable building assessment tools and market transformation. The improvement of assessment tools from the viewpoint of market transformation, the rating of buildings using assessment tools, and the provision of a framework to bring about market transformation are important. Also, strengthening the relationship between assessment tools and carbon neutrality, the continuation of dialog with the various stakeholders, and measurement of energy performance, etc., have been raised as important tasks.

For CASBEE also, the promotion of voluntary market transformation has been adopted as an important task. As the author's personal opinion, the following three points for the promotion have been identified and discussed. (1) The pursuit of ease of understanding and explanation of the benefits, (2) Investigation of the introduction of productivity into assessment tools, (3) Investigation of indices taking into consideration human sensitivity.

1. The pursuit of ease of understanding and explanation of the benefits

1.1 The achievement of ease of understanding in CASBEE for New Construction

First, to clearly demonstrate the CO_2 emission performance and the evaluation of global warming measures. Then to explain in an easy to understand manner the economic benefit, the productivity benefit, the direct effects for buildings of each use, the effect of a building of rank S, etc. Promotion of ease of understanding, ease of visualization, such as 5-star rating, etc., with emphasis on certification rather than ranking.

The results display sheet for the Japanese assessment tool CASBEE for New Construction (2008 version) was designed. This has been revised with the main purpose of clarifying global warming measures, and the three items "Consideration of global warming," "Consideration for local environment," and "Consideration for surrounding environment" have been re-formulated as evaluation items for the off-site environment (LR-3). Also, the tool has been revised to reflect simplified calculation of life cycle CO_2, and the evaluation of "Consideration of global warming" by the ratio of emissions compared with a reference building. Further, the ranks S, A, B^+, B^-, and C have been linked with a 5-star rating, for ease of visual understanding.

Figure 1 shows the distribution of CASBEE assessment results for Building Contractors Society 2006 design and built projects (23 companies, 591 projects). Each year the number of CASBEE evaluations by general contractors has been increasing steadily. Also, the trend towards designing for higher ranks (B^+ ~ A ~ S) than the standard level is increasing. In this way, from the rank of a building design and confirmation of the plot position, the use of the tool to promote better environmental performance is promoted.

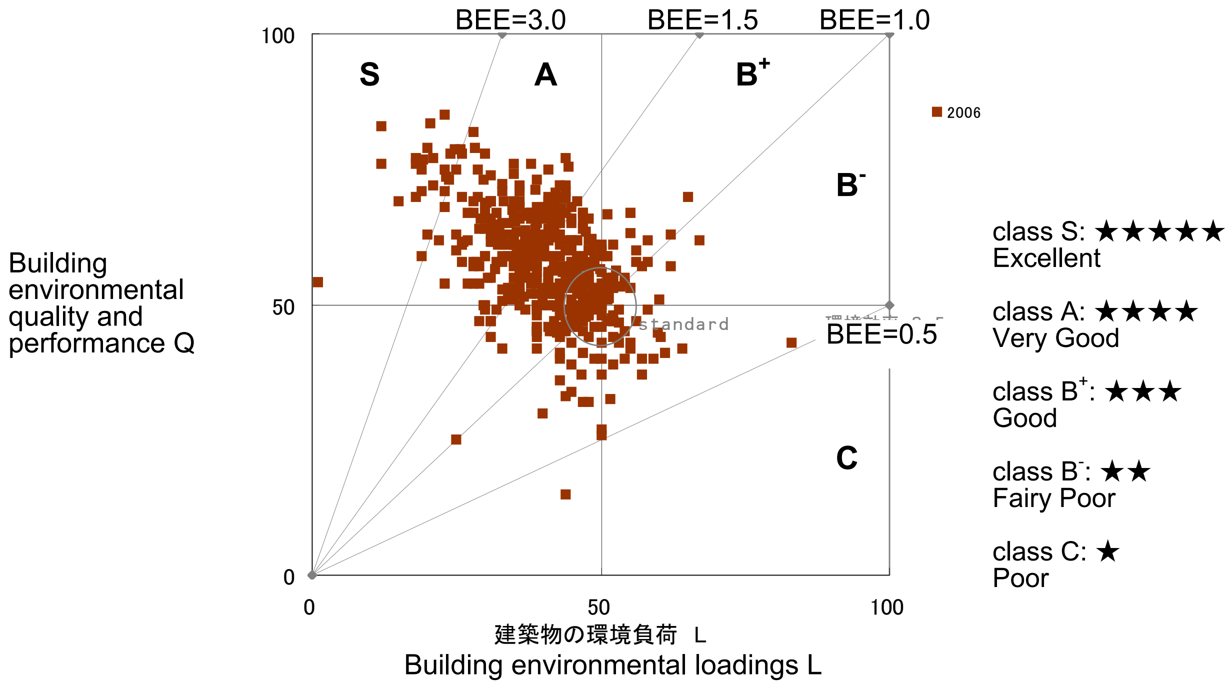

Figure 1. Distribution of CASBEE assessment results for Building Contractors Society 2006 design and built projects (23 companies, 591 projects)

1.2 Revision of CASBEE for Existing Building and investigation of widening use

Following CASBEE for New Construction, CASBEE for Existing Building is being revised. Examples of assessment by CASBEE for Existing Building are still very few, so it is important to increase the number of assessment examples. The items for revision are mainly as follows.

<Clarification of energy performance results and global warming measures>

· As for the new construction version, assessment to clarify measures for global warming is being introduced, and the items in off-site environment (LR3) are being changed to global warming, local environment, and surrounding environment.

· Conversion of energy performance results to CO_2, and calculations of $LCCO_2$ is carried out, and evaluated by comparison with a reference building

<Intellectual productivity>

· Discussed later (see item 3)

<Expansion in the number of assessment examples>

· Encouragement of the transition from new construction certification to existing building certification

· The use of CASBEE for Existing Building for the assessment of renovation in renovation projects such as housing and building, “Model low CO_2 subsidy projects by MLIT," etc.

<Improvement in ease of use and reduction in evaluation load>

· Investigation of a simplified version of existing building assessment

· For large scale refurbishment projects, investigation of mechanisms of submitting CASBEE for Existing Building/Renovation, together with an energy saving plan (however, this would be in accordance with the decisions of each local government).

<Linking with real estate appraisal and valuation>

Real estate appraisal and valuation is almost always concerned with existing buildings. Currently in the real estate appraisal and valuation field, there is momentum towards investigating methods of appraisal and valuation that take into consideration the environment. Here, if each of the items of CASBEE for existing building is recognized in the market, and also if its use in real estate appraisal and valuation spreads, there is the possibility that use of CASBEE spread greatly. Rather than doing nothing until the market becomes aware, it is necessary to raise the awareness of each of the items, by showing the market the results of this kind of research. Table 1 shows a list of the evaluation items of CASBEE for Existing Building. Items related to increase of income are shown in orange, and items related to cost reduction are shown in green. An outline summary is as follows.

(1) “Indoor environment” is a factor that constitutes the building’s grade, it is recognized by the market, and it has potential of quantitative evaluation. In addition to this, if an item for evaluation of improvement in intellectual productivity is added, a quantitative value (increase in income) is obtained.

(2) The item of functionality (spaciousness, refreshment space, décor) of “Quality of service” is a factor that constitutes the building’s grade, it is recognized by the market, and it has potential of quantitative evaluation. The criterion for smooth access for the disabled can be qualitatively evaluated as the improvement in heartful building image.

(3) Durability and reliability, and flexibility and adaptability of “Quality of service” can be quantitatively evaluated (reduction in depreciation load) provided understandable evidence is provided, or qualitatively evaluated (improvement in image, avoidance of risk). (For Existing Building and Renovation, as in New Construction, it is necessary to carry out an study to determine the number of years of service life of the building structural materials.)

(4) It is necessary to raise the awareness of the market for outdoor environment on-site, and in the future it will be possible to qualitatively evaluate it (improvement of image).

(5) Quantitatively, energy reduction is cost reduction, and also has qualitative value (image improvement, risk avoidance). It is necessary to clarify the quantitative effects and analyze the qualitative effects of natural energy, etc. Regarding operational conditions, as the operational time becomes longer and density (people, heat generated by people, etc.) increases, the CO_2 emissions and energy cost increases. Without an energy efficient building, CO_2 emissions and energy cost increases. It is necessary to separate the two in real estate appraisal and valuation.

(6) It is necessary to raise the market awareness of resources and materials, and it is necessary to analyze the qualitative effects (image improvement, risk avoidance).

(7) Under off-site environment, it is necessary to reorganize the items into consideration of global warming, consideration for local environment, and consideration for surrounding environment, and add $LCCO_2$ evaluation, as in New Construction. Consideration of global warming (including evaluation of life cycle CO_2) has value from both the quantitative effect (cost reduction) and the qualitative effect (image improvement, risk avoidance). It is necessary to raise the awareness of the market for consideration for local environment, and consideration for surrounding environment, and it is necessary to analyze the qualitative effects (image improvement, risk avoidance).

Looking at the items separately, from the point of view of resulting in quantitative value, it is considered that the items can be divided into those items that are easy to understand and that can be adopted by the market and those engaged in real estate appraisal and valuation, and those items that for the time being should be analyzed for their qualitative value. It is considered that where possible, the items should be introduced into assessment tool of existing building and renovation.

Table 1. Items for which has potential of quantitative evaluation in real estate appraisal in CASBEE for Existing Building

Q Building Environmental Quality & Performance				
Q-1	Indoor Environment

2. Study of the introduction of productivity into assessment tools

2.1 Study of the introduction of intellectual productivity in offices and others

By reducing the sick building syndrome and improving the thermal and light environment, work efficiency can be improved, and as a result the level of health and productivity is improved. It is clear that the annual benefit brought about by this exceeds by far the associated construction cost.

Currently, the productivity research committee, which is supported by the Ministry of Land, Infrastructure, Transport and Tourism, is carrying out academic research on the improvement in productivity from the architectural viewpoint, and is studying the establishment of methods for planning of architectural spaces, environmental and equipment planning, and their evaluation and rating. In the sub-committee on evaluation and rating, there are various studies being carried out to incorporate intellectual productivity into CASBEE. In the future, equations for the relationship between score and productivity index (productivity value, conversion to a monetary value, etc.) for evaluation items that are associated with intellectual productivity, such as Q1: indoor environment, Q2: part of quality of service, Q3: part of outdoor environment, LR1: part of energy, etc., will be defined for both individuals and organizations as a whole, and the addition of a quantitative index chart for productivity will be studied.

2.2 The concept of the three layer model for productivity in offices and others

At present studies are being carried out on planning of architectural spaces, and environmental and equipment planning, and their evaluation and rating, considering a layered model for productivity from the architectural viewpoint. It is considered that every day people pass through these layers, while carrying out their activities.

The first layer is the “information processing” layer in which standard processing of knowledge and information and work processing is carried out. Under the current paradigm, a work environment and health environment are sought in order to maintain the environment. Evaluation is attempted by measuring absentee rates, health management costs, etc. The yardstick is coarse but measurement is simple, and this has been partially incorporated into assessment tools, etc.

The second layer is the “knowledge processing” layer in which knowledge and information are sought and processed. Under the current paradigm, efforts are made to improve the mental, physiological, and physical comfort environment, the health environment, and the quality of space, with the objective of improving the quality of space and environment. Evaluation is carried out by quantitatively evaluating the work efficiency and the mental and physiological effects, and the target is to carry out economic evaluation. The methods of measurement are rather complex, but research on these methods is proceeding at present.

The third layer is the “knowledge creation” layer, in which value creation and innovation are carried out. Space and environment that can stimulate knowledge creation is sought. For example, a space or environment having the characteristics that it is possible to concentrate, communicate, and relax can stimulate a person to create knowledge. A person’s actions in response to a space or environment are various, such as deep thought, friendly chat, exchange of opinions, etc., but it it is hypothetized that the result is invigoration of the place, leading to knowledge creation. No method of measuring this type of intellectual value creation has yet been established, so it is considered that its evaluation is a task for the future.

However, this is not to say that there are absolutely no indications regarding what constitutes excellent space for productivity. It is possible to imagine offices with lively communication and intellectual stimulation, or serene contemplative space such as shrines and temples, and other spaces. Also, new architectural experiments that aim for improved productivity have intensified in recent years, so there are many architectural spaces that can give us hints.

It is considered that if it is possible to accumulate many examples where there has been a good physiological and mental effect on individuals, resulting in invigoration of the place as an organization, or resulting in knowledge creation by individuals or organizations, then it will open the road to development of architectural design methods for excellent productivity and its evaluation.

2.3 Study of productivity from the viewpoint of users or businesses

The spaces and physical environments created by architecture, such as offices, schools, hospitals, and other facilities, are provided in accordance with the users of each facility. For example, a hospital is a space with comfortable sickrooms and advanced medical treatment equipment, an office is a comfortable workplace, environment and communication space.

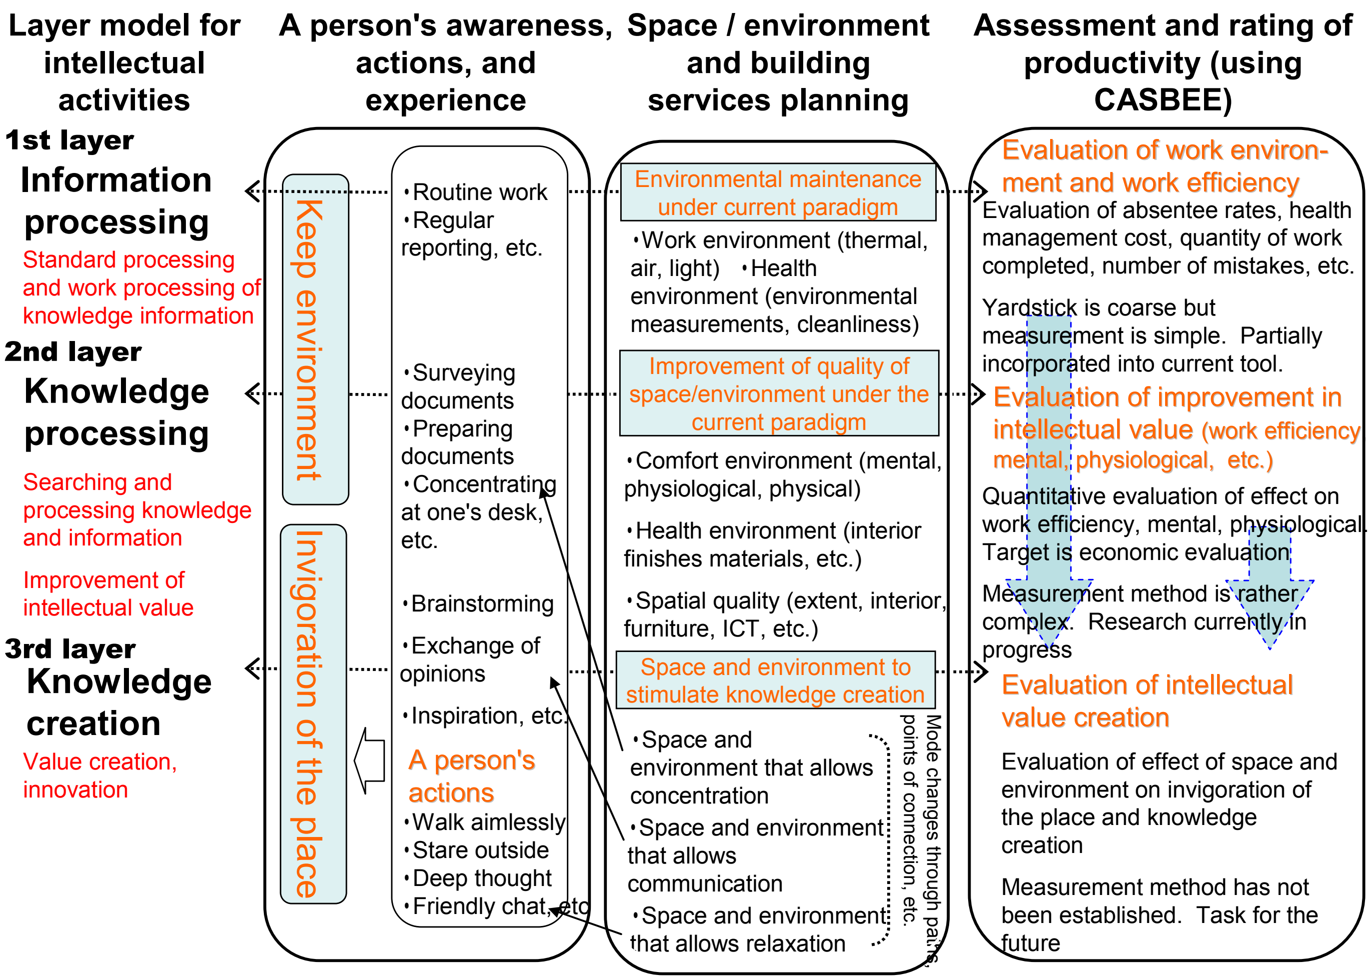

Figure 3 Layer model for Architectural spaces and Intellectual activities

Before these things, a more environmental positive value is created. An improvement in productivity is aimed for, for example, an improvement in test results in a school, and an increase in business in an office. In this way, it is possible to consider how productivity can be improved in buildings of each use, using a table such as Table 2.

Further, by specifically considering, from the viewpoint of a tenant moving into that building, what is attractive, what is the totally expected effect of the building, and so on, it is possible to study the meaning of the effect of improving productivity from the viewpoint of users or businesses, and how to measure it.

The above was just an indication of a part of the methodology under study, but it is necessary that this kind of study and survey continues.

Table 2 Study of productivity from the viewpoint of users or businesses

		Office	School	Hospital	Commercial	Research facility	Factory
Architectural space and environment		Comfortable work space Space for communication with outside Attractive environment to be in	Comfortable classrooms and outdoor space Environment that is attractive for both students and teachers	Comfortable sickrooms Comfortable condition of medical treatment Sufficient medical equipment	Space to encourage buying and satisfaction Space and environment that encourages people to stay in for a long time	Inspiring space and environment Communication space Attractive environment to be in	Physical environment for producing products Space and environment that is comfortable for the workers
Positive value of environment	Increase in productivity	New proposals or increased business	Improved test results Improved rate of success in proceeding to higher education	High treatment rate Early discharge	Increase in sales per unit area	Increase in the frequency of inventions or discoveries	Improvement in productivity per unit time or per unit area
	Stronger attraction for tenants	New ideas forthcoming Possibility of collaboration Always comfortable	Excellent students Excellent teachers	Excellent doctors	Many buyers Buyers spend well	Excellent researchers gather	-
	Expected effect	Reduction in move-out rates and vacancy rates	The maximum numbers of students can always be obtained Possible to select the best students	Higher admissions so that there are no vacant rooms for the wealthier patients	Attract tenants that can attract customers Increase in customers	Creation of new research results	Improvement in productivity per unit investment

3. Study of indices taking into consideration human sensitivity

As stated previously regarding productivity, a built space with thermal, light, sound, air, and ICT environment that places importance on the human sensitivity, is considered to be important for knowledge creation. Also, a rich life in harmony with nature and landscape is important, and these are considered to be communication tools for gaining the understanding of the occupants and residents.

As a specific method for this purpose, indices for universal design evaluation taking human sensitivity into account are being studied. Table 3 shows the essential features of these indices. The evaluation items derived from the five senses are hearing (natural sound, sensible sound, echoes), touch (disposition, sense of walking, sense of touch), seeing (texture of materials, light and shade, spaciousness), smell (natural, materials, smell of a location), and so on. Comprehensive evaluation items include stimulation from the surrounding environment, stimulation due to natural change, comfort, etc. These are weighted to obtain an overall evaluation.

Figure 4 shows an example of an evaluation that was attempted with evaluation by an evaluation index scheme that takes human sensitivity into account and CASBEE assessment on the two axes. It is considered that both good “environmental assessment by CASBEE” and good “index evaluation taking into consideration human sensitivity” is desirable. On the other hand, it is expected that the required rank or grade will vary depending on the building type, the charactor of the building, and the requirements of the owner. Also, it is considered that in the future the creation of buildings with still higher evaluation for both indices will become the target.

Table 3 Main items for evaluation indices taking human sensitivity into consideration (proposed)

Base of sense	Stimulation from the surrounding environment
	Stimulation from natural change
	Trigger from acts of movement
	Take into consideration Comfort
Sense of hearing	Natural sound
	Sound sensible to a person
	Sound of space
Sense of touch	Skin touch
	Sense of walking
	Sensing with hands and feet
Sense of sight	Texture feeling of materials
	Light and shade of space
	Extent of space
Sense of smell	Natural smells
	Smell of materials
	Smell of place

4. Conclusions

(1) For assessment tools, the pursuit of ease of understanding and explanation of the benefits are important. It is required to clearly demonstrate the CO_2 emission performance and the evaluation of global warming measures. Then to explain in an easy to understand manner the economic benefit, the productivity benefit, the direct effects for buildings of each type.

(2) It is necessary to introduce productivity for assessment tools. Especially, space and environment to stimulate knowledge creation is required and measurement method is the task for the future.

(3) Indices for universal design evaluation taking human sensitivity into account should be studied at present and in the future.

Keywords: liveable community, construction, eco-efficiency, evaluation, town

Summary

This paper analyzes the community environment and its characteristics in Chinese towns, discusses main targets, basic principles and environmental considerations associated with liveable community construction in towns. It sets up the life cycle process of liveable community construction which includes four stages: planning and design, buildings construction, operation and management, and building dismantlement. A construction technology system composed of four sub-systems is also established: 1) technologies of ecological environment planning; 2) technologies of environmental protection; 3) technologies of water and energy-saving, waste reduction and reuse; 4) technologies of recyclable materials.

Based on two previous national key R&D programs of our research team funded by Ministry of Science and Technology, P.R.C, the paper introduces four typical construction demonstrations for liveable communities in towns in different areas, and formulates the application of community construction technology system and eco-efficiency evaluation in Yanhe eco-village as a case study.

The paper formulates the concept of eco-efficiency of liveable community construction, suggesting that eco-efficiency can be evaluated by the ecological capacity control indicator (ECCI) and the ecological footprint method. ECCI is established to indicate the integrated ability and ecological capacity of each control factor of ecological capacity of liveable communities, and the evaluation framework of ECCI - composed of a three-level indicator system - is set up. Applying this evaluation indicator system to case studies, we compared the liveability of communities between Mulan town and Huazhuang town, and performed the integrated evaluation of eco-efficiency for community construction.

It is concluded that the construction development of communities in Chinese towns should be liveability-oriented, that this should be prioritized over the entire building life cycle, the eco-efficiency evaluation method should be applied during the process, and the key issues and targets should be clarified in the development of the eco-efficiency evaluation method.

1. Community Environment in Chinese Towns

1.1 Development in Chinese towns

In China, town refers to all settlements with a larger area than a village and usually smaller than a city. According to China's current standards for administrative towns formulated in 1986, a town can be recognized if it includes a county government and has a non-agricultural population of more than 2,000.

In China's urbanization process, towns have been developing rapidly and continuously. From 1978 to 2006, the number of towns increased from 2173 to 19369; the total population in cities and towns soared from 170 million to 577 million; the urbanization rate grew from 17.9% to 43.9%. In 2006, non-agricultural population in towns exceeded 200 million, and the development of sustainable communities in towns became the focus in the process of China’s urbanization. Meanwhile, the communities in towns have formed a unique community construction environment which is different from that in big cities and rural areas.

1.2 Characteristics of community environment in towns

Compared with big cities, community environment in towns has the following four characteristics:

(1) Most residents in towns are rural population. Agricultural population accounts for about 65.3% of the total population in towns.

(2) The density of population in towns is comparatively small. Apart from economically developed areas, farming land takes up a large proportion of the town's total land. In China, the per-capita area in towns is nearly 5.5 times that of big cities.

(3) Community environment in towns has distinctive characteristics. China is a multi-nationality nation with a vast area where the diversity in the natural resources supply, geography and climate, customs, economic and social development levels lead to community environments of different characteristics.

(4) Ecological environment of communities in towns is very fragile. Community environment is easily influenced by pesticide pollution, excessive land development, industrial pollution from factories development, and biodiversity reduction due to the damage to the original ecological environment, etc. Compared to large cities, the ecological environment of towns is more vulnerable due to inadequate environmental protection measures.

2 Construction Technology System for Liveable Community in Towns

2.1 Liveable community in towns

The Ministry of Housing and Urban-Rural Development of China (MOHURD) announced the Scientific Evaluation Criteria for Liveable City (CSUS, 2007), which defines liveable city as "the settlements with good living and space environment, good humanity and social environment, good ecological and natural environment, and clean and efficient production environment". Liveable city has the following six characteristics in China: social civilization, economic prosperity, beautiful environment, resource capacity, convenient life and public safety. Leadership in Energy and Environmental Design for Neighborhood Development (USGBC, 2002) gives quantitative evaluation criteria for green building within communities, in terms of sustainable sites, water efficiency, energy and atmosphere, etc.

Currently, basic liveability factors of community in towns in China should include physical, spiritual and environmental factors (Hua, 2006), which are reflected in civilized community, excellent environment, abundant life, energy-saving and environmental friendliness, safety and comfort.

2.2 Construction technology system and eco-efficiency evaluation of liveable community

Sustainable resource utilization, sustainable economic growth, sustainable environmental improvement and sustainable social justice should be adopted as the basic principles for liveable community construction in towns. Resource and energy-saving, environmental protection, human-orientation, and resource integration should be promoted in community construction and operation so as to form a high-efficiency and low-energy construction model with low pollution, ecological balance and comfortable living.

Construction of liveable communities in towns would be prioritized over the whole building life cycle process. It can be divided into four stages: planning and design, building construction, operation and management and building dismantlement. The related construction technology system and eco-efficiency evaluation includes: 1) technologies of ecological environment planning; 2) technologies of environmental protection; 3) technologies of water and energy-saving, waste reduction and reuse; 4) technologies of recyclable materials.

The Construction Technology System and Eco-efficiency Evaluation of Liveable Communities in Towns (CTSEELCT) is shown in Figure 1.

2.3 Construction and demonstrations of liveable communities in different areas in China

China is a vast nation with different economic and social development levels and different natural resources. According to the geological positions and economic development levels, communities in towns of China are divided into several classes in this paper: economically developed communities in eastern and southern coastal areas, ecological communities in central areas, folk-style communities in western areas and communities in cold northern areas. Four typical construction demonstrations for liveable communities in towns in different areas are shown in Figure 2.

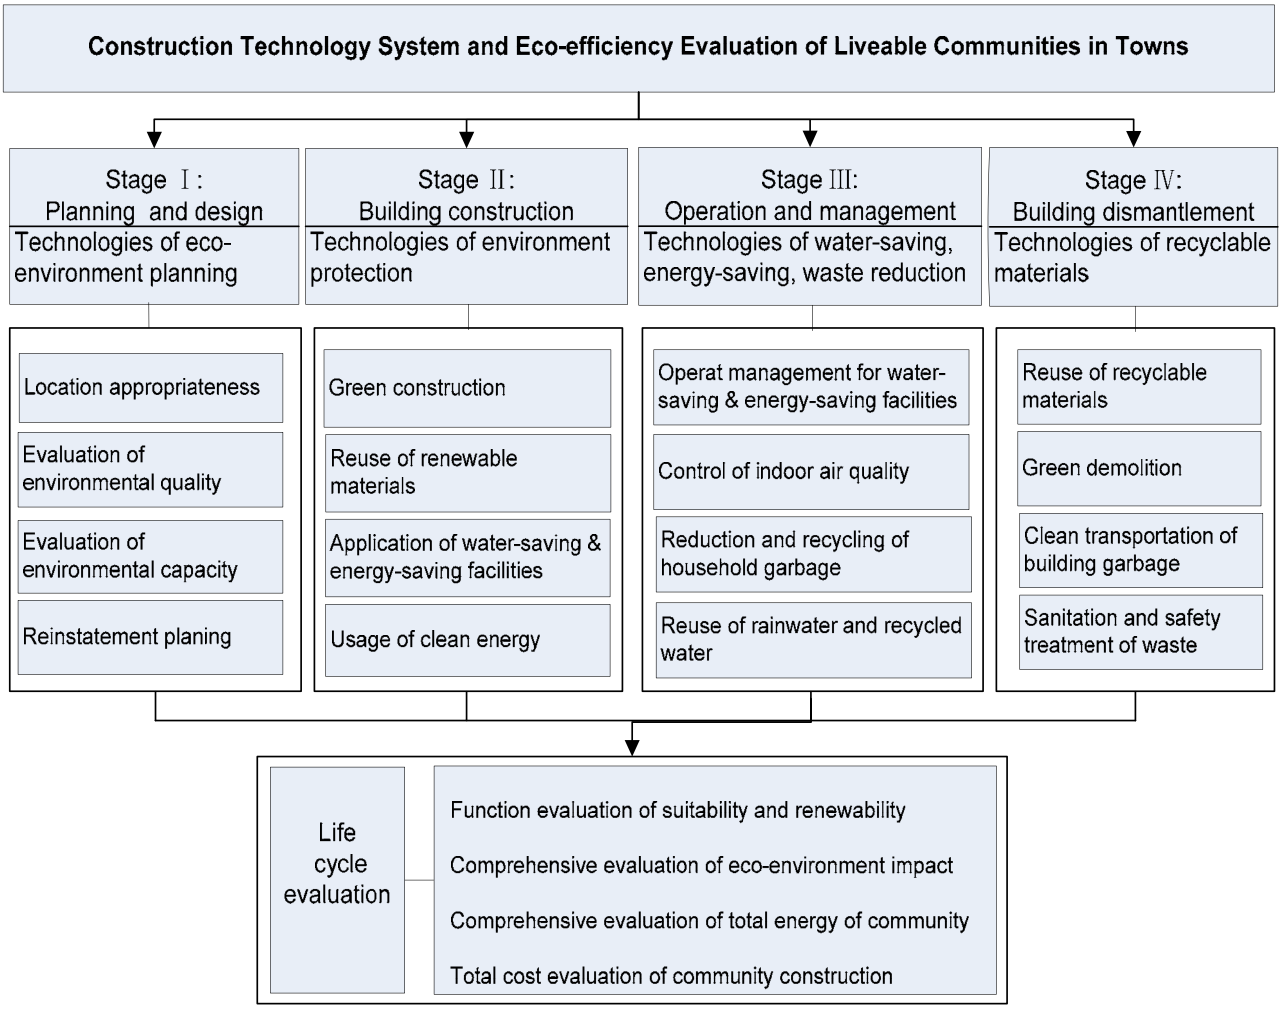

Figure 1 Construction technology system and eco-efficiency evaluation of liveable communities in towns

Developed community Huazhuang town in Jiangsu | Eco-community Yanhe village in Hubei | Folk-style community Tunpu town in Guizhou | Straw-bale community Hongtuya town in Jilin

Figure 2 Construction demonstrations for liveable communities in towns in different areas in China

From 2005 to 2006, our research team at Huazhong University of Science and Technology (HUST) undertook two key R&D programs funded by Ministry of Science and Technology, P.R.C (MOST): “Study and Demonstration on Construction Techniques of Eco-building”, and “Study and Demonstration on Key Construction Techniques for Ecological and Energy-saving Community in Towns". Several demonstration communities have been constructed in Huazhuang town (Jiangsu province), Zhuanghu village in Huairou district (Beijing), Weihushan scenic spot in Hailin city (Heilongjiang province), Hongtuya town in Baishan city (Jilin province), Mulan town in Wuhan city (Hubei province) and Yanhe eco-village in Wushan town (Hubei province). We have successfully applied the above technology system and eco-efficiency evaluation in these construction demonstrations.

An application of CTSEELCT in Yanhe eco-village construction is shown in Figure 3.

Figure 3 Application of CTSEELCT in Yanhe eco-village construction

3 Eco-efficiency Evaluation of Liveable Community in Towns

This paper evaluates the eco-efficiency of liveable community in towns by ecological capacity control indicator (ECCI) and ecological footprint through the demonstration projects. ECCI indicates the controlling level of environmental capacity of liveable community construction in towns, whereas ecological footprint evaluation reveals the eco-share ratio of towns. The eco-efficiency can be deduced from comparison of the results, which can also indicate the measures necessary to improve the condition of liveable community construction.

3.1 Eco-efficiency of liveable community construction

The concept of eco-efficiency is to promote the minimization of environmental impact of production processes. The World Business Council for Sustainable Development states that "Eco-efficiency is reached by the delivery of competitively priced goods and services that satisfy human needs and bring life quality, while progressively reducing the impacts to environment and resource intensity throughout the life cycle to a level at least in line with the earth's estimated carrying capacity." (NRTEE, 2001).

Eco-efficiency of liveable community construction means that all the activities in the life cycle process, including planning and design, building construction, operation and management and building dismantlement, should have minimized ecological impact.

The eco-efficiency of liveable community construction can be evaluated by ECCI and ecological footprint method.

3.2 Ecological capacity evaluation of liveable community construction

The paper analyzes and evaluates the ecological capacity of two types of communities in towns by eco-efficiency evaluation. One is an ecological community beside mountains and rivers in central area in Mulan town of Wuhan city, the main income source of which is eco-tourism; the other is a community in an economically developed area of southeast in Huazhong town, relying on industry for income.

3.2.1 Evaluation of ecological capacity control indicator

According to the CTSEELCT, the paper establishes the ecological capacity control indicator (ECCI) so as to indicate the integrated ability and ecological capacity of each control factor of ecological capacity of liveable communities.

The evaluation framework of ECCI can be classified into a three level indicator system.

The first level is ECCI. The greater the value of ECCI, the better the control ability of ecological capacity, and the better the corresponding comments. The classification and comments of ECCI are shown in Table 1.

Table 1 Level I: ECCI - Classification and Comments

Classification	ECCI	Comments
1	> 0.75	Very Good
2	0.50 ～ 0.75	Good
3	0.35 ～ 0.50	Middle
4	0.25 ～ 0.35	Low
5	< 0.25	Worse

Formula of ECCI is as follows:

$$\mathrm{ECCI} = \sum_{i=1}^{n} V_i W_i \quad (1)$$

Where:

V_i denotes the second level indicator value; W_i denotes its weight calculated by Analytic Hierarchy Process (AHP); n denotes items of second level indicator (Ministry of Environmental Protection of China, 2002).

The second level is ecological capacity control and evaluation indicator, including four sublevels: population capacity, land capacity, resources capacity and waste treatment capacity.

The third level is detailed evaluation indicator for ecological capacity which including 21 sub-indicators.

Evaluation indicator system of ecological capacity in towns is shown in Table 2.

Table 2 Evaluation Indicator System of Ecological Capacity in Towns

Level II	Level III	Level II	Level III
Population capacity B_1	C_1 Natural population growth rate	Resources capacity B_3	C_{11} Energy efficiency
	C_2 Population density		C_{12} Comprehensive grain production capability
	C_3 Proportion of non-agricultural population		C_{13} Per capita fresh water
	C_4 Employment rate		C_{14} Energy consumption of per million yuan of output
	C_5 per capita GDP		C_{15} Energy-saving efficiency
Land capacity B_2	C_6 Per capita arable land		C_{16} Renewable energy utilization rate
	C_7 Water area	Waste treatment capacity B_4	C_{17} Wastewater treatment rate
	C_8 Per capita built-up area		C_{18} Domestic refuse treatment rate
	C_9 Forest coverage rate		C_{19} Percentage of environmental protection input in GDP
	C_{10} Development available wasteland		C_{20} Per capita green area in built-up areas
			C_{21} Comprehensive utilization rate of straw

Using the above evaluation indicator system, we were able to compare the case studies of Mulan town and Huazhuang town.

The comparison of ECCI in Mulan town and Huazhuang town with the Affordable Standard of Towns in China (ASTC) is shown in Figure 4.

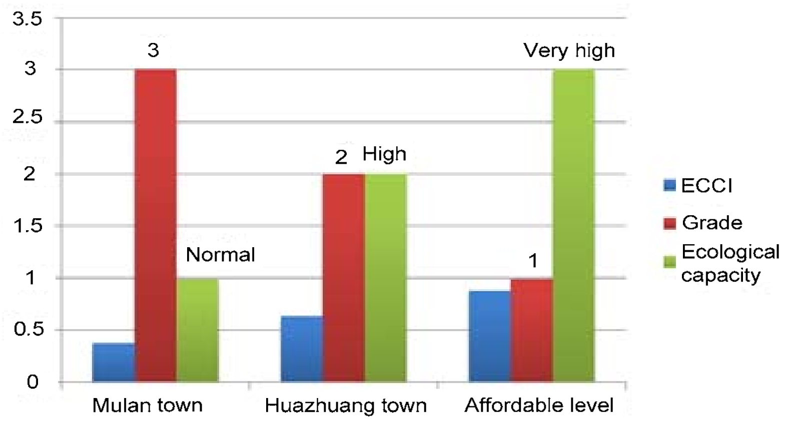

Figure 4 Comparison of ECCI in Mulan town and Huazhuang town with ASTC

The comparison of ecological capacity control factors of Mulan town and Huazhuang town with ASTC are shown in Figure 5.

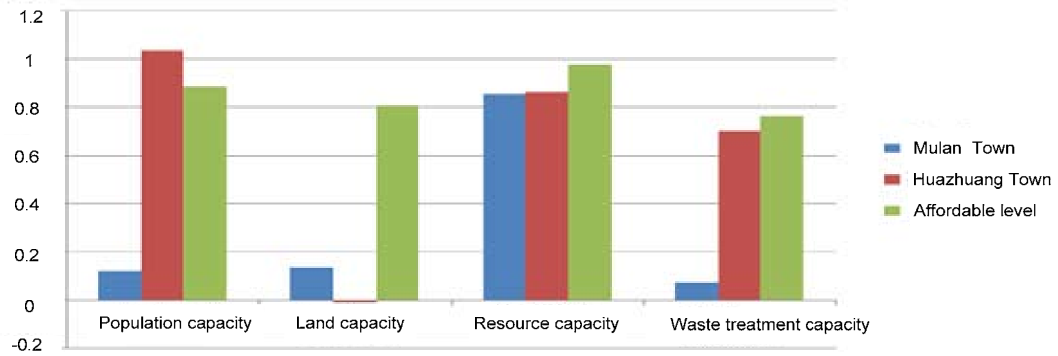

Figure 5 Comparison of ecological capacity control factors in Mulan town and Huazhuang town with ASTC

According to the above analysis, we can find:

1) Most of the ecological capacities of Mulan and Huazhuang are lower than ASTC，but the population capacity in Huazhuang is higher than Mulan and ASTC. This is because Huazhuang, as an economically developed town, can offer more employment and the people there are richer.

2) The land capacities in Mulan and Huazhuang are somewhat lower than ASTC, which indicates that both towns lack land resources.

3) The resource capacities of Mulan and Huazhuang are close to ASTC, because resources supply in both towns is from the outside. Therefore, it is very important to improve the efficiency of energy usage and promote the use of renewable energy for sustainable development of two towns.

4) The waste treatment capacities of the two towns are different. Huazhuang, the developed town, pays more attention to environmental protection, as the indicators of green ratio, air condition, noise, cleaning rates of waste gas and water, rate of multipurpose utilization of solid waste all approach the ASTC benchmark. In Mulan, a town of abundant ecological environmental resources, the indicators of cleaning rate of waste water and solid waste are much lower than ASTC. Therefore, measures to improve planning and construction for liveable communities have been taken in Mulan.

3.2.2 Ecological capacity evaluation of community

Taking the eco-footprint method, the eco-share ratio, the per capita ecological footprint and the per capita ecological capacity of Mulan town and Huazhuang town were evaluated.

1) Evaluation of eco-share ratio. Eco-share ratio was 80.00% in Mulan and 226.1% in Huazhuang in 2005.

2) Evaluation of per capita ecological footprint and per capita ecological capacity. The comparison of per capita ecological footprint between Mulan and Huzhuang in 2005 is shown in Figure 6, and the comparison of per capita ecological capacity between Mulan and Huzhuang in 2005 in Figure 7.

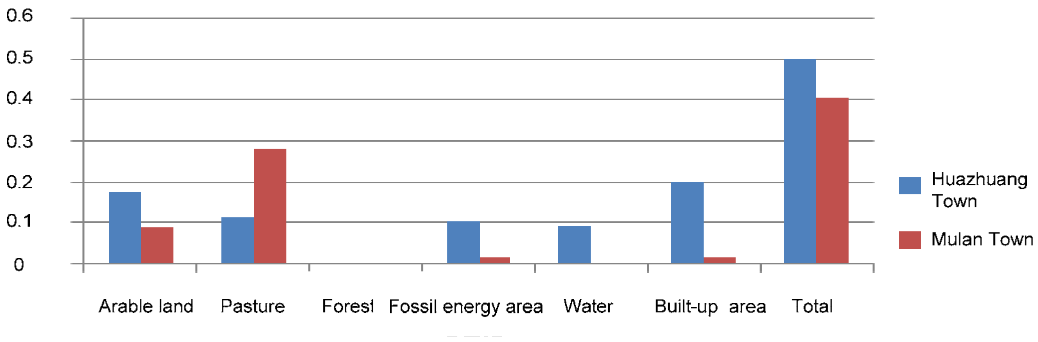

Figure 6 Comparison of per capita ecological footprint between Mulan and Huazhuang in 2005

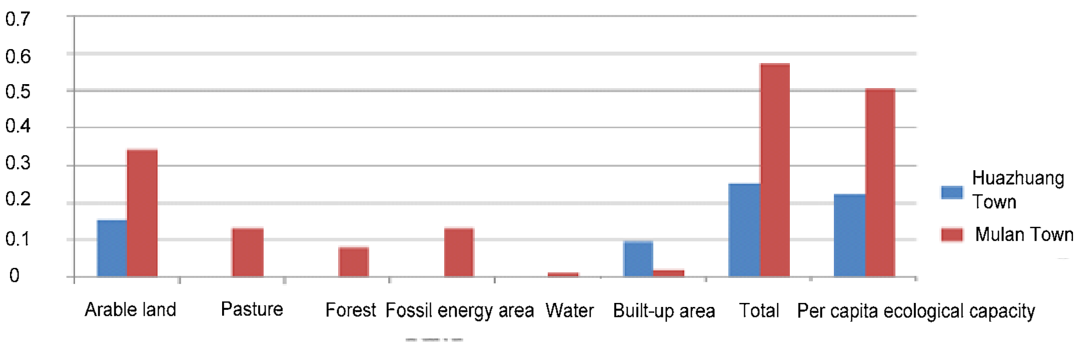

Figure 7 Comparison of per capita ecological capacity between Mulan and Huazhuang in 2005

3.2.3 Integrated evaluation of eco-efficiency for community construction

(1) The integrated evaluation outcome

If the eco-share ratio of community is lower (or eco-capacity is higher), but the control ability of environmental capacity (ECCI) of community is higher, then the eco-efficiency of community is higher, and the liveability in this kind of community is better. But when the results of these two data are conflicting, the eco-efficiency should be deduced from ECCI.

(2) Comparison of eco-efficiency

1) Eco-share ratio: The eco-share ratio in Mulan town is 0.8000 while that in Huazhong town is 2.2610.

2) ECCI: ECCI in Mulan town is 0.4049 while that in Huazhong town is 0.6325, but both are lower than ASTC. The eco-efficiency of Huazhong is higher than that in Mulan, i.e. the community of Huazhong is more liveable than that of Mulan.

3) Control ability of eco-capacity: Huazhong is a developed town with higher employment rate and GDP than that of Mulan, so the population capacity of Huazhong is higher than that of Mulan. Therefore, the control ability of eco-capacity of Huazhong is higher than that of Mulan.

4) Economic development factor: Economic development is a very important factor to improve environment for liveable community in towns.

4 Conclusions

(1) The construction development of communities in towns of China should be liveability-oriented. The five developing principles should be followed: civilized community, excellent environment, abundant life, energy-saving and environmental friendliness, safety and comfort.

(2) The liveable community construction should be prioritized over the whole life cycle process. The four stages of the process are planning and design, building construction, operation and management, and building dismantlement. The related construction technology system should be developed and promoted in this process.

(3) The liveable community construction should apply the eco-efficiency evaluation method. There are many different and unique characteristics of community construction in towns of China. Therefore, to establish the eco-efficiency evaluation method is beneficial for guiding and promoting the liveable community construction.

(4) The key issues and targets should be clarified in development of eco-efficiency evaluation method. The key to develop eco-efficiency evaluation technology of liveable community in towns is to improve the

eco-capacity evaluation system. The aim of eco-efficiency evaluation is to lead the liveable community construction in towns of China in a more sustainable way.

ACKNOWLEDGEMENTS

The research program has been supported by the National Key Technologies R&D Program of Tenth Five-Year Plan of China (2005BA807B08LA02) - "Study and Demonstration of Key Construction Techniques for Ecological and Energy-saving Community in Huazhuang Town, Jiangsu Province", and the National Key Technologies R&D Program of Tenth Five-Year Plan of China (2005BA807B08) - "Study and Demonstration for Construction Techniques of Eco-building in Different Areas".

Thanks for the efficient work with the cooperation of all the members in our research team. Thanks for the contribution from Ms. Wu Lili and Mr. Ho Simon Wang.

DEFINING SUSTAINABILITY FOR AUSTRALIAN ROAD INFRASTRUCTURE PROJECTS

Jay Yang[1]
Soon Kam Lim[2]

[1]Associate Professor, Queensland University of Technology, Brisbane, Australia, j.yang@qut.edu.au
[2]PhD Candidate, Queensland University of Technology, Brisbane, Australia, sk.lim@qut.edu.au

Keywords: Sustainable development, road infrastructure, construction management, project delivery, performance enhancement.

Abstract

Australia is currently riding on a resource boom, thanks to the economic development of its northern neighbors. This demand and the country's own growing economy and population, has resulted in an unprecedented scale of infrastructure upgrade and new development in many states across Australia. Road and highway construction often leads other infrastructure development. Under the public awareness on sustainability and due to their impact on the environment, road infrastructure projects put pressure on all stakeholders, including local, state and federal governments, to look for economically feasible, socially viable and environmentally responsible project outcomes. This calls for the adoption of sustainability principles through project delivery. Literature study and consultation with some professions of the industry found that there is an absence of common understanding on what constitutes sustainability in the infrastructure context. Its priorities are often interpreted differently among stakeholders. As a result, policies on sustainability remain largely ideological and are often not realized to the full potential through actual project delivery.

A research is being conducted to identify the common perceptions and expectations by different stakeholders towards achieving sustainability in road and highway infrastructure projects. Face to face interviews on selected representatives of these stakeholders were carried out in order to select and categorize, confirm and prioritize a list of sustainability performance targets identified through literature and past research. This effort is being followed by a Delphi study with the assistance of industry professionals and academic experts, which will further consider the interrelationship and influence of the sustainability indicators. By identifying and integrating different perceptions and priority needs of the stakeholders, coupled with the identification of key sustainability indicators and solutions for critical issues in subsequent development stages, a set of decision-making guidelines can be developed to help promote and drive tangible sustainability agenda in road and highway infrastructure projects.

1. Introduction

Australia is currently in the grip of buoyant national economy. A few catalysts have contributed to this growth, surge in resources export, substantial foreign investments and increased population, to name a few. These development patterns have coupled with improved living standards and growing societal expectations, which in turn caused an unprecedented demand for infrastructure development.

Road and highway construction often leads other types of infrastructure development. Substantial and comprehensive transport networks are critical to the booming mining, mineral processing and export industries. The fact that the majority of the population lives outside the greater metropolitan areas of Australian capital cities and growing regional communities adds further pressure to the already bottle-neck situations on roads and highways.

Having recognized the potential as well as impending hindrance to the economy if the problems of inadequate roads infrastructure worsens, the Australian government is committed to build, improve and upgrade. With increasing public concern over the environment, it is also natural to expect that any infrastructure development is integrated with the concept of sustainable principles, as it will not only bring about economic gains, but also social and environment benefits for which large infrastructure developments are held accountable.

Although in an ideal sense the principles of sustainability should drive road infrastructure development, many stakeholders can be involved in the process and this has seemed to complicate the matter. Different disciplines are unwilling or unable to consider the views represented by others because there is no common language place (Lombardi and Brandon, 1997). Different individuals and organizations have expressed different perceptions and definitions of sustainability (Shelbourne, et al., 2006). The fragmented and diverse business nature of the industry accounts for such scenarios, which are exacerbated by the adversarial cultures within the industry (Chan et al., 2005). As a result, policies on sustainability often remain largely ideological and are often not reflected in the actual project delivery. Without common understanding among these stakeholders, achieving sustainability outcomes in road infrastructure projects remains a formidable task.

2. Overview of Australian Infrastructure Industry

Integral to the Australian building and construction industry, infrastructure development is an engine of growth driving its national economy. The infrastructure industry has direct impact on Australian's well-being and progress by providing roads and highways, water and electrical supply and communication essential for daily living and business operations. The industry has a significant influence on the effectiveness and efficiency of other industries to compete locally and in global market and provides for a myriad of support businesses (CRC for Construction Innovation, 2006). Infrastructure development is both critical and inevitable.

The demand on Australian infrastructure development is constantly on the rise. This is being fuelled by strong economic position with substantial foreign investment in the country and increased global demand for resources and energy particularly from neighboring countries, general prosperity with improved living standard, population growth and major migration which calls for greater infrastructure needs. Moreover, Australians have become used to high standards of infrastructure and their expectations will continue. This is becoming a major concern as new capital works still predominate in the public mind and the renewal of existing infrastructure is often taking for granted by the general public (Burns et al., 1999).

An analysis conducted by the Commonwealth of Australia (1999) on Australian building and construction industries revealed that the engineering construction market segment is employing 35,600 people (4.8% of the total industry's employment) with approximately 3100 firms. Given the booming economy, it is expected to rise. The engineering construction market segment is mainly engaged in engineering or infrastructure projects such as railways, dams, roads and bridges, major pipelines and eletricity and other utilities infrastructure.

The resources-led boom, particularly in Western Australia and Queensland, has resulted in high pressure on infrastructure. In Queensland, it is reported that the state government will invest over AUD$ 82 billion in the next 20 years under an ambitious infrastructure program, to cover four main types of infrastructure demands. (Table 1). Large projects which is over AUD$ 1 billion in value each will take up almost AUD$20 billion in that AUD$82 billion as a whole (Queensland Government, 2007). Road, rail and public transport infrastructure that top the list account for over 60% of the total investment.

Table 1: Infrastructure Spending for Queensland for 2007-2026.

TYPE OF INFRASTRUCTURE	INVESTMENT VALUE (AUD$'billion)
1. Road, Rail and Public Transport	50.78
2. Energy Networks	16.00
3. Social and Community	8.00
4. Water Infrastructure	7.50
Total	82.28

The geographical widespread of Australia and its necessary decentralized economic and social development means substantial transport network is required for its own mobility and for movement of a vast range of goods and services, and their providers, to meet its needs. From employees accessing their workplaces, students traveling to and from schools, and families going for weekend leisure outings, our society places enormous demand on road infrastructure to move people about in a safe, timely, efficient and environmentally friendly manner.

As these infrastructure systems experience unprecedented demand for both new built and regeneration, disturbances to human life and the ecosystem can be resulted. Therefore, enhancement of sustainability in infrastructure development is crucial in order to ensure minimal impacts to the environment, social and cultural aspects of a community and at the same time, achieve economic outcomes. To do so, integrating sustainable principles in infrastructure development by respective stakeholders is the only way forward.

3. Stakeholders in Road Infrastructure Projects

Road infrastructure development is complex. This is due to the large scale and use of huge resources that characterizes the nature of its development. Necessarily, it involves multiple parties to undertake the multi-faceted development as 'stakeholders'. In general, stakeholders are individuals or organizations that are either affected by or affect the development of the project; and therefore, capturing their input is a crucial component of the project development process (El-Gohany et al, 2006).

Infrastructure stakeholders span a wide spectrum of people and organizations, bringing together a vast a array of skills as well as disciplinary capabilities necessary for the implementation of infrastructure projects. El-Gohany et al. (2006) categorized infrastructure stakeholders into three types:

- *Responsible Stakeholder* refers to an organization or individual who has some degree of responsibility or liability with regard to the development process;
- *An Impacted Stakeholder* refers to an organization or individual who is directly or indirectly affected by the development process; and
- *An Interested Stakeholder* refers to an organization or individual who is not directly impacted by the project, but who would like to participate and provide his opinion in the infrastructure development process.

Adapting from the above, for this research, the definition on stakeholders is expanded to identify the various stakeholders in road infrastructure projects development, as below:

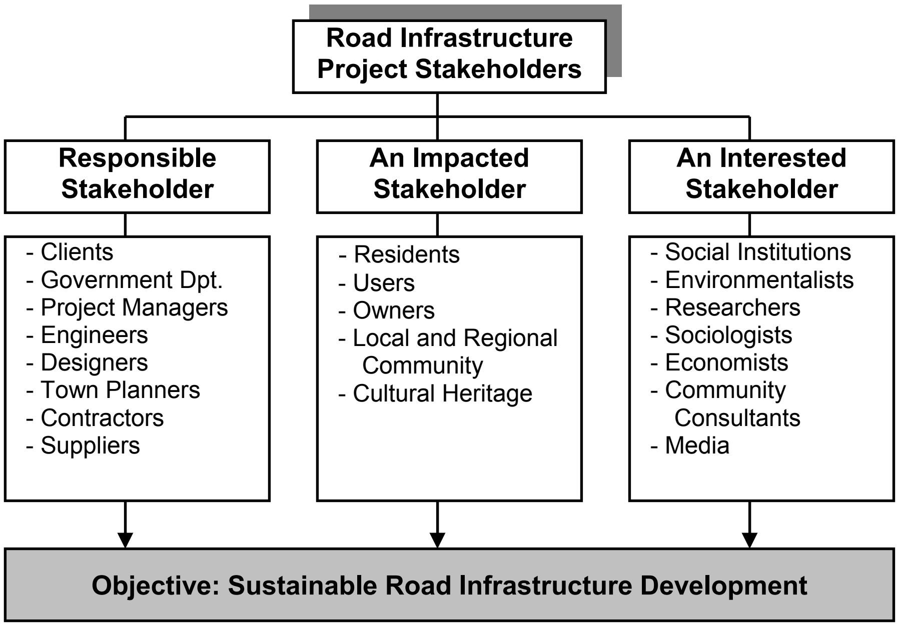

Figure 1: Road Infrastructure Project Stakeholders

Depending on their professional requirements and business nature, they enter the competitive infrastructure market with specific drive. Different stakeholders have different levels and types of investment and interest in construction project (Newcombe, 2003). It is important for the project's objectives to mesh with its stakeholders', and that they continue to fit with stakeholders' strategic interests as the project evolves, conditions vary and the interdependencies of key systems, stakeholders and their objectives change (Morris, 1994). Failing to realize this would potentially jeopardize the project objectives and its smooth implementation. Successful completion of construction projects is therefore dependent on meeting the expectation of stakeholders (Cleland, 1995).

Each stakeholder is motivated by their own interests. As a result, their perceptions on what constitutes sustainable road infrastructure development vary accordingly. Often, they perceive from their own point of benefits and priorities. Therefore to achieve infrastructure sustainability, understanding their varying perceptions and needs and integrating them into the design and delivery of road projects becomes crucial.

4. Defining Sustainable Road Infrastructure Projects

A research project is being done in Queensland to develop integrated decision-making guidelines for the improvement of sustainability outcomes in infrastructure projects. The on-going project employs a combination of face-to-face interviews with industry professionals, a Delphi study among experienced practitioners and academics, and case study techniques to collect expert opinions as well as real-life project information.

The project began by interviewing 20 targeted senior representatives within the collaborating infrastructure stakeholders in Queensland, Australia. Many have the experience of working with all professions represented in this group and even with each other (businesses) as partners of major consortiums for large projects in Queensland, interstate and in some cases, overseas. They comprise of government departments, financier/banks, environmentalists, community consultants, contractor/builders, designers, engineers, project managers, town planners and cultural heritage experts. Collectively, these high-ranking professionals possess a wealth of experience in a diverse range of infrastructure projects such as roads and highways, rails, seaports, airports and dams. However, the interview was specific on roads infrastructure development.

Literature studies have helped the compilation of over 16 categories and 300 sustainability sub-indicators overall. This long list reduced to 10 categories and around 200 sub-indicators through the interview as the most appropriate and applicable under local conditions. The triangulation of interview results provided an overall picture of sustainability in relation to roads infrastructure development in Australia. Table 2 summarizes the findings on sustainability priorities and indicators:

Table 2 Sustainable Roads Infrastructure Indicators

NO.	SUSTAINABILITY PRIORITIES	INDICATORS	SUB-INDICATORS
1.	INSTITUTIONAL	**Appropriate Development Control**	Guidelines control, National sustainable development strategies, Environmental Impact Assessment, Program of integrated environmental and economic accounting.
		Legislative Requirements	Policy/ strategy match, Match design standard with project function, Compliance with contract document & project specifications, Compliance with environmental legislation.
2.	ENVIRONMENT	**Land Use**	Extent of loss of habitat and feeding grounds, Extent of erosion and sediment, Maintain good agricultural land.
		Soils/Topography/Geology	Soil types and erosion risk, Reuse of topsoil, Minimize soil disturbance.
		Water Quality	Maintain water quality in water bodies, Polluted run-off control in construction site, (eg. spills, heavy metals, hydrocarbon etc.), Impact on downstream environments & groundwater resources, Sensitivity of surrounding water bodies and receiving environments, Water consumption.
		Hydrology/Hydraulics	Maintain catchment integrity, Preserve drainage pattern, Retain flood ameliorating areas (eg. wetlands).
		Air Quality	Reducing greenhouse emissions, Dust from construction site
		Noise and Vibration	Potential increase in noise in future, Acceptable level of noise on site.
		Ecology	Habitat protection, Reprovision of habitat, Maintain canopy connectivity, Minimize fragmentation of species populations (eg. habitat loss and isolation), Maintain under-storey habitat connectivity, Plant recovery, stored for later introduction to the site.
		Visual Impact	Visually prominent areas, Areas of natural and cultural significance, Contributing factors to scenic quality.

		Waste Management	Reducing and avoiding generation of wastes, Resource recovery (eg. reusing and recycling wastes), Conservation of highly valued resources, Site clean up, Waste disposal at approved disposal site.
		Vegetation Management	Vegetation protection and conservation, Preserve existing riparian vegetation at creek, Impact to significant flora species, Re-vegetation treatment and maintenance, Regeneration of native flora.
		Fauna Management	Impact to fauna populations & species, Impact on fish (eg. fish habitat, fish passage), Presence of forested habitat areas, wetlands and water bodies, Creation of fauna habitat, Fauna fencing and underpasses, Provide dispersal routes/wildlife corridors/crossing points, Provide compensatory habitat, Weed invasions, Connectivity of wildlife corridors, Connectivity of fauna corridors (eg. canopy bridge).
		Erosion Management and Sediment Control	Permanent control, Temporary control.
		Temporary Site Management	Site camps away from natural areas, Site camp hygiene and cleanliness, Energy consumption.
3.	**ECONOMIC**	**Direct Cost**	Life cycle cost (eg. Initial Cost, Capital cost, Operation cost, Maintenance cost)
		Indirect Cost	Resettling cost of people, Rehabilitating cost of ecosystem/ environmental cost, Adverse impact on tourism values.
		Revenues	User fees, Reserve funds, Private sector investment (eg. PPP).
4.	**SOCIAL & CULTURAL**	**Cultural Heritage**	Indigenous heritage, Shared and natural heritage, Artifacts/archaeological site, Documentary records and works of art.
		Public Access	Reduce commuter times, Distance from public access, Pedestrian/cycle/vehicle access, Suitability in ease of access, Provision of scenic routes, Provision of recreational facilities (eg. lookouts, picnic areas etc), Travel mode choice.
5.	**RESOURCE UTILIZATION & MANAGEMENT**	**Site Access**	Routes for construction traffic, Controlled site access to legitimated traffic, Vehicles wash down before & after leaving the site.
		Material Availability	Use of local materials, Availability of construction material.
		Type	Prefabricated material, Innovative material.
		Constructability	Early contractors' involvement
		Reusability	Re-cyclability of materials, Reusability of moulds and formworks etc.
		Quality Assurance	Ease of quality control
6.	**HEALTH & SAFETY**	**Occupational**	Short-term health (eg. spread of disease, cleanliness of site etc), Long-term health (eg. respiratory duct disease, permanent deafness etc), Accidents, injuries and fatalities etc., Management system (eg. policy, program etc), Construction working time.
		Public	Road safety, Hazardous goods.
7.	**PROJECT MANAGEMENT**	**Contract**	Type of contract, Inclusion of sustainability clauses, Project duration, Incentives for meeting sustainability performance, Penalties for non-compliant operations, Project Risk, Auditing.
		Procurement Method	Approach/criterion towards contractor, Choice of delivery system (eg. Alliance, design-build etc), Experience in environmentally sensitive works as prequalification requirement, Documented and implemented environmental due diligence system.
		Training and Education	Pre-start training courses as part of condition of contract,

			Training program for new, replacement and temporary staff.
8.	**RELATIONSHIP MANAGEMENT**	**Responsible Stakeholders**	Clients, Government Departments, Project Managers, Engineers, Designers, Town Planners, Contractors, Suppliers
		Impacted Stakeholders	Residents, Users, Owners, Local and Regional Community, Cultural Heritage.
		Interested Stakeholders	Social Institutions, Environmentalists, Researchers, Sociologists, Economists, Community Consultants, Media.
9.	**PUBLIC GOVERNANCE &COMMUNITY ENGAGEMENT**	**Public Governance**	Public viability & impact, Early community/public consultation, Social Impact Assessment, Open assessment, Appropriate links for communities, industry and other infrastructure amenities.
		Community Involvement	Local communities' involvement, Support existing social campaigns, Community awareness in environment, Community acceptance, Responsibility.
10.	**ENGINEERING**	**Performance**	Carrying capacity, Durability, Reliability, Resiliency, Robustness, Adaptability.

Ten sustainability priorities for roads infrastructure projects were identified. While four were the so-called traditional sustainability components (institutional, environment, economic, and social and cultural), six were road infrastructure project specific components (resource utilization and management, health and safety, project management, relationship management, public governance and community engagement, and engineering issues). To obtain measurable outcomes, each component was categorically broken into related indicators and sub-indicators. Each sub-indicator represents issue to be addressed in order to achieve sustainability deliverables in roads infrastructure projects.

The interviews have also yielded stakeholder responses towards the driving factors for them and their businesses to engage in sustainability issues in infrastructure (Table 3). It is interesting to note that contrary to previous belief that the construction sector are mainly 'forced' to accept responsibilities towards sustainability due to external pressure, there have been considerable elements of internal volition, which motivates the individuals and businesses to take on the challenge. How to use this improving self-esteem to uplift the general take-up rate on sustainability measures at all fronts will prove to be an interesting and important aspect of new research.

Table 3 Drivers and motivation of stakeholders towards infrastructure sustainability

SOURCE	CATEGORY	ELEMENTS
External Pressure	***Global pressure***	Concerns on climate change, global warming and other environment disasters; call by UN and world organizations
	Government requirements	Complying to government legislations, contract documents and project specifications
	Business survival	Sustainability is currently being seen as a new cutting-edge business commodity; Keeping up with latest market trends
Internal Volition	***Human survival***	Ensure long-term survival of human beings; Concepts of "the earth, our home" "our common humanity", and "our common future"
	Community expectation	Community as the major stakeholder; Used to high quality of infrastructure due to improved standard of living
	Individual volition	Proud be to good citizen; Education and training, and up-bringing has direct impact on individuals taking up sustainability initiatives voluntarily

Based on the initial list of sustainability indicators as presented above, a Delphi study is being conducted to further identify key sustainability indicators in terms of strengths, along with identifying the critical issues that impede on infrastructure sustainability initiatives and the possible relationships among them. The list of key sustainability indicators and critical issues identified through the Delphi study will reflect the consensual opinions of a group of highly experienced and regarded industry professionals and academic experts on both the theory and practice aspects of infrastructure sustainability in road projects. While not meant to be exhaustive, the list will serve as a basis for finding solutions for the critical issues identified in a defined context.

By integrating the different perceptions and priority needs of the stakeholders, identifying and applying key sustainability indicators and solutions for critical issues, a set of integrated decision-making guidelines for enhancing sustainable deliverables can be expected for the promotion and implementation of sustainability strategies in projects delivery processes.

5. Conclusion

Australia is currently experiencing unprecedented infrastructure demands especially on roads and highways construction to sustain its buoyant economy and general prosperity. The incorporation of sustainability principles in the infrastructure development is a crucial element to ensure economically feasible, socially viable and environmentally responsible project outcomes. Thorough understanding on different perceptions and priority needs of various stakeholders and ways of working with and integration these differences should be an imperative step leading to sustainability engagement for mutual benefits of stakeholders. It will also be vitally important, as proved in this research, to establish key sustainability indicators and identify critical issues that may guide sustainability initiatives through project delivery. The list of key sustainability indicators under ten sustainability priorities specific to roads infrastructure development will serve as a starting point for finding solutions of dealing with sustainability in this particular type of projects. A framework of integrated approaches to decision-making will be necessary for the practical implementation of sustainability strategies in road infrastructure projects.

AMOUNT OF BODY ENERGY VERSUS EXTERNAL ENERGY – A DECISIVE RATIO FOR SUSTAINABLE STRUCTURES

Thomas MACOUN Prof. Dr.

Institute for Transport Planning and Traffic Engineering,
University of Technology, Vienna, Austria,
thomas.macoun@tuwien.ac.at

Keywords: mobility, settlement structures, human behavior, energy amount, body energy, attractiveness

Summary

Sustainable development may only be reached by taking into account the characteristics of human beings. In particular this implies to include - beside of the needs of humans - the abilities of perception and assessment by the human species.

One of the main problems lies in the human's self circumvention by orientation on current aspects of quality of life. Problems likely will return in the course of feedback loops.

A great part of the steering forces of humans are unconscious. We have to realize that we are genetically intended to measure e.g. distances (and time) by the use of our own body-energy. Humans spend a certain percentage of the average daily available body energy for mobility. Therefore time (stability of travel time budgets) is only an indicator for a cause lying behind this, namely the constancy of the expended body energy.

Both the perception of time and body energy as well as of causalities is subject of the sensory perception. According to Weber- Fechners law the resulted feeling goes down with every additional (stimulus) unit. In the traffic sphere the named law occurs in a negative overvaluation of longer activities using body energy eg. by exponential negative acceptance of long way distances or excessively increasing negative assessment of waiting times.

Since, we have no sensorium and experience for using external energy we loose any control if we try to substitute in most cases small reductions of body energy by use of non renewable energy. In principle, the diminution from body energy expenditure (as is striven for in car oriented structures with car parks in a short distance) is an immanent from the entropy´s derivable target in all living beings. The indicator "body energy" therefore is an essential indicator of the control of the settlement structure used as an indicator describing body energy amount assessing accessibility of means of transport in a comprehensive way.

1. Current state of discussion, introduction

The connections represented by Newman, Kenworthy 1989 between energy consumptions of different towns in proportion to the (settlement) densities in the continental comparison are essential to create a fundamental sensibility for the problems. However, the use of average densities is already problematic due to the different town structures. By the way span widths of about 1000 inhabitants per km^2 (e.g. Houston) and more than 9000 inhabitants per km^2 (e.g. New York) in American towns are given too.

In principle, such an intercontinental comparison in the current situation always leads to high correlation qualities (see Figure 1). The density parameters disguise however planningly essential influence factors of the various aspects of the accessibility. However accessibilities like access distances and with that transgressions of boundaries of means of transportation like riding a bike or mobility forms like to go afoot to count physical aspects, as well as also financial aspects of the accessibility like prices of petrol (in proportion to the spending power) or also accessibilities and acceptance of public transport (modal-split) or the fall apart of functions have to be considered.

It is largely undisputed that the „driving forces" of the increasing extension of spatial settlement structures development come from increasing speeds in the transport system. The use of external energy sources allows to overcome borders of specific means of transport using only body energy.

The bases of the constancy of travel time budgets (about 60-70 minutes of mobility time per day) are to be found in evolutionary mechanisms (ratio of the effort to obtain food in comparison to the benefit of body energy). Life time needs life energy. The human being must expend body energy constantly to get his existence and to keep the proportion of food supply and food consumption. By that humans spend a certain percentage of the average available body energy per day for the mobility. Therefore time (time constancy) is only an indicator for a cause lying behind this, namely the constant budget of expendable body energy.

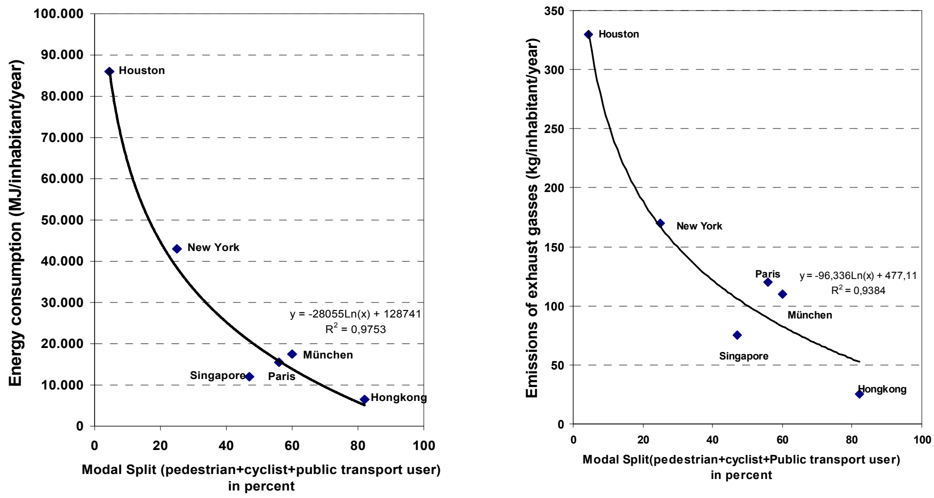

Figure 1: Comparison between parts of mobility based on body energy (pedestrian, cyclist, public transport user) and energy consumption respectively emission of exhaust gasses, source: World Statistic Yearbook

The figures show that a number of different essential traffic-orientated parameters actually show significant connections in the intercontinental comparison. These connections, however, can if needed be for example set the direction in the continental context or also in the municipal area.

There are considerable effects of settlement densities on access distances as well as on application boundaries however they do not offer feedback possibilities to the bases of the mobility.

2. Speed, travel time and structures

2.1 Correlations between speed and settlement structures

Settlement structures orientate themselves towards the dominating traffic system of the respective epoch. Older settlement structures (up to the 19th century) had to orientate themselves at biological borders (man, horse). Outer limits like town embankments arrived.

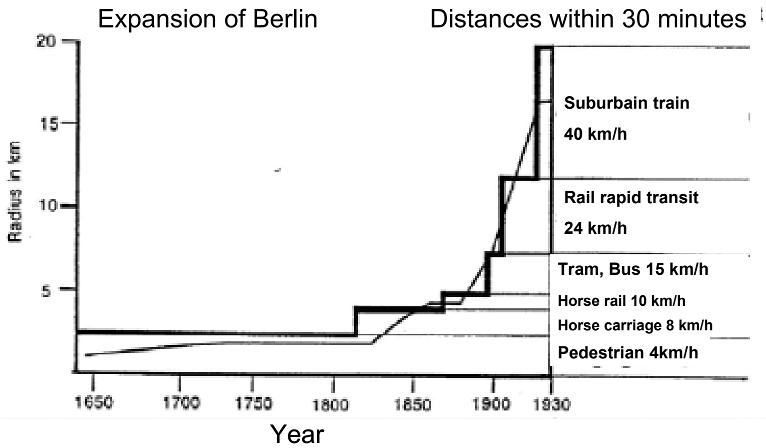

Figure 2: Settlement extension as a result of the dominating means of transportation of the respective epoch

The biological boundaries of human beings lie in average at about 60 to 70 minutes per day (mobility time budget as a constant). The limitation of the extension of the settlement structures known in the Anglo-American sphere under "Marchetti´s constant" can be derived directly from biological constants. Every rise of the speeds therefore runs by the supply of external energy (in comparison with the internal body energy) for an extension of the settlement structures automatically.

The connections between speed of transportation means and the extension of the settlement structure are already known and named in numerous works (see Knoflacher 1996, Macoun 2005 and others).

2.2 Times and distances

The cumulative frequencies (see Figure 3) show that way distances put back with body energy lie to about 80% within 2 kilometres. These mobility forms hold the settlement structures together. On the other hand, there are about 80% of the ways by means of car or public transport over 2 kilometres, about 20% even over about 20 kilometres.

While more than 70% of the ways covered by individual modes of mobility amount to less than 30 minutes, the users of public transport lose this opposite increasingly time, caused by considerable access distances to the stops of the public traffic partly.

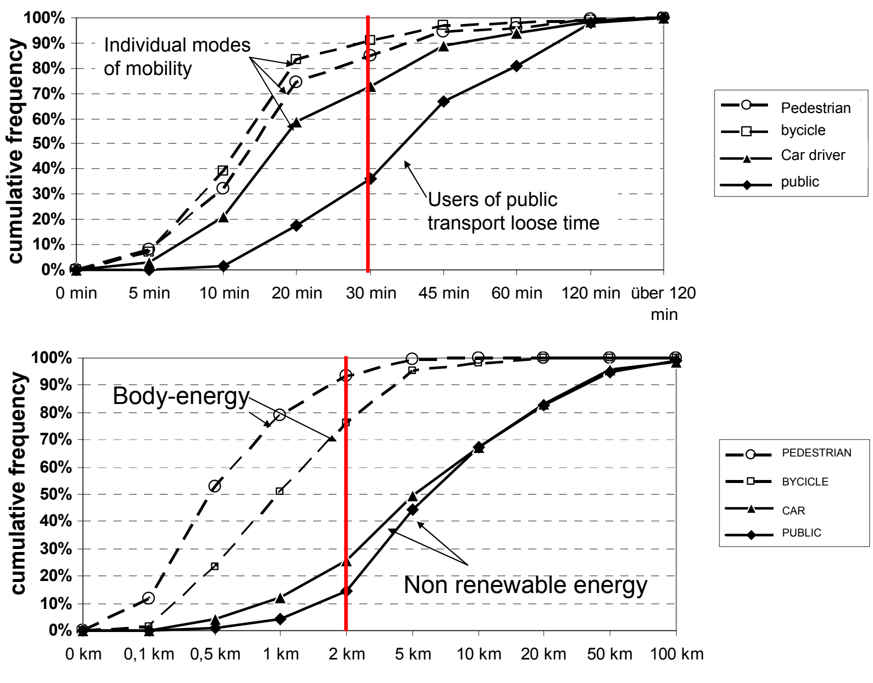

Figure 3: Cumulative frequencies of trips with different modes of transport in Austria, depending on trip length respectively travel time, source: Herry, Sammer 1996

3 System point of view versus individual perception

3.1 Body energy constancy and mobility time constancy

Based on the evaluation of empirical data on driving times provided by the UK´s National Travel Surveys Kölbl R., Helbing D., 2003 concluded in their study that the empirical data as given statistically rather assure a concept of constant daily journey energy (with energy in the mobility phase the body energy is meant here) than a concept of constant mobility time.

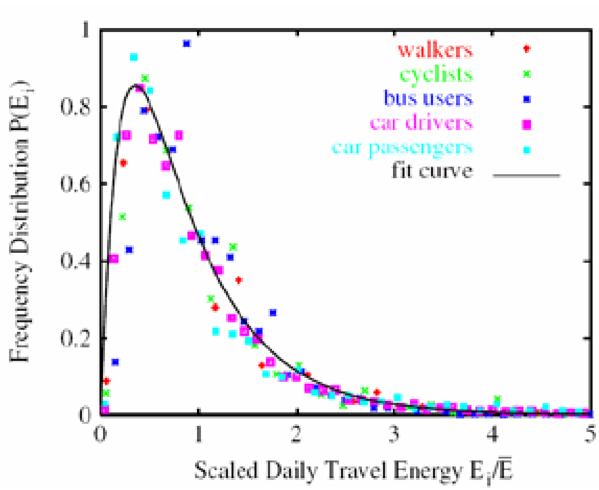

Figure 4: Scaled, time-averaged travel-time distributions for different modes of transport in linear representation, source: Kölbl R., Helbing D., 2003

Within the statistical variation (and rounding errors for small frequencies, which were magnified in a semilogarithmic plot) the mode-specific data could all be fitted by a universal curve, the travel-energy distribution. In contrast to utility functions of classical decision models which were typically based on preferences, this approach contains only physical variables such as journey times and energies, which are better measurable.

The far-reaching constancy of the body energy consumption in the daily mobility time budget is the result of an assessment mechanism of benefits for the energy to be expended in proportion to the effort.

3.2 Perception problem

The acceptance of the effort of body energy in the daily mobility phase is subject to a permanent assessment according to costs and benefits. The acceptance of footpath distances (and with that the effort of body energy) follows a negative exponential function which can be referred to laws of nature (entropy - main clause of the thermodynamics). Derived connections are known in biology as the “Weber-Fechner law”, in the economy as the “law of the diminishing marginal utility”.

The charging mechanisms of the assessment of the body energy consumptions are carried out on an unconscious cellular one to instincts level (Riedl 1981). It is fundamental to acknowledge that human beings are subject to difficulties at the perception of our environment. The individual intuitions are therefore different from the system view particularly (with respect to time, space and causalities)

Table 1: Comparison of system point of view with (objective und subjective) point of view of the individual represented for the problems of knowledge time, space and energy/causality (following Kantsche Apriori); source: Riedl 1981, Macoun 2000

	System point of view	Individual point of view	
		objective	**subjective**
Time	Constancy of time	(physical) Time	Assessment of time
Space	Depends on speed	Habitat	Space of experience
Energy (Causality)	Total energy amount (non renewable)	Body energy	Weighted body energy (e.g. Pulse, Stress)

Obviously the subjective individual perception of time advantages in the traffic and settlement system is compensated for by system effects. Streets for example built for the improvement in accessibilities and higher speeds are used for the attainment of remote (and cheaper) locations. Therefore putative time advantages are converted due to the mobility time constancy to larger distances. Obviously time advantages are weighted less compared with other influence factors and advantages (for example cost advantages).

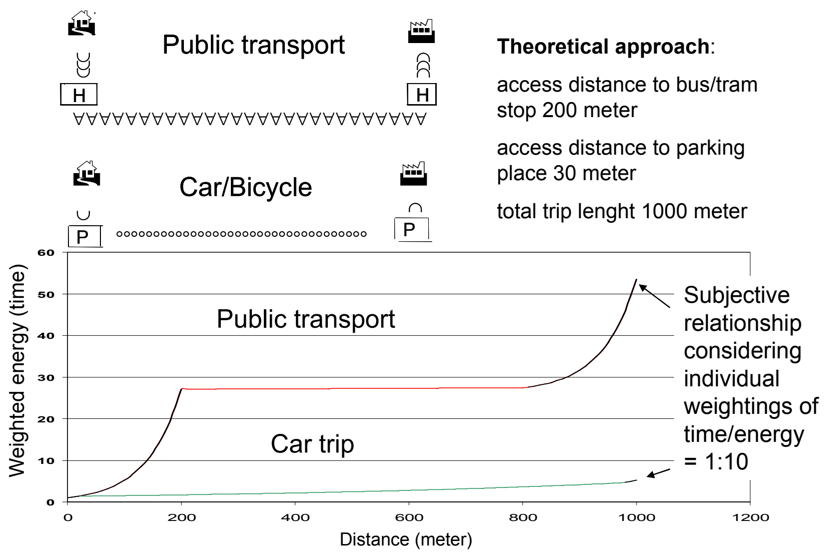

Figure 5: Schematic representation of the weighted (individual assessed) body energy consumption in case of journeys with public transport or with the passenger car. (door-to-door trip length of 1 kilometer, resistance function after Walther, 1997).

Time, body energy but also causalities as basically all sensory perceptions will be (Knoflacher 1996, Walter 1997) assessed in the transport sphere in accordance with Weber-Fechner´s law, this means that e.g. longer waiting times or footpath distances are judged excessively negative and show an acceptance falling exponentially in the consequence.

However, just like with every sensory perception, the Weber-Fechner law must be applied. The Weber-Fechner law attempts to describe the relationship between the physical magnitudes of stimuli and the perceived intensity of stimuli. Fundamentally the Weber-Fechner law as well as the acceptance of footpath distances or the acceptance of waiting times is finally based on the first main clause of the thermodynamic (entropy, Boltzmann equation)

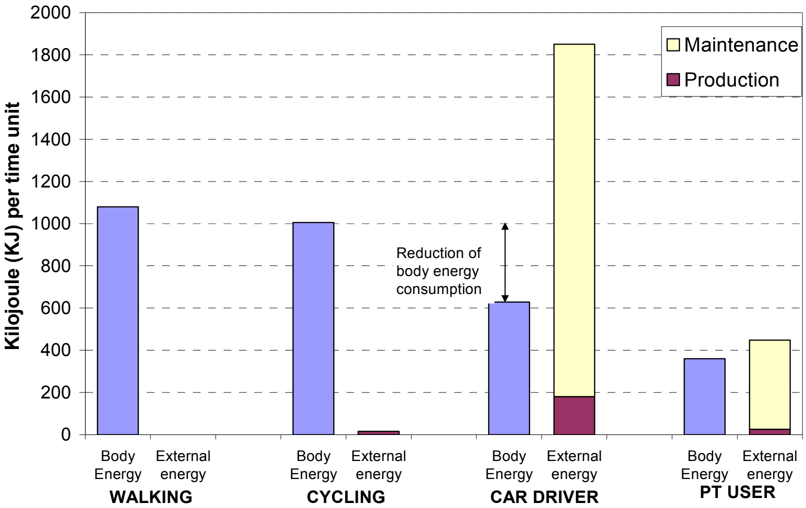
The assessment substantial of the time (advantages) and body energy consumption for the behaviour therefore show weightings (see a schematic representation Figure 5).

To this one the excessive weighting of the foot way distances shows the problems of differently access distances to means of transportation (e.g. bus stop 200 m, parking place 30 meters). The body expenditure of energy to reach the systems is therefore an essential term of the control of the traffic behavior. It is here major in the general comparison to achieve equal opportunities. We have to bear in mind that additional amounts of body energy also will be caused by bad weather conditions (cold, heat), information procurement necessities, waiting times and so on. All of these are calculable.

4. Body energy versus external energy

This obviously given assessment mechanism of the diminution and minimization of the body energy consumption immanent in human beings (something what is sensed as something to strive for and logically) led for the time being to a preferential treatment of private motorized transport means (with short distances to the vehicle) due to the charging mechanism to the saving of body energy and in the consequence to the road construction and due to the mobility time constancy for the extension of the settlement structures.

The minimization of the body energy by the use of external energy (over centuries by the use of the horse) at present is particularly reached by exceeding use of not lasting energy sources.



Walking (4 km/h), Cycling (10 km/h), Car (mean town/rural trip), Public transport (Sitting in means of transport, without Access)

Figure 6: Confrontation of energy charges for body energy and external energy in kJ at different mobility forms; Body stocking Energy: KJ/hour, External Energy: KJ/minute.

Body energy expenditures are highly dependent on the situation however they represent a function of the speed primarily. The usage of external energy overcomes natural biological (application-) limits and makes higher speeds possible. Figure 6 shows that rather small body energy savings (about 200 kJ/h) are substituted by consumptions of external energy of more than 100.000 kJ/h. (please note that Figure 6 displays external energy for production and maintenance in KJ/ minute).

A consistent putting into action of body energy saving approaches like in car oriented settlement parts or in an extreme form in some American and Australian towns leads apparently and inevitably to the preferential treatment of the car and by this to a car oriented settlement structure. As a consequence application boundaries of body energy oriented mobility forms are exceeded.

In the consequence due to larger access distances in disperse settlement structures public transport is not a traffic type identical in chance due to the body energy assessment at the access to the stop either.

5. Conclusion

In principle, the representation of the positive effects of higher densities makes sense for several reasons of e.g. needs to reduce the waste of space, ecological footprint and so on. Settlement structure planning however needs basic indicators to get orientation. Settlement density as an indicator conceals indicators like accessibilities, acceptance of public traffic, function mixture, inhabitant/ workplace conditions, falling apart of functions like shopping centres and localisation in the area. Older towns this one show also clear differences between settlement parts (see Macoun 2005).

However higher densities strengthen energy saving transport modes.

Future city and regional planning has to bear in mind that human beings are planning out of their specific demands, which seem to change with the dominating system of the respective epoch. Nevertheless there are constants which are lying in nature of human beings.

Indicators shall provide guidelines and make control options possible. Indicators of sustainability have to be system spanning and/or distance-to-target indicators (if target definition is possible) as an essential prerequisite. A reliable indicator of sustainability describing settlement structures also has to take into account the necessities of minimising energy (body energy and external energy).

The body energy of the transport system users is an essential indicator for the city and regional planning. Since body energy minimization is a target of all living beings (in comparison with the benefit) a minimization only then can be target of the settlement structure planning if the indicator is used system spanning for instance as a comparison of body energy consumption at the attainment of the different motorized transport means or in the complete way chain. The control will be carried out via the body energy requirement at the accesses to the transport systems (Car, PT).

The reaction of the settlement structures to the new mobility forms therefore follows the laws of nature, it seems therefore possible to carry out a future sustainable planning on a high extent based on physical (and biological) indicators claiming that the settlement structure planning takes into account these laws and principles.

Summary

Assessment methods, management guidelines or environmental charters for Industrial and Business Parks (IBP) have grown since the end of 1990's in response to their increasing development, including in a variable extent environment and sustainable development related concerns. Creation of IBP can bring several benefits to local authorities, notably with regard to economical and social issues. Existing tools have mainly contributed to design and running phases. Nevertheless, upstream phases concerning, for example, the adequate choice of the localization of IBP and the definition of project features, constitute key moments to achieve sustainability.

The OASIS method, (Outil d'Analyse et Système d'Indicateurs pour les Sites d'accueil) Analysis Tool and Indicators System for the hosting Sites of Industrial and Business Parks, presented in this paper, aims at facilitating integration of sustainable development principles from the earliest studies of an IBP project. By taking into account multiple themes, scales and actors, OASIS fosters the development of dialogue between project stakeholders. OASIS is a decision making tool intended for contracting authorities and park manager teams.

After explaining the national and international context of the OASIS development and the approach used, the sustainability criteria on which the method is based are presented. The paper focuses on the upstream phase of an IBP project by presenting the unit processes at the diagnosis phase, the rating system of the sustainability criteria and the form, content and benefits of OASIS outputs. Finally, first results of test of the method and prospects for evolution are discussed.

1. Stakes for Industrial Business Parks

The economic observatories noticed the multiplication of IBP development projects. Local authorities are interested into theses projects because of their:

- Economical impact through companies' settlements, and the economic dynamics which result.
- Social impact through jobs creation. These jobs rise living standards and promote the development of population,
- Financial impact through various tax incomes,
- Political impact by enhancing the status of the community on a regional or on a national scene.

Given these significant impacts, an IBP project must be a worthwhile investment, considered on the long term. It must be attractive to encourage settlements and provide a sustainable management system. It must be also healthy and respectful of its urban and natural environment.

To achieve this goal, our research group set up a decision making tool for working out project specification brief, design and monitoring of IBP project. At this stage of the research, the tool is meant to be used particularly in the French context and is operational at the diagnosis phase.

By 'project specification brief' we refer in this paper to a structured document which records contracting authority's objectives, needs and requirements about the features of the project in terms of functional, architectural, technical and notably of sustainability aspects, taking into account the specific urban, environmental, economical…context. The project specification brief represents the starting point of the design team work.

2. Context of the Work and Chosen Approach

2.1 French Context: Methods and Tools

Several methods and tools have been developed and tested today in France. We have particularly analysed and taken into account these methods because they deal with main relevant issues for the French context.

Different kinds of methods and tools are available for IBP contracting authorities with different objectives:

- Methods to set up environmental charters. These charters should be the result of debates and consensus. In the framework of our study we analyse the charter's models supplied by ARENE Ile-de-France1 and by PALME2 association.
- Methods to set up and implement management systems and to follow up sustainable development issues. They are often based on a framework (tables, indicators). They can provide situational awareness of the site. They help to define the project and its priorities. These include methods of Orée[3] and of APDD[4] associations.

These methods and tools aim at involving different stakeholders by consulting or inviting them to take part in various debates. Thus, charters in particular represent a consensus and a common commitment tool. The use of this tool is widespread in French IBP projects claiming environmental approach. Mobility, water, energy and waste management, as well as environmental quality of building, are the main issues of the charters.

The analysis of existing methods and tools has highlighted relevant and most common sustainable development issues. These issues are closer to the environmental concerns than sustainable ones. For example, environmental topics such as waste management are well taken into account. The IBP integration in the territory is a key element as well but relatively less common in methods and approaches.

Existing tools and methods seem not to take into account all the necessary issues to make decision, i.e. the choice of IBP site.

2.2 European and International Context: Experimentations and Approaches

Environmental quality and sustainability of Industrial and Business Parks is a relatively new concept at the international scale. Voluntary experimentations, initiatives and approaches aiming at minimising environmental impacts have been set up since the 90s in the United States, Asia and Europe. The United Nations Environment Programme (UNEP), Division of Technology, Industry, and Economics worked out and published at the end of the 90s guidelines[5] for environmental management focused on providing environmental services for companies, on encouraging companies' environmental initiatives, on monitoring environmental quality, on developing and implementing environmental action plans, etc. UNEP also carried out a survey on IBP projects in Canada, China, Thailand, Indonesia, India, UK and Denmark[6]. As far as Europe is concerned, a French consultant, e-parc, has benchmarked European environmental IBP located notably in North of Europe. Some European countries, such as Italy, have introduced environmental requirements for IBP in a national law entrusting to each Region the working out of detailed list and methods. Thus, many ecological IBP have risen putting into practice principles on mobility, water, waste, landscape, energy, noise, equipments and services. Environment Park in Torino is one of the most famous and broke the new ground. Despite of all of these interesting dynamics, there is no consensus at the international or European level how best to tackle IBP sustainability issues.

The analysis of these different surveys and initiatives shows that the concept of IBP's sustainability is tackled firstly from an environmental and from a management point of view. Social and economic issues are considered as goals or results of the environmental quality (i.e. providing an attractive field for companies, opening the way to specific funding) and are not directly involved in assessment or actions' implementation. Industrial ecology and environmental management such as ISO14001 or EMAS represent the most common ways to introduce environmental principles in IBP. The choice of activities to be hosted, the setting up of common services and of an authority to manage them seem to have priority over location choice, upstream environmental performances identification, and sustainable design. Nevertheless many environmental and socio economic (i.e. mobility, noise, landscape, energy supply…) impacts are influenced by location choice and can be minimized by a sustainable design of buildings and outdoor spaces.

Thus, we have decided to focus our method on upstream phase and on all sustainable issues and to support decision making on location and activities. In this sense, our method can supply a complementary approach to management during the running phase and to industrial ecology.

3. Description of the OASIS Features, Analysis Framework and Method

3.1 Presentation of OASIS main features

OASIS (*Outil d'Analyse et Système d'Indicateurs pour les Sites d'accueil*), Analysis Tool and Indicators System for the hosting Sites of Industrial and Business Parks, is a decision making tool targeted at the contracting authority team (at the upstream and design phases), carrying out a diagnosis of the IBP project regarding the constraints and opportunities of the site, and making recommendations in order to elaborate the project specification brief. OASIS integrates the three dimensions of sustainability – environmental, social and economic – in a transversal and operative way from the earliest feasibility studies. It is based on an analysis framework, structuring and detailing sustainability issues adapted to IBP.

Nowadays it supplies:

- The setting up of project first requirements
- A diagnosis for the creation of an IBP
- Recommendations for the project specification brief
- A management assistance

From the earliest stages OASIS allows to draw up a first general survey of the site and its exchange basin[7] characteristics regarding sustainable development. The OASIS method is implemented by an operator who can be a consultant, a member of the contracting authority team, etc. OASIS permits to establish a sustainability diagnosis specific to the considered project. Thus it reinforces or introduces questions about choices concerning location of the IBP or activities to be hosted.

OASIS provides clarity on the sustainable objectives to be integrated in the project and notably in the project specification brief. This method identifies sustainability potential (strengths and weaknesses) related to the considered site and/or to the considered project. Some themes are identified by the contracting authority team to take priority for the considered project. They are called "Priority Themes".

Once diagnosis is performed and expectations, stakes and performances are identified with regard to the sustainability themes (list of themes supplied by the method), the OASIS tool can be used to follow-up the integration of sustainability during the design phase (ex-ante assessment of the project).

OASIS is designed to foster dialogue between the different stakeholders regarding the choices for the location of the IBP, the contents and the sustainable requirements of the project.

3.2 A Criteria Tree Structure for the Analysis Framework

The OASIS analysis framework is made of a criteria tree structure containing the relevant sustainability items, in order to give a synthetic view of the hosting site and territory features. The tree structure includes Objectives, Themes, Analysis Elements, Basic Questions and Indicators.

The main issues to be studied when dealing with a sustainable project of Industrial and Business Park are represented by six Objectives, linked to one or more of the three dimensions of sustainability, as shown in table 1.

Table 1 The six Objectives of the framework

Objective	Sustainability dimension		
	Environment	Economy	Society
Quality of the local environment	✓		✓
Natural resources and heritage preservation	✓	✓	
Planet preservation	✓		
Integration of the park into the territory		✓	✓
Internal cohesion of the park		✓	✓
Actors' commitment for sustainability	✓	✓	✓

At the second level, the Themes specify the issues of concern included in each Objective. Then the Analysis Elements detail in a concrete way the different facets of each Theme.

The following table shows, under the six Objectives, all the Themes and Analysis Elements of the OASIS tree structure.

[7] The exchange basin describes all the territories which have a relationship with IBP (relation with the surroundings in terms of ecological or economical impacts, but also relation with further territories which have economical relationship such as other cities of the region).

Table 2 OASIS tree structure

Quality of the local environment	
Landscape and visual aspects	Natural and rural landscapes
	Urban landscapes
Acoustic comfort	Site sensitivity
	Activities - Traffic
Outdoor air quality and olfactory comfort	Local air quality
	Activities
	Traffic
Sewerage	Water collection network - Sewerage
	Pollution and rejected water quality
Waste	Collection
	Management and treatment
Electromagnetic fields	Fittings
	Electromagnetic field levels
Risks	Natural risks
	Rainwater infiltration – Permeability
	Technological risks
Hygiene and repair	Cleaning
	Citizenship
Security and safety	Thefts and offences
	Accidents on public road

Natural resources and heritage preservation	
Energy	Local resources
	Consumption (operation phase)
Water	Source – Feeding network
	Consumption and management
Land	Pollution
	Management
	Land value
Materials	Construction materials
	Recycling and valorisation
Natural and built heritage	Natural heritage
	Built heritage

Planet preservation	
Climate change	Greenhouse gases
Ozone layer	Ozone-depleting substances

Integration of the park into the territory	
Close equipment and services	Services to enterprises
	Services to users
Mobility, transport and telecom networks	Major transport axis
	Access to the zone
	Vehicle parking
	Telecom networks
Employment and territory economy	Employing territory
	Skill poles and major economy poles
Training, influence and dynamism	Training
	Influence and dynamism
Urban diversity	Usage distribution
	Urban sectors in recession
Population	Social features
	Project acceptability by population
Social integration through employment	Unemployment
	Social insertion through employment
Functional changes	(to be used at running phase)

Internal cohesion of the park	
Welcome and accompanying	(To be used at running phase)
Management and follow-up of the park	
Synergy inter-enterprises	

Actors' commitment for sustainability
Citizenship
Local authority's commitment
Developer's commitment
Enterprises' commitment

Basic Questions correspond to detailed questions enabling to go more deeply in the Analysis Elements. Two types of Basic Questions have been defined: "state" and "response" oriented ones. "State" questions relate to an existing situation, most of time local, whereas "response" ones deal with actions implemented by local public or private actors in order to improve a situation or reduce an impact. Example of a "response" question linked to "local energy resources" element: "Is the local authority leading a political strategy in order to diversify the energy sources by promoting local ones?"

Indicators are diversified. They may be quantitative (where possible) or qualitative. OASIS indicators system is composed by a mix of indicators found in scientific or technical literature and of other ones specifically developed for OASIS. They focus on the most important points of each Analysis Element. They form the concrete information on which the rating system will be based.

As OASIS wants to be flexible and adaptable, Basic Questions and Indicators, or possibly Analysis Elements can be added to reflect the specificities of the project and improve the relevance of the diagnosis.

3.3 OASIS Unit Processes for the Diagnosis Phase

Concerning the carrying out of the diagnosis, four unit processes can be distinguished. These processes are not steps which are clearly separated with a start and an end, but they are following each other and they are often overlapping each other.

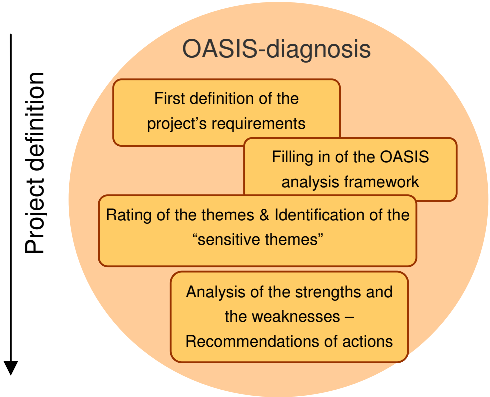

Figure 1 OASIS unit processes for diagnosis

The first unit process is the starting point of all the OASIS procedure. At this point the dialogue process with the contracting authority team starts. This process allows a strong involvement of the contracting authority team in the diagnosis. The first project's requirements and priority themes are identified here. The "Priority themes" require a special attention. Thus special warning thresholds are pointed out for the measure of the associated indicators (see below the OASIS rating system paragraph). The success of this unit process represents a key point and influences the following of the OASIS diagnosis.

The second unit process corresponds to the filling in of the OASIS analysis framework. In order to fill in the diagnosis, the OASIS operator answers to a string of questions and fill in indicators linked with each analysis element of each theme. This phase enables the operator to gather all the information connected with the hosting site and its exchange basin necessary for the diagnosis.

The third unit process consists in rating the themes which have been completed. In order to rate a theme each indicator is marked out by the OASIS operator. One interesting output of this unit process is the identification of the "sensitive themes" on which a particular attention must be paid.

The fourth and last unit process permits to analyse the gathered data in terms of strengths and weaknesses, and to make recommendations on the basis of the diagnosis. These recommendations will be integrated into the project specification brief.

3.4 OASIS Rating System

The OASIS rating system enables to rate indicators supplied by the analysis framework. As indicators express issues belonging to themes, rating indicators and gathering the results enable to assess the sustainable themes. The rating is made by the OASIS operator. The rating is given from the point of view lead by the trinomial: site (or exchange basin) / sustainability issues / project's requirements.

The assessment of themes highlights the strengths and the weaknesses of the site and of its exchange basin beside sustainability issues and project's requirements. Those rates serve as starting points for the identification of the sustainability potential, for the analysis and thus for the working out of recommendations for the project specification brief.

Indicators are rated by values included in the interval [-1; +1]. The negative limit (-1) corresponds to the maximum of weaknesses. Reciprocally the positive limit (+1) corresponds to the maximum of strengths.

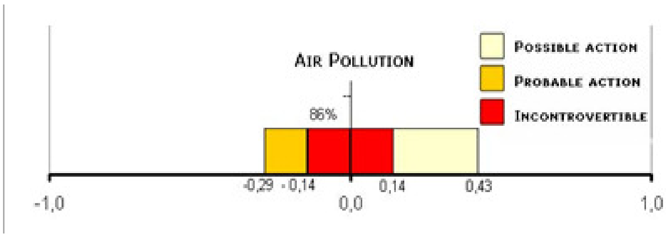
OASIS rating system enables the contracting authority team to point out the sensitive themes regarding sustainability and project's requirements. In order to point out the sensitive themes, two warning thresholds are defined for each theme: one high threshold for the strengths and one low threshold for the weaknesses. The exceeding of these warning thresholds should draw the attention and require a specific treatment. Thus these warning thresholds represent some interest filters. The exceeding of these thresholds for a theme makes declare it as sensitive beside sustainability (it can be a positive sensitivity or an unfavourable sensitivity). It is important to note that the warning thresholds are chosen and validated by the contracting authority team.

The values located between the low and the high warning thresholds describe a situation that doesn't have priority for the project.

OASIS rating system is based on the following principles:

- Total traceability of the data and the rates. It is possible for each theme to visualise all the rates of the indicators linked to the theme and to visualise the warning thresholds.
- No compensation of the weaknesses (negative note) by the strengths (positive note). The rates given for the weaknesses and the rates given for the strengths are counted separately in order that a weakness cannot be balanced by one or several strengths. Graphically, the right side of the rating segment shows the strengths while the left side shows the weaknesses (see figure 2 below).

- Differentiated visualisation of the common data (ordinary data which correspond neither to strength nor to a weakness) and of the remarkable data. Graphically a common data corresponds to a value located in the central interval.
- Visualisation of the non available data. The lack of data is a useful piece of information in order to assess the relevance of the results (relative uncertainty). The diagnosis is not frozen because of this lack of data but the reliability of the result is incomplete and needs to be pointed out. Graphically an indicator which is totally filled in will be represented by a segment with a thickness of 1. On the contrary an indicator which is only filled in at a rate of 70% will be represented by a segment with a thickness of 0.7.
- Opportunity to design and to visualize some useful families of data for the project (e.g.: scale at which actions should be performed, priority of action, reliability of the data)
- Opportunity to modify the warning thresholds of the themes (it corresponds to a change of the frame of reference so as to match to more demanding requests notably in order to take into account themes having priority for the project).



Visualisation of the available data: thickness: 0.86 (86%)

No compensation: a rating for the strengths and a rating for the weaknesses: 43% of strength and 29% of weaknesses

- **Visualization of the common data:** warning thresholds that define a limit between common values and the need of a specific action. The 2 sticks (negative and positive) are less than 0.5 (default value) and do not need special actions
- **Design of useful families:** In this example the family concerns priority of action (translated into colour categories)

Figure 2 Example of the rating system concerning the « Air Pollution » theme

3.5 OASIS Outputs

Once the indicators and the sustainability themes are assessed, these results are organised into summarized and operative forms in order to enable further use and to be communicated to the different project stakeholders, these requiring different levels of information. Thus, OASIS outputs are presented through Analysis Sheets (detailed information) and/or Profiles (synthetic information).

3.5.1. Analysis Sheets

As far as the Analysis Sheets are concerned, a template is provided to the user. They are organised according to the sustainability themes and contain three parts that sum up:

- The main results of the inventory (answers to the Basic Questions see § 3.1) and of the rating of indicators. This information is given for each analysis element belonging to the theme;
- The main results of the analysis with focus on strengths and weaknesses regarding to IBP location, choice of activities to be hosted, sustainability issues and project requirements;
- The recommendations for the project specification brief. This part, based on the analysis results, highlights the strengths to be enhanced and the weaknesses to be reduced. The need to carry out complementary and detailed surveys may be pointed out at this step. In this part, the OASIS operator may also warn the contracting authority on the appropriateness (possibly bad) of the chosen IBP location to implement the project (in terms of activities and of sustainability objectives). In order to address recommendations in an operative way and to make easier the link between the project specification brief and later the design phase, they are formulated according to physical objects (like roads, green spaces, building…) or organizational elements of the future IBP. A matrix connecting sustainability themes to a list of operational elements is supplied to the OASIS operator.

3.5.2. Sustainability Profiles

In order to give visual and synthetic view of the diagnosis results according to the work scale of each stakeholder, OASIS generates three profiles according to the three main scales of an IBP project, more explicitly:

1- Building and building surroundings – reflecting companies' concerns and duties,

2- IBP site – reflecting IBP developer's or manager's ones,

3- Territory – reflecting local government's ones.

The profiles are represented by diagrams showing the assessment of sustainability themes (according to the rating system). In order to be relevant for the setting of the project goals, each profile takes into account only indicators the actors of the project can influence. In this sense this kind of outputs represents effective means to point out responsibilities, to raise awareness and to organize actions improving project sustainability at different scales.

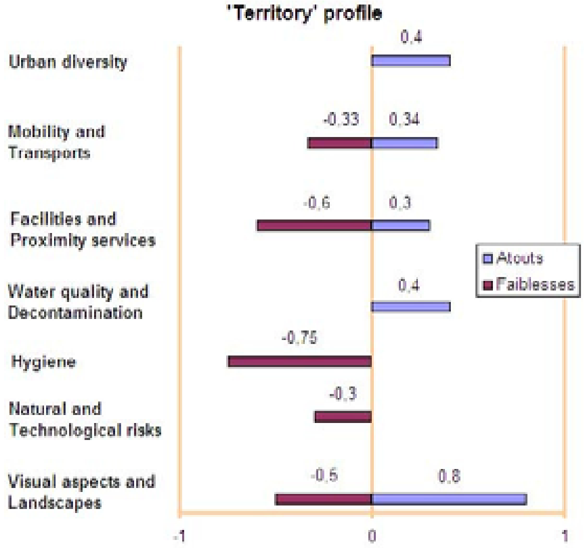


Figure 3 Example of "territory" profile showing strengths and weaknesses of each theme

A fourth profile focused on chosen activities may be useful for IBP development. This profile shows the assessment of sustainability themes according to a specific filter: the chosen (or to be chosen) activities to be hosted by the IBP. As the other three profiles described above, this profile does not visualize assessment of the whole indicators. Those taken into account here are the indicators that can be negatively or positively affected by chosen activities. Thus, this 'activities profile' allows validating choices and highlighting, from a sustainability point of view, need to change activities. In case of this change cannot be done, this profile helps pointing out specific requirements to be introduced in the project specification brief.

All these profiles represent a good communication tool on the basis of which dialogue among stakeholders can be set up.

4. First Results of the Grenoble Experimentation

A test of the method has been carried out on the site of a new IBP in Grenoble (France). The contracting authority has just started the project process and clearly announces the willing to build an exemplary IBP in terms of sustainability focusing notably on the Factor 4 concept.

This test perfectly showed the need of a tool allowing the starting and the first definition of clear project requirements. Used from the earliest stage of the project, OASIS has helped contracting authority specifying expected project features regarding sustainability and to better address his communication actions towards stakeholders. Compared to a standard environmental analysis, OASIS has taken into account a large panel of issues also related to economy and social aspects that made the contracting authority team think about "unusual" topics such as social insertion through employment. The sustainability profiles have been particularly appreciated by the contracting authority for their overall and comprehensive view on the site features.

Table 3 Strengths and weaknesses of the Grenoble site

Sustainability Objectives	*Strengths*	*Weaknesses*
Quality of the local environment	Landscape	Hygiene and repair
Natural resources and heritage preservation	Energy	
	Land	
	Natural heritage	
Integration of the park into the territory	Employment and territory economy	Close equipment and services
	Training, influence and dynamism	Access to the site
Actors' commitment for sustainability	Local authority's commitment	
	Enterprises' commitment	

5. Discussion

5.1 OASIS Benefits

Today OASIS is an operational method and gives an undoubtedly support to the contracting authority team in working out the project specifications brief (upstream phase). Complementary with more urban oriented analysis, OASIS provides an overall picture (because of the joint use of questions and indicators) but relatively exhaustive diagnosis on main sustainability issues concerning IBP. It is an undoubted help focused on two points. On the one hand OASIS allows defining the first project's requirements in agreement with the project stakeholders. On the other hand OASIS provides an analysis and some recommendations based on strengths and weaknesses of the site and of the project beside sustainability issues.

5.2 Prospects for OASIS Evolution

CSTB intends to continue to make OASIS more operational for practitioners, by developing a software tool and some guidelines.

In order to guarantee the creation of sustainable Industrial and Business Parks, the approach enhanced in the developed method must not stop at the diagnosis and definition of project specifications phases. It is necessary to help also the next phases of a project: the design and the running phases. The analysis framework will need to be adapted in order to address all the relevant topics, with adapted indicators, especially for the operation phase. This has to be studied from an assessment point of view, promoting a continuous improvement approach, and developed in close co-operation with practitioners.

NEIGHBOURHOODS, LOCAL AUTHORITIES AND COMMUNITY DEVELOPMENT: OPPORTUNITIES FOR IMPROVED SUSTAINABILITY

Keywords: neighbourhoods, local government, housing, sustainability, built environment

Summary

Over the last four years Beacon Pathway Ltd has been developing a Neighbourhood Sustainability Framework through which the sustainability of neighbourhoods can be assessed. In the development phase prototypes of the framework and tools have been tested. This has involved working with developers and local authorities. In doing so, opportunities to retrofit neighbourhoods for greater sustainability through active local partnerships have emerged. This paper reviews the way in which the prototype Neighbourhood Sustainability Framework and tools combined with some house level research into housing conditions opened up and assisted with opportunities for community development as well as improved environmental outcomes in a lower to middle income suburb in West Auckland at both the neighbourhood and house levels.

1. Introduction

Beacon Pathway Ltd (Beacon) is a research consortium that seeks to radically change the design, construction and renovation of New Zealand's homes and neighbourhoods. Beacon aims to bring about a significant improvement in the sustainability of the residential built environment in New Zealand through science-based New Zealand research.

To improve the sustainability of neighbourhoods both existing and new in New Zealand, Beacon has been developing a Neighbourhood Sustainability Framework which includes two tools to assess neighbourhoods and identify opportunities for improved sustainability. This reflects on the process, findings and outcomes of Beacon's participation in the West Harbour Project through which Waitakere City Council and Housing New Zealand Corporation are now actively considering options for the rejuvenation and retrofitting of West Harbour, an area in Waitakere City, part of the Auckland regional conurbation. Beacon's participation in the West Harbour Project has involved two key activities. Firstly, the application of the Neighbourhood Sustainability Framework and its prototype neighbourhood assessment tools. Secondly, an analysis of the condition of the housing stock to establish the nature and extent of house-based retrofit opportunities. These two components together highlighted, perhaps in a very unique way, the profound connections between dwelling sustainability and neighbourhood sustainability.

2. Beacon's Role in West Harbour

The West Harbour Neighbourhood Sustainability Project (now coined Tatou West Harbour) is part of the wider ***Massey Matters Project.*** Massey Matters was initiated by Council in 2006. This project has seen Waitakere City Council working alongside the local community and other partners to develop a programme for long term, community driven, sustainable neighbourhood renewal and development in the Massey area designed to deliver:

A Sustainable Urban Massey

- *Building community activity, networks, connectivity and sense of pride and identity.*
- *Improving current urban form and infrastructure (e.g. services, facilities, connectivity, natural environment)*

Four key principles continue to guide the development of Massey Matters:

- Working with the Massey community
- Sustainable suburban development
- Collaboration and partnership
- Concurrent planning and action.

The initial conversations between Beacon, Waitakere City Council and Housing New Zealand Corporation identified West Harbour as a site for neighbourhoods retrofit. There were opportunities for Beacon to test its Neighbourhood Sustainability Framework and to use that research as a key contributor to the development phase of Tatou West Harbour and a way of flagging local issues around sustainability and the identification of options to make the neighbourhood work better. The research has practically acted as a catalyst for ongoing discussion with local communities, Waitakere City Council and other stakeholders in the West Harbour area about the options and sequencing of retrofit work.

Beacon's involvement in the West Harbour Project was prompted by Beacon's recognition that its retrofitting packages at the house level and its Neighbourhood Sustainability Framework and associated tools must work for practitioners, investors and decision-makers. Beacon's role was to provide the Tatou West Harbour stakeholders with: robust assessment of the sustainability of a neighbourhood in West Harbour; robust data on the house condition of the West Harbour housing stock; and a set of neighbourhood retrofit options for further consideration designed to optimise the sustainability of the neighbourhood as a whole and the dwellings within it.

3. The Neighbourhood Sustainability Framework

Beacon Pathway Ltd. (Beacon) has developed a Neighbourhood Sustainability Framework (NSF) and prototype tools to assess New Zealand neighbourhoods. That framework is developed around six critical domains and a specified neighbourhood goal (Figure 1).

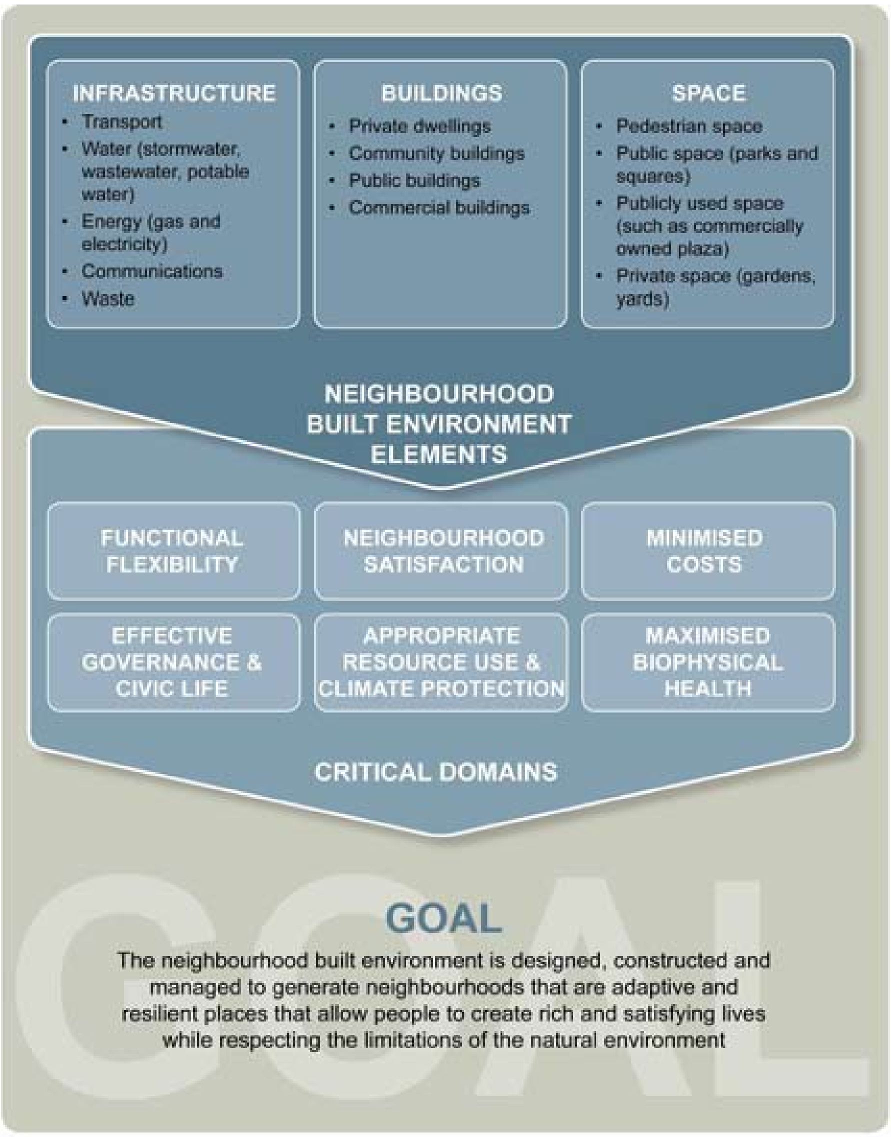

Figure 1: The Neighbourhood Sustainability Framework

The tools that support the Neighbourhood Sustainability Framework are the:

- Built Environment Observational Assessment Tool[1] which involves a structured, expert assessment of the built environment; and
- Resident Self-report Tool which involves collecting and analysing resident's behaviour and perception in relationship to the critical domains of the NSF.

The Observational Assessment Tool consists of a mixture of measurement and professional judgement structured through a set of well-defined requirements and guidelines. The Resident Self-report Tool is applied as a resident questionnaire that is delivered to householders. The results are reported as relative values to a baseline database of neighbourhood behaviours and perceptions. The aim of the tools is to pinpoint neighbourhood strength and weaknesses and assist in identifying the critical priorities for the management and retrofit of neighbourhoods.

Both tools are described in detail in the report *NH103a The Beacon Neighbourhood Tools* (Lietz et al, 2007). Broadly, however, they measure a series of critical sustainability issues that a substantial body of international research indicates affects, and is affected by, the built environment. Those are:

- *The use of motor vehicles, particularly private motor vehicles*. Greenhouse gas emissions, storm water pollution and air pollution are associated with vehicle emissions. Travelling time in motor vehicles has significant social and economic costs and presents the second highest direct costs to households. Those unable or unwilling to drive are at risk of social exclusion and marginalisation. Walking is associated with neighbourhood interaction and increased informal surveillance. Neighbourhood form impacts on both motor vehicle use and walking.

- *The provision and accessibility of quality and nature of public space*. Public space can generate interaction, provide local natural habitats. They also can be used to manage storm water. Well designed public space can increase walking and provide for creative and physical activities.

- *Neighbourhood built environments work when they are flexibility and adaptable*. Robust neighbourhoods stand the test of time. Key action pathways to ensure flexibility and adaptability include a mixture in building typology and dwelling size, mixed use, local facilities and the availability of public transport.

- *Higher density can reduce resource use and generate economies of scale*. Density intensification can reduce sprawl, reduce the amount of land that is taken out of natural ecosystems, generate population critical mass, affect travel and neighbourhood behaviours. Higher density therefore improves the viability of town centres and public transport and directly affects travel behaviour. Higher land prices inevitably encourage the market to reduce lot sizes. Intensification, whether through pricing or through regulation, is occurring in many neighbourhoods and presents challenges to current neighbourhood built environment design and the construction of the buildings in them.

Both the Observational Assessment Tool and the Resident Self-Report Tool are directed to measuring the extent to which neighbourhood plans and existing neighbourhoods respond positively to those challenges. Initially, a draft version of the United States Green Building Council's LEED-ND was tested as the observational assessment tool for the NSF. This was found to be unsuitable for New Zealand conditions, was very labour intensive, was directed at scoring designs rather than facilitating decision-making, was less useful in relation to existing neighbourhoods, and generated some quite contradictory outcomes. For instance, a number of existing New Zealand neighbourhoods on which the draft LEED-ND was applied had good surveillance although no had the features that would generate a good score in relation to surveillance. Consequently, an alternative Observational Assessment Tool was developed that measures:

- Access to basic every day facilities within walking distance
  - Schools
  - Reserves
  - Local shops
- Access to and adequacy of public transport within walking distance
- Quality of space
  - Streetscape, including but not limited to walkability
  - Public open space
- Efficient use of space and viability of local centres
  - Residential density
  - Previous use of the site
- Diversity
  - Mixed use

[1] Referred to as the 'Observational Assessment Tool'.

  - Public space
  - Housing Diversity (cost, size and typology)
- Protection and enhancement of the natural environment
  - Stormwater management
  - Protection and creation of habitat
  - Riparian, coastal and wetland management.

The Resident Self-Report Tool collects data related to:
- intention to move because of housing
- use of foot/bicycle/public transport for work/ study
- intention to move because of neighbourhood
- condition of house
- condition of garden
- perceptions of safety
- noise disturbance
- knowing neighbours
- perceptions of the neighbours
- identification with the neighbourhood and belonging
- car use
- composting
- provision for wildlife
- gardens and pools
- organic gardening
- participation in local groups
- use of public spaces
- dwelling energy efficiency
- dwelling water efficiency
- neighbourhood food expenditure.

Scores are currently banded as follows:
- Outstanding sustainability over 60 points
- High sustainability 46-60 points
- Medium sustainability 30-45 points
- Low sustainability under 30 points

For Tatou West Harbour, the Observational Assessment Tool was applied in the same manner as it has been for all previous case studies. The questionnaire used for the Resident Self-Report questionnaire, however, was accompanied by an additional set of questions to assist the Tatou West Harbour Project in collecting some additional data of interest without over-burdening residents with repeated social surveying. The questionnaire was distributed to the neighbourhood households through direct delivery. A 36 percent response rate was achieved. This is somewhat less than in previous case studies. The number of returns (149 responses), however, are adequate to drive the assessment calculator.

4. The House Condition Survey

The House Condition Survey undertaken in West Harbour involved surveying 100 houses to establish the physical condition of the dwellings in the area. The sample was stratified to ensure a selection of 75 privately owned houses (either in private rental or owner occupier) and 25 houses owned by Housing New Zealand Corporation. Houses were selected randomly and field surveyors were provided with a strict set of replacement rules and protocols to ensure that field surveyors did not undertake a biased sampling pattern. The surveying was undertaken using a slightly modified version of the BRANZ House Condition Survey which has been used for community-based condition surveying in low income communities. It provides data comparable to the data reported by BRANZ for the New Zealand House Condition Survey. Surveying was undertaken by Eco-Matters Environment Trust, a Waitakere-based organisation with considerable experience in dwelling energy and water retrofitting.

5. Results of the Neighbourhood Assessment

West Harbour achieved a medium sustainability rating using the Observational Assessment Tool, which can be seen as a positive result for a suburban neighbourhood, such as West Harbour. The Resident Self-report Tool however generated a low sustainability ranking. Table 1 puts West Harbour's results in context with the results from some of Beacon's earlier case study neighbourhoods. The different results generated by the two tools suggest that priority should be given to interventions that will improve resident experiences. Table 2 summarises the strengths and weaknesses of West Harbour.

Table 1: West Harbour Beacon Neighbourhood Assessment Results

Sustainability Rating	Observational Assessment	Resident Self-Report Assessment
	46-60	15 +
High	▪ Blake St – Ponsonby ▪ Petone	▪ Petone ▪ Blake St – Ponsonby
	30-45	10-14.9
Medium	▪ Aranui ▪ ***West Harbour*** ▪ Harbourview ▪ ChCh East Inner City	▪ Harbourview ▪ ChCh East Inner City
	<30	<10
Low	▪ Waimanu Bay ▪ Dannemora	▪ ***West Harbour*** ▪ Aranui

Table 2: West Harbour Key Strength and Weaknesses

Key Strengths	Key Weaknesses
• Good walking access to local services and facilities (shops, school, early childhood centres, community facilities and parks). • Food shopping is highly localised. • Good quality of space (parks and streetscape). • Good passive surveillance of streets and quite good surveillance of parks and walkways. • Protection of riparian area along the Manutewhau Stream. • Proximity to Westgate. • Affordable Housing. • Smaller homes available (2 bedroom). • Convenient bus stops and access to five bus routes.	• Serious concerns around safety when walking at night. • Noise considered to be a problem by many. • More than average number of people looking at moving because their house no longer suits them. • More than average people looking to move because of the neighbourhood. • Lower than average levels of neighbourhood interaction. • Low Public Transport usage. • No bus service after 7pm. • Low levels of walking and cycling. • Lack of stormwater treatment. • Disconnected street network.

6. Results of the House Condition Assessment

The results of the House Condition Survey can be summarised as follows:

- The condition of the West Harbour stock is slightly poorer than the national stock: The National stock, on average, is in the Very Good category while the West Harbour stock is, on average, in the Good category.
- Average costs of outstanding maintenance was 42 percent higher in the West Harbour stock than the cost of repair for stock nationally.
- West Harbour dwellings appear to be particularly vulnerable to issues associated with water damage, cold and damp. Indicators of those problems include:
  - 53.3 percent of West Harbour dwellings have Poor or Moderate ceiling insulation
  - 15.2 percent of West Harbour houses having mould to Serious or Poor levels compared to only 2.7 percent of dwellings in the BRANZ's 2005 New Zealand House Condition Survey.
  - 20 percent of West Harbour houses with rising damp compared to 8 percent of dwellings in the BRANZ's 2005 New Zealand House Condition Survey.
  - 7 percent of West Harbour houses with water ponding compared to 2 percent of dwellings in the BRANZ's 2005 New Zealand House Condition Survey.
  - 6 percent of West Harbour houses with timber decay compared to 1 percent of dwellings in the BRANZ's 2005 New Zealand House Condition Survey.
  - 4 percent of West Harbour houses with subsidence compared to 0 percent of dwellings in the BRANZ's 2005 New Zealand House Condition Survey.
  - 4 percent of West Harbour houses with cupped floor boards compared to 1 percent of dwellings in the BRANZ's 2005 New Zealand House Condition Survey.
  - 13 percent of West Harbour houses with fungi on the wall claddings compared to 6 percent of dwellings in the BRANZ's 2005 New Zealand House Condition Survey.
  - 3 percent of West Harbour houses with leaks at the joints of wall claddings compared to 1 percent of dwellings in the BRANZ's 2005 New Zealand House Condition Survey.

- 33 percent of West Harbour houses with moss growth on the roof cladding compared to 24 percent of dwellings in the BRANZ's 2005 New Zealand House Condition Survey.
- 11 percent of West Harbour houses with cracked roof tiles compared to 3 percent of dwellings in the BRANZ's 2005 New Zealand House Condition Survey.
- 7 percent of West Harbour houses with rust in gutters compared to 1 percent of dwellings in the BRANZ's 2005 New Zealand House Condition Survey.
- 15 percent of West Harbour houses with shower lining decay compared to 7 percent of dwellings in the BRANZ's 2005 New Zealand House Condition Survey.
- 8 percent of West Harbour houses with leaking kitchen outlets compared to 1 percent of dwellings in the BRANZ's 2005 New Zealand House Condition Survey.

7. Some Options for a West Harbour

Three key findings had emerged from the Neighbourhood Sustainability Framework application. Those were that:

- There were some critical built environment issues that inhibited neighbourhood satisfaction and interaction including:
  - concerns about safety associated with:
    - anxieties around walking at night
    - noise
    - dissatisfaction with and a desire to move because of the type of housing.
    - poor connectivity and some areas in which amenity values could be better optimised.
- The physical condition of the neighbourhood appeared to be affected by very wet ground conditions, with surface flows over footpath and properties in places.
- There was a strong foundation of attachment to the community with potential to promote this further through on-going improvement of the built environment and amenities.

The House Condition Survey found that the area did have a higher than average level of unmet house maintenance. It also found that many of the problems with houses appeared to be associated with higher than usual levels of damp. Those findings were consistent with and supported the findings of the Observational Assessment Tool and the Resident Self-Report Tool. That data and Waitakere City Council's and Housing New Zealand Corporation's own experience in West Harbour suggested that neighbourhood built environment projects should focus on providing opportunities for people to interact, on improving safety and on creating community pride and engagement. Community development and management initiatives were identified as an important investment in this neighbourhood. Built environment projects can be used catalyst for the community to come together around a practical and achievable initiative.

The findings emerging from the application of the Neighbourhood Sustainability Framework were the basis for the Beacon Neighbourhood Team's identification of retrofit priorities and options for West Harbour. Those findings alone were not sufficient to develop a set of retrofit options. The following data was also compiled to contextualise and inform the development of retrofit options:

- A summary of information about the houses in the neighbourhood contained in the Quotable Values New Zealand database held by Waitakere City Council;
- A summary of relevant 2006 census data for the closest matching mesh blocks;
- The locations of Housing New Zealand Corporation properties;
- Water use statistics from WCC; and,
- Observations from a night walking audit undertaken to pinpoint safety issues while walking at night.

Following discussions with the stakeholders the retrofit options set out in Table 3 were recommended for further investigation.

Table 3: Retrofit Options for West Harbour

Project	Contributes to
Intersection of Moire Rd and West Harbour Drive as a neighbourhood focal point This could include HNZC neighbourhood office, WCC community broker, etc. Could have affordable accommodation above. This could be the beginning of a community/commercial hub.	• Local focus point • Catalyst for other development • Neighbourhood management • Provision of local facilities
Raintank retrofit Retrofit houses with rain/detention tanks and connect overflows to stormwater system.	• Stormwater management • Water efficiency • Reducing dampness problems in homes and gardens. • More useable outside space for homeowners
Stormwater retrofit of roads Possibly concentrating on Moire Road	• Stormwater management • Quality of Space
Household sustainability retrofit Retrofit homes with • energy and water saving measures • replace unsafe/unhealthy heating • ventilation measures • Compost bins • Smoke alarms • Washing lines	• Energy efficiency • Water efficiency • Occupant health • Waste minimisation • Fire safety • Increased pride in individual houses and the neighbourhood
Reclaiming the road reserve Provide planting, seating, art, play opportunities.	• Community interaction • Sense of place
Lighting Improvements Improve street lighting by better maintenance, etc	• Safety while walking at night
Manutewhau Stream clean up Clean up stream and improve walkway	• Access to Moire Park • Recreation
Develop walkway from 19a West Harbour Drive to Manutewhau Stream Formalise this walkway	• Access to Moire Park • Recreation
Disused Reserve at 19a West Harbour Drive Develop into community managed neighbourhood reserve that could include a community building or hub	• Community engagement • Visibility of Tatou West Harbour • local community workers

8. Houses, Neighbourhoods and Pathways to Sustainability – Some Reflections

From Beacon's point of view, this project was designed to:

- Test the nature and limits of the contribution that the Neighbourhood Sustainability Framework and its tools could make to stakeholders concerned with the rejuvenation and retrofitting of neighbourhoods.
- Establish the extent of retrofit need at the house-level in an ordinary, 1970s, entry-level subdivision and options to address those needs.

The Neighbourhood Sustainability Framework has demonstrated its utility in planning and management of existing neighbourhoods to improve neighbourhood performance. In this, the Neighbourhood Sustainability Framework differs from other neighbourhood or community directed planning tools such as the LEED-neighbourhood tool promoted by the United States Green Building Council and the Greenprint developed by BRE (BRE Sustainable Communities Team). The latter has been developed to "assist design teams in delivering masterplans that maximise the potential for sustainable communities."

With regard to the latter, the House Condition Survey is a well-tested tool and it provided a strong indication of the major patterns of condition problems and repair/maintenance needs in the area. That data was critical to identifying the types of retrofit options that were most likely to generate the greatest performance benefit while minimising costs. Given that the two key stakeholders, Waitakere City Council and Housing New Zealand Corporation, are involved in existing energy retrofit programmes, this provided the ability to assess likely demand for and adequacy of programme coverage.

Perhaps more importantly, however, this project demonstrated an unexpected synergy between the results of applying the Neighbourhood Sustainability Framework's tools and the results of the House Condition Survey. Both indicated issues around housing. The Neighbourhood Observational Assessment indicated issues around storm water management. The Resident Self-Report Tool identified issues around a desire to move because of housing dissatisfaction. The House Condition Survey indicated house-level problems, particularly associated with damp and poor managed water in and around dwellings. The resolution of storm water issues at the neighbourhood level became indicated as both a pathway to improved neighbourhood performance and improved dwelling performance.

This connection between neighbourhood and housing sustainability has, in recent years in New Zealand, at least, has been largely forgotten. It is also largely absent from the discussion about the continuum of sustainability that reaches from individuals to households to neighbourhoods to settlements to regions and, eventually, to nations. The latter continuum is often conceived of as simply a matter of aggregation. That is, neighbourhoods, cities and regions are seen as not being sustainable if individuals are not, collectively, living sustainably. Similarly, there is acceptance that households can not act sustainably if the form of settlements and if city system infrastructure such as transport fail to support low-resource styles of living. This is a sort of 'nesting' conception of sustainability in which individuals are seen as needing to be 'nested' in sustainable houses, and sustainable houses 'nested' in sustainable neighbourhoods and so forth. This research, however, demonstrates the iterative impacts on house-level and neighbourhood sustainability of the quality of sub-divisions and the quality of the housing placed on those sub-divisions.

The results of applying the Neighbourhood Sustainability Framework also prompted some very real and practical responses. Waitakere City Council secured a Low Impact Design grant from the Auckland Regional Council to investigate retrofit options aimed at improvements in storm water quality. This work is currently being completed. It is hoped that this will result in some demonstration rain gardens to improve local storm water quality. . In addition, the concerns about neighbourhood safety prompted some immediate Council responses such as tree trimming, fixing broken street lighting and graffiti removal. Research results also continue to feed into ongoing discussions at street level and within Council, with the need for long term 'master' type plan for the area now acknowledged ***Tatou West Harbour*** is fast becoming a successful demonstration of community based action aimed at positive changes to make the West Harbour a better place to live for both current and future generations.

Community development practitioners that have been working in ***Massey Matters*** and in ***Tatou West Harbour*** see the NSF as having limited usefulness in the neighbourhood retrofit context unless it is integrated and applied within the context of community development processes. This is absolutely consistent with both international best practice and the NSF itself. The NSF is designed to assist practitioners. It is a tool to assist with planning, reflection and decision-making. It does not replace practitioners or processes. Just as 'green building' tools such as the LEED-ND in the United States or Beacon's NOW Home® or New Zealand's recently released Lifetime Design guidelines do not replace the designer or architect, nor does the NSF and its tools replace the myriad of practitioners that make neighbourhood rejuvenation and retrofit a pathway to liveability and sustainability. The NSF tools do not replace the processes of stakeholder and community engagement. The application of the NSF will not bring change nor the resources needed to generate change. What the NSF does do is identify a variety of built environment adjustment options. Indeed, in some circumstances, it can indicate whether the critical focus should be on built environment change or on community engagement. For instance, West Harbour, like Aranui, another of our case studies, shows a 'split' pattern in which the observational assessment of the built environment generated a higher sustainability score than the resident self-report. It is relatively early in the application of the NSF, so it the precise conditions that generate this split pattern are unclear. But it appears to emerge where residents feel somewhat marginalised. Community engagement is critical in those communities, even when, perhaps especially, when the focus of action is on the built environment.

BEACON NOW HOMES® AND NOW HOME® RENOVATIONS: TRANSFORMING NEW ZEALAND'S HOUSING STOCK

Lois EASTON,[1] Andrew POLLARD[2] and Roman JAQUES[2]

[1] Beacon Pathway Limited, Auckland, New Zealand loise@beaconpathway.co.nz

[2] BRANZ Limited, Porirua, New Zealand

Keywords: New and existing homes, existing technology, resource efficient housing

Summary

New Zealand's housing stock is well known for being cold, damp and resource inefficient. Beacon Pathway Limited aims to drive change in the New Zealand housing sector to see a significant improvement in the sustainability of our housing stock. In particular Beacon's focus is on "ordinary" homes and occupants – rather than the top 5% niche normally the subject of eco home and high sustainability aspiration.

In order to achieve this Beacon has developed two NOW Homes® and nine NOW Home® Renovations – houses built and renovated for an average budget for ordinary families which perform significantly better than the vast majority of New Zealand houses. These homes have been monitored in terms of their resource use, quality of the indoor environment and overall sustainability against key performance indicators and benchmarks set by Beacon. The homes have now demonstrated that development and retrofitting of these homes with current technology and for prices within the reach of ordinary households, significantly higher quality and healthier and more resource efficient housing is able to be developed. These results have been achieved without any specific training or behaviour modification of the occupants.

1. Introduction

The sustainability of the residential built environment is an important issue for New Zealand, as a significant proportion of the energy and water consumed (Statistics New Zealand, 2006) and waste produced (Kazor and Koppel, 2007) in the country occurs in people's homes. Similarly the health of the indoor environment within homes has a significant impact on the overall health of the community, particularly as relates to respiratory conditions.

Beacon Pathway is the vehicle chosen by a number of like-minded organisations that seek to radically change the design, construction and renovation of New Zealand's homes and neighbourhoods. Our goal is to significantly improve housing sustainability through scientific research, communication, information sharing, and advocacy, opinion forming and networking.

The Foundation for Research, Science and Technology matches funding from Beacon's shareholding partners, a unique mix of industry, local government and research organisations: Building Research, Scion, New Zealand Steel, Waitakere City Council and Fletcher Building.

Established in 2004, with a focus on new technology for new homes, it became quickly apparent the principal opportunity for Beacon to impact lies not with the 25,000 new homes we build each year, but in transforming our existing 1.6 million homes. A large proportion of these homes are poorly insulated, damp, and consume relatively high quantities of energy and water (Storey, Page, van Wyk, Collins and Kreil 2004).

As part of its applied research approach Beacon has built two resource efficient NOW Homes® in Waitakere and Rotorua and retrofitted nine "average" existing homes in Porirua in the Wellington Region These homes have been monitored against benchmarks that Beacon has set around what defines a High Standard of Sustainability™ for homes. The homes are all occupied by ordinary families with no special training in sustainability behaviour.

1.1 Beacon's High Standard of Sustainability™

In order to provide a framework for Beacon to measure the influence it is having on the sustainability of houses at a national level, and to provide a useful benchmark against which individual households can evaluate their home's performance, Beacon has developed benchmarks for a High Standard of Sustainability™ (HSS) in homes (Easton, 2006). These benchmarks have focused on five key aspects of dwelling sustainability:

- Energy Use
- Water Use
- Indoor Environment Quality
- Waste
- Materials

Underpinning these five technical aspects of dwelling sustainability are the issues of affordability and future flexibility. When considering the individual household benchmarks at which the HSS performance indicators should be set, affordability was a significant consideration (Easton, 2006). The benchmarks have therefore been set at levels where many of the features used to bring about their achievement are:

- low cost (eg simple measures such as fitting of draught stoppers and use of low-flow shower heads)
- have a payback period of less than the expected life of the product
- In the case of new development, can be undertaken at no or minimal extra cost (eg passive solar design).

The benchmarks developed represent a preliminary "line in the sand" for Beacon and are expected to be updated and refined over time, and as the research into the state of New Zealand's home performance continues. While detailed comparative work is still being undertaken, new homes built to achieve the Beacon HSS appear to be roughly comparable with a "good" rating (56-69 points) under the BRANZ Green Homes Scheme (New Zealand's only current sustainable home rating scheme), or a Level 4 compliance with the UK Code for Sustainable Homes. This compares with, for example, the average new New Zealand home, which would score around 10-15 points under the BRANZ Green Homes Scheme and not achieve a rating on the UK Code for Sustainable Homes. In other words while the Beacon HSS benchmarks are significantly higher than the minimum requirements of the NZ Building Code, but are set to be within what is a considered to be able to be a reasonable target for all new homes to achieve by 2012.

2. Beacon's NOW Homes®

Beacon has developed two NOW Homes® – in Waitakere and Rotorua. The Waitakere NOW Home® was completed in August 2005 and the Rotorua NOW Home® in September 2006. Both homes were designed and built to budgets and constraints typical of "ordinary" New Zealand housing rather than aimed at the top 5% of the market more typical of other "ecohomes". The Rotorua NOW Home® was developed in conjunction with Housing New Zealand Corporation and was designed and built for a budget at the affordable end of the market.

Passive solar design, resource efficiency, minimisation of hazardous materials and future flexibility were all key considerations in designing and building the homes. As a result less than 2.5 tonnes of construction waste was produced in each home's construction. This compares with a Tauranga study of construction waste produced in the development of new 3 bedroom homes that found that each home produced 6 tonnes of construction waste (Kazor and Keppel, 2007).

2.1 Waitakere NOW Home®

The Waitakere NOW Home® uses timber weatherboards, fixed to a timber frame on a heavily-insulated concrete slab. The roof is concrete tile, and the ceilings and walls are heavily insulated. The entire building is double glazed.

The building is sited to maximise the benefits of passive solar heating, using the highly insulated envelope to trap and retain the sun's warmth – mainly via the polished (no carpets) concrete slab. Passive ventilation is incorporated in the design to facilitate air changes without creating draughts – important for a healthy indoor environment.

A solar water heater is installed on the roof, and a water tank collects rainwater from the roof. The tank water is used for many non-potable water needs within the house. Where possible light fittings are high-efficiency compact fluorescent types.

The majority of the appliances belong to the tenants, however the range, fridge, dishwasher and washing machine are new efficient items supplied as chattels.

The Waitakere NOW Home® was been occupied over the period September 2005 – March 2008 by a family of four (two adults, two children). At the start of the tenancy the two children were of pre school age.

2.2 Performance of the Waitakere NOW Home®

Monitoring of the Waitakere NOW Home® includes the collection of end use information for both the electricity and water use. Temperature and humidity are measured in each room as well as CO_2 in the living room. The water temperatures, solar radiation and water flows for the solar water heater were also measured (French et al, 2006).

Post occupancy evaluation surveys were also undertaken to capture the occupants' experiences compared with the previous house they lived in, to gain an understanding of the occupants' behavior and influence on the house performance as well as the influence of the house on the occupants.

2.2.1 Energy use within the Waitakere NOW Home®

In its first year of occupancy the Waitakere NOW Home® used 7400 kwh/year of electricity, with supplementary heating required on only two days. When compared to the occupants' previous dwelling, this was 45% less electricity than they used in their previous home (French et al, 2006). Figure 2 compares the electricity use between the occupants' previous dwelling and the first year of occupancy of the Waitakere NOW Home®. While there is a substantial difference, it can be seen that the gap was gradually closing over time. This trend continued into the second year of occupancy – with the occupants using 8500 kwh/year. A matched pair analysis of the electricity use was undertaken against the HEEP dataset[1], this showed that in the second year of monitoring the home used 25% less energy than comparable households, a reduction from the 33% less energy than comparable households used in the matched pair analysis undertaken in the first year (Pollard, French, Heinrich, Jaques, and Zhao, 2008).

Analysis of the both the monitoring data and post occupancy survey information reveals that the main cause of this significant rebound effect has been in the form of additional hot water use (longer and more frequent showers) and additional appliances being introduced into the home.

In addition the electricity use was supplemented by the electricity load (850 kwh/year) of the principal income earner in the family setting up a home office in the house, a core component of which was a computer server.

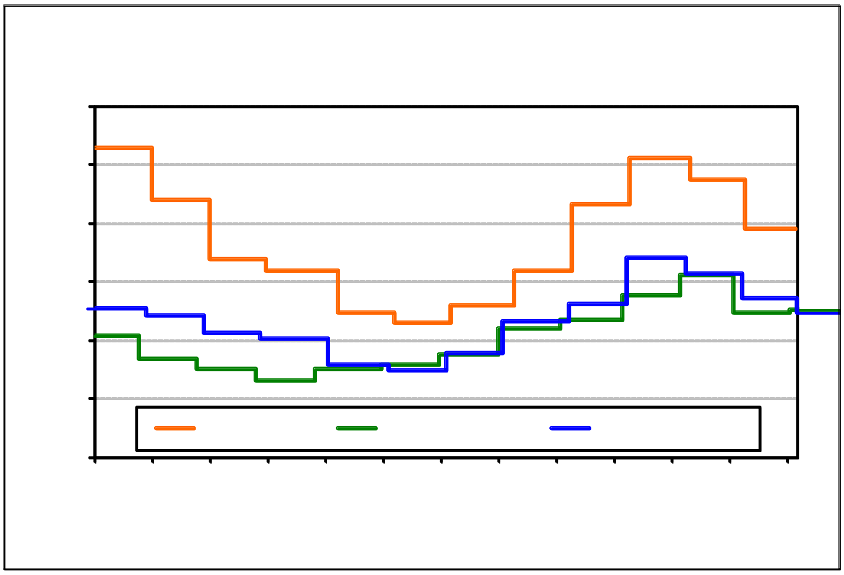

Figure 1 Comparison of electricity use by the occupants of the Waitakere NOW Home® compared to their previous home (after Pollard et al, 2008)

2.2.2 Water use within the Waitakere NOW Home®

Water use in the Waitakere NOW Home® was similar over the two years of occupancy, with a reduction in both total and reticulated water use in the second year (Pollard et al, 2008). Little good data exists on average water use in New Zealand (one of the reasons why NOW Home® data is significant), however comparisons with the surrounding households can be made due to the existence of metering. In their first year of occupancy the household used an average of 100 litres per person per day of reticulated water, with 189 litres per person per day of total water - the difference being supplied by the rainwater tank (French et al, 2006). In the second year of occupancy the household water use dropped to 85 litres per person per day of reticulated water and 172 litres per person per day of total water (Pollard et al, 2008).

[1] HEEP – Household Energy End Use Project – a BRANZ Limited project where the energy end uses of 400 households across New Zealand were monitored and analysed in detail.

2.2.3 Indoor Environment Quality within the Waitakere NOW Home®

Temperature and humidity data collected across the first year of occupancy identified that the temperatures within the home were maintained within healthy and comfortable parameters for the vast majority of the time occupied (Pollard et al, 2008). In terms of user behavior, a portable heater was only required to be used by the tenants twice during what was a colder than average winter. Humidity levels however in the home were sometimes higher than considered desirable, particularly in winter and in the main bedroom next to the ensuite (French et al, 2006). Installation of a mechanical venting system in both bathrooms occurred prior to the second winter of monitoring, as it was suspected that this was a contributing cause to the humidity problems.

2.2.4 Experience of the occupants of the Waitakere NOW Home®

Interviews with the tenants and post occupancy evaluation identified that they considered the Waitakere NOW Home® to be "their best home ever". When compared with previous dwellings the family had occupied, in particular they valued the following features of the home:

- comfort (thermal, fresh air, lighting, sound insulation),
- physical attributes (concrete floor),
- utility (spaciousness, interior layout and flow), and
- service provision (electricity bills and hot water heating, recycling, security[2], clothes line)

In terms of the features that were repeatedly discussed as being exemplary, the three that stood out were:

- the layout of the rooms and good use of space
- the thermal performance of the house, in terms of temperature stability and (almost) negating the necessity for winter-time space heating
- the concrete floor – in terms of its ability to keep clean.

The tenants thought that the overwhelmingly positive features of the house and its surroundings made a significant positive contribution to their inter-family relationships (Pollard et al, 2008).

2.3 Rotorua NOW Home®

The Rotorua NOW Home® has been built on the same principles of design and material selection as the Waitakere house, with the benefit of subsequently available knowledge, as well as meeting Housing New Zealand Corporation requirements for social housing. The house is owned by Housing New Zealand Corporation (HNZC), the main social housing provided in New Zealand, and forms part of their rental housing portfolio.

The Rotorua NOW Home® uses preprimed timber plywood and prepainted steel for cladding, fixed to a timber frame on a heavily-insulated concrete slab. The roof is prepainted steel, and the ceilings and walls are heavily insulated. The entire building is double glazed.

A solar water heater is installed on the roof, and a 5000 litre underground water tank collects rainwater from the roof. The tank water is used for toilet flushing and to supply the washing machine within the house. All light fittings are high-efficiency compact fluorescent types. Unlike the Waitakere Home, appliances were not supplied with the home, with the exception of the stove as HNZC policy is to not include whiteware.

Due to Rotorua's colder climate, the space heating requirement was four times that of the Waitakere NOW Home® and a low emission pellet burner was installed to provide supplementary heating.

The house was designed to provide for wheelchair access, and a second bathroom included was specifically designed for accessibility.

The home has been tenanted since September 2006 by ordinary HNZC tenants.

2.3.1 Preliminary Monitoring Results from the Rotorua NOW Home®

Monitoring results for the first year of occupancy have been analysed. Due to gaps in the data set because of issues with continuous data collection, the findings are considered to preliminary only. Analysis of the results (Jaques, Mathews and Pollard, 2007) indicates that reticulated energy use is lower than for the Waitakere NOW Home®, with 6800 kwh used in the first year of occupancy. In particular the proportion of energy used for appliances is significantly lower than that in the Waitakere NOW Home®.

[2] This rating is somewhat artificial, as their views were based on a private security firm checking the area at regular periods – which would not happen in more standard situations.

Despite the presence of a pellet burner as a heating source, temperatures in the home occasionally fall below the benchmarks set in the Beacon High Standard of Sustainability – and World Health Organisation recommended minimums. Investigations into the cause of this are still underway, but indications are that this is as a result of a combination of factors:

- The tenant has covered the concrete floor thermal mass with carpet, preventing it from functioning as intended
- Tenant operation of the pellet burner does not appear to optimize its performance
- Difficulty in heat circulation to the bedrooms

Total water use is 199 litres per day, however at this stage the reticulated water use is not known, as analysis is still being undertaken.

3. Beacon's NOW Home® Renovations

In order to research how to improve the sustainability of existing homes, over February to June 2007 nine homes in Papakowhai, Wellington have been retrofitted with different packages of interventions. The houses were selected to provide case studies of "ordinary homes" in a middle income suburb. Middle income households were chosen because an evaluation of existing retrofit programmes (McChesney and Amitrano, 2006) found that low income households were the major beneficiaries of current government and community sponsored retrofit programmes, and often where the householders suffer from respiratory health problems. While laudable programmes, the performance data collected from the retrofitted homes is not considered to be representative of the wider performance of New Zealand's housing stock as the homes are generally chronically under heated. In addition, research has found (McChesney and Amitrano, 2006) that because of the very low level of energy retrofits undertaken as part of the programmes, temperatures in the homes remain well below World Health Organisation suggested standards (and the Beacon HSS benchmarks) and, unsurprisingly, significant rebound effect occurs in any energy savings.

Accordingly, the project is testing a range of retrofit options aimed at determining what are the best (lowest cost, easiest to implement and most effective) packages of retrofit options which will substantially improve the resource use of a home and improve the indoor environment to meet Beacon HSS benchmarks. These retrofit packages address a number of core components which Beacon considers need to be included in a retrofit which will substantially improve the sustainability of a home. Different combinations of the following key features have been included in the packages:

- Significant increases in insulation (ceiling, underfloor and walls)
- Double glazing
- Solar hot water systems
- Fixed heat sources (heat pump, pellet burner and low emission wood burner)
- Water efficiency measures such as low flow fittings
- Mechanical ventilation of kitchen (rangehoods) and venting of driers
- Showerdomes (a device fitted over the top of the shower to prevent steam creation or release of moisture to air)
- Compost or worm bin
- Basic energy efficiency measures (draught stopping, compact fluorescent lightbulbs etc)

The pre-retrofit energy and water use, temperature and humidity of the homes was been monitored by BRANZ Ltd, and a pre-retrofit waste audit was also undertaken. While the post retrofit monitoring will continue to the end of winter 2008, some preliminary analysis of the pre-retrofit monitoring data has been undertaken. This analysis indicates that winter time temperatures in all but one of the homes were below desired benchmark levels of 16°C in bedrooms and 18°C in living spaces. Average winter air temperatures in the living room ranged from 16.1°C to 22.2°C during the evening and 11.6°C to 16.7°C during the night in the main bedroom (Buckett, French, Zhao, Burgess and Hancock, 2007).

Detailed analysis of the pre-retrofit energy and water use has not yet been undertaken, but preliminary analysis indicates a wide range of energy use patterns influenced by a range of factors. The highest energy use occurred in a home with all electric heating, cooking and hot water (Buckett et al, 2007).

4.0 Discussion

The findings NOW Home® and NOW Home® Renovation projects to date raise a number of interesting discussion points about the interaction between homes and their occupants, and the effect on occupant behavior of living in a more resource efficient home than their previous experiences. Further research is being undertaken to better understand this interaction, but there are some key points which arise from the data to date.

4.1 Rebound Effects in the Waitakere NOW Home®

The Waitakere NOW Home® was occupied by an "average" income household, who, by comparison with the HEEP matched pairs for energy use and surrounding households for water use (French et al, 2006) were relatively high resource users. In the first year of occupancy, the energy and water use of the household appeared to be substantially mitigated by the features of the Waitakere NOW Home®. This was experienced by the occupants in the form of reduced energy and water bills, with substantial financial savings. Towards the end of the first year, and into the second year, substantial rebound effects occurred (Pollard et al, 2008). This was largely in the form of increased hot water and appliance use, with new appliances introduced into the dwelling. In addition occupancy of the dwelling, in the form of its use as a home office appeared to increase over time – perhaps in response to the level of comfort provided by the dwelling. While not all of the resource efficiency gains have been taken back by the occupants (which still remains, compared to their previous home, 25% more energy efficient), there has been a substantial increase in energy use in particular. The increase in water use through showering has been more than mitigated by a decrease in outdoor garden water use – perhaps reflecting the initial garden establishment process being complete.

Informal discussions with the occupants of the home indicated that they were surprised when their power bills began to increase, and when combined with rising electricity costs, in the second winter became comparable with those from their previous home. It may be that there is a threshold above which the occupants would not increase their resource usage because of affordability limits and that this, combined with the amount of physical space in the home to accommodate more appliances, may result in a tailing off of the rebound effect in subsequent years.

While monitoring data for the second year of occupancy of the Rotorua NOW Home® is not yet available, it will be interesting to compare what, if any, rebound effect occurs for this low income household with little discretionary income. Already appliance use (and therefore electricity) costs, is substantially lower than in the Waitakere NOW Home®, and overall electricity use is lower. It may be that, given the fixed income of the household, that takeback in the form of increased use of the pellet burner to gain additional comfort, ahead of appliance use, may occur. In this respect a carbon neutral heating appliance such as a pellet burner (which burns pellets made from wood waste generated in the plantation timber industry) is an ideal heating source for a low income household. Pellets are purchased in bags and the household is able to manage their heating costs on a weekly basis though how many bags they purchase.

4.2 Passive Solar Design and Thermal Mass in the Rotorua NOW Home®

The response of the Rotorua NOW Home® occupant to the concrete thermal mass floor in the home was unexpected, given that the Waitakere NOW Home® occupants valued this feature very highly. In the case of the Rotorua NOW Home®, the occupants quickly covered the floor with several rugs, adversely affecting its function. This is likely to be a contributor to colder than ideal temperatures being experienced in the home, as the thermal mass function was included in the design phase modeling the expected thermal performance of the home.

The reasons why the floor has been covered raise issues which need to be addressed if this approach is used more widely in this type of housing.

The occupants moved into the home immediately on it's completion in September 2006 – which in Rotorua is still cold and a core part of the heating season. The concrete slab had had little time to dry out, a process which could be expected to occur over the next year or so. To the new occupants it felt cold and they complained of this. In addition, one of the occupants was an elderly lady in her 90s, and the occupants expressed concern that a fall onto the floor may result in her suffering significant harm, or even broken bones. Whether or not such an occurrence is likely was immaterial to the occupants, as the perception issues drove their behavior.

Tenancy agreements do not generally include requirements around use of temporary floor coverings. If thermal mass is to be used in social housing, then it may be that other methods of incorporating high thermal mass, where occupant operation would have less influence may be preferable.

5.0 Conclusions

When considering how to move New Zealand homes towards a higher degree of sustainability, engagement of dwelling owners is a primary consideration. While the NOW Home® projects are showing the ability of features within a home to substantially mitigate against high resource using behaviours, these can easily be taken back by occupants in the form of increased services (eg hot water, heating) or through the addition of appliances.

A fundamental difference between more sustainable, and conventional housing however, is the ability of the home to be operated in an efficient and comfortable manner. Much conventional housing has no ability to be operated efficiently, without significant impacts on the comfort and health of the home. Homes such as the Beacon NOW Homes® are able to be operated with relatively low resource use, while still maintaining healthy and comfortable conditions inside.

The vast majority of homes which will be in use over the next 50 years have already been built (Amitrano, Kirk and Page 2006). Yet, the BRANZ House Condition Survey indicates that New Zealanders already under-maintain their homes (Clark et al 2005). When renovation data is considered, it is clear that much of the renovation undertaken is cosmetic in nature (Amitrano et al, 2006) and does not address the sustainability of New Zealanders' homes.

New Zealander's homes are the single largest investment that many people will make in their lifetime. They are also the place where many people spend most of their time. Yet when compared to a motor car, existing New Zealand homes have very few regulatory requirements placed upon them. A car requires a six monthly warrant of fitness and an annual registration, yet once they have achieved Code Compliance our homes do not require any kind of check, even at change of ownership or tenancy, to determine whether they are healthy, efficient or suitable for the household type who is proposing to live in them.

The Beacon NOW Home® and NOW Home® Renovation Projects aim to provide robust evidence around ways to improve the sustainability of New Zealand homes. While primarily research projects, there has been strong interest in the demonstration value of the homes – how ordinary New Zealanders can live ordinary lives but with a lesser impact on the environment, and in greater health and comfort than is currently the norm.

Acknowledgements

The monitoring of the Waitakere and Rotorua NOW Homes® and the Papakowahi NOW Home® Renovations has been undertaken by BRANZ Limited. The understanding, cooperation and assistance of the occupants of the monitored homes is gratefully acknowledged.

Summary

In order to gain access to the energy use in office buildings, the German Federal Ministry for Economy launched an intensive research and demonstration program in 1995. In advance of the 2002 EU EBPD (Energy Performance Directive) a limited Primary Energy Coefficient of 100 kWh/m² a has been postulated as a goal for the complete building services technology (HVAC + lighting) for all demonstration buildings to be supported. Another specification was to avoid active cooling measures within main parts of the buildings. Techniques like natural or mechanical night ventilation or heat removal by slab cooling with vertical ground poles were applied as well as earth-to-air heat exchangers in the ventilation system. An accompanying research was established to keep track of the results and lessons learned from 24 demonstration buildings realized and monitored until end of 2008.

As one outcome this paper summarizes the energy performance of a selection of characteristic buildings together with an overview on the summer thermal comfort situations achieved. This work will proceed during the next five years. Another result is that a higher quality of energy and comfort building performance will not necessarily cause extra building cost when the project has been planned carefully by an integrated design process. Future results and building data can be downloaded from: www.enob.info.

1. Introduction and Background

1.1 Energy Use in Office Buildings

Numerous office buildings of the eighties were designed to isolate the internal conditions from the outdoor climate as completely as possible, at the cost of high energy consumption. Thermal and visual comfort as well as the air quality is guaranteed by extensive technical building services for heating, ventilation, air-conditioning and lighting (HVACL). High investment and operating costs are accepted to ensure that it can control even extreme indoor conditions caused by generously or even totally glazed building envelopes. In combination with the space demand of wiring for communications technology - double floors, suspended ceilings - it is quite common to occupy 20 to 30 % of the building volume for technical services solely. The main share of the electricity consumption is due to the HVACL facilities and not to the office equipment.

Despite the heat generation associated with electricity consumption within the building (internal heat gains), the space heating demand in Mid and North European Climates is still dominating the overall energy figure due to the high proportion of glazing and the high air exchange rates. Fig. 1a gives a qualitative impression of a typical energy consumption profile as a function of the outdoor temperature, the so called ET- diagram. In addition to a base energy load which is independent of the weather, there is a contribution for heating and humidifying below the balance temperature, and for cooling and dehumidifying above it. The balance temperature is defined by the outdoor temperature at which thermal losses are balanced by the internal and solar gains. The base load is mainly caused by office equipment and the idling consumption of building services technology. The waste heat associated with the base load affects the position of the balance temperature. The higher the base load, the lower is the balance temperature. Due to the decoupling of the room air from the building mass - suspended ceilings, double floors, lightweight walls - and the maintenance of constant indoor conditions throughout the whole year, there are hardly any days when there is neither active heating nor cooling demand.

1.2 Thermal Comfort and Health

The diverse technical approaches to achieve a good indoor climate were often accompanied by complaints from office workers about many types of discomfort and dissatisfaction, which are summarised as the "Sick Building Syndrome". One German investigation of this phenomenon, the so-called "ProClima-Project" (Bischoff, 2003), reaches the conclusion that although buildings with air conditioning maintain an objectively good indoor climate, they are subjectively rated lower than naturally ventilated working conditions by the majority of persons questioned. The rating is significantly affected by

- the magnitude which an individual person can determine the prevailing conditions at his workplace and

- the degree of maintenance of the technical service systems

Today an increasing fraction of office buildings are being constructed or retrofitted which allow individuals to control their own indoor climate to a large extent, and which replace almost complete isolation from the weather outdoors by moderate interaction. Daylit workplaces and the option for natural ventilation are typical characteristics. However, a combination of integrated measures to achieve so-called "passive cooling" is a pre-requisite if summer comfort is to be ensured without actively cooling or dehumidifying the inlet air. This type of concept became known as "lean building", due to the smaller volume of the service equipment required. The task is to design buildings in such a way that even if outdoor weather conditions vary greatly, the indoor conditions remain within a well-defined comfort zone, which fit the occupant's needs, Fig. 1b. The comfort zone is exceeded only for periods of extreme outdoor temperatures. The maximum acceptable number of working hours with temperatures above the comfort zone has to be discussed based on simulation results in the early design phase of a building and checked against legal standards.

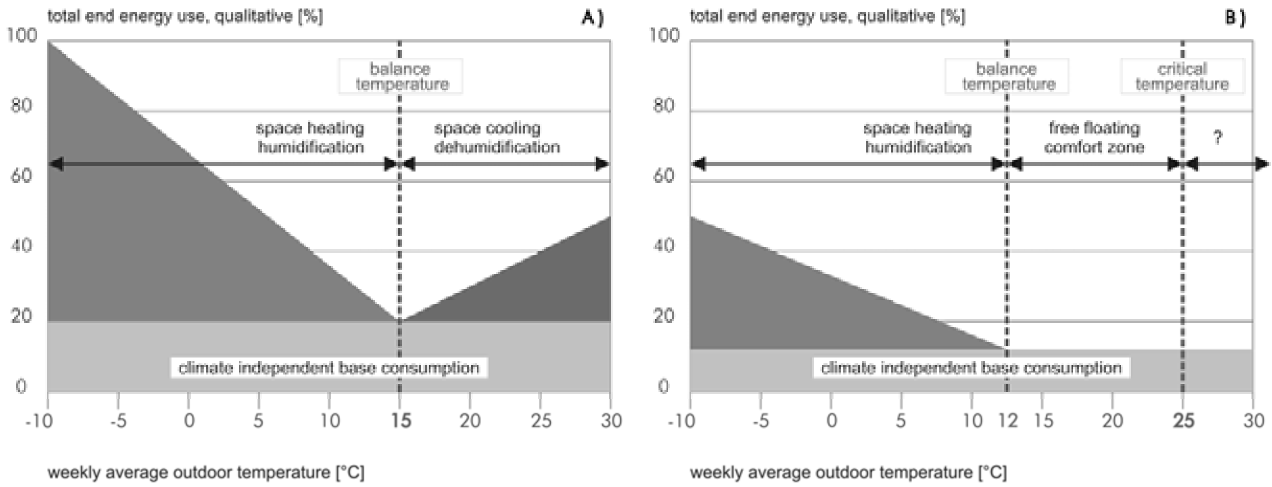

Figure 1 Qualitative profile of the energy consumption of a "conventional building" (A) compared to a "lean building" (B), the so-called ET-diagram.

2. Results and Experiences

2.1 Energy Monitoring

Table 2 gives an overview of the monitored projects and the applied passive cooling concepts. Detailed information together with a comprehensive overview on results and experiences are presented in (Voss et al., 2005). Additional information is available via internet (www.enob.info).

Data are presented for end and primary energy use respectively, taking into account the energy conversion factors for the specific conditions of Germany as given with a national standard (DIN 4701-10, 2001). Using the primary energy factor concept allows the comparison of the building's energy consumption and to rate the energy supply in terms CO_2 emissions.

Figure 2 summarises the monitoring results from buildings for which data from at least one year is available. We have chosen to present the information as a graph rather than numerically, as the boundary from HVACL to user-specific electricity consumption (PC, printers etc.) was difficult to define in some cases. This could cause quantitative but not qualitative changes to the results. Particularly for separating the electricity use for the type of energy service (e.g. electricity for lighting and for computer operation) requires a very detailed and expensive metering concept. It is not common to allocate the electric circuits within a building according to the equipment connected to them. In many cases, detailed analysis of the electricity consumption helped to identify weaknesses in system operation and aid their correction.

In order to separate the effects of reduced energy use and energy efficient energy supply, in case of CHP and photovoltaic to the primary energy balance were shown separately.

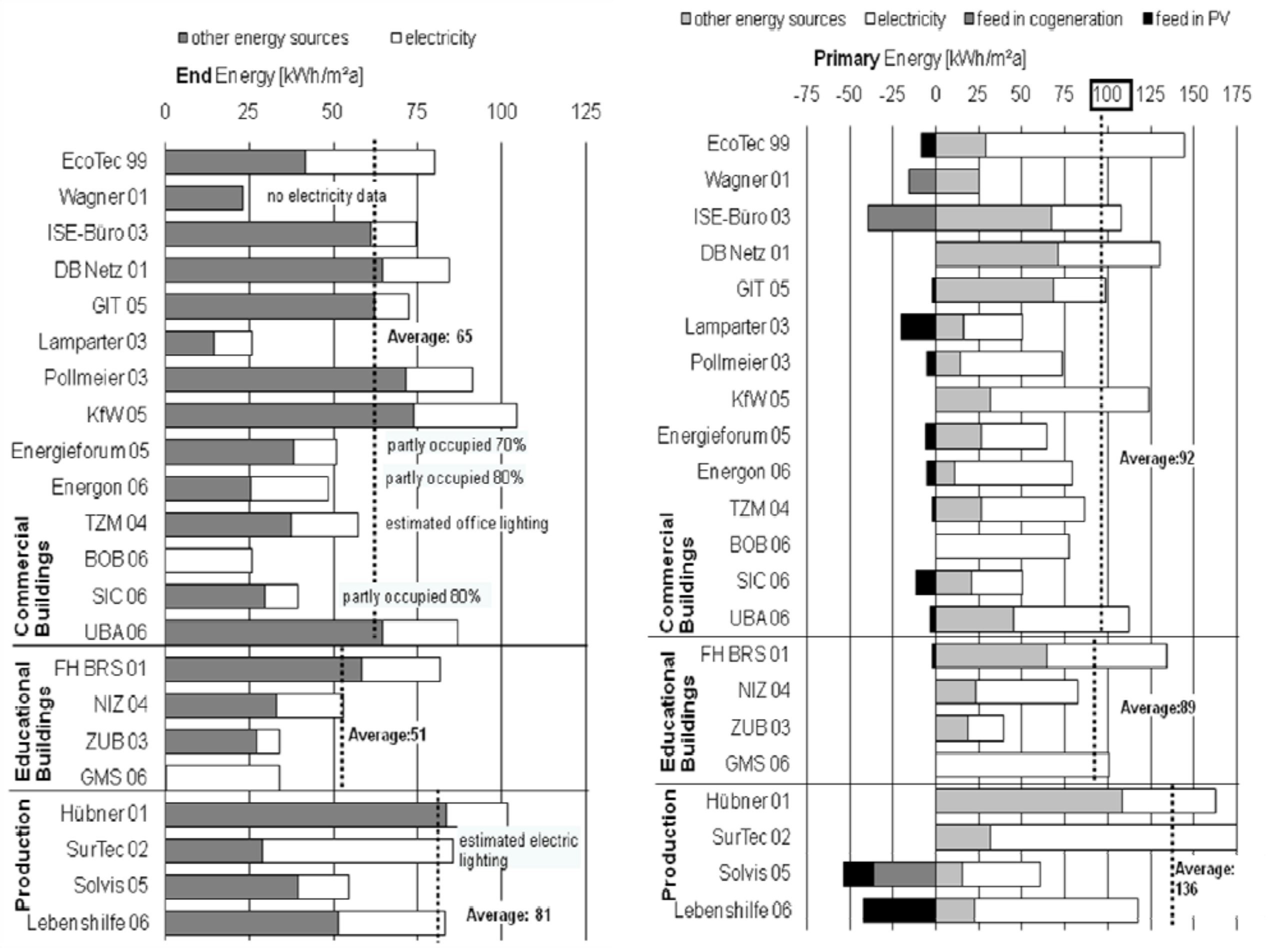

Figure 2 *Measured end energy (left diagram) and primary energy coefficients derived from them (right diagram). All data refer to the heated net floor area. Data are collected from the monitoring institutions according to tab. 1. The primary energy factors and electricity credits are based on German DIN 4701 (DIN 4710, 2001): Electricity 3, fossil fuels 1.1, biomass 0.2. To simplify the balancing procedure, photovoltaic electricity (PV) was evaluated with the same electricity credit as for combined heat and power plants (CHP). The consumption values refer to HVACL. The numbers following the project titles indicate the year for the measurements. The data source in each case was the university which was responsible for the measurement program. In the case of the "ISE-Büro" building, a zone of 525 m² consisting purely of offices plus the adjoining access areas was selected from the Institute building with a total area of 14,000 m². Aside from the Hübner building the so called production buildings have a mixed use of office and workshop or pharmaceutical production.*

Nine out of the 14 office and educational buildings show primary energy consumption below or close to the required limit of 100 kWh/m²a, five buildings range above this limit. As the end energy use for HVACL in production buildings (workshops, factories) strongly depends on the requirements regarding indoor air quality and internal loads strongly depend on the production process, a fixed primary energy target of 100 was achieved by two of the four evaluated production buildings. It is satisfying to see that the consumption of each building is much lower than the comparative values for the building stock according to Fig.3.

Individual design and target values are only available for some of the buildings, as no common methodology for calculation of the energy demand for cooling, ventilation and lighting was used. Heating energy demand was calculated based on the national standard (DIN 4108-6, 1994). Building simulations were performed for most of the buildings. Therefore comparisons with target values are valid only for the same building.

The limit for primary energy use was exceeded in some cases caused by unexpected high heating demands (DB, GIT), high electricity consumption for lighting (FH BRS, Hübner), etc. Some of the causes are due to the building concepts; others could have been avoided by an improved energy management. The Pollmeier building avoided high consumption values for primary energy, despite unexpectedly high heating energy consumption by burning wood off-cuts from its own sawmill, representing a largely CO_2-neutral source. Combined heat and power plants result in a primary energy credit (Wagner, ISE, Solvis), as the measured gas consumption also contributes to electricity generation and thus to substitution of grid electricity. Drawing heat from a district heating network with CHP also proved to be favourable (ECOTEC, ZUB).

	building stock		energy efficient	
lighting	25	75	10	30
cooling	11	30	0	0
ventilation	13	40	10	30
heating	125	140	40	40

Figure 3 Target values for energy efficient office buildings according to the program compared to end energy use values for office buildings from the existing stock in Mid European climate according to (Weber 2002). The net heated floor area is used as the reference area. End energy was transferred to primary energy by a factor of 3 in the case of electricity and about 1 for all other forms of end energy in order to compare it with typical German situation.

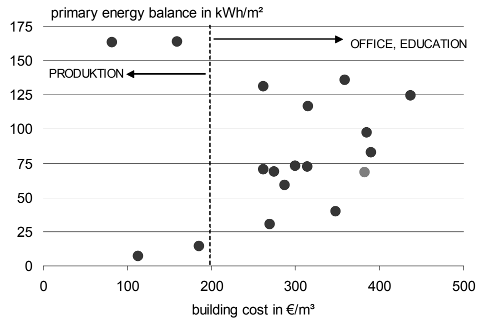

Figure 4 Primary energy use versus building cost. The primary energy use is more or less independent from the cost for construction and HVAC equipment.

Aside from energy saving and thermal use of renewable energy, some of the buildings apply measures such as combined heat and power plants (co-generation) or photovoltaics to produce electricity to feed into the public grid. This energy subsidies grid electricity to be generated on national average conditions with a mixture of power plants. In case of so called "zero energy buildings" primary energy credits for the subsidies grid electricity balance the buildings primary energy consumption on a yearly cycle. Three projects (Wagner, Lamparter and Solvis) enter the range of a "zero energy building" by the combined approach of minimized consumption and more or less equivalent credits (Fig. 5).

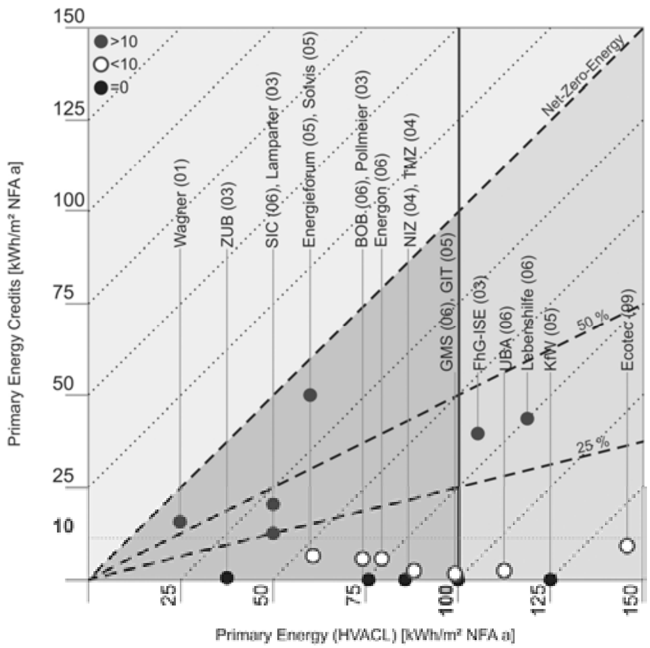

Figure 5 Primary energy consumption versus primary energy credits (from PV or CHP). Dotted lines show buildings of the same primary energy balance. Note: The primary energy consumption of Wagner building does not include electricity for HVACL.

2.2 Technologies Used by the Demonstration Buildings

The combinations of technologies to achieve energy efficiency depend on individual energy goals, specifications of local conditions and building type, use and location. The four tops used in the projects include Heat Recovery, Passive Cooling, Building Automation and Daylighting as illustrated in Fig. 6.

Figure 6 Overview of 19 strategies and technologies used in the demonstration buildings of EnOB.

2.3 Passive Cooling and Summer Comfort

In order to improve indoor conditions in summer, so-called "passive cooling" concepts were an integrated part of each building design in different ways and to a varying extent. Passive cooling means the interaction of all measures which act to reduce the heat gains on the one hand, and on the other, which make natural heat sinks such as night air and ground accessible. So in this paper "passive cooling" includes techniques, which are not using a thermodynamic cycle process. The remaining heat loads are transferred to the surroundings with a certain time delay. Heat storage in the building construction, both during the course of a day and over longer hot periods, is substantial.

In view of the limited cooling capacity and the long time constants, the main design priority is to restrict the amplitude and dynamics of external heat gains. Thus, none of the buildings provides an entirely glazed façade. The average ratio of glazing to opaque area was 43 % or 27 % related to floor area. Almost all of the buildings use external adjustable solar shading except buildings with slab cooling systems (enhanced cooling capacity). Experiences show that the total solar energy transmittance (g_{tot}-value) for glazing and sun-shading should not exceed 10-15% (Zimmermann 1999). This can be achieved for internal blinds or blinds in the gap between the glass panes only in combination with solar control glazing (g_{glass}<40%), or by external blinds and standard heat protection glazing. A detailed analysis regarding manual blind use in two buildings (ISE, Lamparter) shows a strong correlation between solar penetration depth and blind occlusion (Reinhart 2002, Herkel 2005). External loads in these cases range in the order of internal loads (Pfafferott 2005). The average daily total internal heat gains observed range between 100 and 200 Wh/m². The range refers to the density of occupation, the operation mode of the computer systems and the lighting concepts, Tab. 1.

Most of the projects realized in an early period of the funding program applied night ventilation combined with earth-to-air heat exchangers to remove excess heat in summer; several of the recent projects applied slab cooling in concert with vertical ground ducts or ground pillars due to the increased cooling capacity. For mechanical and hybrid night ventilation COPs between 4.5 and 14 have been monitored which are higher than those of conventional cooling but also show the need for quality assurance during the design phase and in building commissioning. The evaluated earth-to-air heat exchangers achieved COPs between 20 and 280.

Within the framework of EnBau:MONITOR the passive cooling concepts were evaluated regarding to the achieved thermal comfort. Thus, standardized graphs had been provided as part of the accompanying research in order to allow the comparison of results on summer indoor conditions between different projects. Figure 7 illustrates the results using annual cumulative frequency distributions for the indoor air temperature. If the upper limit of 25°C according to DIN 1946-2, old edition, is taken as a reference, the buildings demonstrate that the frequency of higher temperatures can be kept below 10% of the usual working hours with suitable passive cooling measures of building design strategies.

Nevertheless this consideration does not indicate whether an acceptable thermal comfort was achieved in the buildings or not. The main disadvantage of a cumulative frequency distribution analysis for thermal comfort is the information loss on the correlation between indoor and real time outdoor temperatures monitored. Four different comfort criteria, ISO 7730 according to Fanger, the proposal for the European standard prEN15251, the former DIN 1946 and the new Dutch NPR-CR 1752 have been used to analyze comparative building comfort performances. For detailed discussion on these criteria see (Pfafferott 2006).

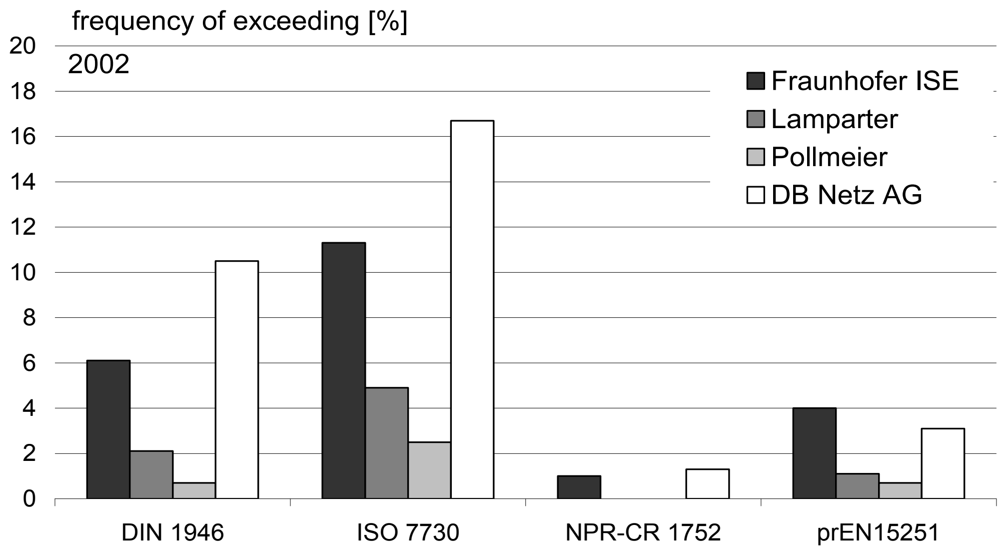

Fig. 7 *Comfort analysis on four buildings in 2002. Each building is not only performing differently for the four used comfort criteria: It is a basic assumption, that the criteria should qualitatively yield the same conclusion: If a building is better than another in criterion A, it is also better in criteria B, C and D. Nevertheless, the comfort criteria can give different quantitative numbers for comfort, since the criteria are based on different studies, databases and assumptions: Criterion A can be exceeded by 5% while criterion B is only exceeded by 2% of all working hours.*

3. Discussion and Conclusions

The results of the monitored buildings show, that the energy consumption of new office buildings can be reduced by 50% compared to the building stock without enhancing building construction costs compared to the average. The limitation of a primary energy consumption of 100 kWh/m²a and even lower is possible.

Future building concepts will focus on the goal of achieving zero energy demand on an annual base, first buildings within the program EnOB already showed the possibility of such concepts combining a low energy demand with a renewable energy supply.

The results of the passively cooled low-energy office buildings provide a high thermal comfort even without mechanical cooling or air-conditioning, when the heat dissipation in summer is enhanced by e.g. thermally activated building components or night ventilation. The evaluation of passively cooled office buildings demonstrates that during a commonly hot summer such as 2003 prevalent criteria for thermal comfort in naturally ventilated buildings (i.e. prEN 15251) are exceeded for less than 5% of the building operation time – considering realistic user behavior.

4. Acknowledgements

The authors sincerely thank the team members of all the demonstration projects for their valuable co-operation and specially the provision of monitoring data. The accompanying research project was funded by the German Federal Ministry for Economics and Technology, BMWi, reference code 033O.

Fig. 8

Consideration of Construction Cost. The demonstration projects have lined up with the purpose to achieve long term energy-savings and cost-effectiveness during building operation. They also show that high performance buildings can be realized to normal market conditions. Finally it is important that there is a balance between architectural quality and comfort, the "right" cost-consciousness of builder-owners and a certain flexibility in dealing with the costs during building design phase and construction (cost shifting).

[2] Landscape Design, SWA Group, Los Angeles, CA, United States

Keywords: Global thinking, Local knowledge, Globalization, Localization, Sustainable Development, Technology transfer

Summary

This paper postulates that design practitioners have much to gain from learning to apply *global thinking* on sustainability, and from bringing the benefits of cultural exchange and *local knowledge*, to international projects. Global thinking and local knowledge can be seen as unifying elements which have the potential to reconcile the two, often incongruous, processes of globalization and localization. Co-optimizing these two approaches can be challenging however; the limited interactions, cultural differences and financial pressures of modern international design projects stretch the ability of design teams to capture these opportunities. This paper proposes a series of strategies for international designers who aim to transcend these barriers. These strategies are illustrated through the contextualization of international projects within broader economic and social movements, through a summary of the benefits and barriers to the application of progressive approaches, and through a series of case studies that highlight the challenges and opportunities of seeking to unify global thinking and local knowledge.

1. Missed opportunities in international design projects

International architectural and design projects have been common for hundreds of years, but never at the scale, speed and frequency of today. There is a clear trend in the development of an international marketplace, whereby architects and engineers, often based in leading economies, or working for multinational corporations, apply their expertise on projects in countries and regions at different stages of development.

The plethora of international collaboration, and the accompanying confluence of worldviews, result in clear benefits for the application of international construction standards and the transfer of technologies, but often miss a host of opportunities. This paper concentrates on two key ‘missed opportunities’: firstly, the chance to put new technological and conceptual tools into use by applying progressive *global thinking* on sustainable development; and secondly, the essential value of *local knowledge* on architecture, climate and culture, for application in both project-specific and broader international contexts.

1.1 Global thinking and local knowledge: a reconciliation of globalization and localization?

The range of different architectural styles used in international projects is a testament to the globalization of the marketplace. Beneath this diversity often lies a tension between cultural forces where global trends clash with local identity and environmental protection is undervalued. Where *local* or *other* knowledge is not considered complementary by incoming international designers, the result has often been the devaluation and engulfment of local knowledge by dominant, sometimes unsustainable, global trends (Satler, 1999).

It is also evident that some international projects have been successful in integrating different cultures and global trends to create both new regional cultures and projects which are coherent with their physical environment (Liangyong, 2000). The processes of globalization and localization in international design projects should be understood as interlinked and inseparable, even if they sometime seem at odds; denying the existence of one in the design process can only have negative effects on the project in question (Liangyong, 2000; Mahgoub, 2003).

Sustainable development - the direction of progressive global thinking - has to be linked to, and guided by, ecological and human social systems, hitherto inherently local in nature. The sustainability challenge tackled in this paper is then the integration and harnessing of global thinking and local knowledge, and the development of an alternative understanding of what international design can be; as seen by Satler (1999) (through the eyes of Frank Lloyd Wright), “one that understands the essential need to preserve and respect diversity, as well as house seemingly disparate philosophies of space, people, and their interactions within the built form”.

1.2 The value of local knowledge

Investors and governments in growing economies, working on projects of national political significance, often look to established international design firms for their status and reputation. These multinational companies can offer unparalleled depth and breadth of expertise, and have access to the nucleus of scientific and technological knowledge. However, these companies may not have specific contextual experience in the countries or local areas in question, and critically may not recognize the value of engaging with local knowledge.

Knowledge of local and traditional construction practices is a pre-requisite in designing architecturally, environmentally and culturally appropriate buildings. Vernacular architecture can inform sustainability thinking in the careful consideration of a building's relationship with its inhabitants, and in providing integrated solutions of climatic problems that optimize physical and social functionality (Liangyong, 2000; Oliver, 2003). These lessons may be applicable both in the project in question, and in other contexts: regions with similar climates and natural resource availabilities, areas where traditional approaches have been lost with time, or projects where a radical conceptual rethink is required. More fundamentally, local knowledge can prevent critical design flaws and help ensure that solutions will be owned and managed successfully by project stakeholders.

1.4 Barriers to the integration of global thinking and local knowledge

Applying the principles and philosophies of local cultures, alongside the values, attitudes, and techniques familiar to the international designer, is a significant challenge for the individual; efforts to take on this challenge are also often stymied by economic factors and client priorities that leave no space or time for 'ancillary' considerations. A key factor in high-profile projects, which tend to attract international collaboration, is that clients often aspire to modes of construction considered to represent modernity, whose performance may be environmentally poor e.g. the 'glass box'. The analysis of the appropriateness of the solution is lost underneath the desire to implement what is seen to signify 'development' (Du Plessis, 2001). 'Symbols of modernity' - SUVs, skyscrapers and sprawling suburbia - become the only perceived routes to modernization (Abel, 1994; Liangyong, 2000).

The needs and priorities of incoming designers, local architects and project stakeholders are often not well-aligned, even when a common commitment to 'sustainability' exists. Indeed, there is often a starkly different emphasis within sustainable development approaches between countries; Guthrie (2006) distinguishes between a 'developed world' agenda where the primary focus is on the *sustainable* and a 'developing world' agenda where the primary focus is on the *development*. It follows that stakeholder engagement and public participation in scheme development is essential to identify contextual factors and local preferences that should influence project design and guide technology transfer (WCED, 1987).

Where local knowledge is concerned, incoming designers have historically taken extreme positions on its importance in project development: alternately as a scapegoat for underdevelopment in opposition to modern knowledge, and as a panacea for sustainability (Nydrgren, 1999). It is neither; while engagement and empowerment of local knowledge should, at its best, result in entirely new architectural, ecological or even psychological perspectives for incoming designers, these will necessarily be contextualized by the designer's own life, culture and training, and by the ongoing process of globalization.

A summary of benefits related to the application of global thinking and local knowledge, and barriers to their successful incorporation, are summarized in Table 1.

Table 1 Benefits of the application of global thinking and local knowledge and barriers to achieving them

Opportunity	Benefit	Barriers
Application of progressive **global thinking**	• Displacement of unsustainable development models • Transfer of new environmental technologies and approaches • Education and long-term technology transfer • Appropriate buildings through integration of local knowledge	• Vision of modernity often based on unsustainable practice (SUV, glass towers) • Proposed sustainability model not aligned with local needs and priorities • Economic structure not conducive to long term commitment inherent to sustainability • Lack of capacity in developing world to assimilate technologies/concepts • Lack of focus on long-term operability and maintenance of projects • 'We know best' attitude of incoming consultants

Application and export of **local knowledge**	• Transfer of relevant low-tech climate control features • District and on-site solutions as alternatives to 'end of pipe' technological fixes • Re-invigoration of traditional materials and construction techniques • Introduction of a holistic approach to materials and resources	• Lack of awareness/interest of consultants or clients as to value of local knowledge • Inability of incoming designers to step out of their frame of reference • Collecting/accessing/distinguishing local knowledge • Pace of modern architectural design schedule not conducive to local studies • Lack of common graphic or technical language to allow for inter-disciplinary studies • Ability of traditional techniques to demonstrate/satisfy stringent international comfort or structural standards

1.3 The role of technology transfer

The environment is one of the major areas where technological transfer and global thinking can make a significant difference to the development path of emerging economies. Concurrently, interest in the wider dissemination of traditional and situated knowledge, in areas such as passive climate control or earthen construction, continues to grow.

There is a tendency to present technology transfer in a unidirectional manner, but the real interaction between technology exchange and situated knowledge is far more complex. For example, various forms of composting technologies for human sanitation have been used successfully in many regions across millennia. Recent analysis of the transfer of 'eco-sanitation' technologies has tracked these ancient ideas from Vietnam, to Sweden and the U.S., and back again to Vietnam, with incremental benefits at each stage (Esry et al, 1998).

Applying global knowledge and local thinking means identifying technologies from a wide spectrum that provide responses to local conditions; technology transfers that meet local needs and priorities are far more likely to be successful (Metz, 2000). We know that the imposition of technologies, concepts and scientific knowledge without the engagement and support of a broad range of local stakeholders will result in failed projects (Clark and Murdoch, 1997). For example, the introduction of high-rise buildings in urban areas of India, without proper attention to the cultural shift this represents, and without due regard to incorporation of unfamiliar maintenance regimes, has resulted in buildings falling rapidly into disrepair (Joshi, 2008). Sustainability thinking, which considers the broader appropriateness of solutions, is a good framework to ensure that the right technologies and concepts from global thinking respond to project–specific requirements.

2.0 Strategies for applying global thinking and local knowledge

It is straightforward to highlight the barriers to the application of global thinking and local knowledge; the next step is to try to develop strategies to overcome them. Understanding which motivations and worldviews are prevalent in projects, and how they are shaping developments, allows us to think about behavioral changes that would make this possible. This section outlines and develops some potential strategies for achieving this.

2.1 Specific barriers, targeted strategies

The strategies summarized in Table 3 represent potential approaches for overcoming the types of barriers introduced in Section 1.3. Strategies highlighted in bold are explored further in Section 2.2.

Table 3 Potential strategies for incoming designers

Opportunity	Barriers	Potential Strategies for Incoming Designers
Application of progressive **global thinking** on sustainability	Vision of modernity based on unsustainable practice	• Showcase high-profile LEED subscribers to clients/investors • **Showcase culturally consistent, world-class buildings to clients/investors (2.2.1)**
	'Sustainability' considered ulterior to local needs and priorities	• Stakeholder engagement and participation in design process • **Development of clear, widely agreed, definitions of sustainability and a means of measurement (2.2.2)**

	Lack of local capacity to assimilate technologies/concepts	• Build-in educational components to collaborative design teams • Run public information sessions • **Find a direct application/or a design metaphor (2.2.3)**
	High cost of environmental technologies	• Investigate international subsidies/trading schemes • Wider assessment of benefits • Focus on low cost, low tech design solutions
	Lack of focus on long-term operability and maintenance	• Build maintenance and operability training and post-occupancy evaluation into scope
	Clients don't recognize value of incorporating local knowledge	• Highlight marketing/community/political value in local stakeholder engagement
Application of **local knowledge**	Lack of awareness/open-mindedness of incoming designers	• Request (or require) multi-week study period in local area in scope and fee proposal
	Lack of time in the design process	• Demonstrate economic value of low-energy designs
	Lack of access to demonstrable technologies and concepts	• **Hire a local architectural historian/professor/anthropologist (2.2.4)**
	Ability of traditional techniques to satisfy stringent comfort or structural demands	• Use of pilot projects before scaling-up

2.2 Further Exploration of Potential Strategies

Four of the key strategies highlighted in Table 3 are elaborated upon as follows:

2.2.1 A new vision of world-class: Showcase green, culturally consistent, world-class buildings to clients/investors

Some projects may be diverted from developing environmentally and socially sustainable solutions by client fixation on a certain type of development. If designers wish to facilitate environmentally sustainable projects, they have a role to play in promoting more sustainable solutions by convincing clients of their financial viability and wider value. Increasingly, high-profile mainstream buildings have looked to improve and promote their environmental performance through the introduction of 'green building' techniques and assessment methodologies such as LEED. It is part of the role of the designer to capitalize on momentum towards greener construction to support a new paradigm of modernity: desirable, 'green' buildings.

2.2.2 Integrating Sustainability: Development of clear, widely agreed, definitions and a means of measurement

If the 'sustainability vision', as understood by the incoming designer, is not shared by others - the client, investors, local consultants or directly affected stakeholders - it will be very difficult to implement sustainability objectives. Bartlett and Guthrie (2005) state that: "for sustainability to be successfully taken into account in building projects there must be an appropriate culture, clear definitions, means of measurement and the use of tools". Creating an appropriate culture is challenging and time-consuming, but progress can be made if commitment to a shared sustainability vision is established from the start. A transparent and open process of engagement with all parties will facilitate an appreciation of local needs and priorities, and pave the way for defining context-specific objectives, that are understood and valued across the board. If definitions and priorities are widely accepted, then targets and indicators can be attached to objectives to provide a means of measurement.

4.2.3 Communicating New Concepts: direct applications, design metaphors

Designers may need to adapt their communication techniques when working on international projects. Technology or knowledge transfer, without effective dialogue, can become an imposition, and hence a potential failure. While enthusiasm for the proven benefits of technologies and concepts on one side can force ideas through, this does not necessarily mean that they will be well understood or received by others. It is the responsibility of the team members introducing new ideas to communicate these benefits to those whose understanding and acceptance is crucial to the success of the project. If ideas represent a departure from the conventional approach, a first step would be to look for historical precedents in the area that might provide context and visualization.

4.2.4 Accessing Local Knowledge: spend time in places, spend time with people

Local knowledge can be important in both realizing immediate project success, and in capturing ideas that have exportable relevance. Design teams that recognize the importance of local knowledge could request and justify in their scope a significant study period in the local area. The value of local knowledge increases when understanding goes beyond local building techniques, to an appreciation of current and traditional modes of interaction with buildings. Culturally specific ideas of functionality may not be immediately apparent to incoming designers. Contributions from participants who are personally, rather than professionally, connected with the spaces and areas in question can be particularly valuable. Beyond professional interactions, simply spending time with local people who have an appreciation of social, political, commercial and anthropological factors can help foster a deep understanding of local conditions that can in turn inform design. One strategy could see the use of junior staff on study periods, or intense periods of engagement in the area in question, as conduits for incorporating that knowledge into the design process.

3.0 Case Studies – Successful application of global thinking and local knowledge?

In our work we often come across different combinations of the barriers and challenges outlined in this paper. In some instances we have been successful in overcoming these challenges, sometimes through strategy, sometimes through luck; in others, constraints of time and money have stymied our efforts. Four specific examples, detailed below, demonstrate aspects of the application of global thinking and local knowledge; each example elaborates on previously highlighted opportunities, barriers and strategies.

3.1. Lutsch Redevelopment, Moscow – Creating a new vision of world-class

Opportunity: Transfer of new environmental approaches
Barrier: Clients vision of modernity not linked to sustainable practice
Strategy: Showcase of high-profile LEED-accredited projects and associated business value

Project Background

The Lutsch project consisted of the redevelopment of a former light bulb factory in Moscow into an office complex with associated retail, parking and external landscape space. The developer was a sizeable Russian company, looking at the time to break into the international market. The developer put together an international design team on which Buro Happold was a key member supplying MEP, Structures and Sustainability services. Originally, there were no particular 'green' aspirations for the development and a marked lack of knowledge and interest in green building assessment on the part of the developer.

Technological/Conceptual Approach

Buro Happold recognized the potential to introduce LEED assessment as a means to drive improved environmental performance and to market the development. Knowledge of the value of LEED and other green building assessments was well established in BH at a senior level across the company. BH hence utilized senior managers to advocate LEED as a means to establish the developer as an international player and to provide a competitive edge over contenders in the international marketplace. Developments and developers who had adopted LEED were showcased and the types of tenants they were attracting highlighted. The developer was convinced by the business case supplied for the marketing opportunity represented by pursuing LEED accreditation.

Outcomes

LEED Core and Shell is currently being pursued and a marketing program was develed to make a statement about the progressive nature of the development. As a result the developer has subsequently changed construction practices in other parts of their business towards a greener performance.

The adoption of LEED represents in this case the successful meshing of client priorities with an international SD-directed assessment approach. The challenge was to understand the developers concerns, values and objectives and interpret them in a sustainability framework. The experience reinforced the understanding that sustainability in its broadest sense can often make for a good business case even when the client is focused only on a single bottom line. It was also a reminder of the influence that personnel with understanding and appreciation of sustainability issues can have on project partners.

3.2 Infrastructure Improvements, Tedrum, Tibet – Building on local practices and precedents

Opportunity: Appropriate development through integration of local knowledge
Barrier: Local suitability of imported design solutions
Strategy: Engagement with community knowledge and local construction experts

Project Background

In August of 2003, a collaboration of design professionals from the San Francisco Bay Area was hired by a Non Governmental Organization to consider planning and design for a 4,000 acre parcel of land in the Tedrum Valley of Tibet. The program sought to upgrade infrastructure while easing the way for eco-tourism in one of the twelve most sacred sites in Tibet. The identification of environmental technologies that responded and resonated with local practices with the added benefits of modern innovations was prioritized.

Technological/Conceptual Approach

Solutions were required to “tread lightly” in order to maintain the pristine natural environment, making decentralized waste recycling a preferred solution. Proposals for human waste-recycling systems in areas where there is no precedent for this type of sanitation system often encounter serious issues (Esry et al, 1998). Engagement with community members, local experts and ‘barefoot’ engineers was key to identifying this opportunity identified local precedents for these types of systems. Systems that were proposed utilized traditional concepts (such as human waste recycling) but with modern technological innovations to improve system efficiencies.

Outcomes

The passive systems that were proposed were widely accepted by the community and its leaders. Success of the project was determined by the group’s prior identification of the importance of integrating local practices and their willingness and ability to spend time engaging with and incorporating these practices into design outcomes.

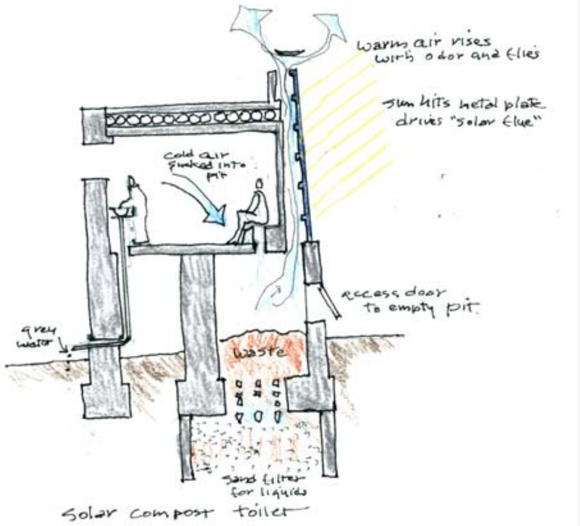

Figure 3 *Drawing for Proposed Solar Composting Toilet Systems Source: The Mountain Institute Peak Enterprise Program*

3.3 Passive Cooling Stacks in Las Vegas – Low-tech technology transfer

Opportunity: Transfer of low-tech passive cooling systems
Barrier: Quantifying/comparing performance of low-tech designs
Strategy: Demonstration of the economic and aesthetic value of low-energy designs through additional study

Project Background

BH have been involved in inputting sustainability concepts into proposals for a new hotel and casino complex in Las Vegas. BH were able to draw on their significant experience on projects in the Middle East to propose passive cooling stacks as functional and aesthetic elements of the architectural design. Natural draft cooling towers were proposed for the Las Vegas project, to provide localized comfort for cafes and park areas, although for architectural reasons were ultimately not included in the final design.

Technological/Conceptual Approach

Passive Ventilation Stacks have been observed through experience on BH projects in the Middle East; climate analysis for Las Vegas showed suitable conditions for the application of similar technologies. Research and case studies were completed to demonstrate the economic and aesthetic value of low-energy designs.

Outcomes

Despite not being integrated into the design the experience of proposing these systems highlighted another key barrier of comparing low-tech designs with other methods of thermal comfort like trees or other shading techniques. The project underlined the importance of quantifiable comparability when applying 'traditional' technologies in other innovative contexts.

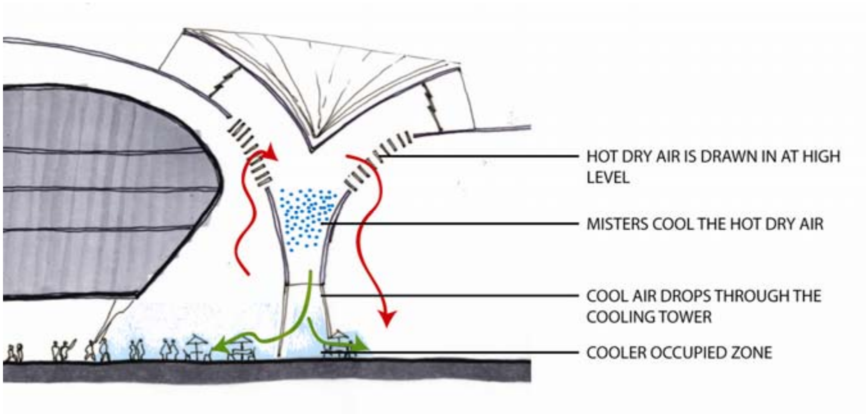

Figure 5 Passive ventilation system proposed for Vegas project. Source: Buro Happold

3.4 Decentralized Wastewater Treatment, Hyderabad, India – Closed loop systems

Opportunity: District and on-site solutions as alternatives to 'end of pipe' systems
Barrier: Access to local technical knowledge of design of biological wastewater treatment systems.
Strategy: Multi-week study period looking at decentralized technologies in the area

Project Background

BH have invested personnel time in visiting projects in India to better understand local approaches with a view to development of future projects in the area. This led to recognition of the need to develop expertise in the application of Decentralized Wastewater Systems (DEWATs), particularly constructed wetlands. After investing time in development this strategic capability, BH was then able to propose and design a DEWAT system at a masterplanning level on a mixed-use development project in Hyderabad.

Technological/Conceptual Approach

Decentralized or on-site systems are individual, multiple-household or small community systems that collect and treat wastewater at or near the point of generation. Decentralized systems can represent better value than conventional systems in situations where infrastructure is created from scratch, reducing both costs of infrastructure and environmental impacts. In India, they are becoming more widely used and understood. In proposing these systems in Hyderabad, these economic and environmental sustainability benefits were highlighted by BH.

Outcomes

BH have subsequently proposed DEWAT systems in a number of projects in India and further afield. Development of knowledge in this area was due to the investment of time into exploring local and innovative approaches. BH has subsequently formally recognized the added-value of local engagement by building time for cultural exchange into new projects, and the importance of looking beyond conventional 'end-of-pipe' infrastructure solutions.

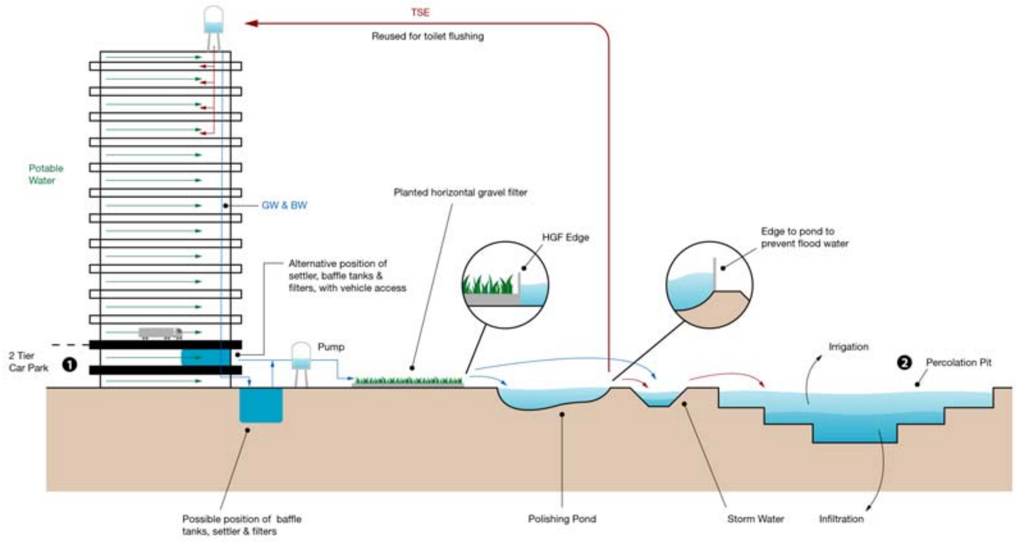

Figure 5 System Diagram for Hyderabad project. Source: Buro Happold

5.0 CONCLUDING REMARKS

A clear message from the case studies introduced in this paper is that assimilating the two areas of global and local expertise can contribute to sustainable development and should be an axiom of international design projects. Applying the concepts of global thinking and local knowledge outlined in this paper is very challenging giving the temporal, financial and communication constraints prevalent in modern international design projects. The approaches and strategies proposed in this paper are designed to inspire and enable architects and engineers who appreciate the untapped potential in international design projects and who want to find ways to add further value. A key lesson is that thinking along distinct developed-developing, modern-traditional, global-local lines, may not always be an appropriate conceptual approach when trying to co-optimize many variables. Optimizing benefits for all parties entails: understanding the motivations and worldviews that shape projects; correctly accessing and assessing local conditions; and subsequently selecting and developing tools and strategies to modify trajectories towards more sustainable development.

[2] Enermodal Engineering Ltd., Calgary, Canada, ctwohig@enermodal.com

Keywords: renovation, office, sustainable, LEED, energy, Canada, replicable, carbon

Summary

This paper assesses the urban-wide potential of a range of sustainable office refurbishment measures that have been implemented and evaluated in a case study exercise.

The office refurbishment project analyzed in this paper is Canada's first LEED Canada-CI (commercial interiors) project and has achieved Platinum certification as a result of the many sustainable design features included: Enermodal Engineering Ltd.'s Calgary office, completed in 2007. The range of measures implemented and evaluated in this paper include

- enhanced lighting design,
- recycling facilities,
- efficient office equipment and appliances,
- low-emitting fixtures and fittings,
- sustainable transport incentives,
- low embodied energy materials,
- occupant comfort control,
- water efficient fixtures and fittings,
- layout for daylight and views, and
- energy management and monitoring.

This paper evaluates the effectiveness of each of the measures that were implemented, and appraises the potential for replication across a large urban area (the municipality of Calgary population approx 1 million). It concludes that there is a great potential for carbon and water savings, increased occupant health and well-being, and for a small incremental cost. It also comments on the potential overall contribution to sustainability of each of the measures, evaluated against a range of sustainability metrics including potential energy/carbon and water savings, capital costs, materials and waste reduction, and social and health impacts, ease of implementation and replicability. It was found that the measures having the highest contribution to sustainability in the case study analyzed were: enhanced lighting design, use of recycling facilities, efficient equipment and appliances, low-emitting fixtures and fittings, and sustainable transport incentives.

1. Introduction

1.1 Office Refurbishment Case Study

This case study is based on the renovation of a 100 m^2 office space carried out by Enermodal Engineering Ltd. in downtown Calgary. Enermodal Engineering Ltd. is a consulting firm committed to improving the sustainability (especially energy and resource efficiency) of buildings and building products. With a staff of 60 in Kitchener (Head Office), Denver, and Phoenix, Enermodal's fourth office in Calgary was designed to showcase the company's longstanding expertise in environmental design and construction, provide staff with a green office to work in, and serve as a replicable demonstration and promotional project for sustainable office practices to Enermodal's clients and office visitors.

The office is located on the 6th floor of an 11 storey building in the historic Mission District of downtown Calgary. The space was formerly used as a dentist's office, with finishes dating to the 1980's, therefore the majority of finishes were not in suitable condition for re-use and could not be retained. The scope of the project included removal of the original internals and the installation of a washroom, a small kitchen area, a boardroom and general office area. The scope of the work included new interior partitions, ceiling tiles, millwork (in the kitchen area), flooring, and furniture. As this project is the renovation of a leased space, two major areas of interest, the HVAC systems and the building envelope. It was not possible to consider either of these were important aspects of building performance as they are both controlled by the landlord.

1.2 LEED Canada for Commercial Interiors

The office refurbishment was designed and constructed following the principles of LEED Canada-CI (Leadership in Energy and Environmental Design Canada for Commercial Interiors), which is implemented by the Canadian Green Building Council (www.cagbc.org) in Canada. LEED-CI is a point-based rating system and a green building benchmark. It is tailored for the tenant improvement market, i.e those projects that do not usually have control over whole building operations but only a renovation of part of an existing building. LEED is currently the most widely used Green Building system in North America (97 certified and 760 registered buildings to date in Canada)[1].

The project was started at the same time as the official launch of the LEED-CI program by the CaGBC, in late 2006. The Enermodal Engineering Ltd. Calgary Office went on to become not only the first project to be certified by the CaGBC under the LEED Canada-CI rating system, but it also achieved a *Platinum* rating, the highest level of achievement and distinction offered. See Appendix A for a LEED Canada-CI Scorecard.

Figure 1 Enermodal Engineering Ltd. Calgary office kitchenette featuring low embodied energy and low emitting materials.

2. Urban Context

The City of Calgary is a city of over 1 million people in Alberta, Western Canada. The city is in a time of economic boom, largely due to oil and gas exploration, and is home to the second largest concentration of corporate head offices in the country[2], which has led to an increased demand for office space. Calgary has over 31 million square feet of office space and has experienced vacancy rates between 0.5% and 3.5% in the past two years[3]. This high demand for office space has meant higher than average levels of churn as: corporations take on new space for additional employees; and other corporations are forced out of the downtown core and into less expensive spaces as rent costs in Calgary have soared to be the 28th highest in the world, amongst the top ten in the world for growth[4]. Therefore this paper is timely as it examines the potential of a range of sustainable office refurbishment practices across the city.

3. Performance Analysis of Sustainable Refurbishment Measures

3.1 Methodology

The measures implemented in the Enermodal Engineering Ltd. Calgary Office were evaluated using the following criteria:

3.1.1 Ease of Implementation

Measures were graded based on how easy they were to implement into the design and construction of the office, relative to standard practice. The acceptability of the practice/technology in the market place was also considered (i.e. level of expertise required for design and installation). The main factors that were taken into account were feedback from the General Contractor (who had 15 years of experience but none in green construction), the requirement for specialist design inputs or the need to use specialist equipment i.e. how much harder was this measure to include compared to the standard alternative?

3.1.2 Cost of Implementation

Measures were graded based on their incremental capital cost relative to standard practice. Although many major manufacturers and suppliers are now offering more sustainable products, there is still a cost associated with many sustainable office measures.

3.1.3 Social/Health and Productivity

Measures were reviewed on their level of contribution to providing a healthy working environment for its occupants. As many office workers spent as much as 90% of their time indoors, avoidance of products that may cause ill health and promotion of measures that enhance well-being take on much significance. Each measure was assessed for their ability to improve occupant health, comfort and well-being.

3.1.4 Carbon Reduction

Reduction in carbon emissions as a result of efficient use of energy in buildings is one of the most pressing issues given current concerns over climate change. Measures were assessed for their contribution, if any, to energy/carbon reduction.

3.1.5 Materials and Waste Reduction

Measures were assessed for their contribution to natural resource consumption and waste reduction. Materials/measures were evaluated over for their impacts over their life cycle. Products and practices' embodied energy, minimal waste production/consumption, and minimal end-of-use environmental impacts were considered.

3.1.6 Replicability

Measures were evaluated for their ability to be replicated on an urban-wide level. The impacts associated with supply and demand of materials and products, varied geographic applicability, and appropriateness for a wide variety of space use types were considered.

3.2 Analysis

Please see Appendix B, which shows a matrix analyzing the performance of the various measures implemented. The measures are described and discussed below:

3.2.1 Enhanced Lighting Design

A combination of low-mercury High-Output T5, T8, and compact fluorescent fixtures were installed throughout. All fixtures are controlled with occupancy sensors, and perimeter lighting is further controlled with daylight sensors (dimming ballasts) and manual on-off override switches. White ceiling tiles were also used to increase reflectance and further reduce the installed lighting power. These measures combine to achieve a 38% reduction in lighting power density below ASHRAE Standard 90.1-2004.

Electrical design for reduced light power density required no specialist expertise. Although fewer light fixture choices are available at the highest efficiencies used, all are available from many well known manufacturers. However, installation and set up of the daylight and occupancy sensors did require a small amount of additional time and adjustment. The resulting lighting levels and controls have provided a comfortable, energy efficient working environment and the principles could be easily applied with good results to most typical office refurbishment projects.

3.2.2 Recycling facilities

The refurbishment included the installation of a recycling storage centre in the kitchenette. Separate storage containers for compostable materials, glass/metal, plastic, cardboard/paper are provided. Paper and cardboard are first collected in “blue boxes” located within each office prior to storage in the kitchenette. The storage area is 0.6 m^3, which is collected by a specialist recycling contractor and delivered to recycling facilities every two weeks.

The recyclable materials storage facilities can be easily and discretely incorporated into almost any office refurbishment project but the ongoing success of the scheme is highly dependent on the quality of the service provided by the local collection service. There were some concerns over odors from the compostable waste at the outset but these have been easily manageable with regular collections and housekeeping. Installing similar recyclable materials storage in other office refurbishments should be easily achievable but the ongoing success of such schemes would rest on user education and the local collection service.

3.2.3 Efficient Equipment and Appliances

All office equipment and appliances are ENERGY STAR rated (where eligible), including: notebook computers, monitors, dishwasher, refrigerator, and printer/copier/fax machine. ENERGY STAR is a joint program of the U.S. Environmental Protection Agency and the U.S. Department of Energy. It provides an energy performance rating system which recognizes energy efficient products and practices[5].

ENERGY STAR appliances are widely available with little or no cost premium and there are no significant barriers to the uptake of this measure. Efficient appliances and equipment were easily specified and can be implemented on any scale of office refurbishment.

3.2.4 Low emitting fixtures and fittings

Construction adhesives, sealants, plus paints and coatings were all selected to be low-emitting. The office achieved over 85% reduction in volatile organic compounds compared to LEED performance limits. The office also installed Green Label Plus[6] certified carpet tile, urea-formaldehyde free composite wood and agrifibre products, and the reused and GREENGUARD[7] Certification Program certified furniture. Green Label Plus and GREENGUARD are the most recognized low emissions certification programs in North America for carpet systems and furniture, respectively.

Selecting low-emitting adhesives, sealants, paints, and coatings required additional research prior to specifying and purchasing products. Experience with this project was that, whilst most contractors required assistance, guidance, and education on low-emitting product selection, most were receptive of the measure. These products had no additional costs associated with their use or application.

The majority of carpet manufacturers now offer low-emitting products, and a selection of Green Label Plus carpet was neither difficult nor significantly more expensive than standard carpets. Similarly, GREENGUARD furniture was found to be readily available from local furniture dealers although this requirement did limit the number of stores and suppliers. GREENGUARD furniture was primarily in the upper range of quality; these products tended to be expensive, but were similarly priced relative to products of comparable quality.

Urea formaldehyde-free wood and agrifibre products were the most time consuming to source due to a lack of readily available product alternatives and difficulty in obtaining product specifications and information from suppliers.

3.2.5 Sustainable Transport Incentives

A bicycle storage system was designed specifically to address the space constraints of this project. A shower stall was also installed in the washroom to encourage employees to cycle, walk, or jog to and from work. The number of parking spaces provided by Enermodal was limited to meet but not exceed the local zoning bylaw. A carpool program was established to provide incentives to employees who carpool regularly to and fro the office.

Additional work was required to survey employees and produce a transportation management plan. The incentives and alternative transportation opportunities presented to occupants was well received and easily managed once implemented. Little cost was required to provide infrastructure to support the alternative transportation options.

3.2.6 Low embodied energy materials

A wide variety of environmentally friendly products were sourced. Products with regionally manufactured and extracted materials were selected wherever available. 45% of furniture and furnishings (by cost) were purchased reused. Products with the highest possible recycled content were selected, including the reflective white ceiling tiles, gypsum board, ceramic and carpet tile, composite wood, insulation, new furniture, and steel studs. The interior doors and sidelight frames were made from FSC-certified cherry. FSC-certified wood has been harvested from forests in an environmentally and socially responsible manner (certification is provided by the Forest Stewardship Council[8]). The highlight of the office materials is the high rapidly renewable content used (over 12%), which includes bamboo flooring, Woodstalk® wheat board casing, and Kirei® board cabinets (made of sorghum). The kitchenette countertop is made from Paperstone®, a surface constructed of 100% post-consumer recycled and FSC-certified paper.

Additional work was required to research and procure alternative materials. In general the costs of low-embodied energy materials was negligible; although some innovative products carried a premium and no similar products were available, other products used such as used furniture provided cost savings. As with using low-emitting materials, some education and monitoring was required to ensure that contractors were aware of the desired product requirements and purchased appropriate products.

3.2.7 Occupant comfort control

Temperature is controlled via four wall-mounted thermostats, and airflow can be controlled manually within each room using operable diffuser grilles.

Design for occupant comfort control does not require any additional level of expertise; however it does require more thought to ensure all work areas have been appropriately addressed. Implementing additional control devices had a negligible impact on capital cost, and provided no difficulties during construction. Post-occupancy feedback showed that the increased level of comfort control was widely utilized, providing a high level of satisfaction and comfort.

3.2.8 Water efficient fixtures and fittings

The washroom was remodeled to include an ultra low-flow shower (3.8 litres per minute), a dual-flush toilet (6 and 3 litre per flush options), and a self-mixing 1.9 litre per minute lavatory faucet controlled with an infra-red sensor. These features, along with a low-flow kitchen faucet (3.8 litres per minute) save over 50% of water consumption compared to the LEED-CI baseline.

There was a small capital cost increase to purchase infra-red sensors and low-flow fixtures. It was found that lavatory faucets were easily sourced, however low-flow showerheads were more difficult to purchase due to a lack of product options and suppliers. Dual-flush toilets are now produced by most major manufacturers and are becoming increasingly easy to specify. The selection of toilets was greatly increased when residential-style fixtures were included in addition to commercial fixtures. It was found that the acceptability of low-flow fixtures varied widely with each individual and company that was dealt with, but are becoming increasingly accepted in Canada.

3.2.9 Layout for daylight and views

The office layout places all regularly occupied rooms along the perimeter, providing a view to the outdoors and naturally lighting all of these spaces.

Space layouts to optimize daylight and views does not require any special expertise, however is not always considered during design, nor might it be possible with deep plan office renovation projects. Regularly occupied spaces such as offices and meeting rooms were strategically placed along the exterior of the floor plate adjacent to windows. Occasionally used spaces such as the foyer, the kitchenette and the hallway were placed adjacent to the exterior spaces, and connected with the outdoors indirectly by using interior sidelights. Storage spaces and the washroom were placed on the interior where daylight and views had the lowest benefit and priority.

3.2.10 Energy management and monitoring

Temperature, relative humidity, and carbon dioxide sensors continuously monitor the indoor comfort conditions, and this data is also available “live” on the educational kiosk display.

Electrical wiring had to be considered during design, and was set up such that all lighting fixtures and plug loads were fed to a circuit breaker located within the office space. Additional cost was required to purchase an electronic meter and set up a management program to record the data collected. The continuous monitoring of electricity consumption has provided a public display feature (it is part of the educational cost) that is very popular with occupants and visitors. It has allowed the energy department of Enermodal Engineering the ability to frequently re-evaluate energy loads within the office and assists them explore opportunities to maximize efficiency. The office has been able to reduce the lighting and plug load electrical consumption to less than 70 kWh/m^2 in the first year of operation.

4. Conclusions

The preceding analysis indicates that there is a great potential for implementing several sustainable building measures for office refurbishment projects in Calgary. Furthermore, the analysis showed that many of the measures can be implemented at relatively little incremental capital cost, but would provide savings of carbon, natural resources, and water, while increasing occupant comfort and well-being.

Although all measures analyzed offer some form of benefit, the following measures were found to provide the most benefit overall, based on the criteria considered:

- enhanced and efficient lighting design,
- recycling storage facilities,
- energy efficient office equipment and kitchen appliances,
- low VOC emitting fixtures and fittings, and
- sustainable transport incentives.

Key Words: Sustainability, facility remodelling, evidence based, acuity-adaptability, whole life cycle costing, uncertainty analysis

Summary:

The aim of this conference paper is to discuss a new approach to redevelopment appraisal for green health-care facilities. Research shows the need to combine various models or approaches to achieve this objective due to uncertainties from clinical outcomes and subjective valuations of decision makers. This study attempts to combine three major approaches/models to green healthcare facility redevelopment: clinical evidence based assessment, whole of life cycle costing (WLCC) and uncertainty analysis.

The design concept behind acuity-adaptability (AA) rooms is patient rooms be designed to accommodate all levels of care and patients to remain in that room throughout hospitalization (Hendrich; Fay and Sorrells 2004). Flexible healthcare services accommodate changes in patients' acuities. The main advantages are reductions in patient movements, improved health care and safety and shorter average length of stay (Ulrich et al 2004). Secondary advantages are reduced staff workloads, maximized bed utilization, increased patient satisfaction and lower costs.

Current health and building related research efforts on green health-care facilities focus on energy savings and indoor environmental quality (IEQ) impacts. However, additional research into systematic assessments of other aspects of sustainability, such as facility flexibility and AA patient room should be considered.

Recent studies indicated that AA patient rooms reduce infection rates, increase the expected occupant health and improved staff/patient satisfaction outcomes in a cost-effective (CE) manner. However, there is still knowledge gaps in the evidence base whether financial investment for this type of facility produces adequate return on investment (ROI).

In this discussion, three public healthcare hospitals in Singapore are to be study samples. They have remodelled and added AA rooms to existing facilities and assessed the building for sustainability. These facilities have now been in service for at least two years and served end users such as patients, clinical and non-clinical workforce, visitors and the local community.

This proposed study program consists of four stages. The first stage is a literature review on how health environment adapts to meet the needs of society in 21st Century in terms of sustainability.

1. INTRODUCTION

Hospitals are some of the most expensive facilities to build due to complex infrastructure, medical technology and government regulations and building codes. Investing in healthcare facility and deciding what components to incorporate into remodelled or new facility requires clear comprehension of intended outcomes (Levin et al 2006).

The largest challenge facing the health sector is the necessity to maintain or improve clinical outcomes, operational effectiveness, revenue and patient/staff satisfaction while reducing capital, operational and support costs (Hosking and Jarvis 2003). At same time, health management must attain unprecedented levels of equipment, staff retention and sustainable adaptability (Mirrielees 2006). Effective management of physical and staff assets play an increasingly important role in optimising CE concerns (Wauters 2005). Health management are increasingly required to demonstrate potential benefits other than costs from a sustainable perspective (Kaatz et al 2006).

This research aims to improve current set of appraisal tools to meet uncertainties resulting from multiple objectives from decision-makers and stakeholders in health sector. The secondary aim is to identify broad goals and sub goals of interested parties to formulate and identify a set of relevant indicators supporting sustainability in health facilities. The literature review (LR) has identified the means to compare investment options with respect to non-commensurable criteria and to quantify uncertainties in a consistent and transparent manner as knowledge gap. This study proposes a holistic whole of life cycle costing (WLCC) model for appraising green healthcare facility investments by aligning and integrating relevant elements of decision-making, uncertainty analysis, project management, logistics, system engineering, maintenance and life cycle costing (LCC) and delivery of care (DC). (Boussabaine and Kirkham 2006)

Objectives of this study are: First, to assess investment appraisal and uncertainties based on a modified LCC methodology (Boussabaine and Kirkham 2006). Second, to evaluate the impact of indoor environment (IE) on staff and clinical outcomes in context of AA rooms within green and conventional facilities (Martini; Discoli and Rosenfeld 2007). Third, to establish design effectiveness on staff collaboration efforts and retention rate (Seppänen and Fisk 2005). Fourth, to discuss issues related to implementing evidence based design with focus on sustainability to link benefits of systematic post occupancy assessment with practice-based research (Hamilton 2003). Fifth, to document the impact of sustainability issues such as single versus multi bed rooms, IEQ, supportive workplace and improved layout; improved physical settings that contribute to safer, effective healing outcomes and better workplaces in remodelled facilities (Bordass and Leaman 2005).

2. LITERATURE REVIEW

There are several reasons for using formal clinical research data and results to guide green facility appraisal in health sector (Okoroh et al 2001). Unlike other building types, where poorly designed IE cause annoyances and minor health problems (Hirota 2005), fatalities could result from similar IE conditions in hospitals.

Just as medicine moves towards ‘evidence-based medicine' where clinical choices are informed by research; ‘evidence-based design’, guided by rigorous research, provide directions to sustainable healthcare facility design and decision-making processes (Ulrich et al 2004). The primary reason is that evidence-based sustainable design; results in demonstrated improvements in clinical outcomes, economic performance, staff productivity and patient satisfaction (Becker and Parsons 2007).

The following research questions are guiding this literature review:

a. What are the differences in construction, operation and management costs, infection control and decision-making between AA rooms and multi-occupancy rooms in green and conventional hospitals?
b. What are the therapeutic impacts (social interaction, patient privacy) of AA rooms versus multi-occupancy rooms in green and conventional hospitals?

2.1 Economic Benefits

Throughout the 1980s and 1990s, demands for greater convenience and new technologies and the resultant cost pressures led to major shifts in provision of healthcare (McDermott; Parsons and Cornia 1994). Focus shifted from a primary in-patient activity to more of an outpatient approach. The LR indicated a profound effect on in-patient activity due to facility remodelling. Data from these studies indicate significant variations in admissions by these facilities. Overall, these studies indicate that most remodelled facilities experience significant growth in in-patient admission activity (Hosking and Jarvis 2003). The increases attributed to demographics and use rates are insufficient to explain the magnitude of increase.

Pursuing a green facility remodelling strategy has tremendous implications for the healthcare sector and its constituents (Holtz 2006). While the potential benefit is significant, such an approach requires capital resources, placing enormous stakes on success or failure of execution (Pelleier and Weil 2003). Good redevelopment appraisal depends not only on quality of data for analysis and evaluation it depends on objectives of both decision-makers and stakeholders (Omura 2004). It is important to identify broad goals and sub-goals of the interested parties to formulate and identify a set of relevant indicators supporting the redevelopment appraisal process (World Health Organisation 2002).

Further investigations into this area of research, including meticulous collection and verification of longitudinal data, would assist in future planning of facilities (Turpin-Brooks and Viccars 2006). Given the magnitude of investments associated with remodelled facilities, it is important to analyse the impact of decision making based on profitability attributes (Chow-Chua and Goh 2002).

2.2 Green Remodelled Healthcare Facility

Green remodelled facilities improve hospital environments in four key ways (Ulrich et al 2004):

a. Enhancing patient safety by reducing the risk of infections, injuries and medication errors
b. Eliminating IE stressors, such as noise, that affects healing outcomes and staff performance
c. Reducing stress and promote healing by providing more pleasant and comfortable environment and support for patients
d. improving staff performance and retention rates

The LR suggests that facility redevelopment or remodelling has significant impact on financial and operational performance (Hui; Wong and Wan 2008) as well as on patient and staff welfare. The costs and risks involved are substantial (Lutzendorf ;Lorenz &Truck 2006). If current trend remains or accelerates, sustainable remodelled facilities would be more prevalent due to competition within the health sector (Simms and Rogers 2006). Studies revealed that site selection; together with operational planning and sustainable facility design; provide efficient staffing and optimal level of health outcome for patients (Kantrowitz et al 1993). Future decision-making needs to be strategic due to a shortage of caregivers and resources. There are significant advantages to organizational innovations and changes for both patients and caregivers by incorporating sustainability concerns into investment and remodelling decisions (Hosking and Jarvis 2003).

2.3 Acuity-Adaptable Rooms

In conventional hospitals, patients are moved to different types of nursing ward to receive the required level of care that match their patterns of acuity during their hospital stay. This leads to problems such as missed treatments, medication errors, infection rates, injuries due to transfer activities and transfer costs (Okoroh; Ilozor and Gombera 2006). Number of patients requiring progressive care has increased sharply and led to demand for special rooms that can adapt to changing medical technology and services (Bodenhelmer 2005).

In AA room, rather than organizing care around levels of patient acuity, rooms or wards are designed to accommodate all levels of care while still organized by specialty (Levin et al 2006). They make it possible to reduce the number of Intensive care units or other specialized units. Patients are assigned to any AA room and remain until discharged (McDermott C. and Stock 2007). Another advantage is that nursing stations can become decentralized throughout the ward or floor facilitated by monitoring technology (Chaudhury; Mahmood and Valente 2005).The results are reduced health and safety related problems as well as increasing retention rate for healthcare givers and their productivity levels. (Fisk 2002)

LR indicated that the satisfaction of staff and patients was higher when patients remained in a single room throughout their entire stay compared to those moved during stay. In addition, the length of stay (LOS), staff workload and mortality/infection rate decreased and fewer transfers resulted in cost savings (McDermott C. and Stock 2007). Findings demonstrated that remote and flexible monitoring decrease the LOS and reduced costs. (Calkins and Cassella 2007)

2.4 Methods

Investments in facilities are assessed with respect to LCC as well as economic lifespan (Shohet 2003). Outcome of redevelopment appraisal with respect to these economic criteria is generally non-deterministic. To evaluate different investment options require probabilistic modelling to account for uncertainties (Suthummanon and Omachonu 2008).

WLCC methodology considers a multitude of different quantitative and qualitative criteria characterising facility redevelopment (Lavelle 2003). Delays due to re-work; reputation of vendors; builder expertise, expected system reliability and performance have direct impacts on outcome of redevelopment decisions related to facility remodelling or refurbishment of healthcare facilities (Lennerts et al 2005).

2.5 Metrics

Typical investment analyses indicate economic feasibility or CE of investment options by calculating WLCC metrics such as Return on Investment (ROI), Net Present Value (NPV) and Payback Period (PB) (Boussabaine and Kirkham 2004). The role of UA is vague in these models (Pelletier and Weil 2003; Pelzeter 2007). For the purpose of this study, a WLCC model based on Temporal Utility Model whereby redevelopment investments are seen as a decision making process focused on achieving a reservation value or utility of possible investment options as precondition. After meeting this precondition, the next step is to determine the maximum value or utility of a set of admissible investment options (Lavelle 2003). However, investments in healthcare facility are unique, as sources of uncertainty stem from variability of clinical outcomes (Mainz 2003; Sohet and Lavy 2004), and subjective valuations of many decision makers given new data as evens unfold (Fleming 2005). Methods that address these uncertainties by supporting subjective judgements include Markov Chain Monte Carlo methods developed for Bayesian probabilistic modelling and statistical inference that support uncertainty analysis (Zhang and Vidakovic 2005; Cooper et al 2006).

2.6 Key findings from Literature

Recent review of the literature (Ulrich et al 2004) on sustainable design demonstrated that patient-centred and acute care environments facilitate positive patient outcomes such as increased patient privacy, better opportunity to recovery and shorter LOS. The few articles' dealing with overall cost issues in hospitals, did not focus on AA room types, and associated costs. Studies on patient/caregivers' perception of the advantages and disadvantages of AA rooms versus multi-occupancy rooms are just as limited (van de Glind; de Roode and Goossensen 2007).

The major issues in the literature synthesized into four main categories and subdivided into empirical and non-empirical studies:

a. Cost and decision making related issues
b. Infection control
c. Healthcare facility management/patient care
d. Therapeutic impacts

Articles on cost and management issues are mainly non-empirical and prescriptive in nature (Sohet and Lavy 2004). A limited number of empirical clinical studies based on therapeutic benefits of AA rooms and infection control have been carried out (van de Glind; de Roode and Goossensen 2007). The authors identified a gap in research supporting cost reductions based on linking AA rooms to other healing environment design principles (Ulrich 1991).

The key drawbacks are higher construction costs required to redevelop entire healthcare facilities into AA rooms (Bodenhelmer 2005). By design, AA rooms require larger rooms and flexible medical infrastructure; means either longer travelling distance or fewer rooms per floor and less revenue per room (Nelson; West and Goodman 2005). Other major obstacles include impacts on existing staff levels. While technology and staff can facilitate different levels of treatment within a unit, it is unrealistic to expect all staff to maintain expertise in all areas (Chaudhury; Mahmood and Valente 2006).

As mentioned earlier, AA rooms and sustainable design are poised to be the leading trend in healthcare facility planning and design (Hamilton 2001; Levin 2006; Becker and Parsons 2007). Both empirical and non-empirical literature demonstrates advantages of AA rooms for improvements in patient care and greater flexibility in operation. However, the LR highlights a limited interpretation of the benefits of AA rooms within the context of care-related issues, environmental concerns and management practices to bring about desired and sustainable outcomes in remodelled hospitals (Liyanage and Egbu 2005; Hirota 2007).

3. APPROACH

The modified WLCC model for evaluating LCC and the question of assessment adequacy, as mentioned by Pelzeter, are investigated in this study. The primary goal of evaluation is to aid health management in structuring and quantifying investment related issues characterised by multiple criteria decision analyses and uncertainty methodology mentioned by Pelletier and Weil. Assessment process are evaluated using Bayesian probabilistic modelling based on Markov Chain Monte Carlo methods and statistical inference in the form of degree-of-belief probabilities methodology proposed by Zhang and Vidakovic. The scope of WLCC assessment determined by the strategic nature of facility remodelling appraisal is considered.

WLCC metrics may be used to compare several investment options. Comparing the ROI, NPV and PB of each solution provides the means to evaluate cost implications over the economic life of a facility. Existing WLCC models fail to provide a method for systematic data collection for a decision making process as mentioned by Sohet and Lavy. As WLCC considers only economic cost of a facility, the methodology has limited impact post handover unless the proposed framework includes operational cost metrics for performance measurement.

For the purpose of this study, the proposed objectives incorporated three levels of detail:

a. Strategic (i.e. structure, envelope, services etc)
b. System (i.e. operations and management, utilities, staff turnover etc)
c. Detail (i.e. head panel, LOS, internet hook-ups, mortality rate etc)

This provides the modified WLCC model the ability to optimise multi-criteria decision-making during the design phase and conduct uncertainty analysis with greater precision.

4. PILOT STUDY

In this study, the basis for choosing a population of patients included consolidation needs, characteristics of bottlenecks, and needs for a population with a predictable clinical course as shown by the survey conducted by Hirota. After the selection of a patient population, the next phase is to focus on the following attributes of AA rooms/wards:

a. Resource wastage
b. Caregivers' work environment and satisfaction
c. Characteristics of care delivery model
d. Flexibility and adaptability of support for future DC and patient flow
e. Cost-benefit and CE within green healthcare facilities

To assess the impact of AA rooms in sustainable healthcare facilities, O'Sullivan et al mentioned various clinical and financial measures to be collected before and after the remodelling exercise. Two years of baseline data, similar to the data collection by Sharshar, to be collected from the two green hospitals and one conventional hospital in Singapore; demographics, admissions/discharge/transfers, LOS, staff and patients' satisfaction levels, bed efficiency, charge/costs, nursing work loads before and after the facility remodelling. A list of 20 survey questions is to be formulated, based on similar inquiry conducted by Hirota, into RA of green healthcare facilities. The proposed areas of inquiry are:

a. Did the patients have fewer complications (adjusted for severity) when compared to cohort of matched patients? Did mortality rate changed?
b. Did the sentinel event index (e.g. falls, medication errors, complaints etc) decreased?
c. Compared with baseline data, did job satisfaction increase amongst clinicians due to incorporation of key sustainability features into healthcare facilities? (Technology, green environment, care delivery model) What are the expected outcomes over time?
d. Will patients' satisfaction levels be higher compared to baseline data?
e. Will nursing recruitment and retention improve in AA rooms in remodelled green healthcare facility?
f. Are flexibility and adaptability features within green AA rooms able to match current medical technology to patient and staff needs?
g. What market impact can be measured or quantified with physician, patient, or patient's family? Will patients recommend AA rooms in green healthcare facility to others?
h. Compare with baseline data on costs of labour (direct, indirect and fixed) resulting from changes to environment, technology and care delivery model

Patient's levels of satisfaction and dissatisfaction in AA rooms in both green and conventional healthcare facilities are to be compared. This provides an indication of how closely patients' experiences match their expectations as well as patient's overall willingness to pay or recommend the healthcare facility to family and friends.

Results from this study would indicate whether AA room design in green healthcare facility provide a more cost effective advantage in reducing costs, staffing hours and improving delivery of care based on World Health Organisation methodology. In the short term, data from this study might indicate the likelihood of stretching additional capacity out of identical number of beds through provision of additional AA rooms. Another possibility is improving CE by the reduction of physical plant space requirements to AA rooms due to decision-making process as mentioned by Nelson, West and Goodman.

5. CONCLUSION

This discussion has examined the possibility of achieving improvements to remodelled healthcare facilities by targeting bed placements in AA rooms, communication and housecleaning in a more CE manner. Previous research, especially studies by Ulrich, has indicated that healthcare decision makers support green design features in new or remodelled facilities that promote the wellness of patients and retain staff. The objective of this study is to provide health administrators with means to reach decisions on redevelopment strategies

The impacts and benefits of a green remodelled facility strategy is to be evaluated by analysing pre-, post-utilisation performance, and benchmarking against conventional facilities under similar conditions based on a proposed WLCC model.

The analysis will focus on data from pre- and post-remodelled in-patient admission and outpatient visits to AA rooms/wards of sample facilities. Primary and secondary data is to derive from three sources for this on-going study: Alexandra Hospital (Singapore), Singapore General Hospital (Singapore) and Changi Hospital (Singapore).

A second stage of the study is intend to track remodelled green facility activity through a combination of interviews with architectural firms, their staff's experience as well as that of facility management, staff and patients. There are seven public hospitals in Singapore including three green healthcare facilities. Two green remodelled and one conventional public healthcare facility would be participating in this study.

External factors such as geographical locations, private versus public, socio-economic status of community and physician practice patterns could have profound effect on green remodelled healthcare facility in terms of operational and financial effectiveness and performance. Other factors that could complicate research include age and type of healthcare facilities investigated as indicated in study by Hosking and Jarvis.

By identifying and making allowances for these limitations, mentioned by Ohkusa and Sugawara, during analysis stage, the appraisal can measure both qualitative and quantitative improvements for health facility over current WLCC model. Once the study is completed, the results will be presented.

6. ACKNOWLEDGEMENTS

The authors wish to thank the Ministry of Health, Singapore, and the management of Alexander Hospital, Changi Hospital and Singapore General Hospital for the support of this on-going study.

The authors regret that the only remaining green public hospital, Tan Tock Seng Hospital (Singapore), is unable to participate in this study as they are still in process of remodelling their existing facilities.

Summary

In 2007, Calgary International Airport surpassed the 12 million passenger mark, continuing the greater than forecast growth seen over the previous four years. The Calgary Airport Authority is reviewing options to accommodate these increases. The existing Calgary International Airport has three concourses. One option under review to address the increased passenger traffic is an expansion to the International/Trans-border facilities. This would take the form of a new 72,000 m^2 concourse. In addition to increased processing capacity, expanded retail and duty free shopping facilities will contribute to the airports overall revenue stream. During planning meetings, the Authority has stressed that their stated environmental goals were a key factor in any solution proposed. A theme that emerged during these initial planning meetings was: could the expansion be accomplished without increasing the net energy consumption and greenhouse gas (GHG) production of the existing campus – the "Net Zero" solution? Through modeling and life cycle analyses, a solution that meets the Calgary Airport Authorities economic and operating criteria was identified that also presents a "Net Zero" option for the expansion with an annualized return on investment of 6.1%.

1. Background

In 2007, Calgary International Airport surpassed the 12 million passenger mark continuing the greater than forecast growth seen over the previous four years as illustrated in Table 1. The existing terminal, with upgrades between 1998 and 2004, is designed to handle 11 million passengers. The Calgary Airport Authority is reviewing options to deal with these increases. One option under review is an expansion of its terminal and airside facilities. The expansion will be designed to accommodate passenger growth for the next two decades.

Table 1 – Calgary International Airport Historical Passenger Traffic

Year	2001	2002	2003	2004	2005	2006	2007
No. of PAX	7,794,519	7,884,194	8,576,541	9,174,039	10,148,718	11,279,080	12,257,865
% Change	-3.66%	1.15%	8.78%	6.97%	10.62%	11.14%	8.68%

As part of the 2004 Calgary International Airport Master Plan, the Authority introduced the following statement:

"... in addition to minimizing the environmental impact of fostering aviation development and economic growth, the Airport Authority will strive to exemplify strong environmental stewardship to local, national and international communities through innovation, leadership and new partnerships."

During planning meetings, the Authority stressed that their stated environmental goals were a key factor in any solution proposed. A theme that emerged during initial planning meetings was: could the expansion be accomplished without increasing the net energy consumption and greenhouse gas (GHG) production of the existing campus – the "Net Zero" solution? As a result, the Authority authorized a Mechanical and Electrical Master Plan, one facet of which would review the feasibility.

This paper presents a synopsis of the analyses that were performed and the recommendations presented to the Authority for its consideration when finalizing its decision on what measures to implement in an expansion scenario. All currency quoted are in 2008 Canadian dollars.

2. Existing Terminal Baseline (Utility and GHG Production)

Calgary International Airport's terminal has three concourses (refer to Figure 1), which have been opened, expanded or upgraded over a ten year period, 1998 to 2004. Pier B/C handles international and trans-border (US/Canada) flights; the passenger segment that has experienced the most growth. The current expansion targets this area. The planned 72,000 m^2 expansion will also increase the processing capacity of Canada Border Services Agency and US Customs and Border Protection pre-clearance operations.

The current terminal covers 141,648 m^2 of roofed area, consisting of Concourse A through D, Main Terminal and Courtyard Infill.

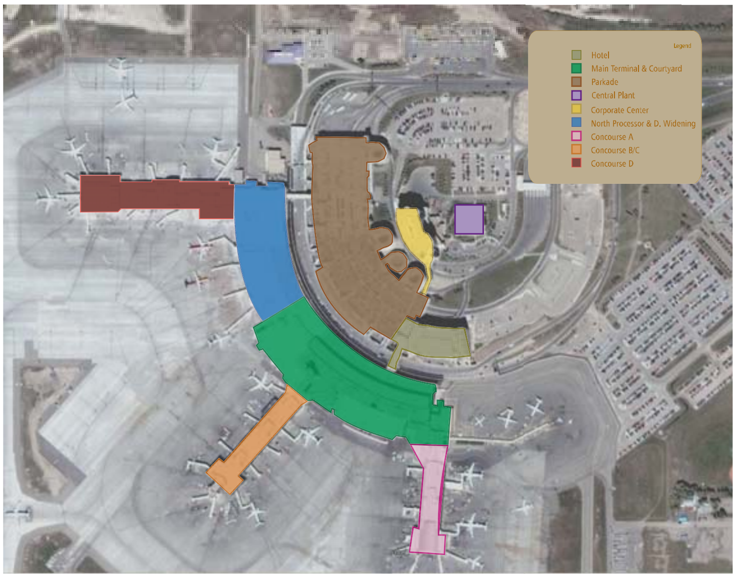

Figure 1 – Existing Calgary International Terminal

The Authority has kept historical data on utility consumption, providing a good basis for baseline development. Figures 2 though 4 represent the historical annual unit (*utility*/m^2) consumptions for each utility of the existing terminal.

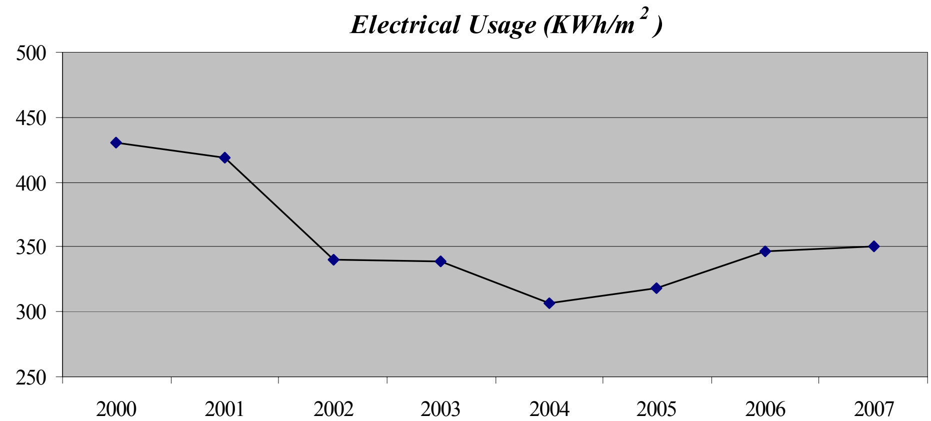

Figure 2 – Historical Annual Electricity Consumption

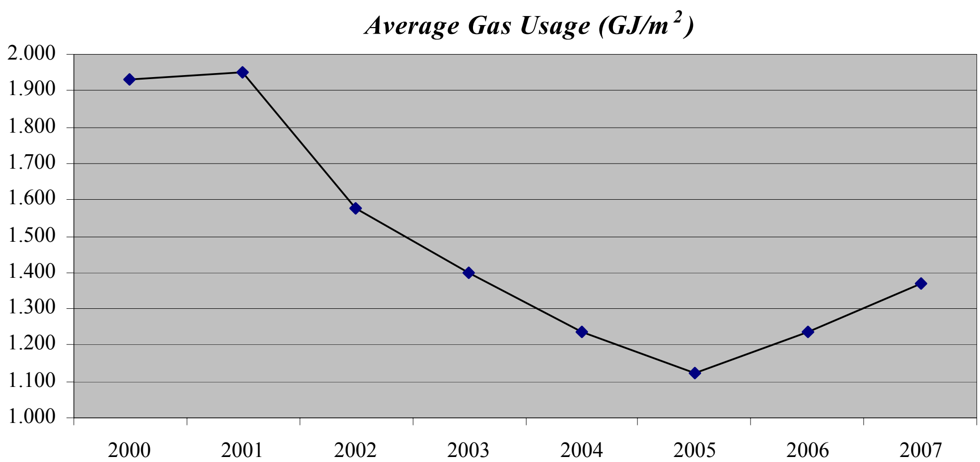

Figure 3 – Historical Annual Natural Gas Consumption

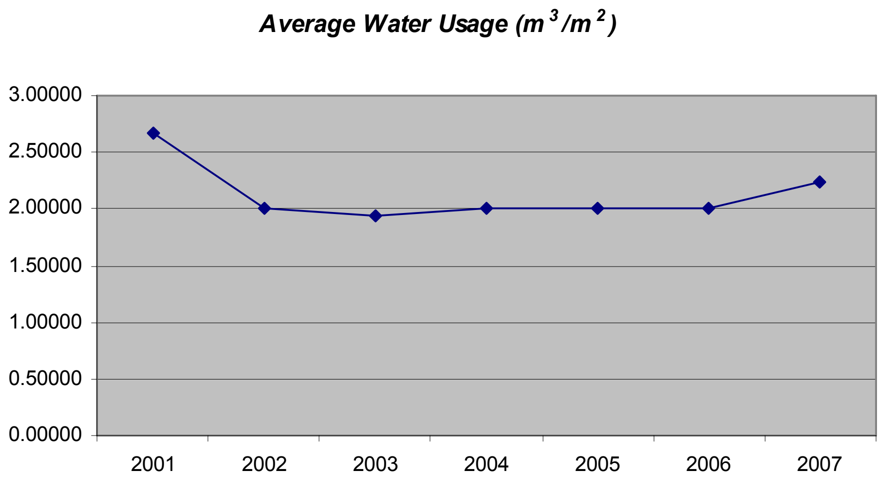

Figure 4 – Historical Annual Water Consumption

The historical utility consumptions were converted to equivalent tons of CO2 equivalents (tCO2e) using the conversion parameters in Table 5:

Table 2 – Tons of CO_2 Equivalent Conversions

Utility	Electricity Consumption (MWh)	Natural Gas Consumption (GJ)	Water Consumption (m^3)
$tCO_2e/unit*m^2$	915/MWh	0.08/GJ	$0/m^3$*

* - treatment, distribution, sewerage energy were discounted as these figures were unavailable

The resulting historical tons of CO_2 equivalents are shown in Figure 5:

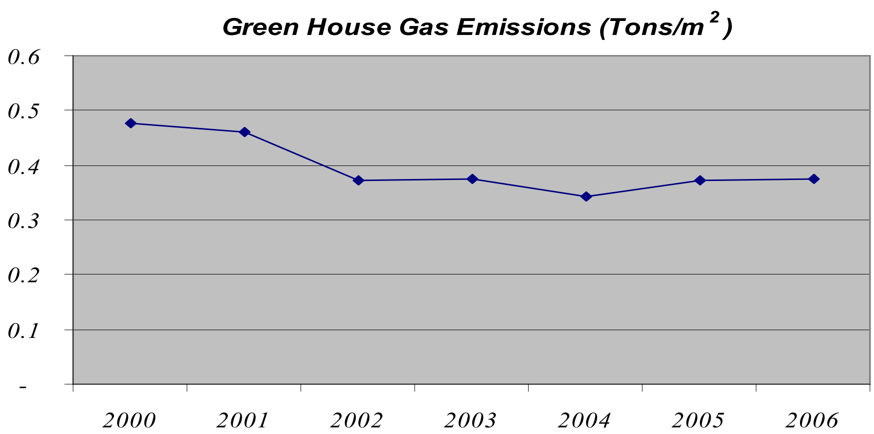

Figure 5 – Historical Tons CO_2 Equivalents

The baseline was chosen as the most stringent value over the prior five years (2002 – 2007). The resulting baseline for the Airport was set as shown in Table 3:

Table 3 – Baseline Figures for Net Zero Comparisons

Utility	Electricity Consumption (kWh/m^2)	Natural Gas Consumption (GJ/m^2)	Water Consumption (m^3/m^2)	CO2e Generation (tCO_2e/m^2)
Baseline	306	1.12	1.93	0.34

A benchmarking study of airports within the Canadian context was simultaneously undertaken at the following airports – Edmonton, Montreal, Ottawa, Toronto, and Vancouver. The results of this study were not available at the time of writing of this paper.

3. Energy/Utility Consumption Models

Several techniques were used to generate energy and utility consumption models. Energy and electrical consumption models were developed using the TRNSYS 16.1 simulation package, and water consumption models were developed using the Canadian Green Building Council (CaGBC) simulation calculations.

The expansion scenario includes a new three level Concourse E, shown in Figure 6. With three levels, this addition will add approximately 72,000 m^2 to the terminal area, thus bringing the total terminal area to 213,648 m^2. This will be an increase of 51 % from the gross area in 2007.

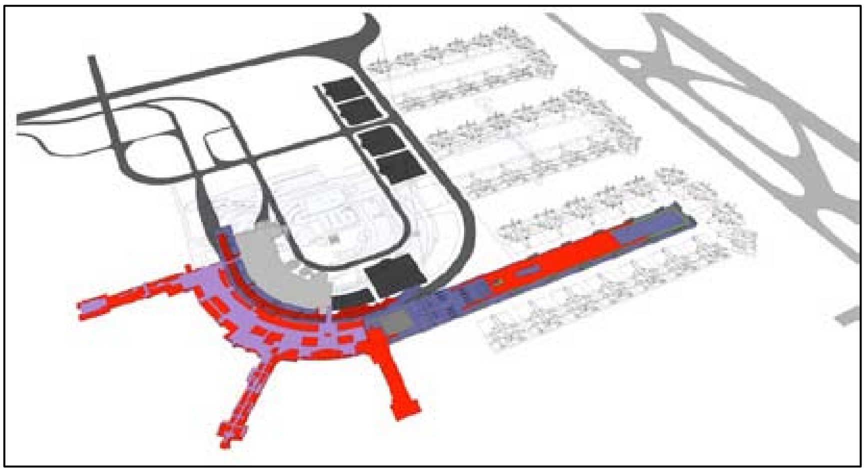

Figure 6 – Expanded Calgary International Airport

An initial 'calibration' consumption model of the existing terminal was developed to identify the deviation between the models used for determining the operating parameters compared to 2006 actual readings. The results of the calibration model, presented in Table 4, revealed an overall deviation of plus 28% for energy and minus 15% for water consumption.

Table 4 – Calibration Model Results

Utility	Power Consumption (MWh/year)	Heating Energy Consumption (MWh/year)	Cooling Energy Consumption (MWh/year)	Water Consumption (m^3/year)
Model	53,801	38,730	2,850	245,953
2006 Actual*	32,022	38,913	3,723	288,872

* - Normalized for Area

Subsequently, six models were developed, labeled V0 through V5. The following is a brief description and intent of each model.

Model V0 – This model represents the most basic form of development of the terminal and its concourses. No emphasis is placed on bettering the existing performance parameters of the facility. Existing envelope, mechanical and electrical systems are matched on the new Concourse E and only maintenance and repair/replacement of these systems are carried out during redevelopment of the existing terminal and concourses. The central plant and services remain in service and are expanded as required to meet the new loads.

Model V1 – This model adds sensible heat recovery to model V0 including the existing terminal. No water consumption reduction measures are taken. The central plant and services remain in service and are expanded as required to meet the new loads.

Model V2 – This model reflects significant upgrades to improve energy performance and water consumption. In this model, total (enthalpy) heat recovery is added to Model V0; moderate water conservation is undertaken by converting all fixtures to low flow water saving fixtures; the envelope of the entire facility, including the existing terminal, is upgraded to a high performance envelope through new construction and redevelopment; and day lighting controls are introduced. The central plant and services remain in service but are not expanded as there is no net increase in load.

Model V3 – Aggressive measures are introduced in this model. The fundamental HVAC systems are replaced with high performance, low energy systems (radiant slabs and displacement ventilation, hybrid ventilation), earth tube pre-conditioning on all new construction, enthalpy heat recovery is fully deployed, the envelope is upgraded, aggressive day lighting strategies employed and water consuming fixtures are converted to ultra-low flow and/or waterless technologies. Energy sources and services are decentralized to reduce distribution losses and to take advantage of 'point of use' efficiencies.

Model V4 – This model optimizes the energy sources and supply systems for Model V3. This involves tri-generation, rain water harvesting and grey water recycling.

Model V5 – This model introduces alternative energy sources, specifically photovoltaic power generation and the purchase of wind generated power to minimize GHG production.

A significant consumer of electrical power was the lighting allowance made for retail operations. The Authority had identified a vibrant retail component as being essential to the revenue generation opportunities for the airport. Building parameters applied to each model are listed in Table 5:

Table 5 – Model Building Parameters

	Model V0	Model V1	Model V2	Model V3	Model V4	Model V5
Lighting (Standard)	14 W/m^2	14 W/m^2	14 W/m^2	14 W/m^2	14 W/m^2	14 W/m^2
Lighting (Retail)	60 W/m^2	60 W/m^2	60 W/m^2	60 W/m^2	60 W/m^2	60 W/m^2
Auxiliary Power	10 W/m^2	10 W/m^2	10 W/m^2	10 W/m^2	10 W/m^2	10 W/m^2
Glazing Light Transmittance	50%	50%	70%	70%	70%	70%
Solar Heat Gain Coefficient	0.45	0.45	0.5	0.5	0.5	0.5
U Value	1.7 W/m^{2}K	1.7 W/m^{2}K	0.7 W/m^{2}K	0.7 W/m^{2}K	0.7 W/m^{2}K	0.7 W/m^{2}K
Shading	Internal	Internal	Reflective, Out of Space	Reflective, Out of Space	Reflective, Out of Space	Reflective, Out of Space
FC	0.95	0.95	0.25	0.25	0.25	0.25

Skylights	None	None	8% of Roof Area, Triple Glazed	8% of Roof Area, Triple Glazed	8% of Roof Area, Triple Glazed	8% of Roof Area, Triple Glazed
Roof U Value	0.45 W/m^{2}K	0.45 W/m^{2}K	0.26 W/m^{2}K	0.26 W/m^{2}K	0.26 W/m^{2}K	0.26 W/m^{2}K
Floor U Value	0.45 W/m^{2}K	0.45 W/m^{2}K	0.26 W/m^{2}K	0.26 W/m^{2}K	0.26 W/m^{2}K	0.26 W/m^{2}K
Opaque Façade U Value	0.7 W/m^{2}K	0.7 W/m^{2}K	0.37 W/m^{2}K	0.37 W/m^{2}K	0.37 W/m^{2}K	0.37 W/m^{2}K
Plumbing Fixture Type	Normal	Normal	Low Flow	Ultra Low Flow/Waterless	Rain Water Harvesting, Grey Water Recycling	Rain Water Harvesting, Grey Water Recycling

The results of the modeling exercise, by model, are shown in Table 6:

Table 6 – Model Annual Utility and Water Consumption Performance

	Model V0	Model V1	Model V2	Model V3	Model V4	Model V5
Heating	389 kWh/m^2	240 kWh/m^2	211 kWh/m^2	108 kWh/m^2	206 kWh/m^2	206 kWh/m^2
Cooling	51 kW/m^2	50 kWh/m^2	24 kWh/m^2	28 kWh/m^2	70 kWh/m^2	70 kWh/m^2
Electricity	349 kWh/m^2	349 kWh/m^2	251 kWh/m^2	208 kWh/m^2	-7 kWh/m^2	-61 kWh/m^2
Potable Water Consumption	1.246 m^3/m^2	1.246 m^3/m^2	0.817 m^3/m^2	0.600 m^3/m^2	0.472 m^3/m^2	0.472 m^3/m^2
GHG Production	0.46 Tons CO_{2e}/m^2	0.41 Tons CO_{2e}/m^2	0.31 Tons CO_{2e}/m^2	0.23 Tons CO_{2e}/m^2	0.08 Tons CO_{2e}/m^2	0.0 Tons CO_{2e}/m^2

Referring to Table 3 – Baseline, it can be seen that Models V2, V3, V4 and V5 present "Net Zero" solutions, referenced to current energy and water consumption, for the expansion and redevelopment.

4. Economic/Life Cycle Analyses

The true value of an investment is often not measured only in the capital cost, but in the long term benefits of systems impacted by the measures. The simulation models developed had Life Cycle Cost (LCC) analyses performed on each in order to gain insight into the long term costs associated with each proposal. These costs can then be used to compare the complete investment and annualized rate of return in terms of capital cost required vs. Net Present Value (NPV) of the running costs (cash flows).

Two tools were used to develop the LCC analyses: PACES and RETScreen. The PACES (Parametric Cost Engineering System) software is based on patented cost estimating techniques and is used to create cost estimates and LCC analyses early in the programming and design phase of a project. PACES uses pre-engineered model parameters and construction criteria to accurately predict construction costs using limited design information. PACES was used for the LCC analyses for models V0 through V3. RETScreen, developed by Natural Resources Canada, is a unique decision support tool developed with the contribution of numerous experts from government, industry, and academia. The software can be used worldwide to evaluate the energy production and savings, life-cycle costs, emission reductions, financial viability and risk for various types of energy efficient and Renewable Energy Technologies (RET's). RETScreen, in combination with PACES was used for the LCC analyses for models V4 and V5. Items that were not factored in the analyses include retail operations revenue, GHG credit values and productivity gains from employees. For the economic analyses, common parameters used for all models are summarized in Table 7:

Table 7 – Economic Parameters for Life Cycle Analyses

Item	Value
Year Existing Terminal Constructed	1976
Year Concourse E Constructed	2013
Year Existing Terminal/Concourses Redeveloped	2016
Year LCC Analyses Start	2008
Year LCC Analyses End	2025
Major Existing Terminal Upgrades	2002
LCC Analyses Centered on	Mid-Point of Timeline (2016)
Existing Terminal Area	126,348 m^2
Concourse E Area	72,000 m^2
Central Plant Area	6,040 m^2
Escalation Rate (Average for 2008 – 2025)	3%
Discount Rate/Capital Interest Rate (2008 – 2025)	3%
Blended Electricity Rate (2008 – 2025)	$0.095/kWh (based on lg. term Enmax Rates)
Blended Natural Gas Rate (2008 – 2025)	$8.63/GJ
Escalation on Utility Rates	0.01% (fixed rates for span of analysis)
Central Plant Labour Costs	$9.79/$m^2$ (no expansion to existing)
Central Plant Labour Costs	$14.63/$m^2$ (expanded to First Class Plant)

Figure 7 and Table 8 summarize the results of the analyses graphically and in tabular form.

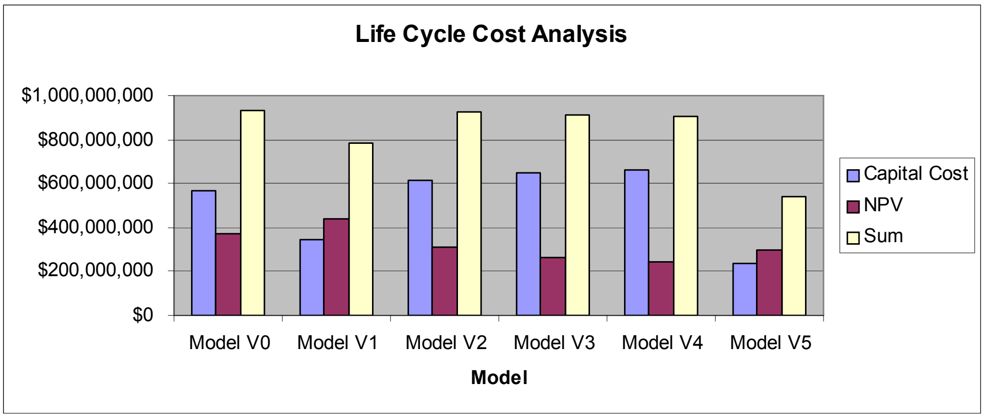

Figure 7 – Capital Cost vs. Net Present Value (NPV)

Table 8 – Annualized Return on Investment

	Model V0	Model V1	Model V2	Model V3	Model V4	Model V5
Capital Cost (2008 $'s)	$566,493,731	$574,840,356	$615,747,749	$647,100,873	$659,737,286	$704,748,571
NPV	$368,426,650	$347,775,157	$308,081,195	$261,985,439	$244,724,643	$238,741,626
Return	---	11.4%	5.6%	6.1%	6.1%	4.3%

From these results, several scenarios emerge. Model V1 shows the best annualized return on investment but does not meet the "Net Zero" criteria. Models V3 and V4 show identical annualized rates of return, and both meet the "Net Zero" criteria. Model V5 has the lowest annualized rate of return. Model V5 is the scenario where renewable energy sources are incorporated and the lower return is an indicator of the relative cost of this type of energy source compared to conventional sources in North America.

5. Ranking

In order to facilitate developing the ideal parameters for the Calgary Airport Authority for future development and redevelopment, a priority system was developed in consultation with the Airport Authority that weighed the importance of the overall parameters identified as critical to the decision making process.

Based on the Airport Authority's view of the level of importance each of these parameters has towards future expansions and/or renovations, the following priority system was established:

3 – High Level of Importance

2 – Moderate Level of Importance

1 – Low Level of Importance

Table 9 lists the parameters and their priorities as developed by the Calgary Airport Authority:

Table 9 – Ranking Parameters and Their Importance

Description	Priority
Capital Costs	3
Operating Costs	3
Redundancy	1
Ease of Implementation	2
Life Cycle Cost/Net Present Value	2
Industry Leadership	2
Environmental Stewardship	3
Reliability	2
Mechanical System Flexibility	1
Electrical Systems Flexibility	2
Airport Operations/Passenger Convenience	2
Ease of Plant Operation	1
Land Use Implications	1
Simplicity	1
Centralized Plant vs. Decentralized Plant	1

Once the parameters had been identified by the Airport Authority, a five point ranking system was developed to evaluate the effect that each model has on the parameters listed above. The five point ranking system was a sliding scale with a 5 meaning the model best met the requirements of the parameter and a 0 least met the requirements of the parameter. Each model rank was then weighted by the parameter priority value. The results of this ranking system are summarized in Table 10:

Table 10 – Ranked Models Based on Calgary Airport Authority Priorities

Parameter	V0	V1	V2	V3	V4	V5
Capital Costs	15	12	9	6	3	0
Operating Costs	0	3	6	9	12	15
Redundancy	0	1	2	5	3	4
Ease of Implementation	10	8	6	0	2	4
Life Cycle Cost/Net Present Value	2	6	4	10	8	0
Industry Leadership	0	6	4	6	8	10
Environmental Stewardship	0	3	6	9	12	15
Reliability	0	2	4	6	8	10
Mechanical System Flexibility	0	1	2	5	3	4
Electrical Systems Flexibility	0	2	4	6	8	10
Airport Operations/Pass. Convenience	0	2	4	10	8	6
Ease of Plant Operation	5	3	2	4	1	0
Land Use Implications	0	4	5	3	2	1
Simplicity	2	1	0	5	4	3
Centralized Pland vs. Decentralized Plant	0	1	2	5	4	3
Total Weighted Points	34	51	60	89	86	85

Based on the total sums Table 10, it can be seen that models V3, V4 & V5 resulted in a very close ranking score, where as models V0, V1 & V2 were collectively ranked significantly lower. This indicates that, based on the parameters outlined by the Calgary Airport Authority, the V3, V4 and V5 model options provide very similar benefits. From Table 10, model V3 has the highest ranking of the proposed modeling options. This proposed design option best addresses the factors outlined by the Calgary Airport Authority.

6. Conclusion

The comparative energy/utility consumption model results for annual primary energy consumption are presented in Figure 8. As can be seen, Models V4 and V5 achieve a 'net zero' status even at the primary energy level. Model V5 has the highest likely capital cost (and the highest degree of difficulty for implementation). Conversely, Model V0 has the highest consumption in all areas and the lowest capital cost and degree of difficulty for implementation.

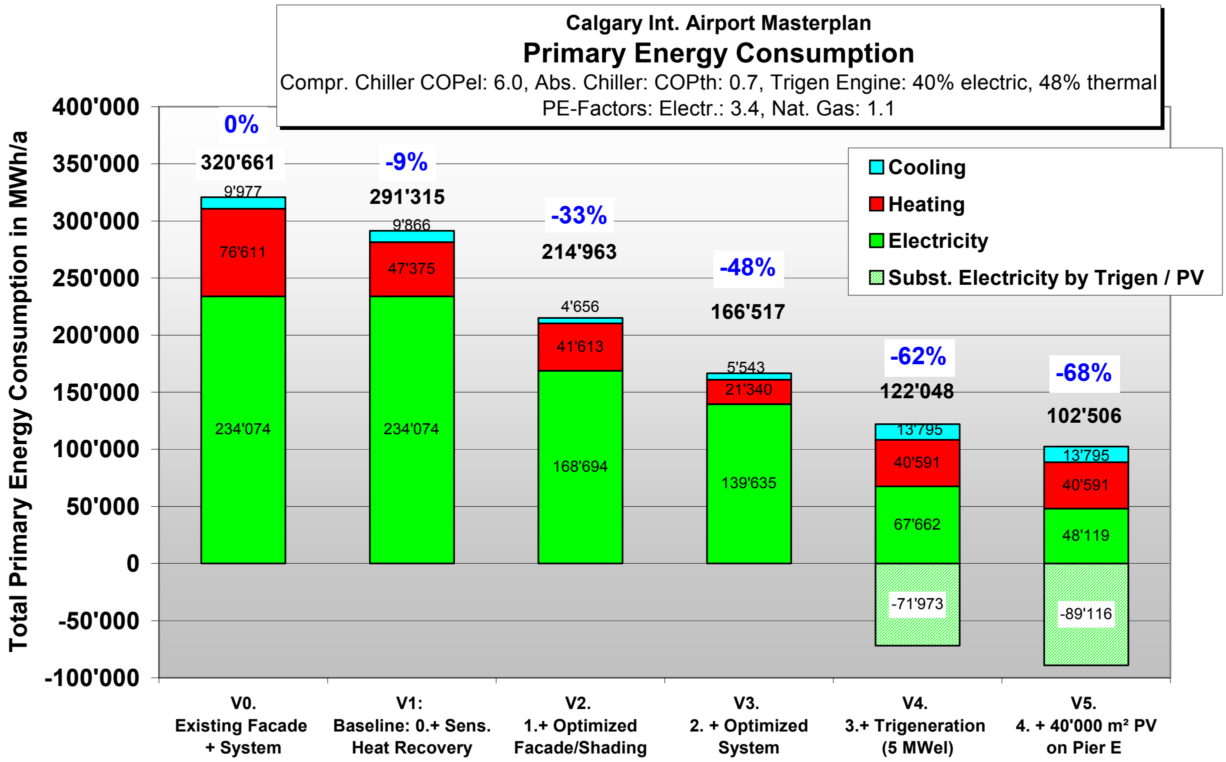

Figure 8 – Total Primary Energy Consumption for All Models

From a Net Present Value (NPV) point of view, Model V4 provides the best balance between capital and operating costs over the life of the model scenario. From the ranking criteria established with the Calgary Airport Authority, Model V3 met the most criteria; however Models V4 and V5 were very close. The annualized rates of return for Models V3 and V4 were identical. The preliminary recommendation to the Calgary Airport Authority was Model V4; achieving a "Net Zero" expansion and redevelopment (both in terms of site energy consumption and primary energy consumption) relative to the energy consumption of the existing campus; and an annualized rate of return on the additional capital cost that provides long term financial benefit. The Calgary Airport Authority has not yet adopted any recommendation.

Keywords: client, users, innovation, network, energy, public policy

Summary

This study will show that clients ***can*** act as change agents in order to reduce the energy consumption in buildings, but not all strategies are equally successful and appropriate. In recent years, the construction client has been called upon by policy makers, the architectural, engineering and construction industry (AEC) and the clients themselves to become a change agent that can stimulate the required reduction of CO_2 emissions. Despite these calls for action, little is known about ***how*** clients can make a difference as change agents. Consequently, this study will critically assess the impact and success of the various strategies deployed by a group of Swedish clients and building owners forming a strategic innovation network in order to become change agents in construction and real estate. Based on documentary analysis and interviews, the analysis will draw on a combination of innovation theories dealing with the role of users, various constructivist approaches on the co-construction of technologies and users along with studies on procurement and the role of clients in changing the construction and real estate cluster.

1. Background

In Europe, 40 % of the total energy consumption is related to buildings. A number of public policies have been implemented in the European countries to reduce the total energy consumption (AID-EE EU project 2006b & 2006c). Despite the impact of these public policies, it has also become clear that further actions from the construction industry itself are necessary to achieve the desired goal of reducing CO_2 emissions. However, it is widely recognized that the construction industry suffers from a low level of innovation. Thus, in recent years the client has been called upon by policy makers, the AEC (Architectural, Engineering and Construction) industry and the clients themselves to become change agents that can stimulate the required reduction of CO_2 emissions.

These calls are now manifesting themselves in various forms like the governmental building policy for public clients in e.g. Denmark and the Netherlands, the revaluing construction initiative of CIB and the establishment of the International Construction Clients Forum (ICCF) as well as a similar network for public real estate owners (PURE-net). Despite these calls for action, little is known about ***how*** clients in practice can make a difference as change agents.

This study will analyze how a group of Swedish clients and building owners have attempted to become a collective change agent by forming a strategic innovation network named BELOK in order to reduce energy consumption in commercial facilities. Further, the study will critically assess the impact and success of the various strategies deployed and the tools developed by the strategic innovation network of clients.

2. Research design

The research design of this study includes data from two main sources. First, this study is based on an analysis of a range of documentary sources: Public policy documents, strategic policy documents of the organization, minutes from steering committee meetings 2001-2007, the internal and the external part of the website of the organization as well as reports, articles and tools from various research and development projects initiated by BELOK.

Second, this study is based on five evaluation meetings held from August to October 2007 with 2-10 participants and representing 3 BELOK members, 4 from the BELOK administration (chairman, coordinator, Swedish Energy Agency and the Swedish Construction Clients Association), 5 other members in the BELOK Committee and 4 participants in BELOK projects. The evaluation meetings were supplemented with informal correspondence by email with the secretariat of BELOK as well as the coordinator and the chairman of BELOK. Last, the pre-conclusion was presented at the BELOK steering committee meeting 12 October 2007 and at the BELOK meeting no. 29 on 14 November 2007, both in Stockholm.

3. Theoretical framework

If we scrutinize the slogan of 'the client as change agent' closer, the three keywords of the slogan will point at key issues and research questions dealt with in different strains of theoretical and empirical studies:

- The keyword 'client' may translate in to the field of 'construction procurement' dealing with issues related to e.g. procurement systems, contractual arrangements, trust and conflict resolution.
- The keyword 'change' may translate in to the field of 'innovation' dealing with issues related to the nature of innovations, drivers of innovation, innovation process and innovation systems.
- The keyword 'agent' may translate in to the field of 'agency' dealing with the dualism of actors and structures in relation to the role as users, clients and stakeholders.

Consequently, the analysis will draw on a combination of insights from these three specialized fields of inquiry. More specifically, the study will draw on a combination of innovation theories dealing with the role of users most notably the concept of lead users, various constructivist approaches on the co-construction of users and technologies, and the role of clients in changing the construction industry as dealt with by the CIB Task Group 58 and the literature on construction procurement.

3.1 Construction procurement: the role of the client

For the past 20 years or so, the Working Commission WO92 on Procurement Systems within the International Council for Research and Innovation in Building and Construction (CIB) has discussed the issue of construction procurement. The focus of WO92 has largely been on the proper design of procurement systems so as to ensure the best performance of the building.

In 1999, the present coordinators of WO92 (Rowlinson & McDermott eds. 1999) edited a thorough overview of procurement systems. First, the collection describes the background of WO92 and introduces the key issues, which have emerged through time like procurement strategies and systems, contractual arrangements, forms of contract and the nature of the construction process. The second part deals with organizational issues in procurement systems with a focus on e.g. the client organization, strategic briefing, value management, organizational design and project success factors and organizational learning. In the third section, emergent issues in procurement systems are approached like the importance of culture, sustainability and the use of new web-based technologies. Finally, the anthology deals with procurement systems in practice in relation to partnering as well as methods and criteria for evaluating and selecting contractors.

While WO92 has largely focused on the proper design of procurement systems so as to ensure the best performance of the building, attention has increasingly been turned towards using procurement to stimulate innovation for example as an element in a public demand-oriented innovation policy (see e.g. Edler & Georghiou 2007). Manseau & Seaden (eds. 2001) sampled an international collection of papers and studies from CIB Task Group 35 focusing on how public policies can stimulate and support innovation in construction.

Most notable internationally is the establishment of the CIB Task Group 58 on client and construction innovation and the 'clients driving construction innovation' conferences in Australia (see e.g. Brown et al. 2005 & 2006).Despite the quality of the individual papers, most of the contributions tends to focus on the subject matter e.g. information and communication technologies, sustainability or performance assessment rather than discussing the concept of the client and how clients act as change agents.

In Sweden, the Swedish Association of Construction Clients has been highly engaged in developing projects and programs to gain experiences with the client as a change agent. In 1997, the Swedish Academy of Engineering Science in collaboration with leading building owners and clients published a highly influential study on organizational competences for clients. The report (IVA 1997) suggests that the client must maintain a broad spectrum of competences in order to manage planning, execution and operation of a building. The report (IVA 1997) goes on to identify the competences needed by a client in order to handle the relationship with the owner, the customer, society and the building sector.

3.2 Innovation management: the client as user

According to Dodgson, Gann & Salter (2002), the literature on innovation management has dealt with four questions. First, researchers have analyzed the nature of innovation activities by asking questions on whether innovations are radical/incremental, continuous/discontinuous, has transilience in its effects on existing ways of doing things, changes over life-cycles, are modular/architectural (systemic), results in dominant designs, or is sustaining/disruptive. Second, other approaches consider the sources of innovation which can broadly be grouped in the science-push model, the demand-pull model, and the coupling model. Third, approaches related to analysis of the innovation process include the chain-linked model, the innovation journey, and various innovation management approaches focusing on organizational integration, technology strategies and knowledge management. Fourth, approaches concerned with innovation systems has focused on systems of innovation on a national, regional, sector and technological level, analyses of networks to which firms belong, and the integration of complex product systems.

Within the demand-pull model, von Hippel (1986) has been highly influential in showing the importance of users in the development of new technologies. Von Hippel (1986: 791) has in particular introduced the concept of lead users:

"Lead users are users whose present strong needs will become general in a marketplace months or years in the future. Since lead users are familiar with conditions which lie in the future for most others, they can serve as a need-forecasting laboratory for marketing research. Moreover, since lead users often attempt to fill the need they experience, they can provide new product concept and design data as well."

Another important concept introduced by von Hippel & Katz (2002) is toolkits for user-centred innovation. Von Hippel & Katz (2002) stress that traditional product development, where manufacturers first uncover users' needs and then develop responsive products, is insufficient, because the users needs change rapidly. By using toolkits the manufacturers have given up the idea, that they can understand the users need in detail. To illustrate the toolkits they use the pizza as an example, where many aspects of the design such as the dough and the sauce have been made standard, and the user choice has been restricted to the single task of designing the topping. Von Hippel & Katz (2002) found that toolkits for user innovation are applicable to essentially all types of products and services with many different user demands. Von Hippel & Katz (2002) stress some conditions that influence the use of the toolkit: It is important that the toolkit is designed in a way that leaves room for “learning by doing via trial and error”, there has to be an appropriate "solution space", the toolkit shall be "user-friendly", there may be module libraries, and lastly there may be a problem in translating user designs into production specifications, because of difference in language, context, elements etc. so the toolkits have to be convertible between user and production.

3.3 Agency and structure: mutual shaping of clients/users and technologies

Since the 1980s it has been argued within science and technology studies (STS), that technology is socially shaped and designed. The point of departure in STS is that technical objects and social relations are bound together and that actors and technology are co-constructed. The distinction between the social and the technical is not given beforehand, but is the result of a mutual shaping process (Bijker et al. 1987; Bijker & Law eds. 1992). Various sociologists and historians of technology have put the image of a modern society created and built by experts, scientist and engineers under pressure. By emphasizing the developments in daily life and the use of new products, the users have been made visible as co-constructers of the modern technology society. In the following some of the different perspectives of the role of the users are described.

Pinch & Bijker (1984) were some of the first to include the users in technology development by introducing the concepts of interpretative flexibility and relevant social groups. In the now classical study of the birth of the bicycle, Pinch & Bijker (1984) illustrate how other perspectives and groups than engineers, designers and scientists enter into the design process by defining problems and develop solutions interpreted through respective technological frames of the groups. The technological frames guide thinking and interaction within and between the different relevant social groups.

Based on a collection of papers from various theoretical starting points, Oudshoorn & Pinch (eds. 2003) attempt to bridge various approaches to the co-construction of users and technology. First, the collection of papers addresses the active role of users as well as resistance and non-use in shaping socio-technical change. Second, focus is on the multiple collectives like advocacy groups and experts who attempt to speak on behalf of the users and the ways in which they represent the diversity of users. Third, focus is turned towards the multiple locations where the configuring of users in the development of technology is taking place. These locations include the design phase of a new technology, testing by clinical trials of drugs and the mediation process between production and consumption, in which mutual articulation and alignment of product characteristics and user requirements is taking place. In sum, although the collection of papers show the creative agency of users in shaping socio-technical change, the studies also show how agency is constrained by government regulations, gender relations etc.

In a previous paper on industrialized single-family house building, Haugbølle & Forman (2006) has shown just how relevant this perspective is for a renewed understanding of the role of the client/user/owner/facility manager etc. as multi-centred. That is, users of single-family houses hold multiple perspectives or focal points which are time-dependent in two ways since they are coupled to the life-cycle of the building as well as the life-cycle of the actor. Further, the different positions will interfere with each other.

4. The case of BELOK: A strategic innovation network

In the following, we will address BELOK as a strategic innovation network dealing with the organization of the network, the development activities being carried out, how the results are being disseminated and the effects of the activities of the network.

4.1 Organization of BELOK

The Swedish government has a national vision of reducing the energy consumption by 20 % from 1995 to 2020 and 50 % from 1995 to 2050. To fulfill this vision, the Swedish Energy Agency has among other means applied a technique procurement strategy (Swedish Energy Agency 2007) as well as cooperation with selected groups of innovative purchasers like BELOK to develop and disseminate energy efficient techniques and methods. Hence, BELOK was established in 2001 on the initiative of the Swedish Energy Agency in collaboration with leading clients and building owners of commercial facilities. The vision, mission and objectives of BELOK are (www.belok.se):

– BELOK is a group of leading building owners carrying out projects on real estate for commercial purposes, which leads the way for reducing energy consumption combined with improved functionality and comfort in the building.

– BELOK supports promising and energy efficient products, systems and methods and create the necessary conditions for implementation and fast introduction to the market.

– BELOK energy solutions must be cost effective, so that the long-term cost balances the energy profit.

– BELOK projects are followed up by evaluation and monitoring the realized energy improvements and their influence on the functionality of the building.

In 2007, 13 commercial real estate owners are members of BELOK, and eight of them have been members since the establishment of BELOK. Five companies are private, two companies are owned by regions and six companies are owned by the government. No members are from municipalities in Sweden. BELOK has got five new members the last five years, and one company has withdrawn its membership in the same period. Although the number of members is fairly small, the 13 BELOK members own 17 % of the total segment of 155 million m^2 heated area of commercial facilities. Further, the 13 BELOK members own buildings at a total market value of 263 billion SEK, and in 2006 the yearly investment by the 13 BELOK members reached 19 billion SEK or 32 % of the total investment in commercial facilities. Thus, the BELOK members represent a significant share of the market for commercial facilities.

The driving force in BELOK is a group of enthusiastic and committed representatives for owners of commercial facilities supported by a chairman and a secretary, all with high technical, research and commercial competences. Since 2005, BELOK has been hosted by the Swedish Construction Clients Association, which is an organization of about 120 professional private and public owners and landlords in Sweden. The board, called the BELOK Committee, has 8 members including one from the Swedish Energy Agency and one from the Swedish Construction Clients Association.

Since 2005, the BELOK Committee has been responsible for drafting two-year development programs and selecting relevant development projects to be initiated. The latest program covers the period 2007-8 with a total budget of 25 million SEK of which 9 million SEK is granted from the Swedish Energy Agency and the remaining 64 % is financed by BELOK members. Although the two-year programs are formally approved by the Swedish Energy Agency, autonomy is de facto granted to the BELOK Committee to make the decisions regarding new projects etc.

The regular appropriation of new development programs by the Swedish Energy Agency for BELOK and the delegation of professional decision-making to the BELOK Committee have been essential for the success of BELOK. All interviewees highly praise the Swedish Energy Agency for the way they support BELOK and the strategy of using the innovative real estate owners as brokers for implementing new and improved energy technology and methods in the construction and real estate sectors.

Suppliers and participants in BELOK projects support this strongly and add, that BELOK is an excellent venue for meeting new suppliers and ideas, where they have the opportunity to get vital experience in front-running projects and to be accepted by a strong group of buyers. Under normal circumstances it would be impossible for them to penetrate the market so quickly.

4.2 Development activities

It is a characteristic of the innovation process that the majority of projects are primarily based on 'a good idea' developed by technicians, based on technically based research and in close collaboration between the main partners in the supply chain and the professional customer – the owner and member of BELOK. This practice, however, has a number of implications.

First, the development projects initiated by BELOK can be divided into two main categories. Until today, BELOK has launched 15 technical product-oriented projects and 8 process-related development projects. Technical projects like the development of HVAC installations and glass façade systems dominate the portfolio of development projects. Among others, the technical projects include:

– Office building with glass facades.

– Ventilation with variable air flow.

– Electro filter in ventilation.

- Chilled beam systems in cooling towers.
- Consumption of electricity.
- Control and monitoring systems.

Management and process-related projects play a smaller role in BELOK compared with technical product projects. Among others, the process-related projects include:

- BV^2-Arch - Energy design of building.
- Demands and specifications.
- Energy management and declaration.
- Tenancy contracts with incentives.

BELOK has put less effort into the process-related projects compared with the technical product-oriented projects, and the evaluation indicates that process projects are more complicated for BELOK to implement. Improved and more efficient processes are a supplement to product development and supporting the dissemination of new energy efficient technologies. It is therefore important for BELOK to improve the process developments in the future. Thus, a challenge for BELOK could be to improve the processes by putting more focus on the needs of the individual target groups and to fulfill specific objectives for development of communication, competence and energy efficient attitudes.

Second, the type of innovations addressed by BELOK tends to be incremental in nature, thereby reducing the associated risk for the involved actors. All development and demonstration projects are based on a solid technical research background, and they are only initiated if they appear to be ready for introduction on the market. More risky projects are seldom initiated, and at least once BELOK felt obliged to stop a project because it did not rest on solid technical ground and was not mature for market introduction.

Third, certain perspectives like the perspective of end-users are largely left out of sight due to the close collaboration with the main partners in the supply chain. All development and demonstration projects are based on a solid research background, and they are executed mainly by technicians and researchers. The documentation and information are aimed at the same group. It is noticeable that far less attention has been paid to the operational end-user in facilities management, how to improve the design and construction process, and how the results could be disseminated to other owners, internally in BELOK companies as well as to other consultants, contractors and suppliers. The result is that more simple and user-oriented information materials is lacking regarding state-of-the-art and actions to be taken for others than the front-runners and the technicians.

4.3 Dissemination

When looking at the dissemination activities of the BELOK network it is worth considering which groups are the target groups of dissemination and information activities. Six target groups may be identified:

- 1. Internally in BELOK companies.
- 2. Between BELOK members.
- 3. Other owners and projects.
- 4. Researchers, universities and schools.
- 5. Technical suppliers.
- 6. Consultants and contractors.

BELOK has carried out a number of dissemination activities, but the predominant method is through internal meetings aimed at the members of BELOK. The stability and commitment of participants in the work of BELOK is noticeable. Since the start of BELOK in 2001, 28 meetings have been held. Seven persons have participated in 75 % or more of these meetings, and they include the chairman, the secretary and the representative of the Swedish Energy Agency. The last four old member companies have participated in around 50 % of the meetings. Three of the new members have participated in 75 % or more of the meetings since becoming members of BELOK, and the last two new members have participated in around 50 % of the meetings. Eight member companies have been represented by only one person in the BELOK meetings, and the rest has been represented by two to four persons.

Frequent interaction is ensured by two-day meetings four times a year, where ideas are turned into action and development projects in an open and friendly atmosphere between professional colleagues. Especially the person to person discussions and exchange of experiences during breaks and in the evening are important. Several interviewees expressed the importance of the informal discussions between the members and the Swedish Energy Agency, and that the Swedish Energy Agency are faithful participants at both BELOK meetings and the BELOK Committee. It is also important that decisions are made on technical and professional grounds and linked directly to demonstration projects and developments on site. Some interviewees even considers the meetings and the professional contacts and discussions as their most important training venue as innovative owners.

Whereas commitment and frequent interaction marks the internal dissemination of results and lessons learned, the external dissemination to actors outside BELOK tends to be more random hitherto. Results and lessons learned from the development of techniques, products and processes are important to disseminate to the individual partners in the sector if the effect should be measurable not only in the development projects but in all commercial facilities in Sweden. Although BELOK recognize the importance of external dissemination to other actors in the construction and real estate cluster, there does not seem to be a clear strategy and operational plan for dissemination from the creative and innovative members in BELOK to other building owners, consultants, suppliers etc. The BELOK website is the main channel for disseminating information from BELOK, but also seminars and competitions on technique procurement are channels for dissemination. However, BELOK does not use e.g. newsletters or professional trade courses as means to communicate results and lessons learned.

First, the BELOK website gives information on all finished projects and projects in progress. Specific tools like BELOK life cycle costs calculation and early energy calculation for architects – BV^2-Arch – can be downloaded free of charge. Common demands and specifications on indoor climate, energy and control and monitoring systems can also be downloaded from the website free of charge. The website also contains a list of members and the description of the BELOK organization with contact addresses. On the front page latest news and cross-reference to the archives of news are given. Managing and updating the website regularly has turned out to be more challenging than anticipated. Thus, BELOK has now hired an external supplier to help improve the website with a monthly updating.

Second, the number of public seminars held by BELOK in 2006 and 2007 has been modest. On the website, information is given on two seminars held in September 2006 and in May/June 2007. The first seminar discussed results on daylight and sun shutters. The second seminar discussed energy consumption, indoor climate, daylight and life cycle cost in glass office buildings. No information is given on the website on new seminars, workshops or site visits to be held in 2007 or 2008.

The third dissemination channel for BELOK is the technique procurement and the announcement of a competition, the winner and the winning project. The competition is part of the technical procurement method that the Swedish Energy Agency uses to improve energy efficient methods and new techniques (Swedish Energy Agency 2007, Persson 2004), and it is followed up by installation, testing and evaluation. BELOK has completed two competitions: one competition on BV^2-Arch and one on control and monitoring systems. The competition on technique procurement proves to the market that BELOK is an important player in the development of commercial building and demonstrates in practice the vision for future techniques, product, tools and processes. At the same time the innovative owners demonstrate their willingness to make energy efficient decisions and buy new energy efficient techniques and processes. The interviewees gave the impression of a successful process that was completed and reported in a professional way but with a number of practical challenges for future improvement like readiness of technologies, sufficient number of competitors and the specifications and the evaluation methods must be documented in advance and fit for the owner and consultant in the decision process.

4.4 Effects

The previous chapters have dealt with the first three out of four bullet points regarding the vision, mission and objectives of BELOK. Now, the attention will be turned towards the last bullet point stating that BELOK projects are followed up by evaluation and monitoring the realized energy improvements and their influence on the functionality of the building.

BELOK is facing a serious challenge of measuring and documenting the overall effect of BELOK and the individual development projects. Scrutinizing the few reports from the finished projects, reveal a number of problems in assessing the results, fixing the reference points and calculating the specific and future cost and energy savings compared with traditional techniques and processes. A similar observation was reported in 2006 by Lars J. Nilsson (AID-EE EU project 2006a) in a European study on energy efficiency policies (AID-EE EU project 2006b & 2006c).

The observed and reported problems of measuring the effect of the finished projects stems from earlier phases of the project, when the development projects were formulated and selected. In the selection process, measurable targets for energy improvements, indoor climate and cost reductions ought to be set if consistent assessments are to be carried out at the end of a project. Further, it should be described how it could be tested in the process and the delivery of the product. However, some of the BELOK projects set vague targets for energy consumption, and only a few of them describe the investments and savings in costs in a measurable way.

Thus, there appears to be little overall reflection on the cost-effectiveness of the individual development project. Often key issues related to dilemmas of investment cost versus life cycle costs as well as reduction of energy consumption versus improved indoor climate are not sufficiently dealt with in the project proposals. Further, the development projects are not primarily initiated because they add substantially to the fulfillment of objectives set in the national vision for energy consumption. Instead 'the good idea' and the technical maturity are more important concerns. Consequently, the initiated development projects do not necessarily provide 'best value for money' when it comes to parameters like low investment costs, quick dissemination, large reduction in energy consumption and large market shares.

The current situation is quite understandable. If BELOK starts claiming measurable targets for improvement in the energy consumption and long-term cost compared with a traditional technique and process, the energy and cost targets together with other performance parameters must be evaluated and reported in a systematic way by the owner and supplier. However, such a system for consistent and systematic evaluations does not exist at present. Thus, an important challenge for BELOK could be to develop simple and cost effective methods for different types of evaluations.

5. Conclusion

This study has analyzed how a group of clients have formed a strategic innovation network in order to act as change agent in the construction and real estate industry cluster with respect to improving energy performance of commercial facilities. The study has shown that clients ***can*** act as a change agent in order to reduce energy consumption in buildings, but not all strategies and tools are equally successful and appropriate. A number of observations lead to four lessons learned regarding ***how*** the client acts as change agent.

First, the driving force in BELOK is a group of enthusiastic and committed representatives for owners of commercial facilities, which represent a significant share of the market. The delegation of professional decision-making power and the regular appropriation of new development programs from the Swedish Energy Agency to BELOK have been essential for the strategy of using the innovative real estate owners as brokers for energy efficient technologies in the construction and real estate cluster. Suppliers and other participants in BELOK projects add that BELOK is an excellent venue for acquiring new vital experience in front-running projects and to be accepted by a strong group of buyers. Thus:

> *Lesson no. 1: If a strategic innovation network based on strong personal commitment is linked together with regular appropriation of public funding and decision-making power, (some) clients can and will act as change agents in the construction and real estate cluster.*

Second, the study has shown that the innovation process is primarily based on 'a good idea' developed by technicians, based on technically based research and in close collaboration between the main partners in the supply chain and the professional client. Some of the implications of this practice are: less effort into the process-related development projects, risk reduction and largely leaving out of sight certain perspectives of e.g. end-users. Thus:

> *Lesson no. 2: Clients are likely to undertake technical product-oriented and incremental innovations rather than process-related and/or radical innovations.*

Third, the internal dissemination activities of BELOK are strongly supported by the small, stable and committed group of actors along with the frequent interaction of that group. The external dissemination activities are, however, more random in character. That raises an important strategic question of what role should BELOK play as change agent: Do clients as change agents pull the rest of clients and/or do they push the supply chain? And how will they do that – by outdoing other actors, by active involvement of other actors, or by informing other actors of results and showing alternative routes? Clients need to be very aware of the differences and how they e.g. communicate in the different settings. Thus:

> *Lesson no. 3: In the role as change agent, clients need to carefully observe the balance between the double ambition of pulling/pushing the supply chain and pushing/pulling other clients.*

Fourth, BELOK is at present faced with the challenge of measuring and documenting the overall effect of BELOK and the individual development projects. Targets and results are not sufficiently set and described in a systematic manner, and there appears to be little overall reflection on the cost-effectiveness of the individual development project. Instead 'the good idea' and the technical maturity are more important concerns. Consequently, the initiated development projects do not necessarily provide 'best value for money'. Thus:

> *Lesson no. 4: The engagement of 'the good idea' needs to be linked closely with strategic objectives and systematic assessment of effects.*

In conclusion, BELOK pull the innovation in the real estate market and in the construction sector supported by universities by formulating common demands and specifications for better products, processes and knowledge. They implement new and better products and processes, and by good examples they demonstrate the effect on improved energy efficiencies, indoor climate and the long-term economy for the owner and end-user. They are also playing a role in the dissemination from the best owners to the rest of the real estate market, and to the construction and building products markets through supporting the best and most innovative consultants, contractors and producers.

CLIENT-LED SUSTAINABLE CONSTRUCTION: DECISION SUPPORT FOR WHOLE-LIFE COSTS IMPLICATIONS

Bee Hua GOH Ph.D

Department of Building, School of Design and Environment, National University of Singapore, 4 Architecture Drive, S117566, Singapore, bdggohbh@nus.edu.sg

Keywords: client, sustainable construction, whole-life costs, green features, the Green Mark Scheme, intelligent rule-based system

Summary

The client's role in leading change in the construction industry has been widely perceived as crucial and, on the theme of sustainable construction, it is advocated that clients must play their role to lead in engaging industry stakeholders in managing sustainable performance of construction projects. In essence, it is the client that makes the initial decision to procure construction works and the way in which procurement takes place. This influences the degree of environmentally-friendly (or sustainable) practice that is implemented in a project. For most building owners and property developers, this decision is affected by cost. And, in view of the significance of cost, the on-going research aims to ascertain the main type of developments that have been awarded the Green Mark, as well as study their winning green features. A proposed rule-based system that contains decision-support rules pertaining to the assessment of (whole-life) cost implications for this type of building projects is described. The system is to be developed to meet the criteria of Singapore's Green Mark Scheme. The Scheme has been devised and implemented by the Building and Construction Authority since January 2005.

1. Introduction

The Green Mark Scheme is a green building rating system used to evaluate a building, new or completed, for its environmental impact and performance. In each case, the assessment is based on five key criteria looking at levels of energy efficiency, water efficiency, site or project development and management (for new buildings) or building management and operation (for existing buildings), good indoor environmental quality and environmental protection, and environmental innovation. A point scoring system is used to quantify and ascertain the extent of environmental friendliness of the new or existing building.

Since January 2005, a total of 60 building projects have been awarded the Green Mark and they ranged from public to private developments, including residential, institutional and commercial types. Broadly intended, the scheme was developed by the Building and Construction Authority (BCA) of Singapore to promote sustainable development by raising environmental awareness among all participants in the construction industry, particularly, property developers, designers and contractors.

2. Aim and Objectives

In this paper, the research aims to ascertain the main type of developments that have been awarded the Green Mark, as well as study their winning green features. A proposed rule-based system that contains decision-support rules pertaining to the assessment of (whole-life) cost implications for this type of building projects is described and to be developed to meet the criteria of Singapore's Green Mark Scheme. Specifically, the objectives are as set out below.

a. To classify projects that have been awarded the Green Mark by types of development and client;
b. To compare the actual classification of projects with the theoretical classification;
c. To ascertain the type of developments that has the largest number of projects which have been awarded the Green Mark;
d. To classify the green features of this type of developments based on projects which have been awarded the Green Mark by building element; and
e. To map the BCA's Green Mark Scheme onto applicable components of whole-life costs by building element to develop rules for the proposed decision-support system.

3. Types of Clients

Traditionally, clients of the construction industry have been classified by interest and motivation in order to better understand their needs in a proposed development. The motivating factors can range from profit to social and use (Ferry et al., 1999). Now, in the contexts of sustainable construction and whole-life costs, the client's responsibility is broadened to encompass environmental impact concerns. The logical argument is that it is the client who makes the initial decision to procure construction works and the way in which procurement takes place. This influences the degree of environmentally-friendly (or sustainable) practice that is implemented in a project. For most building owners and property developers, this decision is affected by cost. Hence, there becomes an increasing pressure for clients to consider whole-life costs in their projects so as to attain overall best value.

From a review of the relevant literature to draw logic on areas of types of clients, sustainable construction and whole-life costs (Bathurst and Butler, 1980; Seeley, 1981; Addis and Talbot, 2001), a mapping of the degree of importance of sustainable construction and whole-life costs onto the different types of clients can be done. Essentially, it is a mapping based on theoretical assumptions. And as verification of the assumptions, classification of the types of projects that have been awarded the Green Mark from 2005 to 2007 will be made to establish the actual practice of different types of clients in Singapore. Table 1 shows the result of this theoretical mapping.

Table 1 Theoretical Mapping of Interest in Sustainable Construction and Whole-life Costs onto Different Types of Clients

	Public-Sector Clients	Private Occupiers (eg. Private Individual)	Private Occupiers (eg. Private Companies)	Private Property Companies
Type(s) of Development	Institutional Residential Industrial Commercial	Residential	Industrial Commercial	Residential Industrial Commercial
Interest in Sustainable Construction/Best Value Concept	Yes	No → Little	Little → Yes	Residential – No Industrial & Commercial – Yes
Interest in Whole-Life Costs	Yes	No → Little	Little → Yes	Residential – No Industrial & Commercial – Yes

Source: Author

4. Classification of Projects Awarded the Green Mark

Projects that have been awarded the Green Mark can be found in the BCA's website. The lists for projects awarded in 2005, 2006 and 2007 are used for the purpose of generating the classification by type of developments as shown in Table 2. There are altogether 60 winning projects that have been classified.

Table 2 Classification of Green Mark Projects by Type of Developments

Year of Award	Institutional	Residential	Industrial	Commercial
2005	3	8	1	5
2006	5	8	1	3
2007	5	11	2	8
Total = 60	13	27	4	16

From the mapping of interest of clients as shown in Table 1, the winning projects are also classified by type of clients to check and verify the theoretical assumptions made. The generated classification is given in Table 3.

Table 3 Classification of Green Mark Projects by Type of Clients

Year of Award	Public-Sector Clients	Private Occupiers (eg. Private Individual)	Private Occupiers (eg. Private Companies)	Private Property Companies
2005	3	0	1	13
2006	5	0	1	11
2007	6	0	2	18
Total = 60	14	0	4	42

As the category 'Private Property Companies' has the largest number of projects (i.e. 42), a breakdown is provided in Table 4 to show the distribution of projects among four main types of use. It is evident that private residential projects have the highest count (i.e. 26).

Table 4 Breakdown of Projects by Type of Use for the Category 'Private Property Companies'

Year of Award	Office	Residential (eg. Private Condominium)	Hotel	Retail
2005	5	8	0	0
2006	2	8	1	0
2007	3	10	1	4
Total = 42	10	26	2	4

5. Adoption of Building Elements of Singapore Standard CP80:1999

The Singapore Standard CP80:1999 has been developed to serve the key purpose of allowing the exchange of data and information to enable communication of design, construction and contractual matters relating to cost via a uniform classification format. The development of the national standard in 1999 involved a review of international standards and an adaptation of a few international standards to suit local use. The main components of the national standard are:

a. an elemental classification,
b. a work-section classification,
c. a mapping dictionary for elements and work sections, and
d. a set of guidance notes.

The elemental classification is adopted for this research. It comprises three main divisions. They are the group element, element and sub element. An example of the classification of elements of the group element "Superstructure" is given in Table 5.

Table 5 Elemental Classification of the Group Element "Superstructure"

Group Element	Element	Sub Element
Superstructure	• Columns and structural walls	• Columns • Structural walls
	• Upper floors	• Slabs • Beams • Steps and ramps
	• Roof	• Roof structure • Roof coverings • Roof drainage • Roof lights
	• Staircases	• Staircase structure • Staircase finishes • Handrails and balustrades
	• External walls and cladding	• External walls • Cladding • Curtain walls • Windows
	• Internal walls and partitions	• Partitions • Acoustic walls
	• Doors	• Internal doors • External doors

The Building Cost Information Service of the Royal Institution of Chartered Surveyors defines an element as a component that fulfils a specific function or functions irrespective of its design, specification or construction. A classification based on elements achieves standardisation. Hence, it is applied as the framework for mapping the Green Mark Scheme onto applicable components of whole-life costs to develop rules for building the decision-support system.

6. Classification of Green Features of Private Residential Projects

From Table 4, it can be seen that a total of 26 Private Residential projects have been awarded the Green Mark since 2005 and it forms the largest group among the types compared. The research now focuses on this category of projects for a further analysis of their winning features in order to gain an appreciation of latest industry trends and practices on environmentally-friendly design and technology. The information is extracted from the BCA's website. The green features are classified according to the various group elements. The result is shown in Table 6.

Table 6 Elemental Classification of Green Features of Private Residential Projects

Group Element and Element	Examples of Key Winning Green Features
1. Site Preparation: Demolition Site clearance Earthworks Soil investigation	• Use of seawater for ground improvement works with substantial water savings.
2. Substructure: Piling Foundation Basement Ground Slab	• Construction using circular diaphragm wall utilises less manpower and strutting materials. • Extensive use of sunpipes to bring natural daylight to the 3 basement levels. • Basement carpark is designed with about 20% opening for natural light and ventilation. This eliminates the need to provide full mechanical ventilation and water sprinkler fire fighting system.
3. Superstructure: Columns and structural walls Upper floors Roof Staircases External walls and cladding Internal walls and partitions Doors	• Staircase shelter – utilizes less concrete and steel for construction and less materials for accessories. • 'Parabienta' Green wall system is used to vertically green part of the building façade on 2nd floor of the Development along footpath adjacent to Orchard Boulevard. The system is lightweight and provides consistent greening. • The use of environment friendly and recycled materials manufactured locally or overseas for doors and dry wall partitions. • Extensive green provided to some areas of the rooftop to help reduce heat gain to the topmost residential units.
4. Finishes: Wall finishes Floor finishes Ceiling finishes	• Thermal insulating paint to all external walls for entire development to reduce solar heat gain and energy consumption. • The use of environment friendly and recycled materials manufactured locally or overseas for rubber floorings.
5. Fittings, Fixtures and Furnishing: Sanitary wares and fittings Fixtures and furniture Artworks and sculptures Soft furnishing	• All units are provided with dual flushing system water closets. • The use of environment friendly and recycled materials manufactured locally or overseas for wardrobes.

6. Services Installations: ACMV Sanitary and plumbing Electrical installations Transportation Communications installations Security systems Fire protection systems Gas installations Maintenance equipment Pool and water feature installations Special installations	• Use of energy efficient equipments such as – energy efficient lightings in common areas, inverter air-conditioning system, motor-roomless lifts. • Use of twin-chute pneumatic waste system to encourage recycling. • All apartments are provided with inverter multi-split air-con systems. • All apartments are provided with dimmer controls for living/dining and master bedroom. • Solar powered system for heated pool and aircraft warning lights. • Gearless traction elevator. • Solar panels are provided at the rooftop to harvest solar energy and motion sensors are provided at strategic locations to help reduce energy consumption from the Grid.
7. External Works: Surface treatments Drainage External services Minor building works	• Solar-powered lamps for landscape and pool deck. • Transplanting of mature trees. • Use of recycled plastic in children's playground equipment. • Environmentally friendly lightweight plastic grid for turfing along fire engine access way. • Rainwater harvesting system for irrigation of landscape.

7. Mapping the Green Mark Scheme onto Components of Whole-life Costs

In order to develop rules for the proposed decision-support system, there is a need to map the requirements of the Green Mark Scheme onto applicable components of whole-life costs. These components include the initial capital costs, operating costs, maintenance costs, management costs, opportunity costs and disposal costs of the asset at the end of its life (Addis and Talbot, 2001). As there are many mandatory and elective requirements under the Scheme, it is only possible to illustrate the mapping for a few group elements. The result is shown in Table 7.

Table 7 Mapping of Green Mark Requirements onto Whole-life Costs Components and Implications

Group Element and Element	BCA Green Mark Version RB/3.0 Category and Points Allocation	Component of Whole-Life Costs and Its Implication
Superstructure: Columns and structural walls Upper floors Roof Staircases External walls and cladding Internal walls and partitions Doors	Mandatory Requirements: M1 Building Envelope – RETV: RETV shall not exceed 25 W/m^2. Mandatory Requirements: M2 Roof – U Value: Weight group: Light, under 50kg/m^2, 0.8 W/m^{2}K; Medium, 50 to 230kg/m^2, 1.1 W/m^{2}K; Heavy, Over 230kg/m^2, 1.5 W/m^{2}K. Mandatory Requirements: M4 Air Tightness and Leakage: All windows on the building envelope shall not exceed the air leakage rates as specified in SS 212.	For External Walls: Initial capital costs – High Operating costs - Low Maintenance costs – Low For Roof: Initial capital costs – Very High Operating costs - Low Maintenance costs - High

	Elective Part 1 – Energy Efficiency: 1-1 Building Envelope – RETV: Max permissible RETV=25 W/m^2; 3 points for every reduction of 1 W/m^2 in RETV from the baseline. 1-2 Dwelling Unit Indoor Comfort: (a)(ii) Design for natural ventilation (applicable to development where air-conditioners are not provided) (0.6 point for every 10% of units with window openings facing north and south directions; 0.6 point for every 10% of living rooms and bedrooms designed with true cross ventilation) Elective Part 3 – Environmental Protection: 3-1 Sustainable Construction: (a) More efficient concrete usage for building components (0.1 point for every % reduction in the prescribed Concrete Usage Index (CUI) limit for residential buildings). Elective Part 5 – Other Green Features: 5-1 Green Features and Innovations: Self cleaning façade system (2 points for high impact item; 1 point for medium impact item; 0.5 point for low impact item).	
Finishes: Wall finishes Floor finishes Ceiling finishes	Elective Part 1 – Energy Efficiency: 1-7 Energy Efficient Features: Cool paints (2 points for high impact item; 1 point for medium impact item; 0.5 point for low impact item). Elective Part 4 – Indoor Environmental Quality: 4-2 Indoor Air Pollutants: (a) Use of low volatile organic compounds (VOC) paints certified under the Singapore Green Labelling Scheme (at least 90% of the total internal wall areas - 2 points). (b) Use of adhesives certified under the Singapore Green Labelling Scheme for composite wood products (1 point).	Initial capital costs - High Maintenance costs - Medium
Fittings, Fixtures and Furnishing: Sanitary wares and fittings Fixtures and furniture	Elective Part 2 – Water Efficiency: 2-1 Water Efficient Fittings: (a) Basin taps and mixers (b) Flushing cistern (c) Showers	Initial capital costs - High Operating costs - Low Maintenance costs - Medium

Artworks and sculptures Soft furnishing	(d) Sink/Bib taps and mixers (e) All other water fittings (at least 90% of the fitting type used; 0.5 points for Good; 1 point for V Good; 2 points for Excellent). Elective Part 4 – Indoor Environmental Quality: 4-2 Indoor Air Pollutants: (b) Use of adhesives certified under the Singapore Green Labelling Scheme for composite wood products (1 point).

8. Rules Development

The rule-based system will be developed using the ILOG *JRules* software. This software is able to manage rules throughout their life cycle, that is, from creation through testing, deployment and retirement to allow for greater flexibility to rules developers and managers, especially in the rapidly changing business environment.

The generic if-then structure of a rule is illustrated for the building envelope design as shown below:

A Rule-Based Decision Target (as an example):
If building envelope design meets "RETV requirement of not exceeding 25 W/m^2",
Then set initial cost to "high" and add the message "the likelihood of high is very high"
And set operating costs to "low" and add the message "the likelihood of low is very high".

It involves applying a set of pre-established vocabulary (see the underlined words) to define the rule's conditions and actions, as well as present the rule in a readable language.

9. Testing the Developed Rules

The different sets of rules developed for the main elements of a building will be verified against the process or product used in those buildings that have been awarded the Green Mark. Essentially, such Green Mark projects would have adopted energy efficient features, water conservation measures, made substantial use of greenery in their projects and ensured a good indoor environmental quality for their users, setting them apart from other buildings. Therefore, the rules will be adjusted or modified according to the best practices adopted in the Green Mark projects.

10. Conclusion and Discussion

The paper has presented the methodological process of ascertaining the type of knowledge and acquiring it for developing a rule-based system that will contain decision-support rules pertaining to the assessment of (whole-life) cost implications for building projects that will meet the requirements of Singapore's Green Mark Scheme. Firstly, it has classified projects that have been awarded the Green Mark by types of developments and clients. It has been found that the largest group is residential projects developed by private property companies (see Tables 3 and 4). Based on Table 1's classification, this finding deviates from the theoretical assumption that this type of clients is the least interested in sustainable construction and whole-life costs since it is generally understood that they develop (the condominiums) for sale and not ownership or use. Evidently, this assumption has been found to be not true in the case of Singapore. Secondly, it has classified the winning green features of this type of developments based on projects which have been awarded the Green Mark by building element to provide an appreciation of latest industry trends and practices on environmentally-friendly design and technology (see Table 6). Thirdly, the BCA's Green Mark Scheme has been mapped onto applicable components of whole-life costs by building element to develop rules for the proposed decision-support system (see Table 7). In the next stage of systems development, efforts will be spent on developing the if-then rules using the ILOG *JRules* software and testing them on actual projects.

Acknowledgement

The on-going research project is wholly funded by the National University of Singapore which is entitled, "An Intelligent Rule-Based System for Whole-Life Cost and Sustainable Building Decisions".

Abstract

The comparison of ventilation technologies is often analysed at peak design, as it is difficult to model all relevant climatic scenarios. The energy of ventilation is a substantial energy load and an informed decision of the designer and owner is needed to ensure a sustainable outcome.

The new ASHRAE standard 62.1-2007 (5.10.1) points toward humidity level of 65%rh to model comparisons. Relevance to each technology with the energy saving initiatives of US standard ASHRAE 90.1 is made. Doing this the comparison of a mixed return system, against Dedicated Out-side Air Systems (DOAS) can be made with air and water cooled chillers. These methods can then be ranked on suitability based on peak demand, operating cost, and ventilation cooling performance requirements of various cases. We look at the use of Binmaker® weather data, and compare the DOAS methods of energy recovery ventilators, run around loop, and humidity control unit direct expansion (DX) desiccant package. The options are compared with the capital cost to model financial expectations of buildings in Darwin (Tropical) Brisbane (humid) Sydney (Moderate) and Melbourne (Mild), quantifying the effect of increasing ventilation for improved IAQ.

1. Introduction

Energy simulation of the ventilation humidity control technologies is required to be made to judge the best solution for the site needs. Considerations for site energy cost peak penalty and site humidity needs. Special considerations for access to high efficiency chiller, waste heat, solar hot water and gas can modify selection further. The return on investment will be made to maximize the savings opportunity.

2. Energy Simulations

2.1 Simulation Model, The Munters Makeup Air Modeling Method. (MMAMM)

The following is a comparison for the conventional mixed fresh air system with various available DOAS technologies. This is reviewed under an Australian Building Code BCA2007 JV4 (10) model where a reference performance is made of the baseline technology. A JV3 model is not practical as ACADS BSG, Trace, and Camel lack the options to match all the technology options. The methodology of JV 3 can then be applied for other components separately.

Binmaker® data in g/kg with average enthalpy in kJ/kg are used and mixture calculations are made and technology credits, for each increment of g/kg. Data is also available in individual hours and results are typically in +/-5% of the compressed version. The compressed version is selected as all the results are readable, however a detailed analysis on sensible heat impact in a building would need the detailed data due to the temperature variance per increment of g/kg. A comparison of the available technologies is made on Table 2 for 23 °C and 65%rh, and Table 3 for 23 °C and 50%rh for prominent Australian cities. A direct system sample comparison of Sydney is made in Table 7 between mixed return air with chiller system coefficient of performance (COP) of 3 and Drycool HCU unit using chilled water as a DOAS configuration.

2.2 Site Model description:

Analysis of only latent considerations is made in this comparison. Each technology provides different supply air temperatures and flow (see section 5.1 Design issues) so sensible analysis need separate consideration.

Comparative technologies

- Chilled water from air cooled chiller or DX set COP of 3 mixed with 81% return air
- Chilled water from air cooled chiller or DX set COP of 3 to fresh air AHU
- Chilled water from water cooled chiller system COP of 5.3
- Energy recovery ventilators ERV combined with Chilled water AHU
- Drycool HCU, Desiccant with DX reactivation fresh air package with MOD and ERV option
- Run around coil energy reclaim
- Indirect Evaporative pre-conditioner OASIS®

2.3 Parameters

Process: 2,800 L/s (10,000 m^3/hr, 6000cfm) ventilation to be proportioned
Duty: Absolute humidity 13.4g/kg and 10.2g/kg equivalent to (23 °C 65% and 50%rh) less nominal latent load from 336 people (23.5kWlatent) capacity from system. (Ref: Figure 12).
Ambient weather data: Binmaker® from Linric (9) in groups of g/kg with coincidental enthalpy's and number of hours (temperature optional)
Performance: From manufactures literature Trane Chiller system COP of 3 and 5.3, Des Champs ERV 70% efficiency, Munters Drycool® HCU 3g/kg credit with Copeland scroll COP of 2.7, 60%, Des Camps Run around coil 60%, Hours of operation: 24hr, 7 days
Utility cost: $A0.10/kWh nominal, excluding peak load and penalty need further consideration.

.

Fresh air latent: Variable dependant on ambient with fixed fresh air flow 2,800 l/s (10,000m^3/hr) Statistical weather data is used to conduct the energy analysis. The annual hours that correspond to certain humidity conditions are shown at increments of 1g/kg. (Refer Figure 12).

Internal latent: The latent load is also considered with respect to the personnel and infiltration. Estimation is made number of people that occupy the space and a value for the ventilation is given based on the m²/ occupant. These values can vary with population or how industrious the area is
e.g Retail varies in:-
Australia :- 1 person per 6.5m^2, 7.5 l/s (27m^3/hr) pp, 5 l/s (18m^3/hr) with approval in tropical climate.
Singapore: - 1 person per 5m
China: 20-30m^3/hr (Restaurant, Office)
USA: - 1 person per 8m is commonly use. US STD: 120 sq.ft. per person based on ASHRAE. Note; Some engineers, subtract the area where the fixtures are, some do not. 15cfm pp (25m^3/hr)

The calculated load for 336 people is 70W or 100g/h of water per occupant. Infiltration is modeled through a conservative estimate of 30 doors, 2 x 2 meters each, opening for a period of fifteen seconds every hour. Results from the calculations (Figure 12) show a value of 13 g/kg for the room's moisture content and 20 g/kg ambient humidity. The velocity of the vapor in still air equals 0.2 m/s and exposed air 2m/s. Therefore, the moisture load is represented by a relation between, mass flow, density and moisture difference giving a total value of 31.3 kWr. (46.48 kg/hr)

Supply air compensation.
The required supply air therefore must compensate for a latent load of 46.48 kg/hr. The required Δ ω is related to the space moisture content (ω) and the supply air ω.

Δ ω = Space ω – supply air ω
Since, 46,480 [g/hr]= 10,000 [m^3/h] x 1.2 [kg/m] x Δ ω [g/kg]
Δ ω = 3.8 g/kg
Baseline supply of 10.6 g/kg or 14.9Cdp for Baseline (see table 7)

Drycool HCU obtains the Free effect of the desiccant is 3 g/kg,
The off coil duty is 10.7/kg (16 °Cdp)
Drycool HCU actual Supply air = 10.7- 3g/kg= 7.7g/kg or 10.1 °Cdp

3 Technology descriptions:

3.1. Air cooled chiller or DX set COP =3 system

As an alternative to a mixed return system a dedicated ventilation system run on chilled water/DX is modeled. This eliminates the energy drain of diluting the moisture in the fresh air before it is treated by a much larger airflow.

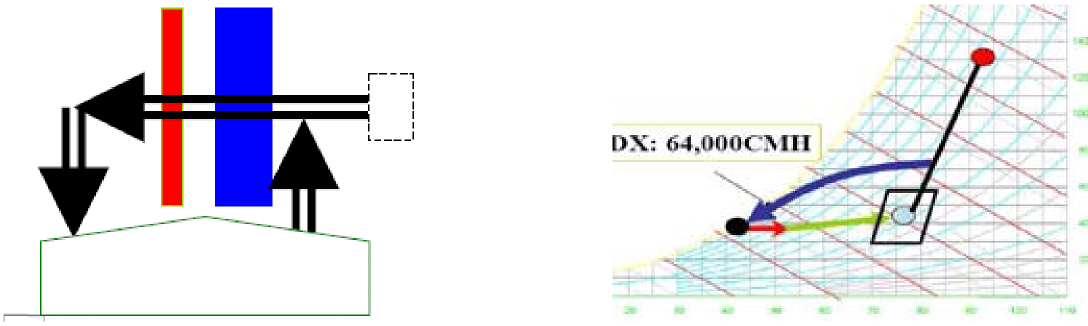

Figure 1 Air cooled chilled water system. Mixed Air supply 18,000L/s (64,000cmh)

3.2. Air cooled chiller or DX set COP =5.3 system for mixed return air
As per 3.1 but more efficiency when using high efficiency water cooled chillers (by cooling tower).

3.3 A water cooled chiller system has an operation assumed at COP=5.3, Legionella implications may not be acceptable to the client. A DOAS from a chilled water coil is treating the fresh air condition. Effectiveness on latent duty is dealt with and allows the central plant to run on cooling or heating only. This also provides better humidity control at part load and allows the central plant to control temperature. Advanced systems like SMAC® Shaw method (1) function this way however reverse cycle may not be possible from the chiller for heating when there is a dehumidification duty i.e. 18 ºC 100%rh.outside. (NOTE 10000CMH =2,800 L/s)

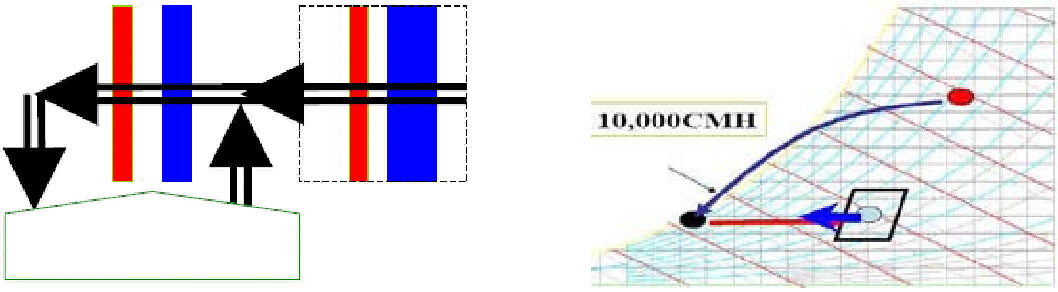

Figure 2 DOAS method, or fresh air chilled water DOAS. 2,800 l/s (10,000cmh)

3.4 Energy Recovery Ventilator (ERV) combines with above

Energy recovery ventilation requires the use of exhaust air from the space to precondition the outside air which is still required to satisfy the design requirement. Assumption of 75% applies to 100% exhaust use, and 50% efficiency applies to exhaust being 2/3 of ventilation.

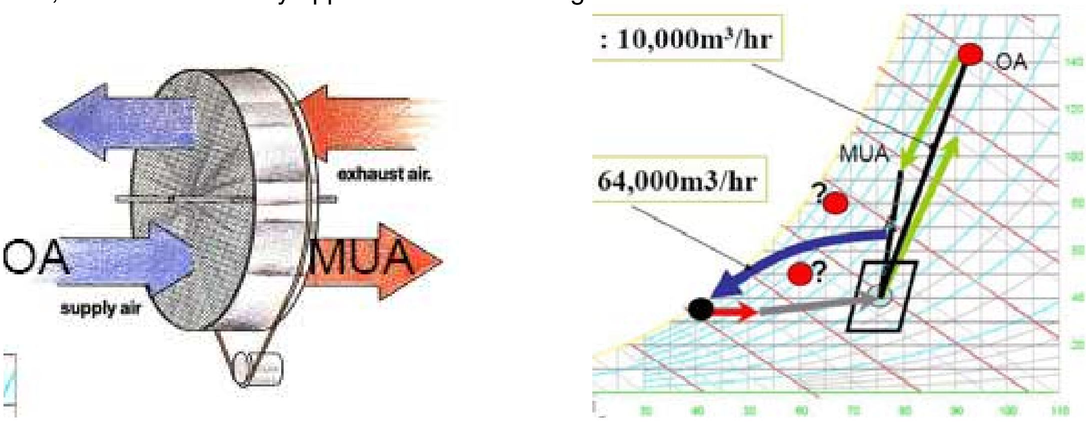

Figure 3 ERV-Chilled Water (NOTE: 10,000 / 64,000 cmh = 2,800 / 18,000L/s)

3.5 Humidity control unit, Desiccant with DX reactivation fresh air package

Full fresh air DX unit designed for ventilation latent load and reusing its own condenser heat for regeneration of the desiccant wheel. Munters Drycool® HCU compressors nominal COP of 2.7, and desiccant credit provides 3g/kg (15kj/kg), with equivalent reheat credit of 11 °C at all stages of compressor capacity. Note also reduces cooling duty for new installations (est. $A 400 per kWR)

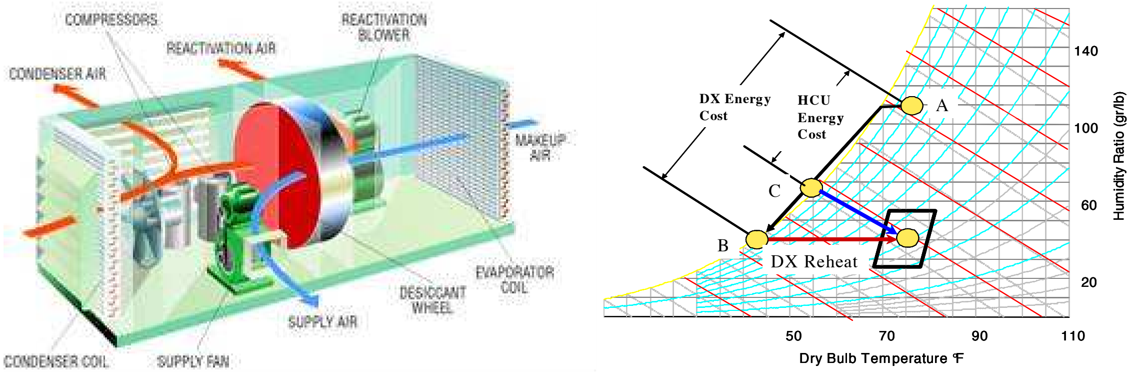

Figure 4 Munters Drycool (HCU) Humidity Control unit and Munters HCU psychrometric

3.6 Humidity control unit, Desiccant with Chilled water module (MOD) with DX fresh air package
Same as 3.5 with chilled water inlet coil from site services for improved efficiency and cost. HCU Copeland compressors nominal COP of 2.7 nominal ¼ cooling duty at 35kWr (10RT), and inlet chilled water module (MOD) coil duty a nominal ¾ of cooling duty 140kWr-0kWr variable

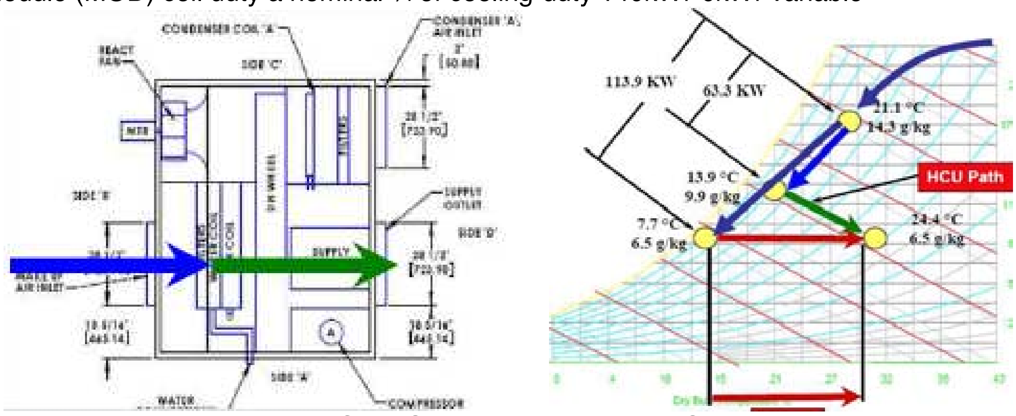

Figure 5: Munters Drycool HCU MOD Unit and Munters HCU psychrometric

3.7 Run around coil/plate sensible heat exchanger
Essentially provides an upstream energy credit equivalent to the 60% efficiency between ambient and the off coil condition. (Eg:- ambient 20 °C, off coil 10 °C, reheat 6K, supply 16 °C, inlet credit 6kJ/kg.)

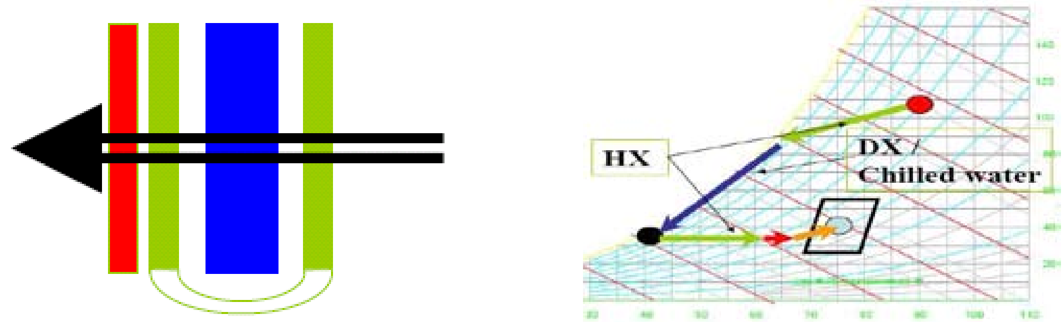

Figure 6 Heat reclaim and Psychrometric operation

3.8 Chilled water precooled Desiccant with gas reactivation fresh air package
Full fresh air chilled water COP of 5.3 preconditioning for a conventional desiccant dehumidifier which is powered by direct fired gas (cost est. 4c/kWh) with COP=1. The electric gas cost ratio of 2 allows the 25kJ/kg latent effect to be equivalent to an electric device with COP 1x2 = 2 for modeling purposes. CO_2 emissions would need recalculation. The supply air temperature would be 30 °C -40 °C and in need of closer sensible load scrutiny.

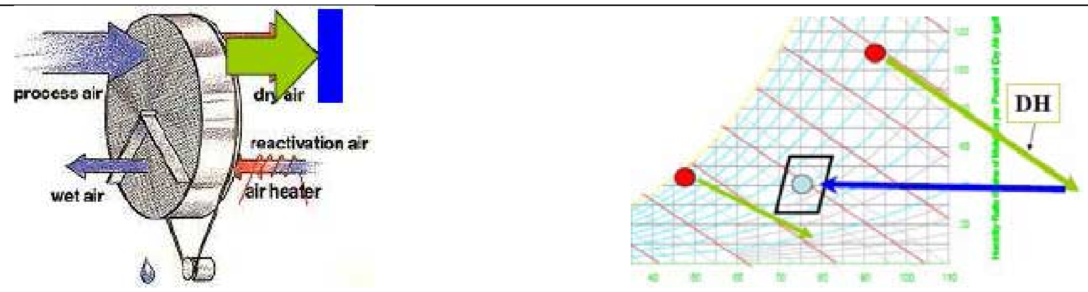

Figure 7: Gas Fired Desiccant dehumidifier and psychrometric chart

3.9 Indirect evaporative cooling on inlet

The system can use the low wet bulb of exhaust air and specially non media systems are able to use grey water. A 75% effect between outdoor air and exhaust wet bulb. Ambient wet bulb can be used to make us pressurization air. A post cooing coil is the calculated coil work, and evaporative cooling post cooling is a convenient option.

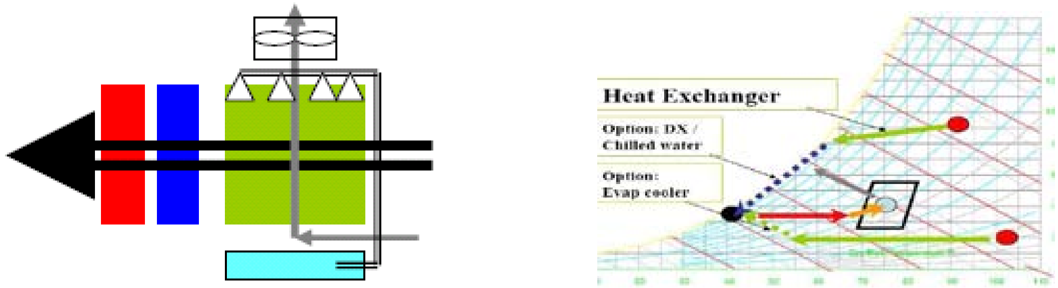

Figure 8: Indirect evaporative cooler and psychometric chart in humid and dry operation

4 COMPARISONS

4.1 Results summary: A review of the nominated technology against baseline follows.

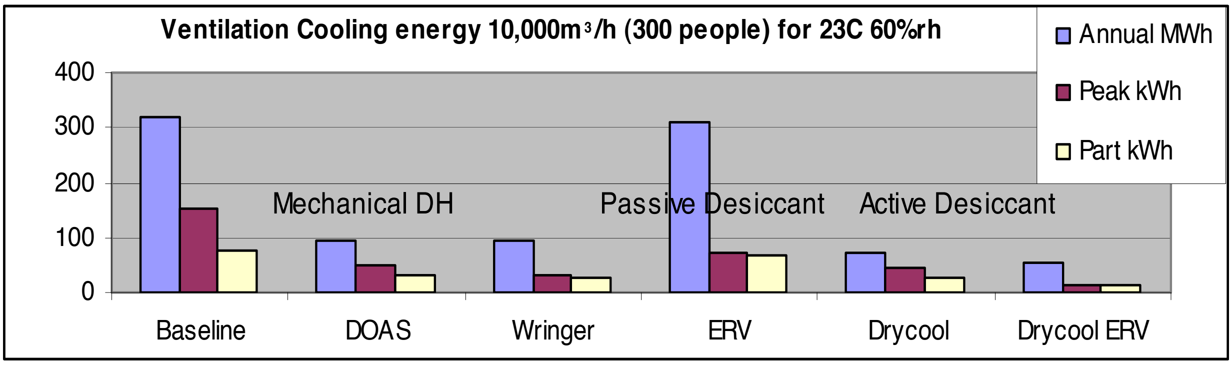

Table1 Sydney Results: Munters Makeup Air Modeling Method MMAMM (Annual, Peak and part load)

The most efficient mixed fresh air system is the COP = 5.3 chiller and comparison with the most efficient DOAS DrycoolHCU with chilled water follows in detail. (Also see Appendix Figure 12)

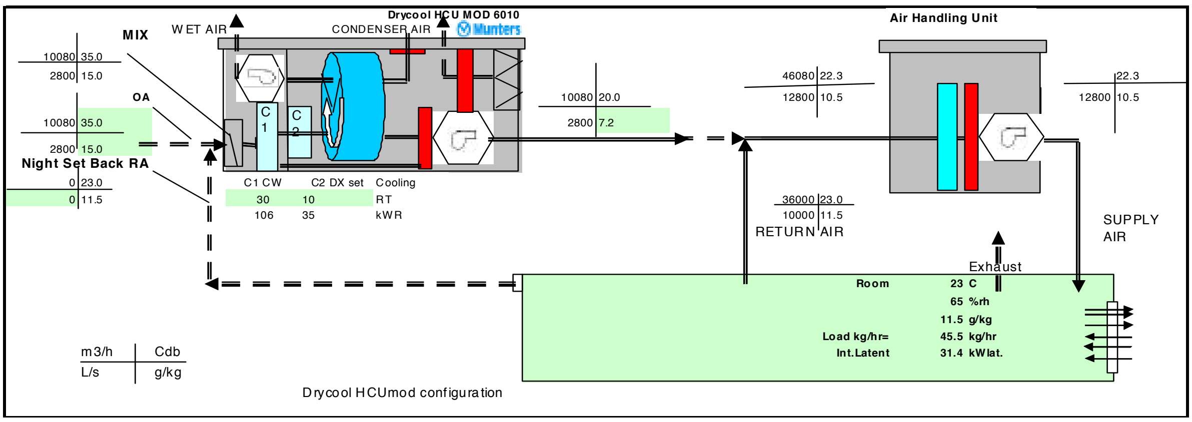

Figure 9 System schematic with Drycool HCU mod on fresh air

4.2 Detail on best mixed return Baseline option Vs best DOAS in Sydney @23C 65%rh

5 Other Design issues

5.1 Equipment discussion

Further to Thirakomen's (1) overview, some operating characteristics need mention.

Chilled water from air cooled chiller or DX set COP 3 or 5.3 to fresh air AHU
May have reheat limitations under ASHRAE 90.1 regarding restriction of reheat for humidity control and Australian Building code (10) limiting reheat to 7.5°C i.e. 10 °C + 5 °C =15 °C, may have difficulty obtaining absolute humidity as it is working toward its operating point, lower chilled water temperature may be needed with worse COP. This method is the commercial norm with cheapest first cost.

Energy recovery ventilators (ERV)combine with above

Unable to achieve humidity set point at part load conditions i.e. 20°C 100%RH will enter untreated without chiller running. Comments for chilled water DX also applies. Needs exhaust air to be ducted to return and can get out of balance with dirty fresh air filters.

Humidity control unit, Desiccant with DX reactivation fresh air package

Qualify for LEED credits (ABGR Australia= 1 point) for maintaining duct RH below 80%rh and room below 60%rh. Able to provide dew point and lower at part load due to the desiccant removing moisture after the DX coil. Supply air typically 10 °C greater than dew point (i.e. 25 °C for 14.8 °C dp supply air in Figure 12). this suites lower average internal space load, post cooling can support peak design space heat loads such as chilled beams. Chiller efficiency is improved by needing 6 °C warmer water than other systems. Drawback is Drycool HCU is unable to operate in reverse cycle under 7 °C, post heater needed. Higher first cost due to the extra technology.

Run around coil

Same issues as Chilled water option although reheat at warmer temperatures is high (i.e. 35 °C ambient and 10 °C off coil, supply 25 °C, winter 15 °C and 10 °C off coil, supply 13 °C. Some adjustment for fan energy due to the extra exchange and the 180degree bend for plate HX is required. There is difficulty in efficiently obtaining 50%rh due to the internal load requiring a supply of 3.5Cdp.

Chilled water pre-cooled Desiccant with gas reactivation fresh air package

Full fresh air chilled water COP=5.3 preconditioning has a lower off coil duty and can therefore run more efficiently at higher temperature. The conventional desiccant dehumidifier which is powered by direct fired gas has a warm supply air temperature suitable for peak demand reduction and heating environments like swimming pools, or industrial process where design conditions below 50%rh.

5.2 Set point for comfort and building mould prevention

With the new summer controls for temperature the level of humidity needs close consideration. Due to this sample run of 65%rh can be compared with 50% rh using Humidex factor which is an operational health and safety indicator used by the Canadian Government. (7)
The conditions of 23 °C 65%rh is 27.2°C Humidex, (near peak of “no discomfort” scale) while 23 °C 50%rh is 25.2 °C is satisfactory, (26C and 65%rh can 32.6C discomfort level in Humidex)

Humidex = (air temperature) + h
h = (0.5555)*(e - 10.0)
e = 6.11 * exp (5417.7530 * ((1/273.16) - (1/dewpoint))) (Source: Environment Canada (7))
Scale Less than 29: No discomfort 30 to 39: Some discomfort, 40 to 45: Great discomfort;

Other RH set point issues are improved comfort, reduced mould and corrosion, dry ductwork and % RH on the building walls. Colder wall surface have a higher relative humidity than the room and should be kept below 60%rh to avoid mould propagation, current US methods employ 45F (7C) dew point buildings OA to evaporate water from construction leakage within a 2 days to avoid mould (6).

5.3 The potential price of Carbon (CO_2 emissions)

A nominal CO_2 emission credit has been included and recent figures of $50A per ton CO_2 has been nominated by Western Australian government.
The potential price of carbon:
“The IPCC summary outlines that the if the target for stabilisation of climate to between 450 and 550ppmv CO_2-eq (i.e. approx 2 degrees C), then the price for carbon should be set at up to US$100/t$CO_2$-eq. (paragraph 21)” (11)
This price would provide credit/reduced penalty of $US14,700 p.a. Vs Mixed chilled water.

6 Conclusions

A comparison of the most current ventilation systems were made and highlighted the benefit of DOAS compared to mixed return air system to control humidity. The energy model demonstrates that there are effective technologies in reducing power cost other than efficient chillers. A nominal guide for energy reduction can now be made to quickly identify viability of various technologies at peak and part load. The trade off of improved IAQ from increased ventilation can now be made against Peak energy cost and annual energy cost and CO_2 emissions.

Summary

A follow-up study in 2007-2008 has been undertaken of 24 'low-energy' dwellings in Milton Keynes, UK, that were originally monitored for hourly energy consumption from 1989-1991. Results were compared under standardised daily external conditions of 5°C. No statistically significant evidence of change over 17 years was found in overall gas consumption at 63kWh/day (95%CI:50,77) and overall electricity usage at 14.6kWh/day (CI:10.6,18.7). Since the distribution of energy usage was skewed, dwellings were classified into three groups according to low, middle, and high energy usage in 1990. At follow-up, the high group accounted for most increases in energy use, consuming more energy than the other two groups combined; their gas usage was 98kWh/day (CI:78,117), and electricity usage almost doubled to 25kWh/day (CI:18-33). The high group comprised dwellings that were on average larger originally and had larger additions by 2007 than other groups. Their energy use was greater than the other two groups combined. The findings suggest that research for development of energy policy, including the effectiveness of building regulations in reducing carbon emissions, should focus both on households where the most energy is used and where future increases in electricity usage are most are likely to occur.

1. Introduction

As one of its stated objectives to deal with the challenge of climate change, the UK government aims to achieve a 60% reduction in carbon emissions by 2050 (Department of Trade and Industry 2007). Since 1990, total CO_2 emissions from the UK have reduced by nearly 6% to 153Mt of carbon in 2005. The domestic sector is estimated as contributing 27% (41.2 Mt) of total emissions, about 2% lower than in 1990. This decline includes the substantial impact of the shift from coal to gas generation, and hence an almost 30% decline in the carbon content of electricity generation over the period (Dept. of Trade and Industry 2007). More to the point, annual energy consumption in the domestic sector has risen since 1990 by 20% (565TWh/yr). While other energy sources, such as solid fuels declined over the same period, even on a per household basis by 2004 gas consumption had risen by 17% (to 15.5MWh/yr) and electricity by nearly 10% (to 4.5MWh/yr) (Dept. of Trade and Industry 2006).

These figures illustrate a central issue in accurately ascribing trends in energy usage in the domestic stock to specific factors and thereby in forming effective carbon emissions policy. Namely, these trends arise from dynamic and diverse environmental, physical, and social influences on the building stock and its occupants over the same period. In addition to warmer winters, including greater prevalence of gas central heating, higher levels of insulation, building fabric deterioration and renovation, house extensions and conservatories, and changes to building regulations. This has been accompanied by the impact of various sociodemographic trends, such as an aging population, fewer people per household, and relative changes in disposable income.

The current study is part of the Carbon Reduction in Buildings (CaRB) project that intends to use empirical data from longitudinal studies of temperature and energy usage to detect trends and assist with the development of socio-technical models for the domestic sector. Rather than rely on initiating a longitudinal study from scratch, where inevitable delays would be incurred before significant trends could emerge, the CaRB project has also sought suitable prior studies with accessible temperature, energy, and social data to serve as a baseline survey.

1.1 Milton Keynes Energy Park Study

In 2005 data was retrieved from a project that had been conducted from 1989-91 and that, in spite of some incompleteness in the range of information available, could act as a baseline. In an area then known as Milton Keynes Energy Park (Milton Keynes is a low density city located about 75km North-West of London), the original study had monitored more than 100 dwellings for hourly electricity and gas consumption. The dwellings essentially follow conventional UK housing design, but were built in 1987 to higher standards for energy performance than were required by the building regulations at that time (Edwards, 1990). They incorporated energy efficiency features, such as increased floor, wall, and loft insulation, double-glazing, and in some cases condensing boilers, so that they broadly corresponded to UK building standards of almost a decade later.

Based on results from the pilot study (Summerfield et al. 2007), the following hypotheses were advanced with respect to changes that would be observed in a follow-up study:

- Energy usage in both baseline and follow-up would have a highly skewed distribution across the sample
- Gas consumption would have risen, but this would be consistent with increases in floor area
- Electricity usage will have increased in line with increased ownership of appliances that either were uncommon or did not exist in 1990

2. Methodology

2.1 Baseline and Follow-up Studies

The original study monitored hourly gas and electricity consumption on more than 120 dwellings over a period of 18 months, from 6 January 1989 to 30 September 1990. Data was retrieved for 62 gas centrally heated dwellings. Unfortunately it was not possible to recover related social data, such as the number of occupants in each household. From late 2006, a follow-up survey was initiated by CaRB with recruitment of 28 households living in dwellings from the original study. None of the households were the original occupants in the dwellings during the baseline study, though some were aware that it had taken place due to remnants of metering equipment still visible by the entrance. Apart from those who were unable to be contacted, the reasons given by occupants for non-participation in the study were ‘lack of availability due to work commitments’, ‘being away during the start of the study period’, ‘moving to another home’, and ‘illness’. Building and interview surveys were conducted for each household, with gas and electricity meter readings taken on an approximately monthly basis. Three households dropped out during the monitoring phase of the follow-up study.

2.2 Statistical Analysis

The final sample with sufficient data at both time points comprised 24 gas centrally heated dwellings. To enable a comparison under standardised winter conditions (and without needing annual data), simple linear regression models were fitted for each dwelling, with weekly mean external temperature (T_{ex}) as a predictor of gas and electricity usage. As illustrated in figure 1, the regression model was restricted to T_{ex} < 15°C for gas usage, with estimate values obtained for both gas and electricity usage under the standardised conditions of T_{ex} = 5°C (Figure 1), a figure close to average heating season temperature in the UK. A similar process was carried out for the follow-up study, except using mean T_{ex} over intervals corresponding to the meter readings.

Since the distribution of energy consumption was found to be skewed, dwellings were then grouped into thirds based on their total energy consumption in the 1990 study, and referred to as the low (n=8), mid (n=8), and high (n=8), energy groups. Once a dwelling had been classified according to its energy consumption in 1990, it remained in the same group throughout the subsequent analysis to simplify interpretation of the results. Thus any change detected in a group has occurred to the same group of dwellings from baseline to follow-up studies. This classification process could have been done separately by gas and electricity, however it was found that essentially the same groups were formed in all cases (in other words high gas usage was likely to be accompanied by high electricity consumption). From the results obtain previously using regression models, average energy consumption of each group for both time points were calculated under the same standard conditions of daily T_{ex} = 5°C. All statistical analyses were carried out using SAS version 9.1.

2. Results

Just over half the sample are detached houses (n=13) and a more than a third are semi-detached (n=9), compared with 22% and 32% respectively across the UK (Shorrock & Utley 2003). The heated floor area of dwellings (that is, excluding unheated extensions, such as conservatories) has increased by 10% from 85m^2 to 93m^2. There are 2.5 (±0.2) people per household at follow-up, which based on the pilot study and national statistics is likely to represent a decline since 1990, especially with respect to the number of children in the housholds (Summerfield et al. 2007).

Table 1 Daily household energy usage (CI:95%) at external T=5°C.

(kWh) (kWh/m^2)	1990	2007
Energy	74 (63,86)	78 (61,95)
Energy/A	0.87 (0.74,1.0)	0.84 (0.66,1.01)
Gas	64 (54,74)	63 (50,77)
Gas/A	0.75 (0.63,0.87)	0.68 (0.54,0.82)
Elec.	10 (8.7,11.3)	14.6 (10.6,18.7)
Elec./A	0.12 (0.1,0.13)	0.16 (0.11,0.2)
Floor Area (m^2)	85	93

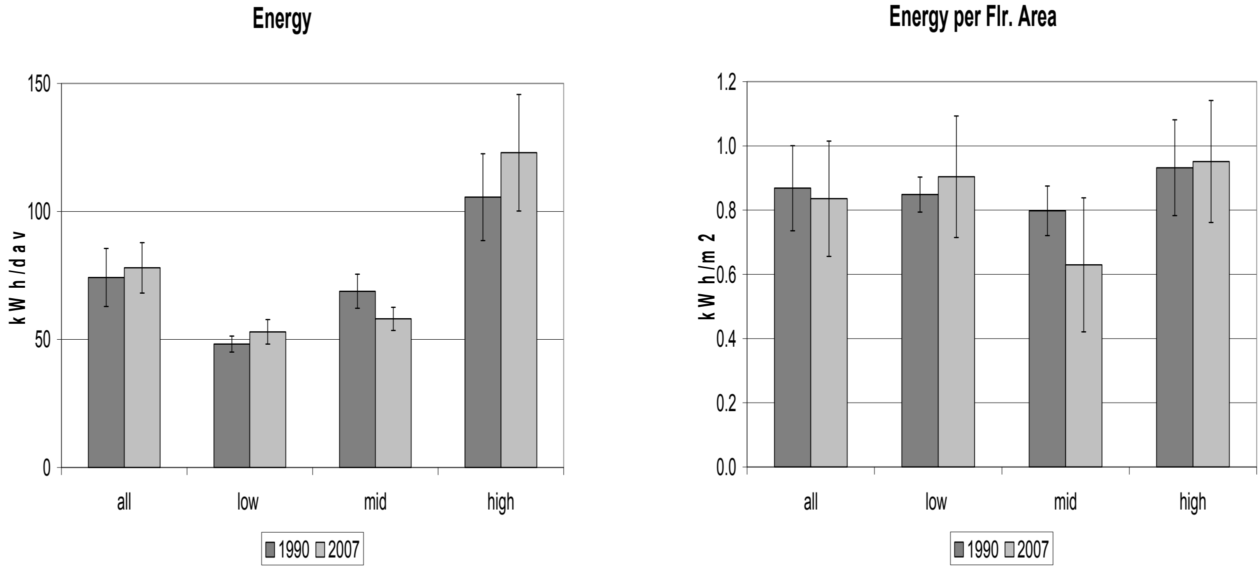

Figure 3. Daily household energy usage (95%CI) and normalised for floor area (right) for 1990 and 2005 by energy group (at external T=5°C).

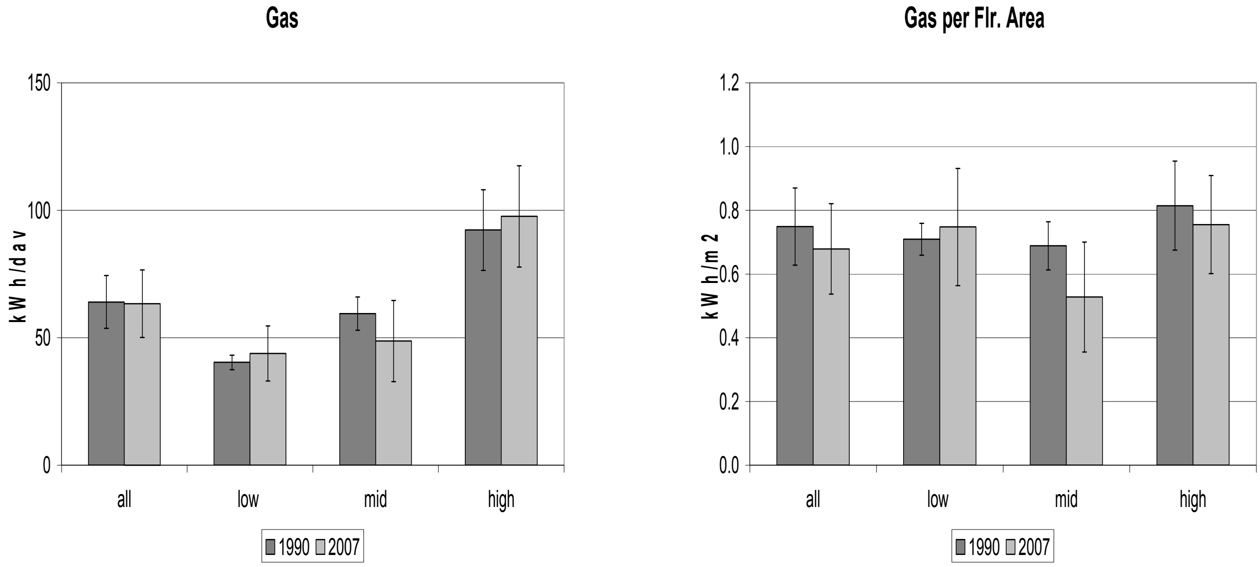

Figure 4. Daily household gas usage (95%CI) and normalised for floor area (right) for 1990 and 2005 by energy group (at external T=5°C).

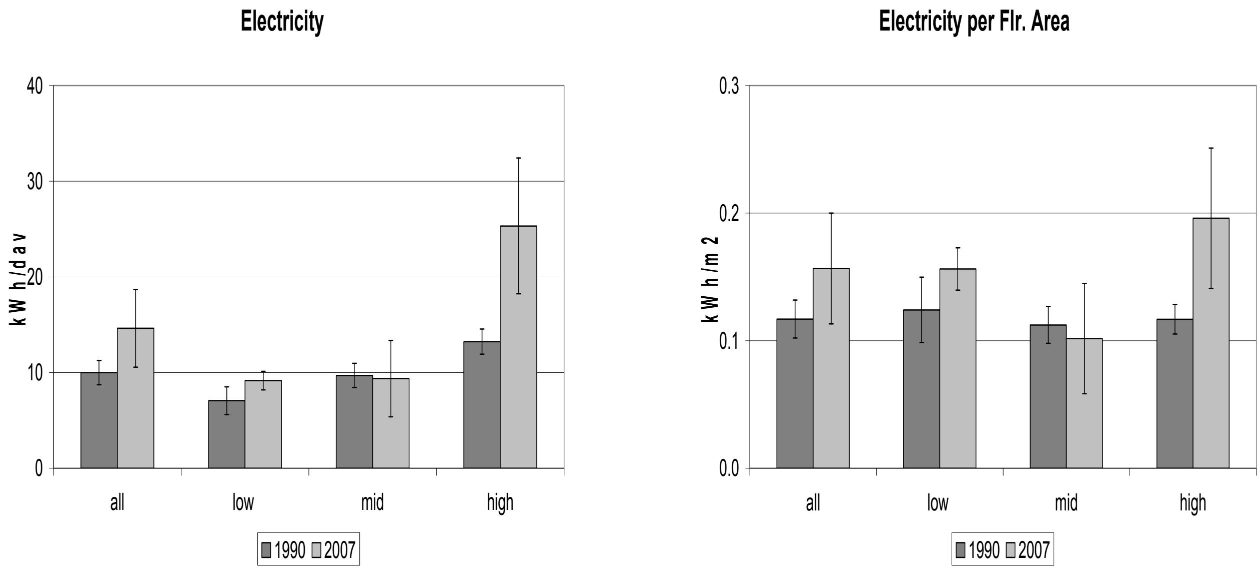

Figure 5. Daily household electricity usage (95%CI) and normalised for floor area (right) for 1990 and 2005 by energy group (at external T=5°C).

Table 1 gives overall results across the two studies, with energy usage at 78kWh (CI:61,95) in 2007 compared with 74kWh (CI:63,86) at baseline under standard winter conditions of external T=5°C. Although no statistically significant change ($P<0.05$) was observed for any of these results, the overall pattern of change hints at some increase in consumption for electricity. Figure 2 indicates that the sample is highly skewed so that it is not surprising that changes in the overall mean values are difficult to detect.

When the results were analysed by group according to low mid and high energy usage in 1990 (Table 2 and Figures 3 to 5), there is no evidence of significant change in the low and mid group. For the high group there was a clear pattern of increases over 1990 levels, that in terms of gas consumption was accounted for by a larger increase in floor area than in the other groups (up by 14% to 129m^2). Electricity consumption for the high group has almost doubled to 25kWh (CI:18,32) over 17 years and this results remains significant ($P<0.05$) even after normalising for floor area.

3. Discussion

The data collected in 1990 has provided an invaluable opportunity to undertake a longitudinal study of 24 low-energy dwellings in the UK and investigate changes in energy usage from baseline (1990) to follow-up (2007) under standard winter conditions of 5°. Gas consumption has essentially remained constant over the 17 years at 63kWh (95%CI: 50 to 77). Even though electricity consumption appeared to rise by 40% to 14kWh (95%CI: 10 to 18), the high degree in variance in the underlying data at follow-up often due monitoring spells where dwellings were possibly unoccupied, meant that changes observed in the overall results were not statistically significant.

However, when the results were analysed with dwellings classified into three groups, of low, mid, and high energy users according to the estimated consumption from the baseline data, a consistent pattern emerged whereby high energy users accounted for almost all of the increases only weakly apparent in the overall statistics. Unsurprisingly this tends to correspond with larger homes. There was weak evidence that energy use by the high energy group rose by 16% to 123kWh/day (95%CI: 98 to 148). Gas consumption may also be higher, but was (statistically) unchanged at ~0.8kWh/m2 when normalised for floor area. The houses in the high group have had additions that have resulted in an increase in heated floor area, and this occurred to a greater degree than in the other groups. Most notably, electricity usage has almost doubled in the high group to 25.3kWh/day (95%CI: 18 to 32). Rather than a change in the energy performance of dwellings, there has been a shift from gas to electricity in the high group, possibly reflecting an increase in appliance ownership and secondary electric heating in house extensions.

The main strength of this study lies in the detailed energy and building data collected in 1990 that forms the baseline survey. Although caution should be applied in terms of any implications at the national scale, since the sample was not a representative selection of the population of building stock, with an over-representation of detached dwellings. Nevertheless the occupants are likely to have undergone broadly similar social and demographic changes, such as owning more appliances. Moreover the results here appear to be consistent with the skewed energy consumption distribution that is evident in national figures, whereby the top 30% of households by income spend (and, by implication, use) more than all other households combined (Shorrock & Utley 2003). The results are also largely consistent with findings from the pilot study with respect to change observed mainly in the high usage group (Summerfield et al. 2007).

There is great value in following up this specific group of dwellings which represented best practice in the UK for the symbolically important year – in Kyoto Protocol terms – of 1990 and which were roughly a decade ahead of their time with respect to building regulation standards. Hence they also provide an indication of what might be expected a decade from now, from dwellings of an equivalent standard. The study has shown that some dwellings have remained essentially at 1990 energy usage or below and that there was no evidence of a decline in the energy performance of the building. Yet this was not necessarily the case for a group of dwellings that accounted for all the observed change. In summary, the high energy group not only increased, accounting for half (50%) of the energy used in 2007, it is almost three times more than the low group and nearly double that of the middle group. It appears that these dwellings increased in floor area more than was the case in other groups, and this may have been accompanied by increased appliance ownership and secondary electric heating. These findings highlight issues regarding the importance of effective targeting of energy conservation measures both to where consumption is greatest and where it is increasing most rapidly.

SUMMARY

The present paper introduces an atlas of air conditioning loads for a standard building form used throughout Australia. These loads were derived from the ACDB, and provide a case-study of the single building design simulated at various locations specified around Australia. Results from two software packages are compared: the Carrier air conditioning method to estimate loads (CAMEL) and DesignBuilder - with the US DOE EnergyPlus engine. We generated NEW CAMEL files derived from ACDB data 1967-1973 and 1995-2001. Then we compare the resulting cooling loads of ORIGINAL CAMEL data from 1970's data. With DesignBuilder we consider the cooling loads from DESIGN and TYPICAL weeks of data of the Reference Metrological Year (RMY) derived from the Australian Climate Data Bank (ACDB), and also the clear sky DESIGN DAY based on ASHRAE 94.6% drybulb and mean coincident wetbulb.

1. INTRODUCTION

The Australian Climate Data Bank (ACDB) consists of 35 years continuous hourly dry-bulb and wet-bulb temperatures, solar radiation, and wind data for each of the 69 locations around Australia [1]. For each location an 8860 hour Reference Meteorological Year (RMY) was developed by others with funding from the Australian Government [2]. The primary data observations were 1967 to 2002. The ACDB is used to provide weather files to building simulation programs such as Accurate (by CSIRO) and EnergyPlus (by US DOE) for use in building simulations. At each location the RMY uses dry bulb temperature only to selects a single one year pseudo dataset from the greater ACDB, by progressively eliminating full years with extreme temperature values, hot or cold, until only one year is left [2].

The ACDB is an hourly weather database – a necessary input to all modern building simulation programs. Prior to the ACDB there were air conditioning design datasets from mid 1970's through 1986 [5], based on 3-hourly measurements taken by meteorological observers that may exclude early morning first six hours. The air conditioning design method (CAMEL from AIRAH's Design Aid 9 algorithms [5]) was previous industry practice in Australia. CAMEL method is based on the extreme dry and wet-bulb temperatures. Design Aid 9 Appendix 1B [5] assumes "monthly one day in two years design conditions". So we calculated the 94% extreme dry bulb and wet bulb temperatures for the same locations as the ACDB localities to produce NEW CAMEL datafiles derived from the ACDB. Be aware that design assumption taken by CAMEL applies the extreme dry bulb and the extreme wet bulb each occurring concurrently, and with a clear sky. CRITICAL CAMEL datafiles were taken from the 100% extreme dry- and wet-bulb concurrently.

Ground truthed solar radiation data exists at a few state capitals with perhaps three years of measurement. The ACDB project extended these time series by remote sensing methods (satellite imagery), and expands the number of climate zones to produce an RMY composite of 12 months with a suit of meteorological data at each of 69 locations. RMY files could be improved by weighting for solar energy in a protocol of the American Society for Heating, Refrigeration and Airconditioning Engineers (ASHRAE) [2].

These given ACDB RMY files are used by simulation programs such as DesignBuilder(EnergyPlus) and FirstRate5(Accurate), but for air conditioning design programs such as CAMEL evaluate the response of the building to extreme value statistics, and so we compared the first 7 years (1967-1973) and last of the 7 years (1995-2001) of the Australian Climate Data Bank (ACDB) to produce two new sets of CAMEL design files: "NEW 1" and "NEW 2". This was done so we could compare with results from the ORIGINAL CAMEL data files (derived from 1970's data). By creating the 1995-2001 files, we analysed cooling loads and searched for any substantial or significant climate change effects since 1967-1973.

The seven-year ACDB weather data time-series 1967-1973 and also 1995-2001 was analysed at each location and results were converted into .txt format so that CAMEL can read the files as the 'new data' files. The procedure of generating data files and running CAMEL is shown in the flow chart below in Figure 1.

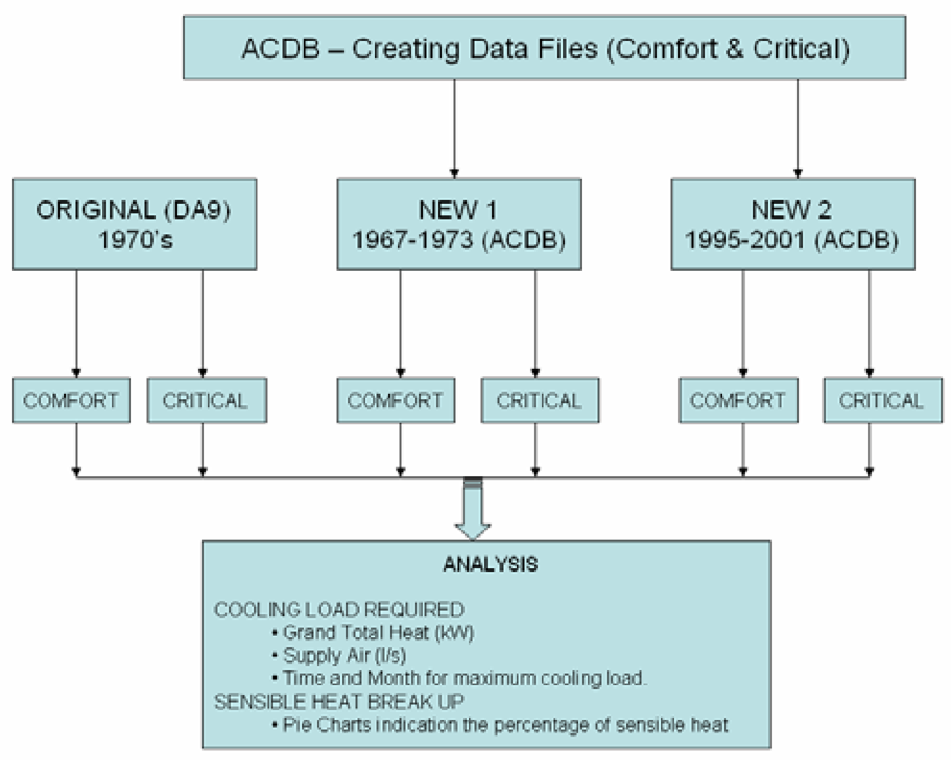

Figure 1: The flow chart indicates the procedure for CAMEL in order to receive an output result.

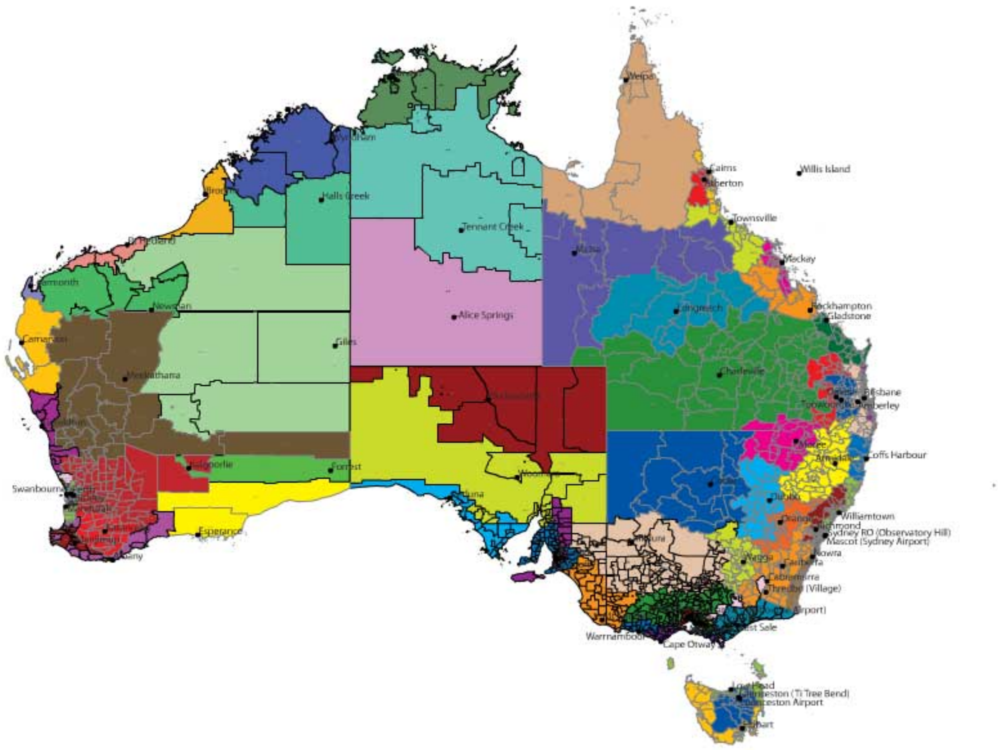

Figure 2 Australian climate databank zone (from www.nathers.gov.au [3]).

2. RESULTS

In various locations contributing factors generally are similar to the percentages illustrated in Figure 3 Albany WA. The break-down of sensible cooling loads from DesignBuilder and CAMEL were generally proportional to each other, but there are differences. CAMEL does not account for thermal storage effects of building mass as explicitly as EnergyPlus (the engine behind DesignBuilder). These pie charts concur that transmission gains through windows are the largest percentage of the overall sensible heat load, but this factor was greater in the CAMEL results. This may be attributed to DesignBuilder's assumption of an active use of shading devices by room occupants to reduce air conditioning loads. These pie charts indicate the amount of heat flows entering a model enhance future designs to use less mechanical ventilation, therefore predicting lower cooling loads. When there are lower cooling loads predicted by a software program, this reduces the cost of capital investment of equipment, and also increases the on-going efficiency of operation.

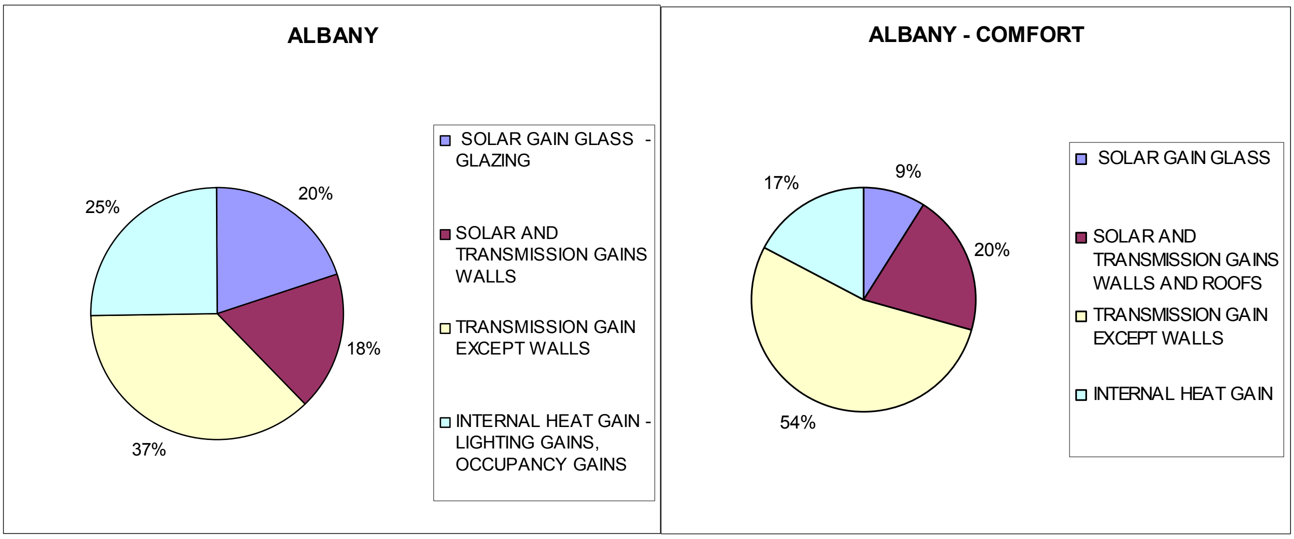

Figure 3 Example sensible heat breakup at Albany (WA) DesignBuilder (left); CAMEL (right).

The results of cooling load estimates obtained with DesignBuilder using the RMY files were compared with six sets of data files that were developed for CAMEL at each location. The CAMEL files are listed below:

- OLD COMFORT pre-1986 comfort condition
- NEW 1 COMFORT 1967-1973 comfort condition
- NEW 2 COMFORT 1995-2001 comfort condition
- OLD CRITICAL pre-1986 critical condition
- NEW 1 CRITICAL 1967-1973 critical condition
- NEW 2 CRITICAL 1995-2001 critical condition

These CAMEL output results are tabulated in tables 1, 2, 3, 4, 5, 6, 7 for Western Australian, Victoria, New South Wales, Tasmania, South Australia, Northern Territory and Queensland, respectively. These compare cooling load estimates obtained with DesignBuilder (EnergyPlus) using the RMY files "Summer Typical Week", "Summer Design Week", and the "cooling Design" from the 99.6% ASHRAE maximum design dry bulb temperature with clear sky solar radiation assumed on 15th January.

The Western Australia results for NEW 1 CAMEL proved fairly consistent with the ORIGINAL (DA9) input in both comfort and critical conditions. However, the NEW 2 data sets for "comfort conditions" are slightly greater, ranging with an increase of 0.10 kW to 6 kW, suggesting a climate change. But the "critical conditions" loads are similar in all cases (ORIGINAL DA9, NEW 1, and NEW 2). When comparing the CAMEL comfort and critical loads, the comfort conditions these appear to have changed in recent time. The critical loads have not changed with time, but have been met by the comfort load from the period of 1995-2001. This supports the practice of using old "critical conditions" to ensure comfortable air conditioning in the face of climate change. DesignBuilder predicts a smaller sensible cooling load than those from CAMEL. In some instances such as Wyndham, DesignBuilder predicted 6kW lower load, even in the heavier "cooling load" mode.

Table 2 Victoria

EAST SALE	38.1	3.90	3.90	7.00	9.89	9.86	10.30	14.20	15.90	16.20
WARRNAMBOOL	38.4	2.90	5.20	7.20	10.10	4.07	10.70	14.70	4.11	16.70
CAPE OTWAY	38.9	-	-	-	7.60	5.12	6.58	12.60	15.10	15.20

The Victorian results from NEW 1 CAMEL proved marginally higher than OLD CAMEL. NEW 2 results were greater than NEW1 results in both comfort and critical conditions. However, both of the NEW data cooling loads were on average 1 to 3 kW higher for comfort and critical cases. These results identify that the cooling loads from OLD CAMEL data have been under-sized. The Victorian DesignBuilder loads are smaller than those from CAMEL. For example in the coastal location Warrnambool, the load from DesignBuilder ASHRAE is 1/3 below NEW 2 CAMEL comfort load.

The New South Wales loads from NEW 2 CAMEL are less than ORIGINAL results for comfort conditions, although among the critical conditions NEW 2 CAMEL loads are generally increasing in recent years. The DesignBuilder cooling loads for NSW are smaller than CAMEL comfort loads. Summer typical week DesignBuilder load was about half of the CAMEL comfort load. DesignBuilder (ASHRAE) cooling design loads are closer to the CAMEL values. These ASHRAE-based results are generally about halfway between the RMY-based design week loads and the CAMEL comfort loads.

Table 4 Tasmania

MT GAMBIER	37.8	5	5.27	8.7	10.74	10.22	11.24	15.05	15.82	16.07

South Australian results from CAMEL were much the same in the ORIGINAL and NEW cases -except Adelaide required more cooling, for both comfort and critical conditions, in the more recent CAMEL cases. The DesignBuilder design loads were generally a quarter lower than those required by CAMEL. In Ceduna, situated in a coastal area, DesignBuilder's load estimate was just 10% below the most recent NEW CAMEL.

Table 6 Northern Territory

NORTHERN TERRITORY		DESIGN BUILDER			CAMEL comfort			CAMEL critical		
		SENSIBLE COOLING (kW)			SENSIBLE COOLING (kW)			SENSIBLE COOLING (kW)		
LOCATION	Latitude (S)	Summer Typical Week (ACDB RMY)	Summer Design Week (ACDB RMY)	Cooling Design (ASHRAE)	OLD CAMEL ?1970's (DA9)	NEW CAMEL 1967-73 (ACDB)	NEW CAMEL 1995-01 (ACDB)	OLD CAMEL ?1970's (DA9)	NEW CAMEL 1967-73 (ACDB)	NEW CAMEL 1995-01 (ACDB)
DARWIN	12.4	6.36	7.22	9.22	11.15	10.81	10.89	11.82	12.4	12.4
TENNANT CREEK	19.7	7.68	7.99	11.15	15.51	15.19	14.66	16.65	17.52	16.26
ALICE SPRINGS	23.8	7.61	8.37	11	14.75	17.08	14.98	16.29	17.24	17.42

The Northern Territory results for CAMEL are fairly consistent among the ORIGINAL and NEW loads, with few variations. The DesignBuilder results were reduced about a quarter of what was required for CAMEL.

GLADSTONE	23.9	5.98	7.03	8.63	10.91	9.24	9.2	10.03	12.95	13.48
CHARLEVILLE	26.4	6.10	5.70	9.40	15.10	15.40	14.70	17.40	20.10	17.50
BRISBANE	27.4	3.30	5.30	7.10	8.80	8.80	8.30	12.00	13.50	11.70

The Queensland loads from CAMEL were similar in both OLD and NEW comfort loads. However, critical loads had increased in recent years in many locations. Gladstone requires 3.5 kW additional load than the OLD CAMEL had suggested. Typical of most of the other States and Territories of Australia, Queensland DesignBuilder cooling design loads were about a quarter less than NEW 2 CAMEL comfort loads.

3. DISCUSSION

DesignBuilder takes into consideration virtually any assembly of materials, and actively models the effects thermal storage mass, whereas CAMEL is not capable of modeling free-running dynamics. Some of the construction templates, and geographical locations listed in CAMEL were not necessarily listed in DesignBuilder menus, and therefore some guesswork was needed to choose comparable sets. Out of 69 locations in Australia, only 41 could be compared in the three input data modes of each software package. Generally southern coastal areas require less cooling than outback and northern regions – attributed to cool sea breezes. Generally we found that DesignBuilder cooling design loads (based on ASHRAE 99.4%) were about 75% of our most recent CAMEL comfort load estimates. In generating NEW 1 dataset 1967-1973 and NEW 2 dataset 1995-2001 we discovered many more instances of increasing cooling loads than the contrary. This might be attributed to global warming in general, and urban heat island developments.

4. CONCLUSION

DesignBuilder's cooling design loads are smaller than of those from CAMEL. The NEW CAMEL and DesignBuilder input files are derived from the same data source (ACDB), but they are derived by very different approaches. CAMEL weather files select the 94% extreme drybulb and 94% extreme wetbulb from seven years of records, resulting in a heavy factor-of-safety for plant sizing. DesignBuilder employs weather files that concatenated twelve disconnected "representative" months from at least 25 years of records into one pseudo year of data. Cooling simulation in DesignBuilder chooses the hottest week from the pseudo year of data, which includes cloud cover and other factors that mitigate the cooling load. Alternatively, the cooling load in DesignBuilder applies ASHRAE 99.6% drybulb and mean coincident wetbulb with a clear sky radiation model on 15th January.

Loads estimated by NEW 2 CAMEL for comfort conditions are understandably higher than the "cooling design" from DesignBuilder because CAMEL is heavy handed in adopting the 94% extreme value of wet- and also the dry- bulb temperature for each combination of hour-of-the-day and month-of-the-year with a return period of 2 years. DesignBuilder has adopted the ASHRAE design dry-bulb temperature as the 99.4% extreme value of temperature, and then taken the mean coincident wet-bulb and the mean coincident daily range of dry bulb, and applied an assumption of clear sky radiation on 15th January (high summer). Given that recent data is available to reflect climate change, it is not justified that CAMEL critical loads be considered in normal applications, nor should extreme wet bulbs be taken together with extreme dry bulbs.

Keywords: energy conservation, existing buildings, envelope of buildings

Summary
Owing to diminishing global resources and the pressure of population growth, energy conservation has become the most critical issue about sustainability in the world. In Taiwan, the hot and humid climate results in a huge consumption of air conditioning system determined by the design of building envelope. Effective shading and heat insulation of the building envelope takes the important part in energy conservation. Hence, the Architecture and Building Research Institute of Taiwan has proposed a series of subsidization plans of the envelope energy efficiency improvement in existing buildings, which provide a linkage to the energy conservation indicator of Taiwan Green Building Evaluation System as well. This paper introduces the operation of improvement process and the performance of energy conservation after implementing the subsidization plan. By measuring and analyzing the performance of these cases, it showed a significant decrease in the consumption of electricity used in air conditioning systems and improved the indoor thermal environment with installing shading devices and roof heat insulation.

1. Introduction
Taiwan, which is located in tropical and subtropical regions, has a hot and humid climate. Air conditioning systems are indispensable equipments in daily life and they account for the majority of electricity consumption in the summer. However, due to improperly designed building envelopes and window ratios, air conditioning systems become inefficient. The research reveals that a building envelope, which has a depth of 5 m in the peripheral area, contributes 37.5% of the total energy consumption of air conditioning systems. Previous architectural designs in Taiwan, which incorporated more window shading and smaller openings in facades, conformed to a specific climatic pattern. Currently, architectural design criteria are being ignored by the designers. Hence, the Architecture and Building Research Institute (ABRI), Ministry of the Interior, has selected existing buildings that have potential for improvement in order to demonstrate and popularize energy-conservation concepts as part of its green building policy. By using window shadings and roof heat insulations, we can realize a comfortable and energy-conserving environment in government and residential buildings. This research will introduce the concepts of energy conservation in building envelopes, and its achievements and benefits will be discussed in the following sections.

2. Concepts of energy conservation in building envelopes
The four facades and roofs of buildings constitute a building envelope, as shown in figure 1. The consumption of energy by building envelopes is defined as the energy consumed by areas influenced by external climatic factors, thereby causing internal energy loss. Since Taiwan is located in tropical and subtropical regions, people rely on air conditioning systems, which maintain the indoor temperature and create a comfortable environment. This leads to a total energy consumption of more than 70% during summer. Therefore, the goal of realizing energy-saving technologies for building envelopes is equivalent to achieving a balance in the indoor temperature by reducing the loading of air conditioning systems due to the hot external environment.

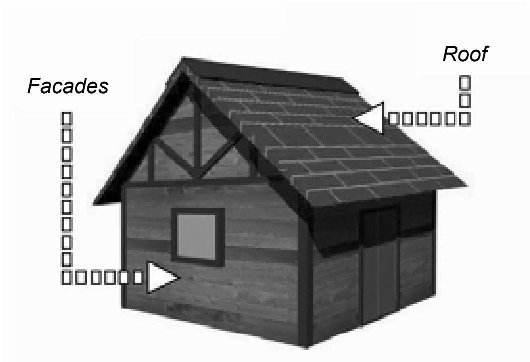

Figure 1 The four facades and roof of a building envelope.

Figure 2 shows the heat flow between the internal and the external environment of buildings. The factors that influence the heat flow are the temperature difference between the internal and external environments, the amount of solar radiation, the ratio of façade opening, and the characteristics of envelope materials. There are two major factors that cause the energy consumptions by building envelopes: the temperature difference between the internal and external environments and heat radiation. Consequently, the energy-saving technologies deal with this temperature difference by employing heat insulation, and they deal with the solar radiation by using window shadings.

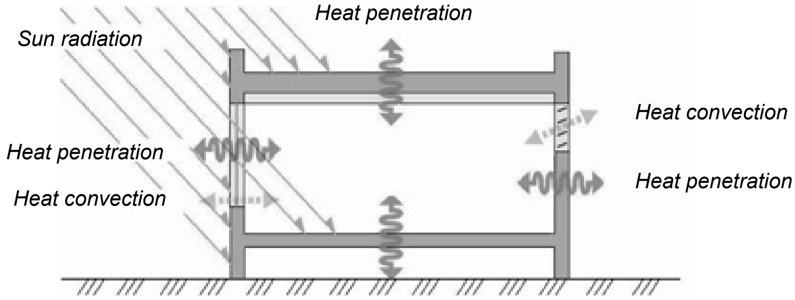

Figure 2 Heat flows between indoor and outdoor of buildings.

2.1 Heat insulation

Heat insulation can be achieved by adopting materials with a lower heat-conduction coefficient for the construction of building envelopes in order to withstand the temperature rise. Materials with a lower heat-conduction coefficient contribute to optimum horizontal roof heat insulation. The purposes of using these materials are given as follows.

1. Roof garden: The heat is reduced by spreading soil and planting various plants on building roofs. Not only the plants but the soil also reduces the heat by assisting water evaporation.

2. Air layer: The circulating air layer dissipates the heat, and thereby reduces the temperature.

3. Light-colored surface: A light-colored surface maintains a lower rate of heat absorption than a dark-colored one, thereby reflecting more heat radiation.

4. Cooling by evaporation: Sprinkling water on roofs helps to absorb heat and reduce temperature.

2.2 Window Shading

Window shading implies the installation of sunshades on any openings that a building might have (for example, windows) in order to prevent solar radiation from entering the room. In particular, external window shadings give the optimum results.

Different angles and directions of the sun's radiation must be considered when designing the outside window shadings. In general, horizontal shadings are suitable for the windows facing the south, while vertical shadings are suitable for the windows facing the east and west. An integration of horizontal and vertical shadings is suitable for the windows facing the southeast and southwest. Figure 3 suggests the type and direction required for the external window shading. The ratios of the solar radiation from different directions are shown in table 1; it appears that the most urgent requirement is window shadings for the windows facing the east and west.

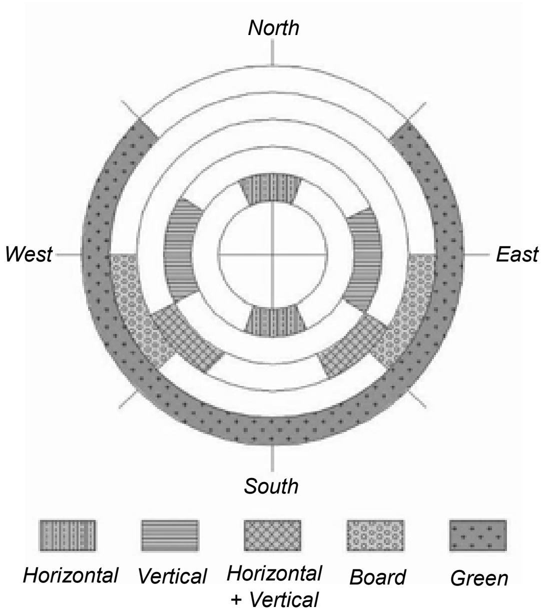

Figure 3 Suggestion for types and directions of window shadings.

Table 1 The ratio of sun radiation from different direction in Taiwan

Direction	South	East	West	North
Ration	1.0	1.24	1.24	0.81

The optimum shading not only blocks the unnecessary heat and light but also provides ample sunlight and a comfortable and warm internal environment. Furthermore, window shading offers sun shading, allows ample sunlight, provides ventilation, prevents rain from entering the room, and provides a beautiful view.

The benefit of sunshades was calculated by using the window shading cover coefficient, *Ki*, which is the ratio of the amount of solar radiation entering indoors by the amount throughout the year. For instance, *Ki* = 0.3 signifies that the window shading can block 70% of the solar radiation. A desirable value of *Ki* is between 0.3 and 0.5. If the coefficient is much lower, the interiors would require auxiliary lighting with artificial lights, which leads to energy dissipation in another form.

3. Subsidized projects applying energy-conservation techniques to improve existing buildings

After noticing that the existing building envelopes consumed large amounts of energy, the ABRI selected some potential buildings that could be used to promote “energy-saving" concepts formulated in the green building policy. The introduction of energy-saving designs in government and residential buildings, such as window shadings and roof heat insulation, which could improve the working and living environment, was subsidized. From 2002 to 2007, there were 116 cases of window shading and 220 cases of roof heat insulation.

3.1 Overall benefits of improvement

After government assistance and subsidies were given for this project, the expected energy-conservation benefits were obtained and the required regulation of building envelopes of green buildings was also achieved. The *Ki* requires a value lower than 0.5 and the roof heat insulation coefficient *Ui* must be lower than 1.2 W/m^2°C.

3.1.1 Benefits of window shading improvement

Taipei Veterans General Hospital (TVG), which represents the most effective case of subsidy in 2007, had changed the window shading coefficient *Ki* from 0.98 to 0.30; the improved benefit is up to 69.39%. Originally, the west facade was influenced by the strong solar radiation although the air conditioner system was operating simultaneously. By setting up the facility of window shading on the west façade, the problems caused to the staffs were solved. For other cases, the benefit ranges between 31.50% and 67.74%, and the average is 53.05%.

3.1.2 Benefit of roof heat insulation improvement

Ching-Hai Hospital in Taichung County, the most effective case of subsidy in 2007, had changed the roof heat insulation coefficient *Ui* from 2.95 to 0.98. *Ui* can be reduced from 2.95 to less than 1.2 in all cases by using the PS board heat insulating tile or rubber heat insulation tile for environmental protection. In other cases, the benefit obtained is between 52.56% and 64.41%, and the average is 59.18%. Roof heat insulation has certain benefits in that it improves the hot environment on the top of the floor.

3.2 Benefit of electrical energy saving

Improvements have been observed in 336 cases and 195 million NT dollars has been given as subsidy since 2002 to 2007; among them, in 116 cases, window shading has been set up over an area of 9445 m^2 and in 220 cases, roof heat insulation has been set up over an area of 58790 m^2. Through calculations, it has been found that 1 million and 933 thousand degrees of electricity can be saved every year. In other words, 4 million and 833 thousand NT dollars can be saved every year (calculate with 2.5 NT dollars for each degree of electricity).

For the window shading facility, energy consumption is reduced by 15% for air conditioners in a building envelope; further, 15 to 20 years are required to retrieve the subsidy. For the roof heat insulation facility, energy consumption can be reduced by 11% for air conditioners at the top floor of the building, and it takes about 4 to 5 years to retrieve the subsidy. Moreover, the southern part of Taiwan, which has a considerably higher temperature, is the most effective region for energy conservation and subsidies retrieval.

4. Improvements in building envelope measurement

In order to recognize the differences in the performance before and after energy-conservation techniques were applied for the building envelope, a few cases were estimated by using equipments. The testing samples were divided into two areas—before and after improvements—in order to check for conformation to the same outdoor climatic environment on the day of the experiment. The experiment was conducted by considering the effect of heat on a building and its residents.

4.1 Experimental equipment and measurement project

The experimental equipment includes a heat flow meter, thermocouple, thermometer, humidity meter, hot wire anemometer, pyrheliometer, and automatic data logger. The data logger can automatically collect the signal for voltages at intervals of 10 s; the parameters include temperature, humidity, air flow, thermal current, and solar radiation. After each 10 min, the data averages the sum recorded. The experimental equipments and field measurements are shown in figure 4.

Figure 4 The experimental equipment and field measurement.

4.2 Human body comfort index

The project adopts the *PMV* (predicted mean vote) and *PPD* (predicted percentage dissatisfied) indices as the criterion for the human body comfort index. This index is based on the body temperature flow, which includes wind temperature, wind speed, air humidity, the average of radiation temperature, body activity level, and clothing. In the indoor thermal environment index of ISO7730, the range for regulating *PMV* is from +3 to 3 (+3 < PMV < –3). When the *PMV* value approaches zero, the comfort quality is better. Table 2 shows the PMV assessment criterion. The *PPD* index is defined as the percentage of unsatisfied prediction, i.e., the range between 0 and 100%. When the *PPD* value is close to zero, it means that the quality of thermal comfort is better.

Table 2 PMV assessment criterion

PMV	Psychology
+3	Hot
+2	Warn
+1	Slightly warm
0	Neutral
-1	Slightly cool
-2	Cool
-3	Cold

This research uses the ASHRAE Thermal Comfort Program Ver1.0 to calculate the *PMV* and *PPD* indices; this program was developed by U.C. Berkeley. According to the ASHRAE regulation, the parameters are set to Met = 1, clo = 0.5, and 101.325 kPa. The interface of the program is shown in figure 5.

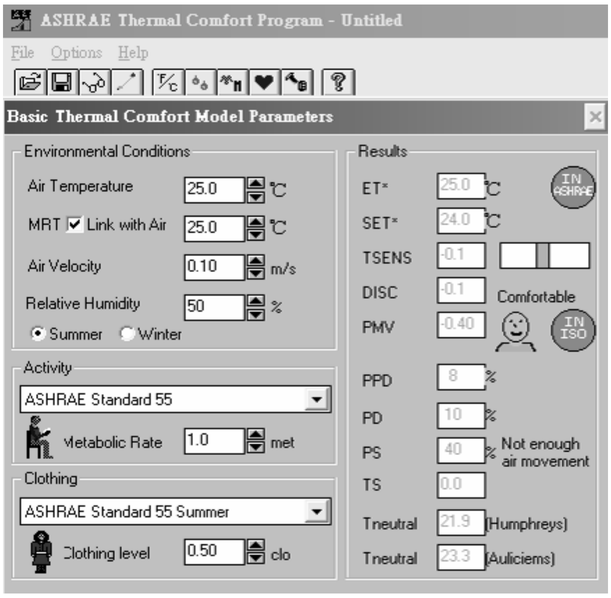

Figure 5 The interface of PMV-PPD evaluation.

4.3 Measurement results

4.3.1 Case of roof heat insulation—Chao-zhou simply court in Taiwan Ping-tung District Court

A. Heat-conduction coefficient *Ui*

The heat-conduction coefficient *Ui* is initially from 2.49 to 1.05 when using a PS board heat insulating tile on the roof. The benefit of improvement is up to 57.83% (2.49–1.05/2.49).

B. Indoor temperature

The indoor temperature that was estimated from the experiment had decreased from 2 to 3°C due to roof heat insulation. Figure 6 reveals that the roof heat insulation contributes to the energy saving of air conditioners and leads to overall thermal comfort.

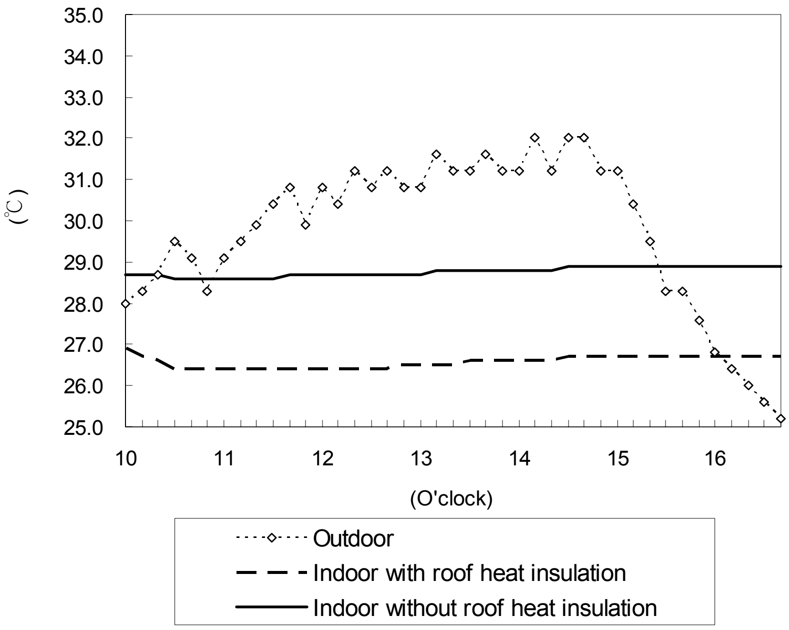

Figure 6 Comparison on temperature of roof heat insulation improvement.

C. Thermal comfort

The *PMV* maintains a value of 0.19 to 0.39 after the roof heat insulation, i.e., the psychological scale between slightly warm and neutral. The *PPD* value can be maintained between 5.9% and 8.1%. Both these values lead to improved thermal comfort.

4.3.2 Case of window shading—Ping-tung Branch, Administrative Executor's Office, MOJ

A. Window shading cover coefficient *Ki*

Ki is initially from 0.91 to 0.35 when the horizontal and vertical window shadings on the south-east side are used. The benefit of improvement is up to 61.54% (0.91–0.35/0.91). The comparison of solar radiation is shown in figure 7.

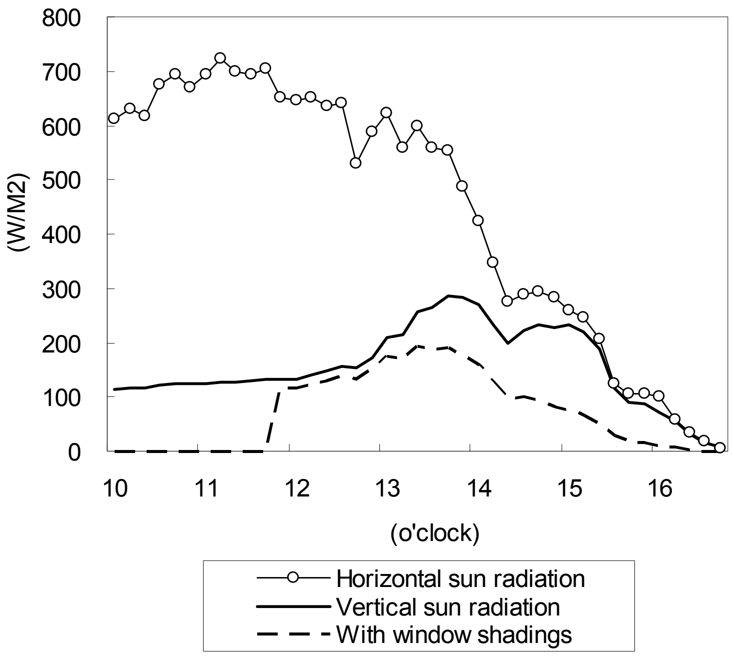

Figure 7 The comparison of sun radiation.

B. Indoor temperature

The indoor temperature that was estimated from the experiment decreased from 2 to 3°C due to the roof heat insulation. Figure 8 reveals that the roof heat insulation contributes to the energy saving of air conditioner and improves thermal comfort.

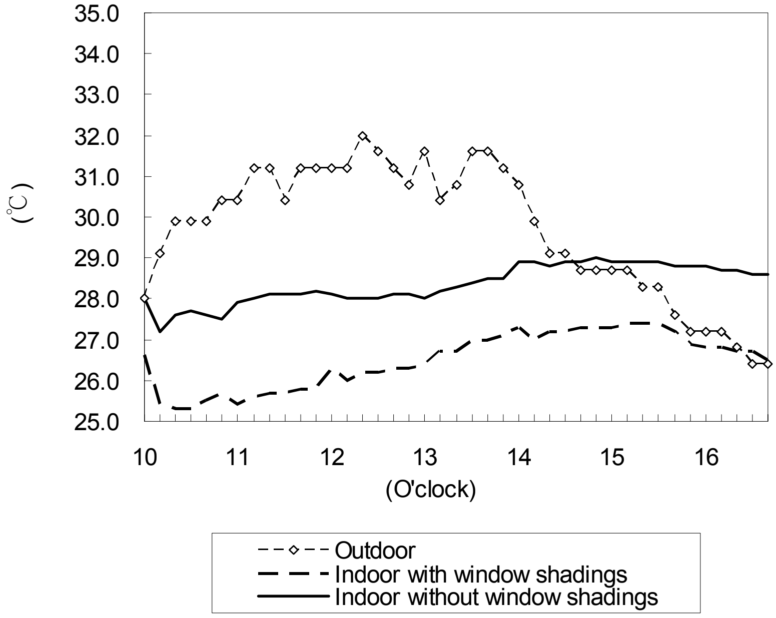

Figure 8 Comparison on temperature of window shadings improvement.

C. Thermal comfort

The *PMV* value is maintained between –0.18 and 0.57 after window shading; the psychological scale ranges as slightly cool, slightly warm, and neutral. The *PPD* value is maintained between 5.0% and 11.8%. Both these values represent a high degree of thermal comfort.

4.4 Discussion

The energy-saving techniques, roof heat insulation, and window shading can efficiently improve the energy consumption of a building envelope and yet maintain a high degree of thermal comfort. Since the measurements were carried out in October, the solar radiation is lower than that in summer. Otherwise, the improvements would have been greater obviously.

5. Brochure of energy-conservation design for buildings

Among the methods used to promote energy-saving, an effective one was using a brochure that will introduce energy-saving results into a citizen's daily life. This brochure introduces a clear description in order to illustrate the improved cases, references, and experiences. It is divided into four parts. The first part describes the general concept of energy conservation that provides a clear concept to the user by explaining the building envelope theory and regulation. The second and third parts provide the roof heat insulation and window shading improvement operations by describing the tactics, design criteria, the procedure of design, the different types, and precautions. The fourth part gives the various cases that showed improvement and the benefit of improvements. This can provide a prototype for designers who will adjust the design in accordance with the requirement and condition. Consequently, the brochure provides a simple explanation, graphic illustration, benefits, and the actual picture for people to examine the building on their own. People can follow the instructions suggested in the brochure to improve their house. In this manner, the idea of energy saving can be popularized universally.

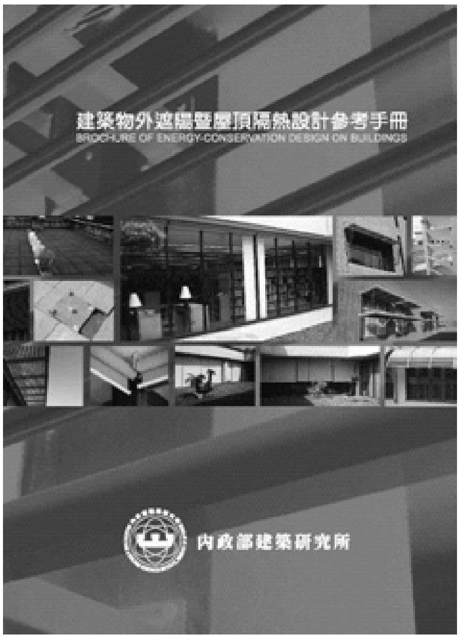

Figure 9 The brochure of energy-conservation design on buildings.

6. Conclusion

Window shading and roof heat insulation could effectively improve the energy consumption of building envelopes. They not only create a healthy indoor environment but also maintain a global ecology. The objective of this research is to attempt to reward and subsidize existing buildings to reduce the use of air conditioners and accomplish the purpose of energy conservation. The final goal of the green policy is to reduce the ozone depletion and balance the ecosystem. The ultimate aim is to promote global awareness for energy conservation. This will make Taiwan a green community and an eco-friendly city.

Keywords: 2000-watt society, energy efficient construction, heating, solar energy, sustainability.

Summary

Eawag, the Swiss Federal Institute of Aquatic Science and Technology in Dübendorf is the internationally active aquatic research institute of the ETH domain. It is committed to the ecological, economical, and socially responsible management of water. In the spirit of scientific advancement, the competition brief for Eawag's new head office, Forum Chriesbach, called for the exemplary and progressive management of all resources and a visionary concept regarding ecological sustainability. The building was constructed in the years 2004 to 2006 and has been in use since June 2006. It meets the requirements of the 2000-watt society, a vision put forward by scientists of the ETH domain, which calls for freezing the worldwide energy consumption at the present level of about 2000 Watts/capita. With its approximately 340 MJ/m^{2}a or 600 Watts/capita, Forum Chriesbach proves not only that the vision is practicable for office buildings but also that this can be achieved by using conventional materials and existing technologies. The building meets high standards of functionality, aesthetics and comfort. Creating such a building, however, is possible only with a team of highly qualified architects, planners, specialists and, of course, dedicated clients. In order to achieve sustainability before fossil energy resources are depleted entirely and climate change effects become too disastrous, more such teams must become active: immediately and forcefully.

1. The Idea of a 2000-Watt Society

World primary energy consumption in the year 2005 amounted to about 123,557,142 GWh, supplied namely by coal (27.8%), oil (36.3%), gas (23.6%), nuclear energy (5.9%) and hydropower (6.3%) (BP 2007). With a world population of 6,514,751,000 people (UN 2006), this annual energy consumption is equivalent to a continuous power per capita of 2,165 Watts. The worldwide consumption of energy is still increasing by about 2-3% annually (Fig. 1). Given the fact that fossil energy resources are limited and their usage environmentally disastrous, scientists from the ETH domain have formulated the vision to stabilize energy consumption at the average level of 2,000 Watts per capita (= 17,520 kWh per year). While the USA uses more than 10,000 Watts per capita, developing and emerging market countries like Pakistan or China still consume less than 2,000 Watts per capita with, however, the trend tending upwards. Switzerland crossed the 2,000 Watt line in the 50s and at present every Swiss consumes more than 5,000 Watts (Fig. 2). The vision stipulates that the transformation should be possible without a loss in the standard of living.

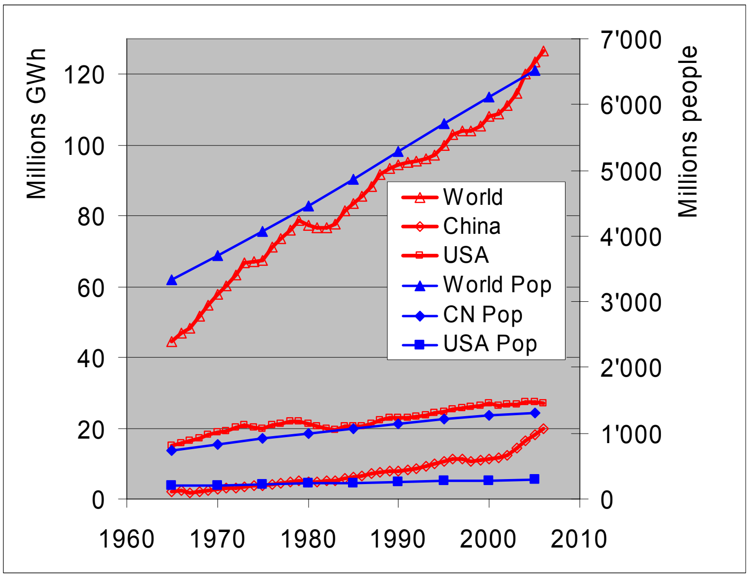

Figure 1 Development of primary energy production (BP 2006) and of population (United Nations 2006) within the past 40 years. The USA and China, with a population of about 25% of the world, consume 37% of the energy.

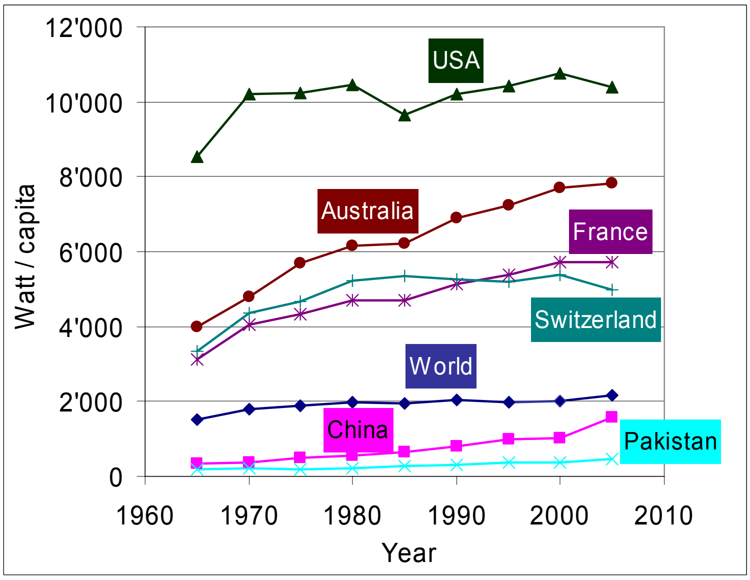

Figure 2 Development of primary energy consumption per capita. From 1980 until 2000 the world average power demand remained relatively constant at a level of about 2000 Watts/capita, but has started rising again since then. While China has developed towards the 2000 Watt line, the USA and other industrialized countries have managed to slightly decrease their consumption. Data sources: BP 2006 and United Nations 2006.

One fourth of the 323,897 GWh of primary energy used in Switzerland in the year 2006 is 'lost' during conversion to final energy (mainly nuclear energy to electricity) and the rest is used as shown in Table 1. We assume that about $^1/_3$ of primary energy, i.e. 600-700 Watts/capita can be used for work space. Koschenz and Pfeiffer (2005) estimate that in Switzerland about half of the total primary energy goes into construction and building operations and thereof 780 Watts/capita is used in office work space and 320 Watts/capita in industry. The grey energy imported with products is not taken into account in this data. Thus, if an office or industry building consumes less than about 700 Watts/capita, it can be considered as compatible with the 2000 Watt-society.

Table 1 Final energy usage in Switzerland 2006 (Population 7,557,000)

	GWh/a	%
Households	72,186	29.3
Industry	49,264	20.0
Services	40,217	16.3
Traffic	81,119	32.9
Agriculture	3,972	1.6
Total	246,758	100.0

2. The Forum Chriesbach Building

2.1 Eawag's Competition Brief for the Building

Eawag, the Swiss Federal Institute of Aquatic Science and Technology, is committed to the sustainable use of water. With its more than 400 employees it does research, teaching and consulting to further this aim both in Switzerland and globally, thereby bridging the gap between basic science and practice. It is located on a campus in Dübendorf together with its sister institute, Empa[1], which is concerned with materials and construction research. The new building is Eawag's head quarters, comprising office space for 150 employees, a lecture hall for 140 people as well as seminar and conference rooms for about 160 people. The room program also includes the new joint library of Eawag and Empa, a staff canteen, and a foyer for exhibitions and conferences.

Eawag and Empa, together with BaFA - their construction agent, insisted that their commitment to sustainability had to be realized in an exemplary and progressive form. The structural and technical measures had to be innovative and, indeed, exceed current technological standards. All resources had to be handled frugally - energy, materials, land and funds. At least $^1/_3$ of the electricity requirements must be covered by the building's own photovoltaic system. Room temperatures must not drop below 19°C and not exceed 26°C. Rainwater had to be used for toilet flushing and urine had to be collected separately for research purposes.

2.2 The Project Winner

In January 2003 the project 'Vision' of Bob Gysin + Partner BGP had been selected by the jury out of 6 projects, and in December 2003 the Swiss Parliament granted 32.72 million Swiss Francs to construct the building. In July 2004 construction started and in June 2006 the keys were handed over to Eawag.

Table 2 Technical data of Forum Chriesbach.

Building volume	38,615	m^3
Floor area	8,533	m^2
Energy reference area (weighted)	11,170	m^2
Roof area (building footprint)	1,886	m^2
Photovoltaic panel area (77 kWp)	459	m^2
Evacuated heat pipe solar collectors	50	m^2
Construction costs	30	Mio CHF

[1] The domain of the Swiss Federal institutes of Technology (ETH domain) consists of the two national technical Universities, ETH Zürich and EPF Lausanne, and the four research institutes Eawag, Empa, PSI, and WSL.

Figure 3 Eawag Forum Chriesbach: Characteristic facade with blue louvers, solar energy equipment on roof and air inlet of thermal register (behind tree on the NE - side of the building. Photo, A. Bryner Eawag 2. March 2007).

Figure 4 Eawag Forum Chriesbach: The impressive atrium with conference rooms jutting out into the void and the model of a water molecule for projections with two beamers inside it (Photo H. Güttinger, 30. January 2007).

The building has no active heating or cooling system except for a few radiators in the ground floor and cooling ceilings in the conference and seminar rooms. The energy concept relies on conserving the heat generated inside in winter and on preventing solar radiation energy from penetrating in summer. The minimized surface area of the compact building and its extremely tight insulation keep the heat 'losses' of people (~70 Watts), personal computers (~100 Watts) and light (~100 Watts) inside. These internal energy sources together with heat recovery from used air, waste heat from kitchen appliances and computer servers provide enough heat to keep the building at comfortable temperatures most of the time. The import of energy from the district network is therefore minimal and amounts to only some 31 MWh/a primary energy (~3,000 liters of oil), a quantity that is normally used for a conventional one-family house. Fig. 5 illustrates the potential of heat and cooling energy reductions in Forum Chriesbach as compared to conventional buildings and the 'Minergie' standards. There are clear limits to the reduction of electricity and grey energy demands; these must be produced with renewable energies to attain sustainability. However, grey energy can be at least partly controlled by clever materials choices and by maximizing the lifespan of constructions.

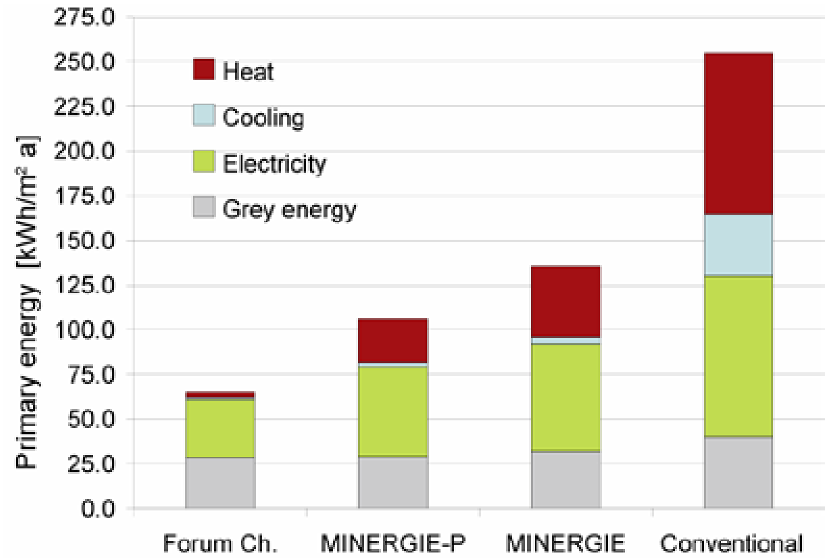

Figure 5 *Energy demand in Forum Chriesbach as compared to a similar building designed and constructed without concern for sustainability (conventional) or according to the Swiss standards Minergie or Minergie-P. Heat and cooling demands can be reduced relatively easily to almost null while electricity and grey energy for construction and materials remain significant.*

Another special feature of Forum Chriesbach is its thermal register, a collection of 78 pipes 20 m long and buried in the soil in the northeast of the building (see Fig. 3). Fresh air enters the building through this register and is thus cooled in summer and warmed up in winter by advective heat exchange with the soil, which has temperatures fluctuating at around 10°C. All the computer servers for the whole of Eawag are installed in the Forum Chriesbach and are cooled mainly by air. During winter this warmed up air is also used to heat the fresh incoming air, which is then distributed into the comfort zone, i.e. into the office, conference and seminar rooms, the library and the restaurant.

The most striking feature of the building is its 1,232 blue glass louvers. They are fixed on the fire egress scaffolding around the building. Their main function is shadowing and to that aim they rotate in 5° movements about their axis, following the daily track of the sun, all panes of each facade in synchrony. However, when outside temperatures rise above 30°C, shadowing by the louvers and cooling in the thermal register are not sufficient to keep room temperature below 26°C as required. Compounding this problem, internal heat sources from men and computers also emit their extra heat in summer. To overcome these difficulties a night cooling system has been installed: when outside temperatures drop below inside temperatures during the night, the hopper windows in each room and in the atrium roof automatically open, allowing convection driven air circulation. The intruding fresh air then cools the concrete mass of the building and thus the inside temperatures can be kept at comfortable levels of 24-26°C the whole day long, even when it is very hot outside.

2.3 Two Years' Experience in Forum Chriesbach

In June 2006 Eawag employees began to occupy their new space in Forum Chriesbach and the theoretical concepts had to prove their everyday fitness. A two-year optimization phase was started to fix everything that has not been properly designed, constructed or installed, and to adjust the control system in accordance with the real behavior of the building and its inhabitants.

To the great relief of the architects and planners, of the directorate of Eawag, and of those working in the building, things have gone well: summer temperatures have remained at perfect levels between 24°C and 26°C in hot July and August. Spring and autumn temperatures were too low but could be adjusted, and winter temperatures did not drop below 19°C - normally. It has turned out that not all of the office spaces are occupied full time and by as many people as planned. Scientists spend part of their time in the laboratory, doing field work, attending conferences, or are lecturing at other institutes, and many of the administrative employees work part time. Additionally, some exposed rooms in the corners of the building have greater losses through the walls and less passive solar gains than projected. Also, many Eawag workers use laptops and flat screens instead of less energy-efficient desk top models. Therefore, more heat energy had to be drawn from the district area network than planned. But, even if this extra heat remained about twice as much as projected, in absolute terms it still is very little energy. And, most importantly, there is optimization potential left because some systems still do not perform properly. One of these is the shading system in the glass roof of the atrium, whose blinds too often shut in winter, not allowing passive solar gains. Another is the heat storage tank, which does not get all the available solar energy but too quickly recharges from the district network; its control system has yet to be adjusted. We are confident, however, that once the remaining problems have been ironed out the building will perform better and the number of Eawag people working in it who are content ,even in cold winters, will increase. In summer everyone is happy with the building's performance.

Table 3 Energy consumption details in Forum Chriesbach. The relative values have been calculated using the height weighted energy reference area of 11,170 m² and the average number of people working in the Forum Chriesbach, some 200 people in total. (150 office workplaces and 50 people using library, restaurant and seminar rooms). The estimations of elevated energy usage (last column) are based on extrapolations from measurements in the months July to December 2007.

	Final energy (plan)		**Primary energy (plan)**		**final energy (real)**
	MWh/a	kWh/m2 a	MWh/a	W/cap	MWh/a (Estimations)
Electricity without servers	181	16.2	543	309.9	190 - 210
Electricity servers (15.5 kW)	136	12.2	408	232.5	130 - 140
Heat from network	24	2.1	31	17.7	30 - 50
Heat export to network	-6	-0.5	-8	-4.3	-10 - 0
Cooling from network	22	1.9	24	13.5	20 - 45
PV-system (77 kWp)	60	5.4	180	102.7	60 - 65
Solar collectors	24	2.2	31	17.9	15 - 30
Grey energy			319	182.2	(37.6 years life span)

Electricity demand has been above projections as well. Luckily enough, the performance of the solar panels has also been above expectations. Several causes have been identified for the elevated electricity consumption: about twice as many people as projected take their meals in the staff canteen and office lights have to be turned on longer because of the shading by the louvers, which have not yet been optimally adjusted. The most extraordinary revelation was that the hopper windows' motors were turned on permanently and consumed an extra 20 MWh/a - about $^1/_3$ of solar production! These have been fixed meanwhile.

In Eawag Forum Chriesbach an extensive monitoring system with several thousand data points has been installed, but not every sensor and energy meter has worked well from the beginning. We still do not have reliable energy usage data for a whole year but we believe that most of the problems observed can be solved and that the real energy consumption will be at levels very close to those projected.

3. Conclusions

The two years of working in Forum Chriesbach illustrate that the main promises concerning its sustainability have been fulfilled. The buildings performance meets the requirements of a 2000-watt society, namely the 600-700 Watts/capita energy demand. With a demand of 340 MJ/m2a it also meets the 2000-watt society requirements for office buildings, which have been stipulated to be 480 MJ/m2a (including 140 MJ/m2a for mobility, SIA 2006). Fig. 6 shows how much energy per person is used in Forum Chriesbach for construction, cooling, heating, electricity and computer servers. With heating and cooling minimized, it is particularly electrical energy that remains to be produced sustainably and used efficiently. The optimization of usage and performance of computer servers is of particular importance and must be given high priority. Grey energy can be controlled, at least partially, by careful choices of materials and by taking into account the life spans of buildings. With 572 CHF/m3 the construction costs of Forum Chriesbach has not been significantly different to those of comparable buildings. Intelligently designed buildings are not only affordable and can be energy efficient, they can also provide more comfort than conventional buildings, as summer working conditions in Forum Chriesbach demonstrate.

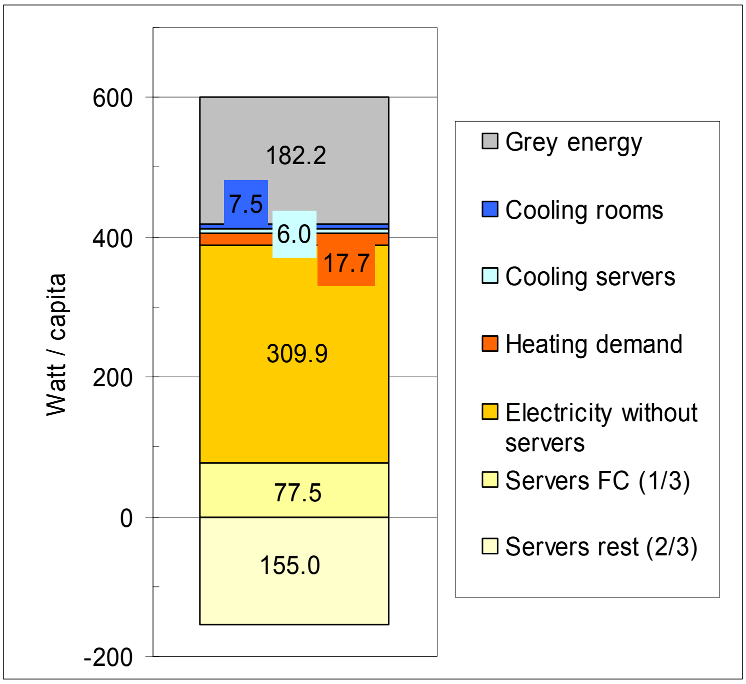

Figure 6 Per capita primary energy consumption of Forum Chriesbach for the different usages (see Table 3 for absolute values).The calculations have been performed assuming that 200 people work in the building. Because the computer servers installed are for the whole of Eawag, only $^1/_3$ of their total electricity demand has been allocated to those employees in Forum Chriesbach. Thus the energy demand per capita amounts to about 600 Watts.

There are some prerequisites to the realization of such a building. Daniel Wentz (2007) has put these down in his beautifully written book about Forum Chriesbach:

It is not the central architectural concept that is new (super-insulated passive solar buildings have existed for decades). The significant distinction here is how the people behind the project worked together with a shared sense of responsibility, commitment, and purpose. Showing social, environmental, and scientific engagement, the client prescribed standards for the design that go far beyond the norm, beyond any building code, and expressly sought to test the limits of what is possible. The design team shares the client's philosophy, and delivered the necessary background and know-how, working together with the client, users, and contractors throughout the five-year duration of the project. ... The lessons of Forum Chriesbach have global ramifications. The building proves that by using conventional materials and known transferable technologies, a high level of performance is not only possible, but affordable and practicable. This level is vital to a sustainable future. This building makes sense in every respect - economically, socially, ecologically, functionally, and aesthetically. In a world in which sustainability is in question, in which better ways of shaping and managing our environment must urgently be adopted, Forum Chriesbach stands as a model of how to build for the future.

The goal to stabilize energy consumption at a level of 2000 Watt/capita means that industrialized countries have to reduce their energy demand drastically while developing countries might still increase theirs. It also means that fossil fuels have to be substituted for within the next 80 years2 at the latest because they will then be exhausted. Therefore, 1.25 % of fossil fuels have to be compensated for annually and an additional 2-3% for the growth in demand. These challenges require all our creativity and effort and must be tackled as soon and as quickly as possible. Avoiding the additional negative effects of climate change, of course, would demand an even faster substitution of fossil fuel energy.

Keywords: Measurements, occupancy, indoor environmental quality, energy use, residential buildings

Summary

Increasing demands on lower energy use in buildings have resulted in a demand for better energy calculations and better input data regarding the building user's energy related behaviour. Parameters that are important for these issues are occupancy levels, household electricity use, facility electricity use, domestic hot water use, heat use, indoor temperature and indoor relative humidity. For residential buildings, there is a lack of these data, which also needs to be resolved over time, in a way so that both short term and long term variations can be described. If all these data are measured at the same time for the same case, it would be possible to search for relationships between the different parameters. This would help to perform energy calculations in the design phase as well as energy investigations in existing buildings. An intended study will measure the mentioned parameters in approximately 20 Swedish residential buildings spread throughout the country, from an intended latitude of N56° to N67°. The measurements will be performed hourly during one year. All parameters will be measured at the building level, providing average values including many apartments. This paper describes the study approach and gives preliminary results from a pre test case.

1. Introduction

In the building industry, it is necessary to perform calculations regarding energy use and moisture levels in different parts of the construction to ensure that a building will be sustainable and healthy. To make accurate predictions on energy use and moisture levels, input data are needed in order to simulate energy use and indoor climate and verify results from simulation programs. As a part of a new study, several indoor related parameters will be measured in several Swedish residential multi family apartment buildings during at least one year with hourly readings. Since several parameters are measured, there will be an opportunity to correlate different parameters. Since the outdoor is also monitored, occupancy levels will be calculated as well as moisture supply and production.

Tso and Yau (2003) studied the daily use patterns of household electricity in about 1500 households in Hong Kong. The use was about the same during the whole day except for a large peak in the evening. Riddell and Manson (1995) studied power usage patterns of domestic consumers in New Zealand. It was found that the different patterns for mid morning and early evening peaks could be observed in both studies. Capasso et al (1994) monitored the electricity use during 22 working days in 95 households in Milan. The daily average load profile showed a smaller peak at eight o'clock in the morning and a bigger peak at eight o'clock in the evening. Paatero and Lund (2006) monitored use of household electricity in 702 households in Finland. The use was least around 5 o'clock in the morning. After the morning peak the use stayed at a higher level compared to the use during the night. The variations during the day have a large peak around eight o'clock in the evening during both weekdays and weekends. The use increased during the morning but there was no peak. Between mornings and evenings, the use was higher during weekends compared to weekdays.

Papakostas et al (1995) monitored domestic hot water heating in four apartment buildings in a Solar Village in Greece. Average domestic hot water use patterns by day of the week were analysed. During weekdays, the patterns showed equal characteristics. The highest peak in use was between 20:00 and 22:00 and the second highest peak around 13:00. During weekends the peaks appeared earlier and the use was more uniform. Vine et al (1987) monitored domestic hot water use in four low income apartment buildings in San

Francisco. During a typical day, there was a peak in use during the morning and another peak in the evening. These peaks were related to bathing practice and cooking and dishwashing. Different usage patterns were observed for weekdays and weekends.

Lee et al (2001) measured CO_2 concentration in living rooms and kitchens in six homes in Hong Kong. The average concentration varied between 500 and 1000 ppm. High CO_2 concentration was generally found in small kitchens with insufficient ventilation. Parent et al (1998) studied difference in CO_2 concentration between rooms in buildings that used different types of ventilation systems. The CO_2 concentration differed a lot between rooms in buildings that used natural ventilation while the difference was minor betweens rooms in buildings that used mechanical ventilation. Lawrence and Braun (2007) developed and tested a methodology for estimating schedules for CO_2 generation rates using short-term field testing. Lech et al. (1996) measured the amount of time spent indoors and Johansson (2005) measured occupancy in offices but there is a lack of reliable data on residential buildings related to the apartment.

Papakostas and Sotiropoulos (1997) studied occupational and energy patterns for 158 families living in the outskirts of Athens, using questionnaires. Attendance rate patterns during the day are described for different family members and typical families, and activity patterns for different electrical appliances are presented.

There seems to be a lack of data, showing annual variations, particularly for many parameters that can be correlated, including many apartments. The objective of the study is to measure a number of parameters in residential buildings in order to give the opportunity to correlate these different parameters with each other. This paper presents the study approach and a test case which has been used to provide insight into potential problems, both methodologically and practically, so they can be solved before the measurements are started in full scale.

2. Methods

By measuring different parameters in the exhaust air of residential buildings, a large number of apartments can be included in the study at a reasonable cost, compared to measuring in individual apartments. On the other hand, it will not be possible to find distributions between apartments inside a certain residential building or distributions between different rooms in an apartment. In the future, verifications are planed to be carried out in the test case or in more cases by use of questionnaires or apartment loggers regarding some of the parameters.

2.1 Measured parameters

The parameters to be measured are carbon dioxide levels in both the central exhaust unit and outdoors, ventilation airflow rate, temperatures in the central exhaust unit and outdoors, relative humidity in the central exhaust unit and outdoors, household electricity use, overall electricity use, use of space heating and domestic hot water heating. Using these parameters, occupancy levels, moisture supply, moisture production, indoor temperatures and parts of the power balance needed for energy calculations of buildings can be calculated. Measurements will be performed hourly to make it possible to obtain daily and weekly time variations. The purpose is to measure for at least a year to obtain annual time distribution and be able to evaluate the methods during different outdoor conditions. The residential buildings are not yet determined.

2.2 Errors

The study will not give detailed information about levels in each room of each apartment but will instead give airflow rate weighted averages of the apartment levels for a large number of apartments, which is the aim of the study. By that, it will be difficult to know if a measured value is the airflow weighted point value at the exhaust devices or if it is the airflow weighted average value of the entire apartments. In fact, it will be a combination of both.

A major methodological error in this study is to determine the airflow rate that changes the air in the building. Buildings are exposed to leakage due to wind and buoyancy that changes the air in the apartments as well as the mechanical ventilation system does. The actual air change rate can be measured with tracer gas methods but it would be expensive to do it annually so it is not realistic if many buildings are included. On the other hand, this error can be minimized with the use of buildings with mechanical exhaust air only. That leads to a depressurisation of the building which reduces the exfiltration and by that the air change per hour from leakage. Typically, it is decreased by a factor of 5 compared to a building with balanced ventilation (Johansson, 2005). If a building has mechanical exhaust and an air tightness of 0.8 $l/(s \cdot m^2$ surrounding walls) at 50 Pa testing pressure, a constant airflow rate of $1\% \cdot 0.8$ $l/(s \cdot m^2)$ can be assumed in normal conditions (Johansson, 2005). If it is assumed 1.4 m^2 surrounding area per 1 m^2 floor area, 0.011 $l/(s \cdot m^2$ floor) is added to the mechanical ventilation. This can be corrected for in the analysis but is small compared to the former Swedish Building regulation (Boverket, 2002) that demands a ventilation airflow rate of 0.35 $l/(s \cdot m^2$ floor). Therefore, exhaust ventilated buildings that take the kitchen stove air through the same ducts as the rest of the exhaust air will be used in this study. Exhaust air is taken from bathrooms, kitchens and laundry rooms. Outdoor air inlets are located in bedrooms and living rooms in almost all Swedish residential buildings.

If people in the buildings open windows, the air change per hour increases dramatically (Nordquist, 2002). That could mean that during the summer period, the measured values regarding moisture and carbon dioxide are not applicable for supply and production calculations. Still, they give point level information at the exhaust devices. The window airing may be checked in the test case at some points by visual checks from outside or by a questionnaire.

Even if carbon dioxide production indoors can be obtained, it can be influenced by, for example, pets, burning candles and plants. The carbon dioxide production from the human being also varies a lot depending on, for example, activity and body mass. The measurements will not specify where the carbon dioxide comes from and the occupancy calculations have to rely on typical figures of production rates for human beings. On the other hand, the intended measurements will tell how a demand controlled ventilation system will react since such a system is usually controlled by carbon dioxide. Verification in the test case on occupancy and other carbon dioxide producers or reducers can help.

The temperature indoors can have errors such as if it is measured in the central exhaust unit, if the ducts are not insulted and located in cold or warm spaces. These things might be visible in the buildings. There can also be leakage in the exhaust duct system that means that cold air is drawn into the system and the airflow rate measurement becomes wrong.

2.3 Theories and analysis

The measurements and calculations of temperatures, relative humidity, moisture supply and moisture production are discussed by Bagge and Johansson (2008). The production of carbon dioxide can be described by Equation 1 where C_p is the carbon dioxide production in l/s, C_{in} is the carbon dioxide volume concentration in the exhaust air and C_{out} is the carbon dioxide volume concentration in the outdoor air and q is the ventilation airflow rate of the building in l/s. It is assumed that there is no buffering. The effect of buffering and time lags will be analyzed in the study.

$$C_p = \left(C_{in} - C_{out}\right) \cdot q \qquad (1)$$

If a person produces c_p l/s carbon dioxide that enters the building indoor, Equation 2 gives the equivalent number of persons, N, that need to be in the building. Here, C_p can be corrected for other producing or reducing species in the building.

$$N = \frac{C_p}{c_p} \qquad (2)$$

Since the activity level varies in residential buildings, it is difficult to determine an average c_p. For typical office work, c_p is given to 19 l/h for adults but for other activity levels it can vary between 10 l/h and 170 l/h (Nilsson, 2003; Ashrae, 2001; European Conserted Action, 1992). In residential buildings, people are suspected to be sleeping a large part of the time they occupy their homes and that certainly gives lower c_p. The verification will give some results on correlations between occupancy and total carbon dioxide production.

The variations of parameters during the day were studied. A difference can be calculated between each hourly value and a corresponding daily average value. The variations are presented as averages of these differences for all weekdays and weekends respectively.

2.4 Measuring equipment

The measurement sensors will be placed close to the exhaust fan in the main duct of the exhaust ventilation system for measuring the indoor temperature and relative humidity. Outdoors, the placement is shielded from too much wind and preferably from rain. Temperature, humidity and carbon dioxide concentration will be measured and wind and solar radiation will be bought from SMHI (2005) if possible. Since the loggers will measure for a year at each location, the set up must be robust and may not disturb the daily work or living.

The carbon dioxide sensors have a typical error of ±20 ppm. Since levels should vary between 400 ppm and approximately 800 ppm of carbon dioxide, the error of the difference can reach 10% of the scale if the exhaust air logger shows +20 ppm and the outdoor logger -20 ppm.

Temperatures are measured with loggers with a specified error of ±0.35°C. Generally, the experience from these devices is that it is seldom more than ±0.2°C. The relative humidity is measured with the same loggers that also have voltage input for pressure drop measurements for obtaining airflow rates and carbon dioxide concentrations. The relative humidity error is given to 2.5% absolutely. The voltage error is small compared to the error of the pressure drop sensor. The flow can be believed to have an error of ±7% of the reading including pressure sensor and variations in the fan pressure drop outlets.

The loggers will be calibrated regarding temperature and relative humidity to decrease the possible combined errors due to the fact that the error of the difference can be much higher.

Electricity and energy use should be measured by existing meters used for billing. The accuracy of these meters should be good enough but has to be checked in each case.

2.5 Number of studied cases and their location

The idea with the study is to receive useful data that is time resolved over average values. Since the method does not give apartment distributions, the only location distribution will be from the averages of the different buildings. If 15 buildings are measured and there are 20 apartments in each building, the entire study will give an average value of 300 apartments. The 15 buildings can also provide some distribution data between the buildings, or at least information on geographical distributions if they are located in different cities. Preferably, five buildings close to each other will be found in three different cities from south to north Sweden to represent different outdoor climates. Each group of five buildings will make it cheaper to measure outdoors and make it possible to look at differences between buildings. The setup and number will be discussed with statisticians.

2.6 Test case

The test case is a five-story multi-family building located in Malmö, Sweden. It was built during 2000 and 2001. The building consists of 16 apartments. The ventilation system is mechanical exhaust air. An exhaust air heat pump supports space heating. Additional space heating and domestic hot water heating is supported by district heating.

3. Results from the test case

Details regarding relative humidity, moisture supply and moisture production is presented in Bagge and Johansson (2008). Figure 1 presents measured indoor and outdoor temperatures. The average outdoor temperature during the measurement period was 4.8°C and varied between 0.7°C and 8.2°C. The average indoor temperature was 20.3°C and varied between 19.8°C and 21.0°C.

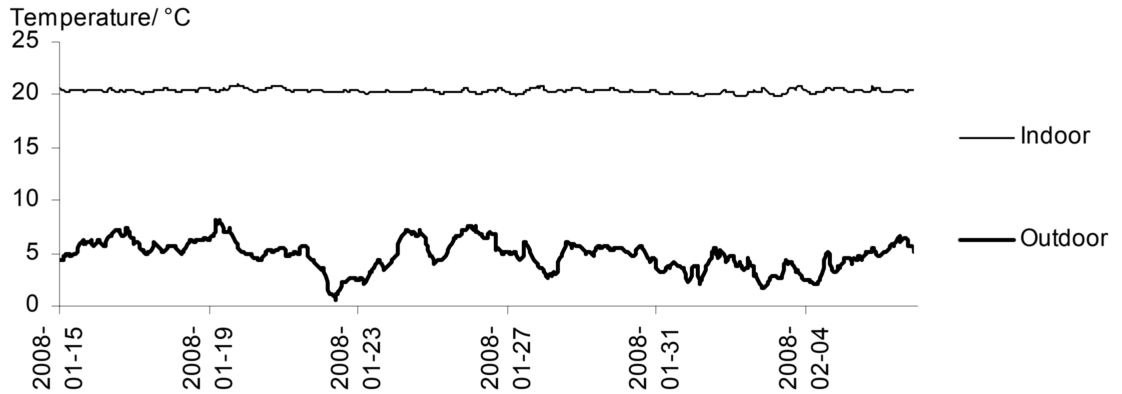

Figure 1 Indoor and outdoor temperatures during the measurement period.

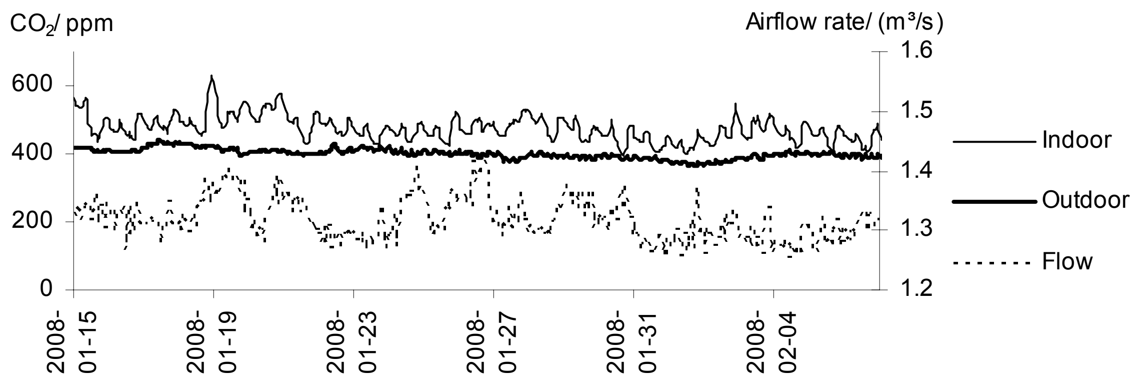

Figure 2 Indoor and outdoor CO_2-levels and airflow rates during the measurement period.

Figure 2 presents the carbon dioxide levels indoors and outdoors and the airflow rate. The average airflow rate was 1.32 m³/s and varied between 1.25 m³/s and 1.42 m³/s.

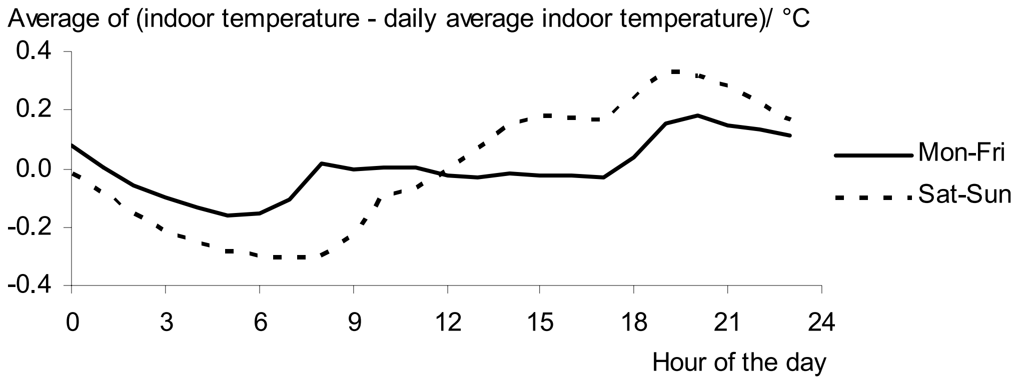

Figure 3 Variations in Indoor temperature during the day, presented for weekdays and weekends respectively.

Figure 3 gives the daily variations in indoor temperature for weekdays and weekends respectively. The average indoor temperature during weekdays was 20.35°C and during weekends 20.38°C. During weekdays the temperature decreased during the night, increased during the morning where after it decreased slightly during the day, increased during the evening and reached a maximum at 20:00. During weekends the temperature decreased during the night, increased during the morning and the afternoon and reached a maximum at 19:00. During weekends, the increase in temperature during mornings occurred later compared to weekdays.

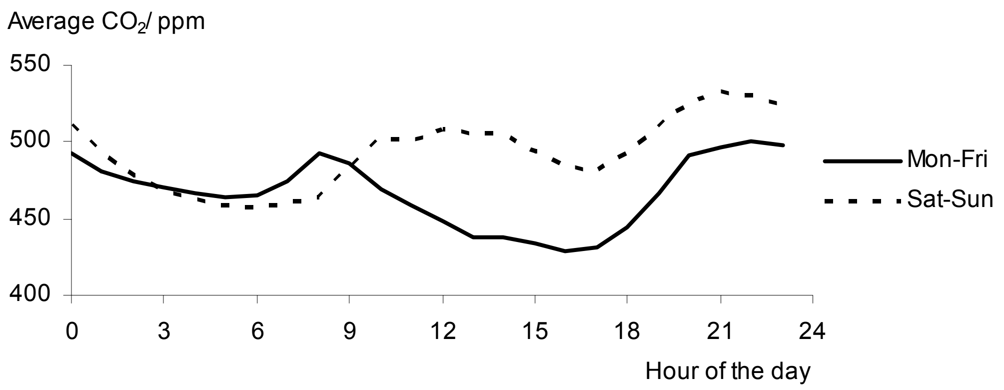

Figure 4 Variations in CO_2-concentration indoors during the day, presented for weekdays and weekends respectively.

Figure 4 presents the variations during the day of the CO_2 concentration indoors. The average CO_2 concentration during weekdays was 467 ppm and during weekends 493 ppm. During weekdays the CO_2 concentration decreased slightly during the night, had a peak at 08:00 where after it decreased during the morning and stayed on a low level during the afternoon where after it increased during the evening. During weekends the relative humidity decreased slightly during the night, increased during the morning and stayed on a high level during the day where after it decreased slightly during late afternoon followed by an increase during the evening. During weekends, the increase during mornings occurred later compared to weekdays.

Figure 5 presents the CO_2-production during the day. The average CO_2 production during weekdays was 0.085 l/s and during weekends 0.13 l/s. The CO_2 production, given by Equation 1, follows the CO_2 concentration since the airflow rate and the outdoor CO_2 concentration is rather constant. Increased airflow rate can only be caused by stove ventilation that the user higher during cooking.

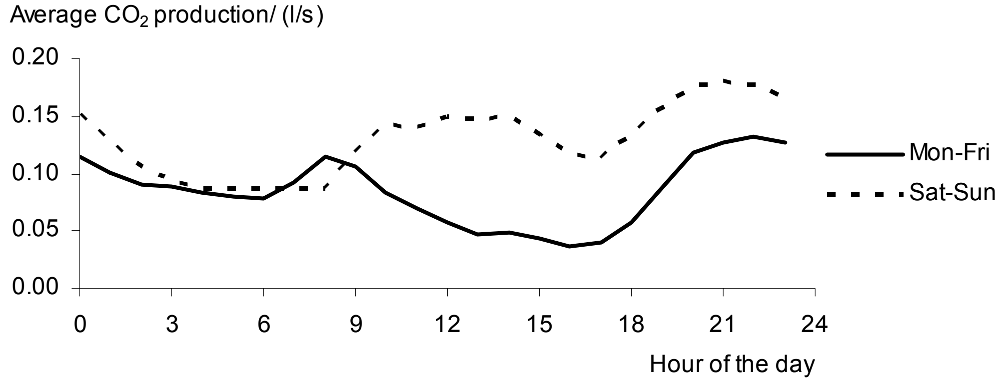

Figure 5 CO_2-production and estimated occupancy during the day, presented for weekdays and weekends respectively.

3.1 Use of electricity and domestic hot water

The energy use at the property was studied earlier by Bagge (2007). Use of electricity was measured hourly during 2005. The use includes both household electricity and common electricity. Figure 6 presents the daily variations in use of electricity during weekdays and weekends respectively.

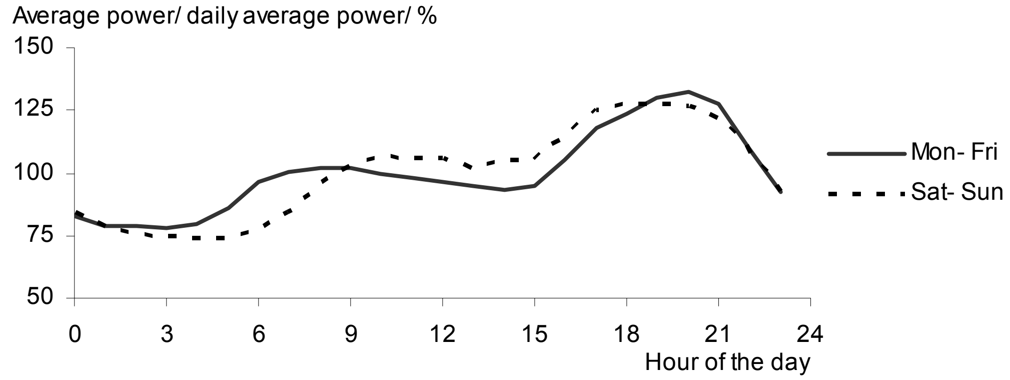

Figure 6 The variation in use of electricity, including household electricity and common electricity, during the day, presented for weekdays and weekends respectively.

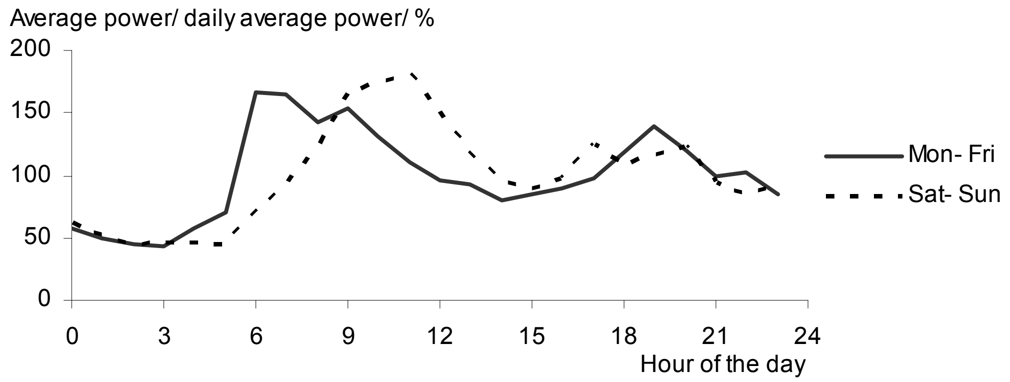

Figure 7 The variation in use of domestic hot water heating during the day, presented for weekdays and weekends respectively.

The use of domestic hot water was not measured separately, neither the volume used nor the energy used for domestic hot water heating. However, during the summer there should not be any need for space heating and thus the use of district heating should be used solely for heating the domestic hot water. During 2005 use of district heating during July and August was measured hourly. Since the measurements are from the summer months when people typically have vacation, the usage patterns during the day might be different from the rest of the year. Figure 7 presents the daily variations in use of domestic hot water heating during weekdays and weekends respectively.

The daily variations in use of household electricity and domestic hot water have equal characteristics. There are peaks at the same times during mornings and evenings. However, the peak during morning is larger for domestic hot water and the peak during evening is larger for household electricity.

Figure 8 presents weekday variations during the day in the indoor temperature, use of energy for domestic hot water, total electricity, moisture supply and CO_2 production. All these parameters have equal characteristics with one peak during morning and one during evening. The peaks for the different parameters had different phase displacement which can be caused by buffering and time lags between different physical phenomena.

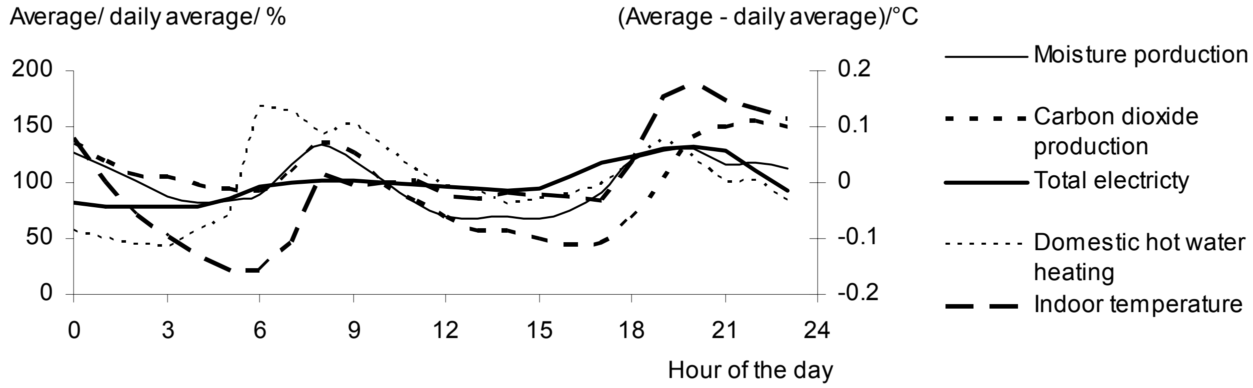

Figure 8 Weekday variations during the day in the use of energy for domestic hot water, total electricity, moisture supply, CO_2 production on the left axis, and temperature on the right axis.

4. Discussion and conclusions

In the study, a number of uncertain, user related parameters are going to be measured in several residential buildings. The idea to measure many parameters in many apartments for a reasonable amount of money forces a number of assumptions into the study that increase the errors and make some analyses impossible. Examples are window airing and leakage that influences both moisture measurements and occupancy measurements or distributions between apartments in a certain building or between single rooms inside an apartment. Despite the weaknesses, a lot of useful information can be provided by the data that will be obtained if they are representative.

With the amount of needed equipment, there is a need for cost effective sensors and measuring equipment. It seems that the equipment that was tested will be appropriate but calibration is needed according to the error analysis. The carbon dioxide sensors seem to show large errors due to their automatic calibration used in the test case. This auto calibration will be switched off and the sensors will be calibrated manually before measurements and checked again after. Measured data will be linearly corrected for the drift over the measured period.

The average CO_2 production during weekends was 53% higher compared to weekdays which might indicate higher occupancy level during weekends. For all measured parameters the peak during weekends occurs later compared to weekdays, which is believed to be due to earlier mornings for the residents during the weekdays.

Several of the measured parameters have equal characteristics as shown in Figure 8. This indicates a relationship between different parameters and that it could be possible to correlate them in such a way that one parameter can be estimated from another. Hopefully, this study and presented test case will give data on averages, distributions between houses, daily variations, annual variation and correlation levels between several parameters to help to improve simulations of indoor climate and energy use in residential buildings.

Keywords: building façade, materials defects, manufacturing faults, module malfunction

Summary

Photovoltaic (PV) cells, integrated within a building façade are an application of growing interest, in Europe and Greece. In order to assess their performance after their installation new tools and methods of investigation are needed. In this work a non destructive technique, infrared thermography was used as a diagnostic tool for the performance assessment of a photovoltaic array integrated on the southern façade of public building, NTUA's Chemical Engineering Building. This grid-connected 50 kWp solar photovoltaic array, installed under an EC Thermie Project (SE-142-97-GR-ES), operates in a standard and hybrid PV-Thermal configuration, meant to save conventional energy. The thermographic system used for the analysis covers the wavelength region 8-12 μm. The thermal images obtained showed that there are notable temperature differences on number PV panels, which may be attributed to material defects, manufacturing faults, module malfunction, and external abuse.

1. Introduction

Photovoltaic (PV) cells, when integrated within a building façade, offer the possibility of generating electric power and heat for local use or export. At the present time there is significant R&D activity through Europe, which attempting to improve operational efficiency of photovoltaic cells, ensure their attractiveness to designers for use as a façade element and develop know-how in relation to façade integration. The expectation is that such facades, especially at public buildings will enhance the thermal performance of the envelope and provide and economic delivery of electric power (Clarke et al. 1996).

In this work a BIPV system, installed on the southern facade of a public building in Greece, Chemical Engineering School Building of the National Technical University of Athens (NTUA), was investigated with the aid of infrared thermography.

The use of infrared thermography in the analysis of a building's envelope is really developing in recent years. The use of IR data for the calculation of heat transfer coefficients is reviewed in Astarita et al. 2000, while Grinzato et al. (1998) analyse quantitative infrared thermography in buildings. Avdelidis & Moropoulou (2004) discuss the use of IR thermography in buildings of historic interest and Bazilian et al. (2002) use thermographic analysis of a building integrated photovoltaic (BIPV) system. This analysis allows for the interpretation of the surface emissivities and operating temperatures, as well as qualitative graphic analysis of temperature gradients. The use of an infrared camera is invaluable in the study of the thermal performance and the relevant parameters in a BIPV system, especially as a diagnostic tool for potential problems, since it involves a relatively quick procedure, which can be accomplished without the need for interrupting system operations.

2. BIPV project study

2.1 BIPV project description

In this work was performed thermographic analysis on the PV arrays of the southern façade of the NTUA's Chemical Engineering building complex (Figure 1). The photovoltaic project was realized under a Thermie Program (SE-142-97-GR-ES), which involved integrating 50 kWp grid-connected solar photovoltaic arrays on the facade and the roof, operating in a standard and hybrid PV-Thermal configuration, meant to save conventional energy (thus limiting pollution normally associated with the latter) and, at the same time, to improve the thermal comfort in the adjacent large laboratory space. The project was inaugurated at October 2002.

Figure 1 Building façade with the first six PV arrays

The concept of the hybrid operation (Figure 2) is simple enough : in the winter, the working area air is heated up by rising via free convection in the narrow space between PV's and external wall, and is returned to the interior, thus utilizing the rejected heat due to the low electrical conversion of the PV modules.

In the hot season, on the other hand, the same kind of draft behind the arrays can lead cooler air from the northern side of the laboratory into the laboratory, before venting it into the atmosphere.

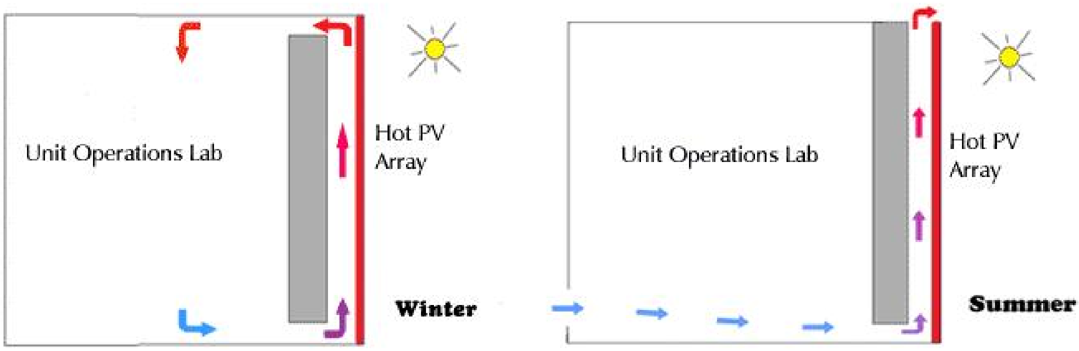

Figure 2 Schematic of the thermal operation of the hybrid system

The installed arrays, which have a direct-south orientation, use a total of 752 polycrystalline Si modules (Eurosolare PL810), each having a 67 Wp rating, and 8 Fronius IG60 inverters that supply the grid with a maximum power of about 33-34 W.

Such integration demonstrates the potential of solar retrofitting, using appropriate photovoltaic systems and basic heat transfer techniques. As shown above, the technology applied in the hybrid arrays exploits the synergy between the need for cooling the PV cells and the existence of a heating load in the adjacent working space.

The vertical facade arrays are located outside the southern walls of the large corridors and the Computer Centre, as well as on the southern side of the Unit Operations Lab. The tilted roof-top arrays, on the other hand, are situated above the laboratory, on the southern side of its protruding central dome. The conversion of DC into AC current is effected in the inverters' room, on the laboratory's mezzanine, and is finally led to the power distribution cabinet in the basement (Figure 3).

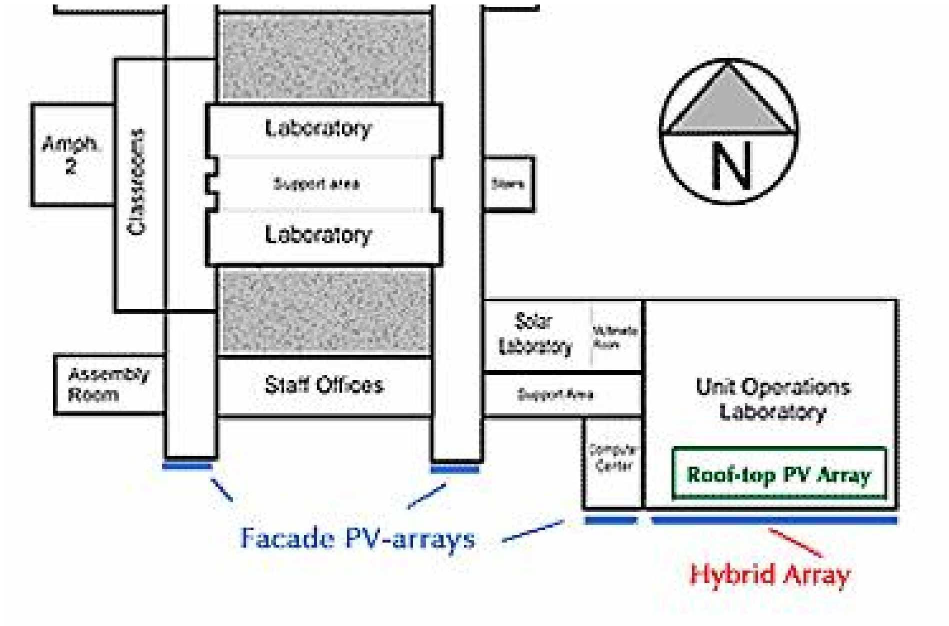

Figure 3 Ground plan of Chemical Engineering Building where PV arrays are placed

The conversion of DC into AC current is effected in the inverters' room, on the laboratory's mezzanine, and is finally led to the power distribution cabinet in the basement.

2.2 Experimental Procedure

Infrared thermography is the technology of converting incoming IR radiation into visible light that can be converted to an electronic form for representation. The use of IR thermography has grown considerably in the last decade. Hand-held IR cameras allow consultants and engineers to do on-site work in the built environment. The cameras, though expensive, are relatively robust. The IR detector is a transducer that reads the incoming radiative energy and transforms it into a voltage or a current so it can be digitally rendered (Astarita et al. 2000).

Thermographic analysis is both non-destructive and non-evasive, which contribute to its benefits in investigating operating electric (PV) systems already installed as a roofing product (Titman, 2001). This allows the analysis of a power system without having to interrupt its operation. In many cases the evaluative process can take place without ever having to enter a facility or structure. This is valuable in terms of time and safety.

In this work it was used an infrared camera was used, which operates in the 8-12 μm range of the spectrum (TVS-2000 MKIILW Nippon Avionics).The thermographs were taken in September and October of 2006, between the hours 10am to 5pm.

The thermographs were continuously recorded using a pal video, but also at selected time intervals. The ambient conditions were also recorded (air temperature, relative humidity, velocity). Better quality had the images at sunny, windless days with low ambient moisture content.

3. Results

In the series of images which follows, the left column presents the surface under investigation, while the right column shows the corresponding thermograph. As expected, the best IR thermographic testing images resulted during sunny windless days with low relative humidity.

In the thermograph of Figure 4 hot spots were detected corresponding to areas where the panels have been severely damaged as a result of vandalism, i.e. by stone and bottle throwing.

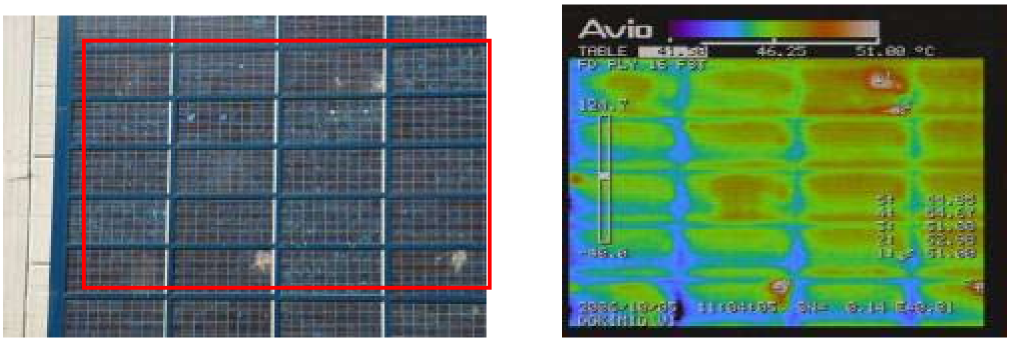

Figure 4 Hot spot detection in a vandalized array

In Figure 5 hot spots were detected in an array without visible external damage on its surface. Thus, the problem must be attributed to internal causes, such as corrosion, or shadow effects, e.g. from the mounting system's aluminium joint covering ribbons. Such hot spots appear in the same areas of the array modules.

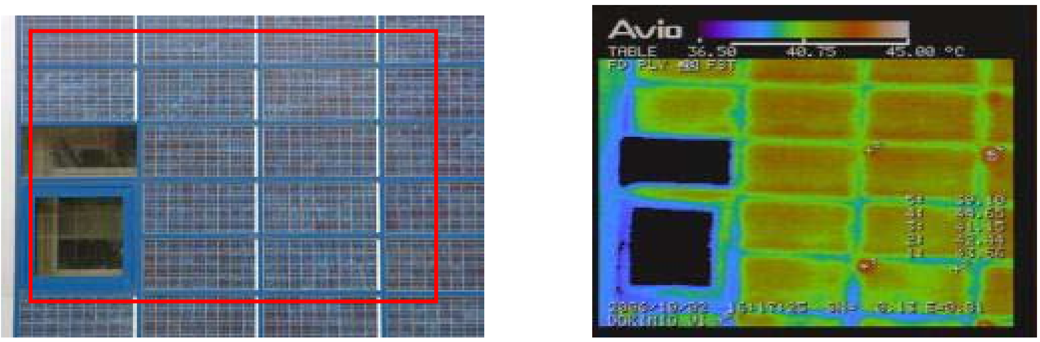

Figure 5 Hot spot detection in an externally undamaged array

Areas around windows exhibiting lower temperatures are shown in Figure 6. Thermal alternation is steep, while the difference between maximum and minimum temperature is substantial. On the upper thermograph two hot spots were also detected, just below the window.

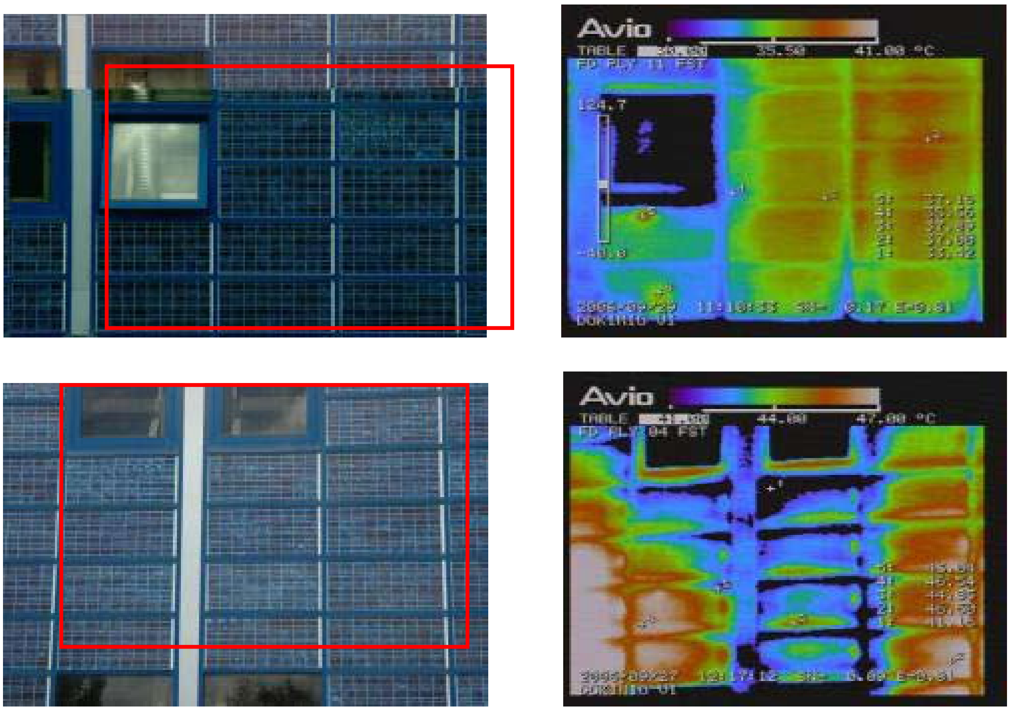

Figure 6   Areas around windows exhibiting lower temperatures

Elongated horizontal hot spots are shown in Figure 7, producing almost vertical temperature gradients in the modules. Main cause of this temperature differentiation is the shadow effect from the horizontal aluminum profiles of the mounting system, under certain angles of solar incidence.

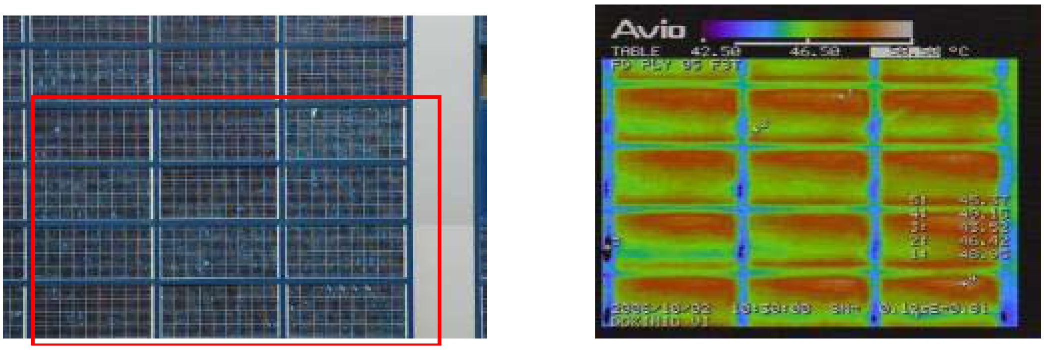

Figure 7   Elongated hot spots in the modules.

The identification of a shadow effect caused by elements of the mounting system was probably the most interesting finding of this thermographic investigation, and convincing proof of the effectiveness of the IR camera as a fault diagnosing tool. The mounting frame turned out to be slightly problematic, because the horizontal metal profiles which cover the joints between modules in the array, under certain solar incidence angles create a thin shadow on the PV material along their upper side. Besides lowering the power output, such shadows cause local overheating and, in the long term, accelerated aging of the modules involved.

The damages which resulted from vandalisms (Figure 4) caused a substantial decrease in the power output of the particular array, estimated at 13.5 %. Moreover, there is no way of telling how fast the unavoidable corrosion – from water penetration through the cracks – will further degrade the array operation.

4. Conclusions

BIPV in the National Technical University of Athens is one of the first large scale PV building applications in Greece. Infrared thermography can be used as a diagnostic tool for photovoltaics during their operation. Malfunctions, semiconductor material and insulation defects, as well as external damages, can be detected easily and quickly, without complicated procedures. IR thermography can be applied both to large and small-scale systems, in order to help restore or even improve the operation of the array.

Summary

After decades of development and marketing efforts, passive houses have finally reached the mass market, especially in (Central) Europe. Along with the drastically reduced energy demand for the operation of passive houses, energy autonomous and self-sufficient building solutions have become technically and economically feasible. Research projects carried out by the Center for Appropriate Technology (GrAT) focus not only on the lifecycle of passive houses and use of renewable materials, but also on the vision of “wireless” (energy self-sufficient) buildings.

Currently small-scale stand-alone energy supply solutions are in operation. Depending on their size and application they may include wind turbines, PV modules or power blocks, possibly combined with lead acid batteries. However, these systems are cost competitive only in areas without grid connection. GrAT does not aim at these niche market solutions, but develops strategies and technical solutions for the mass market within the scope of the “Wireless House” project. The research tasks include the development of highly cost-effective small scale Concentrated Solar Power (CSP) systems for self-sufficient solar housing, including medium temperature (MT) storage for electricity generation, cooling and cooking. The whole system is heat driven and therefore avoids conversion losses. Generated heat (~300°C) will be stored to be flexibly used for different user needs. If this concept proves its practical feasibility, it will be an important step in the development of affordable solar housing solutions succeeding the current passive house trend.

1 Introduction

As a result of energy efficient building design and passive house technology, heating and cooling demands can be drastically reduced. Based upon this significant achievement, new and more radical solutions for energy supply strategies have become more feasible than before, both economically and technically. The passive house technology is therefore an important pre-condition for the next step. It can be seen as an enabling technology for further innovations towards the “Wireless House”. In this paper, the applied research and development of the Wireless House is presented. ‘Wireless’ in this context describes the independence of the house, free from public energy infrastructure and grid connection. In other words, the wireless house is totally energy self-sufficient. Application of the concept is, however, not limited to a single house, but it can be expanded to groups of houses and residential areas, where these houses may be connected into a micro net sharing energy generation and/or storage facilities.

The entire development of the Wireless House will be progressed based upon previous research results and demonstration projects. For example, the *Factor 10* building “S-House” (www.s-house.at, Wimmer, et al. 2005; Wimmer, et al. 2006) which demonstrates the feasibility of extremely energy efficient constructions will be taken as the prerequisite for the next innovation steps. By using natural materials such as straw, clay and wood, the consumption of resources during the construction of a building could be minimized by Factor 10.

The development for the Wireless House started from an analysis of actual needs of inhabitants rather than the current level of energy consumption in a modern household. This approach is typical for the philosophy of Appropriate Technology, which focuses on human needs and natural boundaries. This perspective often leads to radical system innovation instead of incremental improvements. Appropriate technology has two major goals: to improve the quality of life, and to reduce the environmental load and resource consumption. These goals are not in contradiction, but often can be achieved at the same time.

2 Background

Because of the progress in building design and solar architecture during the last fifteen years, room heating and cooling in passive houses no longer holds the major share of energy consumption. The average annual heating demand in passive houses can be reduced even below the required standard of 15kWh/m2a. The significance of household appliances and electrical/electronic devices for the energy demand in households is steadily increasing (Austrian Association of Electricity Companies- VÖE, 2007). The share of electricity in total energy consumption worldwide is projected to rise from 16% in 2004 to 21% in 2030. The annual growth rate varies from 2% in Europe up to almost 8% in China. The demand for electricity grows most rapidly in households, due to increasing use of electric and electronic appliances (Priddel, 2006). Supply and demand management for electric energy on a national level shows the drastic problem of secure supply of electricity. Electricity capacity margins are necessary to guarantee a secure energy supply. As energy demand is growing the capacity has to be increased and also the margins are augmented. The margins in different countries, like the US, the UK and Austria are between 15% and 25% (EIA, 2007, Grimston, 2005, Boltz, 2007). High costs for new power plants and high voltage grids as well as a growing opposition among the society against such projects demand for radical new solutions.

Availability and convenience are among the main factors why most of our household appliances run on electric energy. Consumers are used to a "plug and play" habit with regard to household equipment. Although an extensive study of Least Cost Planning in Austria showed an increased ecological and economical efficiency by systematically integrating the energy reduction potential of the demand side (Adensam, H. 1996) producers still do not see energy efficiency as an important development goal (Paula, et al. 2007). This behaviour results in the constantly rising consumption of electric energy.

However, is it really electricity what is actually needed? We want a hot meal, a cool storage for food and beverages, a hot shower and light for reading. In other words, what we need is not electricity but ‘energy services’. A closer look at the actual needs unveils what types of energy services are required in our everyday life. Table 1 shows the current average energy consumption used for appliances providing various energy services.

For comparison, three different consumption scenarios have been defined: Scenario one represents a conventional house, characterized by high energy demand for room heating (or cooling) due to poor energy efficiency of the building. For this scenario, it is assumed that the house is equipped with standard household appliances. This model fits the current consumption patterns in Western Europe. Scenario two is referred to as “modern house”. The energy standard of the building meets the latest legal regulations and it is equipped with A-rated household appliances. Compared to the “average house”, energy for heating is saved up to 50%, and the electric energy demand drops to one third of that of an average traditional household. Scenario three represents the best practice. In particular, heating and cooling demands are reduced to a minimum level due to passive house design and technology. The energy demand of household appliances is the same as in scenario two, but thermal energy is provided directly without conversion losses.

Table 1 Comparison of energy demand for different scenarios

Energy applications	Energy demand of an average house(hold) (kWh/a)		Energy demand of a modern house(hold) (kWh/a)		Energy demand of the Wireless House concept (kWh/a)	
	total	electric	total	electric	total	electric
Kitchen stove	1000	1000	500	500	500	*low*
Oven	78	78	39	39	39	*low*
Washing machine	378	378	189	189	189	15
Cloth dryer	528	528	264	264	264	*low*
Dish washer	456	456	228	228	228	110
Refrigerator	333	333	167	167	167	*low*
Freezer	356	356	178	178	178	*low*
Small devices	170	170	170	170	170	170
TV - / Hi-Fi – System	250	250	250	250	250	250
PC	70	70	70	70	70	70
Light	500	500	100	100	50	50
Hot water	2373	2373	2373	0	2373	0
Heating	14000	0	6000	0	600	0
Total	20491	6491	10527	2154	5077	665

According to Table 1, quantitative ranking of the appliances providing energy services in an average household[1] is as follows:

1. Hot water representing almost 1/3 of the total energy demand
2. Electric kitchen stove, due to its high load
3. Washing machine dryer and other appliances
4. Freezer and refrigerator
5. Light, computer, TV

Other than light and computer equipment which can only be run on electricity, other energy services actually require either heat or coldness, and transform electricity into thermal energy. Appliances that convert electricity into thermal energy of high or low temperature consume most of the energy in an “average household”.

Taking into consideration the conversion losses, however, the use of electric energy is a very inefficient way of providing thermal energy services. Instead, solar radiation can be used directly to produce heat, especially in regions where plenty of sunshine is available. High temperature is required for cooking, and therefore, the solar energy needs to be concentrated and stored. The temperature obtained from water-based flat panel systems reaches up to 100 degrees centigrade. For higher temperature levels thermal oil can be used instead of water.

Research and development efforts focusing on electric power generation from renewable sources including solar radiation often aim at making components more efficient and production more economical. Nevertheless, a huge portion of the generated energy is lost during the conversion. Additionally there is substantial potential for energy conservation regarding the optimization of the demand side, which is currently not utilized

3 The Wireless House Concept

Buildings that produce equal or even more energy than they consume are in existence. The available concepts can be categorised into *grid connected* and *stand alone* solutions. The idea of grid connected systems is to compensate the energy demand in periods of energy shortage with an energy surplus inducted into the grid at another time. These so called “plus energy” houses, generate a surplus of electricity based on an annual balance. In other words, a shortage in winter is compensated or even overcompensated by a surplus in summer. The grid connection ensures a continuous energy supply for the house over the whole year. It absorbs the surplus of energy and delivers energy in case of shortage.

Stand alone energy systems however have different requirements. As they are independent from infrastructure they have to provide *enough* energy at any time. This requires capacity margin as well as a storage system that is able to buffer the difference between supply and demand over the annual cycle. Nevertheless, most of the stand-alone systems only focus on the supply side. The major concern is “how to generate and store as much energy as necessary, given the current demand level?” These systems, depending on their size, including wind turbines, PV modules or power blocks, are often combined with lead acid batteries. They are regarded as expensive and only suitable for very remote areas without any grid, like mountains or undeveloped rural regions.

The Wireless House concept is not just another stand alone system but it aims to develop a new strategy for a house or a living unit which is not connected to an energy infrastructure, by actively taking the real demands into consideration. As explained earlier, most of current electric energy demands are related to heating and cooling rather than direct use of electricity. Therefore, the most intuitive solution will be to use the thermal energy from the sun instead of redundantly converting solar radiation to electricity and then to heat again.

Just like other stand-alone systems, the new solution has to provide the required amount of energy with sufficient margin to be used at any time even in periods of poor supply conditions (e.g. night time, cloudy days). However the developed concept focuses on both, the supply and the demand side, and it aims to make use of thermal energy as efficiently as possible. Figure 1 shows, that a house powered by solar energy can be realized only by drastically reducing the energy demand. Whereas the total energy consumption of modern house (holds) exceeds the produced solar energy during six months of the year, the Wireless House can be served by solar energy all year round. Only for less than two months yearly, additional energy from other energy sources (such as a biomass back-up system) may be necessary in order to assure sufficient energy supply.

[1] room heating is excluded

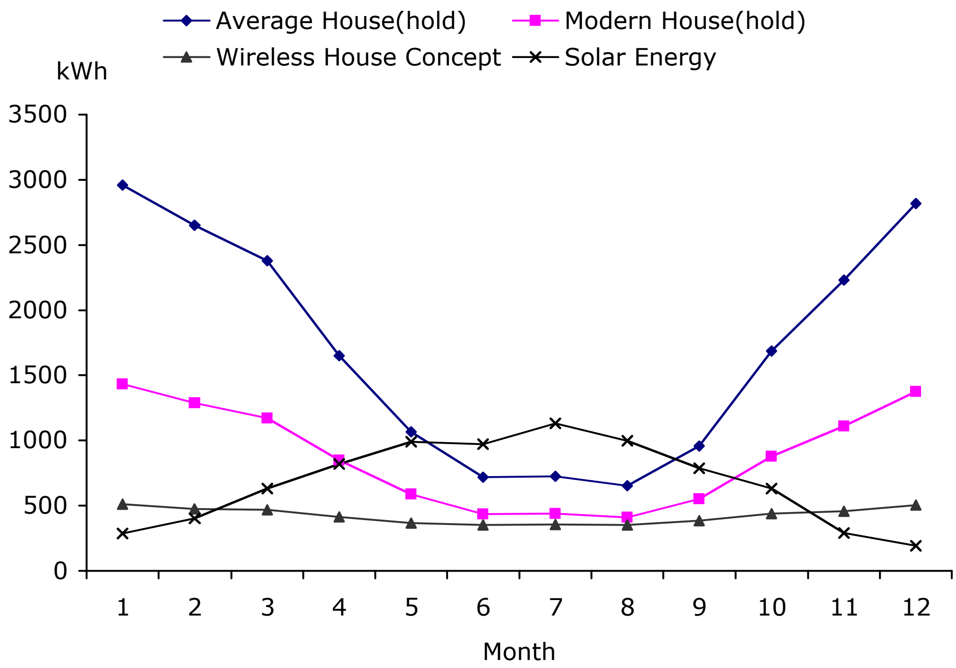

Figure 1: Total energy demand of different house(hold) types and available solar energy over the annual cycle

The concept is based on a number of assumptions, which are described as follows:

• Assumption 1: Heating and cooling demand is reduced to a minimum by passive solar architecture.

Compared to conventional existing buildings passive houses reduce energy demands for heating and cooling by a factor 10 to 20 (Wimmer, et al. 2005). Whereas the focus in cold regions is put on the reduction of heating energy, in warmer regions the reduction of demand for cooling energy is a bigger concern. The house design consequently varies according to local situation and user needs.

• Assumption 2: Thermal energy on mid temperature level is generated from concentrated solar energy and biomass.

The required temperature levels are defined by the need areas in modern households (e.g. baking, cooking, washing, and cooling). Kitchen stoves and baking ovens have to provide a temperature of up to 300°C, which is the highest temperature level. Therefore, about 300°C is the threshold for generating devices as well as for storage. Parabolic trough or dish concentrators can easily provide this level of temperature in any climate regions as far as there is sufficient direct solar radiation. A back up system running on biomass can cover the periods of poor solar gain. The new system operates with high margins over the hot period of the year (see Figure 1). During the cold period the necessary margin will be guaranteed by the proper dimensioning of the biomass system.

• Assumption 3: Thermal energy services are provided directly from collected heat, therefore minimising conversion losses.

Conventional household appliances are operated by electricity, which is afflicted with conversion and transport losses. For the Wireless House these losses can be considerably reduced. Thermal energy produced mainly by solar energy will directly supply household appliances like kitchen stoves and ovens. The heat is transported from the point of generation to the storage and to the household appliances by the help of thermal oil as a heat transfer medium, which works at ambient pressure up to 355°C (Fragol Schmierstoff). The concept allows for cascade use of the produced heat from 300°C down to 60°C. The highest temperature level of up to 300°C is necessary for baking. Cooling and freezing can be operated by applying absorption cooling machines requiring temperatures between 90°C and 150°C. Further household appliances like washing machine, dryer, and dish washer will be provided with temperatures below 100°C. Space heating and warm water needs even lower temperatures of approximately 60°C.

• Assumption 4: Electric energy demand will be minimized due to highly efficient components for lighting, computing and media operation.

Household appliances, which need electricity like TV set, Hi-Fi stereo, computer, electric motors and lighting, already have a relatively low energy demand. Furthermore in the new Wireless House the electricity demand will be further reduced by the use of latest energy efficient equipment (e.g. LED lights instead of light bulbs or energy saving lamps). However the trend of growing numbers of electric and electronic devices in the household, and bigger screens for TV, computer monitors, and the constantly rising energy consumption for stand-by mode (Paula, et al. 2007), requires an intelligent management system as well.

• Assumption 5: The remaining rest electricity demand can be generated from thermal sources.

The supply of electricity is realised with the help of technologies, which convert thermal energy at the given temperature level of approximately 300°C into electricity. Among the different energy technologies (steam power, thermo-electric generator, ORC) examined, the Stirling engine proved to be most appropriate for a household installation. Its successful integration into the Wireless House concept needs the adaptation of a low-temperature Stirling engine.

Based on these five assumptions the Wireless House has been developed as a new demand-and-supply matching system. This includes multiple sources of input with planned capacity margin (the buffer between supply and consumption) to secure stabilised supply of energy.

3.1 System layout: Multi-source and multi-use system

The input side of the system is realised by the combination of solar concentrators, solar panels and a biomass back-up system. The system is designed to run mostly on solar energy at a mid-temperature level of 300°C, and a biomass system is used as a back-up. The input- and output-components for different temperature levels are shown in the following figure.

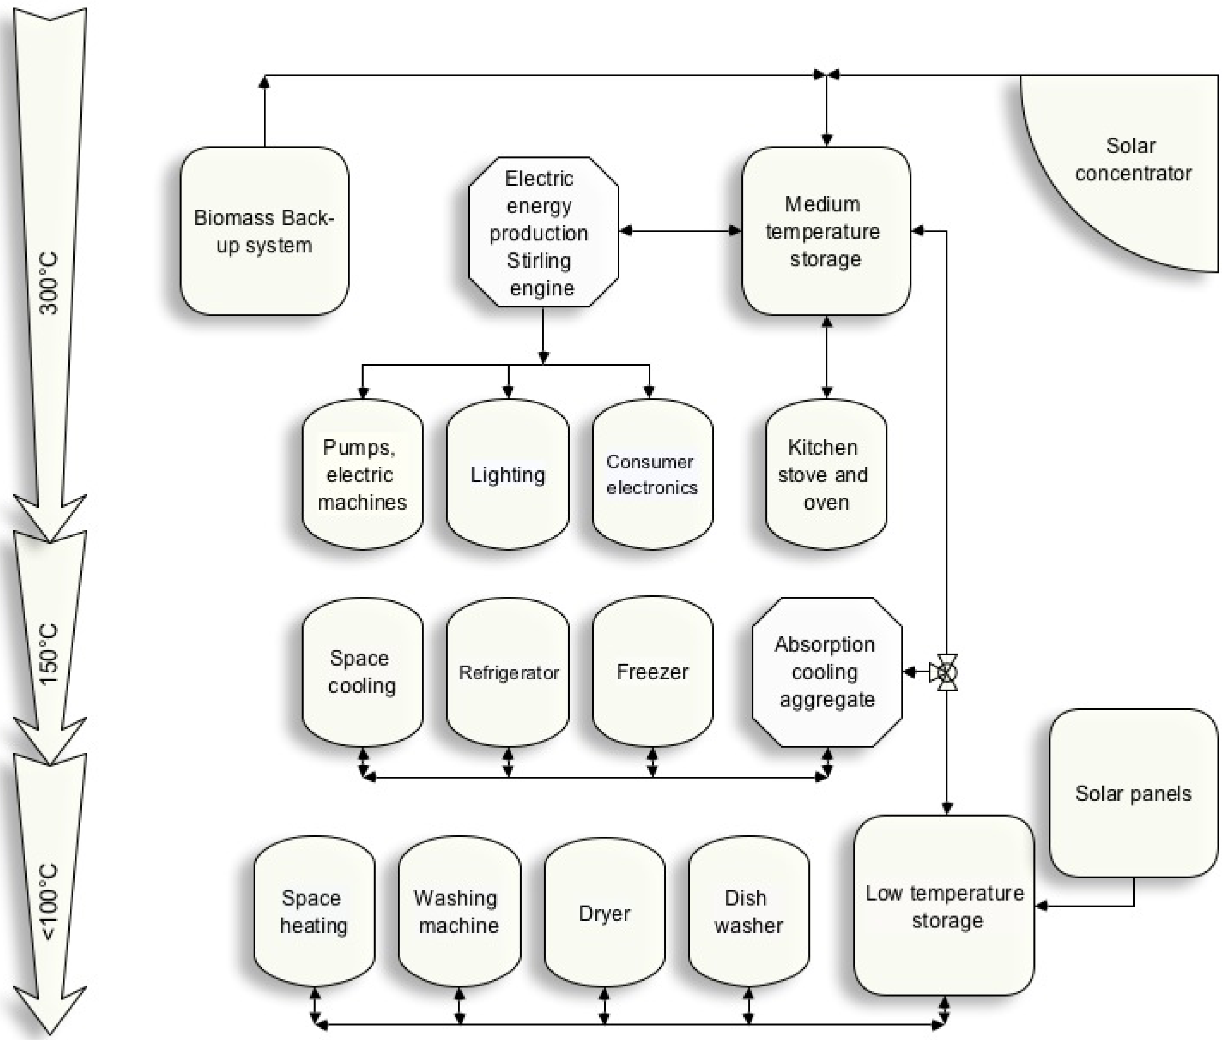

Figure 2: The Wireless House concept, input and output components and temperature levels

3.2 Technology and components

One of the main innovations of the system is the consequent chain of utilization of thermal energy. The generated energy at mid-temperature level is stored for a cascade use to operate heat-driven household appliances from 300°C down to 60°C and to produce the small amount of electric energy, which is still needed in the Wireless House.

3.2.1 Concentrating solar energy

A low cost parabolic dish concentrator has been developed. The main innovations are the receiver and the newly developed tracking system aiming at minimization of investment costs. The receiver contains the heat transfer medium, thermal oil, which is heated up to 300°C. Compared to dish Stirling engines, for example, the temperature is not maximized but kept at a mid-temperature level and subsequently transported to the thermal storage.

3.2.2 Mid temperature thermal storage

The storage of heat at mid-temperature level without losses over a certain period of time is the challenge as well as one of the key components of the Wireless House system. Although heat storage systems are used in industrial processes, the development of this mid-temperature storage for the use in buildings is rather new. The storage is responsible for the supply of heat-driven household appliances and for the production of electricity. There are different technologies available for the storage of thermal energy. The combination of solid stone storage with thermal oil storage was examined. The result was the storage volume of around $10m^3$ that could supply 380kWh, enough for a period of two weeks without solar gain. As the reduction of thermal losses at the temperature level of 300°C is extensive, the use of other technologies like chemical storage systems (e.g. magnesium hydride MgH_2) was also considered. These chemical-based systems have advantages of loss-free storage and a drastically reduced storage volume by a Factor 10, compared to the state-of-the-art latent-heat stone storage system (Kleinwächter, 2003).

3.2.3 Low temperature Stirling engine

The chosen technical solution for the conversion of thermal energy at 300°C into electricity is a low temperature Stirling engine. As it is designed to constantly generate electricity, it can be kept at a rather small power capacity (less than 1kW). Furthermore the battery back-up is calculated only for the peak loads. Latest developments in the field of Stirling engines demonstrate first prototypes of low temperature Stirling engines with between 1kW and 10kW power capacity. The energy efficiency of the developed engine has reached more than 12% (Takeuchi, 2007a, b). Based on these results, the Stirling engine will be adapted for the specific application in the Wireless House.

3.2.4 Heat-driven household appliances

As explained above, in the Wireless House, appliances can be categorised by the energy form they require (i.e. some can be powered by thermal energy, and some are operated with electricity only). Presuming that all the heat-driven household equipment is powered by thermal energy, it is necessary to redesign and reengineer current appliances that run on electricity. As mentioned earlier, this alteration can result in the drastic reduction of electric energy demand, and create a higher and relatively constant demand of thermal energy, over the whole year. The household appliances can be categorised according to the temperature level they need for operation. This leads to four classes of appliances. Those which need the highest temperature up to 300°C are kitchen stoves and ovens. The second temperature class up to 150°C contains the cooling devices, refrigerators, freezers and air conditioners. The first two classes need thermal oil as a heat transfer medium. The third group, with temperatures below 90°C, contains devices for washing, drying and cleaning dishes and clothes. The lowest heat, 60°C and lower, is used for the production of hot water and for space heating.

A number of technical solutions based on existing components like absorption cooling devices and thermal oil ovens used in the food processing industry, have been adapted to the scale of households. First low cost prototypes were already tested to be positive. The results show that the chosen technologies are suitable to reach the aims of the Wireless House and meet the needs of the users.

3.3 Application possibilities
